specifies the OUTACTUAL, OUTERRORS, OUTLAGS, OUTPREDICT, and OUTRESID options.

OUTERRORS

writes the equation errors to the OUT= data set. These values are normally very close to 0 when a simultaneous solution is computed; they can be used to double-check the accuracy of the solution process. This option applies only if the OUT= option is specified.

OUTLAGS

writes the observations that are used to start the lags to the OUT= data set. This option applies only if the OUT= option is specified.

OUTOBJVALS

writes the objective function value to the OBJVALS variable in the OUT= data set. The objective function value is computed only when the OPTIMIZE solution method is specified. This value is close to 0 when an unbounded simultaneous solution is computed and can be greater than 0 when bounds are active in the solution. This option applies only if the OUT= option is specified.

OUTPREDICT

writes the solution values to the OUT= data set. This option applies only if the OUT= option is specified.

The OUTPREDICT option is the default unless one of the other output options is specified.

OUTRESID

writes the residual values that are computed as the *actual – predicted* values and is not the same as the *RESID.variable* values. This option applies only if the OUT= option is specified.

OUTVIOLATIONS

writes the equation violations to the OUT= data set. The equation violations are computed only when the OPTIMIZE solution method is specified. The violations provide information about how much each equation contributes to the objective function value when bounds are active in the solution. This option applies only if the OUT= option is specified.

PARMSDATA=SAS-data-set

specifies a data set that contains the parameter estimates. See the section “[Input Data Sets](#)” on page 1172 for more details.

RESIDDATA=SAS-data-set

specifies a data set that contains the residuals to be used in the empirical distribution. This data set can be created using the OUT= option in the FIT statement.

SDATA=SAS-data-set

specifies a data set that provides the covariance matrix of the equation errors. The covariance matrix that is read from the SDATA= data set is used to generate multivariate normal pseudo-random shocks to the equations when the RANDOM= option requests Monte Carlo simulation.

TIME=name

specifies the name of the time variable. This variable must be in the data set.

TYPE=name

specifies the estimation type. The name that is specified in the TYPE= option is compared to the `_TYPE_` variable in the ESTDATA= and SDATA= data sets to select observations to use in constructing the covariance matrices. When TYPE= is omitted, the last estimation type in the data set is used.

Solution Mode Options: Lag Processing**DYNAMIC**

specifies a dynamic solution. In the dynamic solution mode, solved values are used by the lagging functions. DYNAMIC is the default.

NAHEAD=n

specifies a simulation of n -period-ahead dynamic forecasting. The NAHEAD= option is used to simulate the process of using the model to produce successive forecasts to a fixed forecast horizon, in which each forecast uses the historical data available at the time the forecast is made.

Note that NAHEAD=1 produces a static (one-step-ahead) solution. NAHEAD=2 produces a solution that uses one-step-ahead solutions for the first lag (LAG1 functions return static predicted values) and actual values for longer lags. NAHEAD=3 produces a solution that uses NAHEAD=2 solutions for the first lags, NAHEAD=1 solutions for the second lags, and actual values for longer lags. In general, NAHEAD= n solutions use NAHEAD= $n-1$ solutions for LAG1, NAHEAD= $n-2$ solutions for LAG2, and so forth.

START=s

specifies static solutions until the s th observation and then changes to dynamic solutions. If the START= s option is specified, the first observation in the range in which LAG n delivers solved predicted values is $s+n$, while LAG n returns actual values for earlier observations.

STATIC

specifies a static solution. In static solution mode, actual values of the solved variables from the input data set are used by the lagging functions.

Solution Mode Options: Use of Available Data**FORECAST**

specifies that the actual value of a solved variable is used as the solution value (instead of the predicted value from the model equations) whenever nonmissing data are available in the input data set. That is, in FORECAST mode, PROC MODEL solves only for those variables that are missing in the input data set.

SIMULATE

specifies that PROC MODEL always solves for all solution variables as a function of the input values of the other variables, even when actual data for some of the solution variables are available in the input data set. SIMULATE is the default.

Solution Mode Options: Numerical Solution Method**JACOBI**

computes a simultaneous solution using a Jacobi iteration.

NEWTON

computes a simultaneous solution by using Newton's method. When the NEWTON option is selected, the analytic derivatives of the equation errors with respect to the solution variables are computed, and memory-efficient sparse matrix techniques are used for factoring the Jacobian matrix.

The NEWTON option can be used to solve both normalized-form and general-form equations and can compute goal-seeking solutions. NEWTON is the default.

OPTIMIZE

computes a simultaneous solution by minimizing a norm of the equation errors with respect to the solution variables. The OPTIMIZE method obeys constraints on the solution variables that are imposed by the BOUNDS and RESTRICT statements.

SEIDEL

computes a simultaneous solution by using a Gauss-Seidel method.

SINGLE**ONEPASS**

specifies a single-equation (nonsimultaneous) solution. The model is executed once to compute predicted values for the variables from the actual values of the other endogenous variables. The SINGLE option can be used only for normalized-form equations and cannot be used for goal-seeking solutions.

For more information about these options, see the section “[Solution Modes](#)” on page 1184.

Monte Carlo Simulation Options**COPULA=(*copula-options*)**

specifies the copula to be used in the simulation. You can specify the following *copula-options*:

- CLAYTON(θ), where θ is the Clayton copula parameter
- FRANK(θ), where θ is the Frank copula parameter
- GUMBEL(θ), where θ is the Gumbel copula parameter
- NORMAL
- NORMALMIX($n, p_1 \dots p_n, v_1 \dots v_n$), where p_i are the probabilities and v_i are the variances
- T(df) < ASYM>, where df is the degrees-of-freedom parameter

The normal (Gaussian) copula is the default. The copula applies to covariance of equation errors.

PSEUDO=DEFAULT | TWISTER

specifies which pseudo-number generator to use in generating draws for Monte Carlo simulation. The two pseudo-random number generators that are supported by the MODEL procedure are a default congruential generator that has period $2^{31} - 1$ and a Mersenne-Twister pseudo-random number generator that has an extraordinarily long period $2^{19937} - 1$.

QUASI=NONE|SOBOL|FAURE

specifies a pseudo- or quasi-random number generator. Two quasi-random number generators are supported by the MODEL procedure: the Sobol sequence (QUASI=SOBOL) and the Faure sequence (QUASI=FAURE). The default is QUASI=NONE, which is the pseudo-random number generator.

RANDOM=*n*

repeats the solution *n* times for each BY group, with different random perturbations of the equation errors if the SDATA= option is specified; with different random perturbations of the parameters if the ESTDATA= option is specified and the ESTDATA= data set contains a parameter covariance matrix; and with different values returned from the random number generator functions, if any are used in the model program. If RANDOM=0, the random number generator functions always return zero. See the section “[Monte Carlo Simulation](#)” on page 1188 for details. The default is RANDOM=0.

SEED=*n*

specifies an integer to use as the seed in generating pseudo-random numbers to shock the parameters and equations when the ESTDATA= or SDATA= option is specified. If *n* is negative or 0, the time of day from the computer’s clock is used as the seed. The SEED= option is relevant only if the RANDOM= option is specified. The default is SEED=0.

WISHART=*df*

specifies that a Wishart distribution with degrees of freedom *df* be used in place of the normal error covariance matrix. This option is used to model the variance of the error covariance matrix when Monte Carlo simulation is selected.

Options for Controlling the Numerical Solution Process

The following options are useful when you have difficulty converging to the simultaneous solution.

CONVERGE=*value*

specifies the convergence criterion for the simultaneous solution. Convergence of the solution is judged by comparing the CONVERGE= value to the maximum over the equations of

$$\frac{|\epsilon_i|}{|y_i| + 1E-6}$$

if they are computable, otherwise

$$|\epsilon_i|$$

where ϵ_i represents the equation error and y_i represents the solution variable that corresponds to the *i*th equation for normalized-form equations. The default is CONVERGE=1E-8.

MAXITER=*n*

specifies the maximum number of iterations allowed for computing the simultaneous solution for any observation. The default is MAXITER=50.

MAXSUBITER=*n*

specifies the maximum number of damping subiterations that are performed in solving a nonlinear system when using the NEWTON solution method. Damping is disabled by setting MAXSUBITER=0. The default is MAXSUBITER=10.

Printing Options

INTGPRINT

prints between data points integration values for the DERT. variables and the auxiliary variables. If you specify the DETAILS option, the integrated derivative variables are printed as well.

ITPRINT

prints the solution approximation and equation errors at each iteration for each observation. This option can produce voluminous output.

PRINTALL

specifies the printing control options DETAILS, ITPRINT, SOLVEPRINT, STATS, and THEIL.

SOLVEPRINT

prints the solution values and residuals at each observation.

STATS

prints various summary statistics for the solution values.

THEIL

prints tables of Theil inequality coefficients and Theil relative change forecast error measures for the solution values. See the section “[Summary Statistics](#)” on page 1203 for more information.

Other Options

Other options that can be used on the SOLVE statement include the following that list and analyze the model: BLOCK, GRAPH, LIST, LISTCODE, LISTDEP, LISTDER, and XREF. The LTEBOUND= and MINTIMESTEP= options can be used to control the integration process. The following printing-control options are also available: DETAILS, FLOW, MAXERRORS=, NOPRINT, and TRACE. For complete descriptions of these options, see the PROC MODEL and FIT statement options described earlier in this chapter.

TEST Statement

TEST < "*name*" > *test1* < , *test2* ... > < , / *options* > ;

The TEST statement performs tests of nonlinear hypotheses on the model parameters.

The TEST statement applies to the parameters estimated by the associated FIT statement (that is, either the preceding FIT statement or, in the absence of a preceding FIT statement, the following FIT statement). You can specify any number of TEST statements.

If you specify options on the TEST statement, a comma is required before the “/” character that separates the test expressions from the options, because the “/” character can also be used within test expressions to indicate division.

The label lengths for tests and estimate statements are 256 characters. If the labels exceed this length, the label is truncated to 256 characters with a note printed to the log.

Each test is written as an expression optionally followed by an equal sign (=) and a second expression:

< expression > < = expression >

Test expressions can be composed of parameter names, arithmetic operators, functions, and constants. Comparison operators (such as =) and logical operators (such as &) cannot be used in TEST statement expressions. Parameters named in test expressions must be among the parameters estimated by the associated FIT statement.

If you specify only one expression in a test, that expression is tested against zero. For example, the following two TEST statements are equivalent:

```
test a + b;
```

```
test a + b = 0;
```

When you specify multiple tests in the same TEST statement, a joint test is performed. For example, the following TEST statement tests the joint hypothesis that both A and B are equal to zero.

```
test a, b;
```

To perform separate tests rather than a joint test, use separate TEST statements. For example, the following TEST statements test the two separate hypotheses that A is equal to zero and that B is equal to zero.

```
test a;
```

```
test b;
```

You can use the following options in the TEST statement.

WALD

specifies that a Wald test be computed. By default, the Wald test is computed.

LM

RAO

LAGRANGE

specifies that a Lagrange multiplier test be computed.

LR

LIKE

specifies that a likelihood ratio test be computed.

ALL

requests all three types of tests.

OUT=SAS-data-set

specifies the name of an output *SAS data set* that contains the test results. The format of the OUT= data set that is produced by the TEST statement is similar to that of the OUTEST= data set produced by the FIT statement.

VAR Statement

VAR *variables* < *initial-values* > ... ;

The VAR statement declares model variables and optionally provides initial values for the lags of the variables. See the section “[Lag Logic](#)” on page 1230 for more information.

VARGROUP Statement

VARGROUP *label=variable*... ;

The VARGROUP statement applies a group label to the specified list of variables in the model program. Variable groups are used to identify sets of related solve variables. The variable groups can be used by the ANALYZE= option in a subsequent SOLVE statement to help specify and understand the role of groups of solve variables in a SOLVE step. If a variable appears in more than one VARGROUP statement, the label that is specified in the last VARGROUP statement is applied to that variable.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters.

If the weight of an observation is nonpositive, that observation is not used for the estimation. *variable* must be a numeric variable in the input data set.

An alternative weighting method is to use an assignment statement to give values to the special variable `_WEIGHT_`. The `_WEIGHT_` variable must not depend on the parameters being estimated. If both weighting specifications are given, the weights are multiplied together.

Details: Estimation by the MODEL Procedure

Estimation Methods

Consider the general nonlinear model:

$$\begin{aligned}\epsilon_t &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \\ \mathbf{z}_t &= \mathbf{Z}(\mathbf{x}_t)\end{aligned}$$

where $\mathbf{q} \in R^g$ is a real vector valued function of $\mathbf{y}_t \in R^g$, $\mathbf{x}_t \in R^l$, $\boldsymbol{\theta} \in R^p$, where g is the number of equations, l is the number of exogenous variables (lagged endogenous variables are considered exogenous here), p is the number of parameters, and t ranges from 1 to n . $\mathbf{z}_t \in R^k$ is a vector of instruments. ϵ_t is an unobservable disturbance vector with the following properties:

$$\begin{aligned}E(\epsilon_t) &= 0 \\ E(\epsilon_t \epsilon_t') &= \boldsymbol{\Sigma}\end{aligned}$$

All of the methods implemented in PROC MODEL aim to minimize an *objective function*. The following table summarizes the objective functions that define the estimators and the corresponding estimator of the covariance of the parameter estimates for each method.

Table 19.2 Summary of PROC MODEL Estimation Methods

Method	Instruments	Objective Function	Covariance of θ
OLS	no	$\mathbf{r}'\mathbf{r}/n$	$(\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{X})^{-1}$
ITOLS	no	$\mathbf{r}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{r}/n$	$(\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{X})^{-1}$
SUR	no	$\mathbf{r}'(\mathbf{S}_{\text{OLS}}^{-1} \otimes \mathbf{I})\mathbf{r}/n$	$(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{I})\mathbf{X})^{-1}$
ITSUR	no	$\mathbf{r}'(\mathbf{S}^{-1} \otimes \mathbf{I})\mathbf{r}/n$	$(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{I})\mathbf{X})^{-1}$
N2SLS	yes	$\mathbf{r}'(\mathbf{I} \otimes \mathbf{W})\mathbf{r}/n$	$(\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}$
IT2SLS	yes	$\mathbf{r}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{W})\mathbf{r}/n$	$(\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}$
N3SLS	yes	$\mathbf{r}'(\mathbf{S}_{\text{N2SLS}}^{-1} \otimes \mathbf{W})\mathbf{r}/n$	$(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}$
IT3SLS	yes	$\mathbf{r}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{r}/n$	$(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}$
GMM	yes	$[\mathbf{nm}_n(\theta)]'\hat{\mathbf{V}}_{\text{N2SLS}}^{-1}[\mathbf{nm}_n(\theta)]/n$	$[(\mathbf{YX})'\hat{\mathbf{V}}^{-1}(\mathbf{YX})]^{-1}$
ITGMM	yes	$[\mathbf{nm}_n(\theta)]'\hat{\mathbf{V}}^{-1}[\mathbf{nm}_n(\theta)]/n$	$[(\mathbf{YX})'\hat{\mathbf{V}}^{-1}(\mathbf{YX})]^{-1}$
FIML	no	$\text{constant} + \frac{n}{2}\ln(\det(\mathbf{S})) - \sum_1^n \ln (\mathbf{J}_t) $	$[\hat{\mathbf{Z}}'(\mathbf{S}^{-1} \otimes \mathbf{I})\hat{\mathbf{Z}}]^{-1}$

The column labeled “Instruments” identifies the estimation methods that require instruments. The variables used in this table and the remainder of this chapter are defined as follows:

n = is the number of nonmissing observations.

g = is the number of equations.

k = is the number of instrumental variables.

$\mathbf{r} = \begin{bmatrix} r_1 \\ r_2 \\ \vdots \\ r_g \end{bmatrix}$ is the $ng \times 1$ vector of residuals for the g equations stacked together.

$\mathbf{r}_i = \begin{bmatrix} q_i(\mathbf{y}_1, \mathbf{x}_1, \boldsymbol{\theta}) \\ q_i(\mathbf{y}_2, \mathbf{x}_2, \boldsymbol{\theta}) \\ \vdots \\ q_i(\mathbf{y}_n, \mathbf{x}_n, \boldsymbol{\theta}) \end{bmatrix}$ is the $n \times 1$ column vector of residuals for the i th equation.

\mathbf{S} is a $g \times g$ matrix that estimates $\boldsymbol{\Sigma}$, the covariances of the errors across equations (referred to as the \mathbf{S} matrix).

\mathbf{X} is an $ng \times p$ matrix of partial derivatives of the residual with respect to the parameters.

\mathbf{W} is an $n \times n$ matrix, $\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$.

\mathbf{Z} is an $n \times k$ matrix of instruments.

\mathbf{Y} is a $gk \times ng$ matrix of instruments. $\mathbf{Y} = \mathbf{I}_g \otimes \mathbf{Z}'$.

$\hat{\mathbf{Z}}$ $\hat{\mathbf{Z}} = (\hat{\mathbf{Z}}_1, \hat{\mathbf{Z}}_2, \dots, \hat{\mathbf{Z}}_p)$ is an $ng \times p$ matrix. $\hat{\mathbf{Z}}_i$ is a $ng \times 1$ column vector obtained from stacking the columns of

$$\mathbf{U} \frac{1}{n} \sum_{t=1}^n \left(\frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \mathbf{y}_t} \right)^{-1} \frac{\partial^2 \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \mathbf{y}_t \partial \theta_i} - \mathbf{Q}_i$$

\mathbf{U} is an $n \times g$ matrix of residual errors. $\mathbf{U} = \boldsymbol{\epsilon}_1, \boldsymbol{\epsilon}_2, \dots, \boldsymbol{\epsilon}_n'$.

\mathbf{Q} is the $n \times g$ matrix $\mathbf{q}(\mathbf{y}_1, \mathbf{x}_1, \boldsymbol{\theta}), \mathbf{q}(\mathbf{y}_2, \mathbf{x}_2, \boldsymbol{\theta}), \dots, \mathbf{q}(\mathbf{y}_n, \mathbf{x}_n, \boldsymbol{\theta})$.

\mathbf{Q}_i is an $n \times g$ matrix $\frac{\partial \mathbf{Q}}{\partial \theta_i}$.

\mathbf{I} is an $n \times n$ identity matrix.

\mathbf{J}_t is $\frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \mathbf{y}_t}$, which is a $g \times g$ Jacobian matrix.

\mathbf{m}_n is first moment of the crossproduct $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \otimes \mathbf{z}_t$,
 $\mathbf{m}_n = \frac{1}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \otimes \mathbf{z}_t$

\mathbf{z}_t is a k column vector of instruments for observation t . \mathbf{z}_t' is also the t th row of \mathbf{Z} .

$\hat{\mathbf{V}}$ is the $gk \times gk$ matrix that represents the variance of the moment functions.

k is the number of instrumental variables used.

constant is the constant $\frac{ng}{2}(1 + \ln(2\pi))$.

\otimes is the notation for a Kronecker product.

All vectors are column vectors unless otherwise noted. Other estimates of the covariance matrix for FIML are also available.

Dependent Regressors and Two-Stage Least Squares

Ordinary regression analysis is based on several assumptions. A key assumption is that the independent variables are in fact statistically independent of the unobserved error component of the model. If this assumption is not true (if the regressor varies systematically with the error), then ordinary regression produces inconsistent results. The parameter estimates are *biased*.

Regressors might fail to be independent variables because they are dependent variables in a larger simultaneous system. For this reason, the problem of dependent regressors is often called *simultaneous equation bias*. For example, consider the following two-equation system:

$$y_1 = a_1 + b_1 y_2 + c_1 x_1 + \epsilon_1$$

$$y_2 = a_2 + b_2 y_1 + c_2 x_2 + \epsilon_2$$

In the first equation, y_2 is a dependent, or *endogenous*, variable. As shown by the second equation, y_2 is a function of y_1 , which by the first equation is a function of ϵ_1 , and therefore y_2 depends on ϵ_1 . Likewise, y_1 depends on ϵ_2 and is a dependent regressor in the second equation. This is an example of a *simultaneous equation system*; y_1 and y_2 are a function of all the variables in the system.

Using the ordinary least squares (OLS) estimation method to estimate these equations produces biased estimates. One solution to this problem is to replace y_1 and y_2 on the right-hand side of the equations with predicted values, thus changing the regression problem to the following:

$$y_1 = a_1 + b_1 \hat{y}_2 + c_1 x_1 + \epsilon_1$$

$$y_2 = a_2 + b_2 \hat{y}_1 + c_2 x_2 + \epsilon_2$$

This method requires estimating the predicted values \hat{y}_1 and \hat{y}_2 through a preliminary, or “first stage,” *instrumental regression*. An instrumental regression is a regression of the dependent regressors on a set of *instrumental variables*, which can be any independent variables useful for predicting the dependent regressors. In this example, the equations are linear and the exogenous variables for the whole system are known. Thus, the best choice for instruments (of the variables in the model) are the variables x_1 and x_2 .

This method is known as *two-stage least squares* or 2SLS, or more generally as the *instrumental variables method*. The 2SLS method for linear models is discussed in Pindyck (1981, p. 191–192). For nonlinear models this situation is more complex, but the idea is the same. In nonlinear 2SLS, the derivatives of the model with respect to the parameters are replaced with predicted values. See the section “[Choice of Instruments](#)” on page 1153 for further discussion of the use of instrumental variables in nonlinear regression.

To perform nonlinear 2SLS estimation with PROC MODEL, specify the instrumental variables with an INSTRUMENTS statement and specify the 2SLS or N2SLS option in the FIT statement. The following statements show how to estimate the first equation in the preceding example with PROC MODEL:

```
proc model data=in;
  y1 = a1 + b1 * y2 + c1 * x1;
  fit y1 / 2sls;
  instruments x1 x2;
run;
```

The 2SLS or instrumental variables estimator can be computed by using a first-stage regression on the instrumental variables as described previously. However, PROC MODEL actually uses the equivalent but

computationally more appropriate technique of projecting the regression problem into the linear space defined by the instruments. Thus, PROC MODEL does not produce any “first stage” results when you use 2SLS. If you specify the FSRSQ option in the FIT statement, PROC MODEL prints “First-Stage R^2 ” statistic for each parameter estimate.

Formally, the $\hat{\theta}$ that minimizes

$$\hat{S}_n = \frac{1}{n} \left(\sum_{t=1}^n (\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t) \right)' \left(\sum_{t=1}^n I \otimes \mathbf{z}_t \mathbf{z}_t' \right)^{-1} \left(\sum_{t=1}^n (\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t) \right)$$

is the N2SLS estimator of the parameters. The estimate of Σ at the final iteration is used in the covariance of the parameters given in Table 19.2. See Amemiya (1985, p. 250) for details on the properties of nonlinear two-stage least squares.

Seemingly Unrelated Regression

If the regression equations are not simultaneous (so there are no dependent regressors), *seemingly unrelated regression* (SUR) can be used to estimate systems of equations with correlated random errors. The large-sample efficiency of an estimation can be improved if these cross-equation correlations are taken into account. SUR is also known as *joint generalized least squares* or *Zellner regression*. Formally, the $\hat{\theta}$ that minimizes

$$\hat{S}_n = \frac{1}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)' \hat{\Sigma}^{-1} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)$$

is the SUR estimator of the parameters.

The SUR method requires an estimate of the cross-equation covariance matrix, Σ . PROC MODEL first performs an OLS estimation, computes an estimate, $\hat{\Sigma}$, from the OLS residuals, and then performs the SUR estimation based on $\hat{\Sigma}$. The OLS results are not printed unless you specify the OLS option in addition to the SUR option.

You can specify the $\hat{\Sigma}$ to use for SUR by storing the matrix in a SAS data set and naming that data set in the SDATA= option. You can also feed the $\hat{\Sigma}$ computed from the SUR residuals back into the SUR estimation process by specifying the ITSUR option. You can print the estimated covariance matrix $\hat{\Sigma}$ by using the COVS option in the FIT statement.

The SUR method requires estimation of the Σ matrix, and this increases the sampling variability of the estimator for small sample sizes. The efficiency gain that SUR has over OLS is a large sample property, and you must have a reasonable amount of data to realize this gain. For a more detailed discussion of SUR, see Pindyck and Rubinfeld (1981, p. 331-333).

Three-Stage Least Squares Estimation

If the equation system is simultaneous, you can combine the 2SLS and SUR methods to take into account both dependent regressors and cross-equation correlation of the errors. This is called *three-stage least squares* (3SLS).

Formally, the $\hat{\theta}$ that minimizes

$$\hat{S}_n = \frac{1}{n} \left(\sum_{t=1}^n (\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t) \right)' \left(\sum_{t=1}^n (\hat{\Sigma} \otimes \mathbf{z}_t \mathbf{z}_t') \right)^{-1} \left(\sum_{t=1}^n (\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t) \right)$$

is the 3SLS estimator of the parameters. For more details on 3SLS, see Gallant (1987, p. 435).

Residuals from the 2SLS method are used to estimate the Σ matrix required for 3SLS. The results of the preliminary 2SLS step are not printed unless the 2SLS option is also specified.

To use the three-stage least squares method, specify an INSTRUMENTS statement and use the 3SLS or N3SLS option in either the PROC MODEL statement or a FIT statement.

Generalized Method of Moments (GMM)

For systems of equations with heteroscedastic errors, generalized method of moments (GMM) can be used to obtain efficient estimates of the parameters. See the section “[Heteroscedasticity](#)” on page 1121 for alternatives to GMM.

Consider the nonlinear model

$$\begin{aligned}\epsilon_t &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \\ \mathbf{z}_t &= \mathbf{Z}(\mathbf{x}_t)\end{aligned}$$

where \mathbf{z}_t is a vector of instruments and ϵ_t is an unobservable disturbance vector that can be serially correlated and nonstationary.

In general, the following orthogonality condition is desired:

$$E(\epsilon_t \otimes \mathbf{z}_t) = 0$$

This condition states that the expected crossproducts of the unobservable disturbances, ϵ_t , and functions of the observable variables are set to 0. The first moment of the crossproducts is

$$\begin{aligned}\mathbf{m}_n &= \frac{1}{n} \sum_{t=1}^n \mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \\ \mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \otimes \mathbf{z}_t\end{aligned}$$

where $\mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \in R^{gk}$.

The case where $gk > p$ is considered here, where p is the number of parameters.

Estimate the true parameter vector θ^0 by the value of $\hat{\theta}$ that minimizes

$$S(\theta, \mathbf{V}) = [n\mathbf{m}_n(\theta)]' \mathbf{V}^{-1} [n\mathbf{m}_n(\theta)] / n$$

where

$$\mathbf{V} = \text{Cov}([n\mathbf{m}_n(\theta^0)], [n\mathbf{m}_n(\theta^0)]')$$

The parameter vector that minimizes this objective function is the GMM estimator. GMM estimation is requested in the FIT statement with the GMM option.

The variance of the moment functions, \mathbf{V} , can be expressed as

$$\begin{aligned}\mathbf{V} &= E \left(\sum_{t=1}^n \boldsymbol{\epsilon}_t \otimes \mathbf{z}_t \right) \left(\sum_{s=1}^n \boldsymbol{\epsilon}_s \otimes \mathbf{z}_s \right)' \\ &= \sum_{t=1}^n \sum_{s=1}^n E [(\boldsymbol{\epsilon}_t \otimes \mathbf{z}_t)(\boldsymbol{\epsilon}_s \otimes \mathbf{z}_s)'] \\ &= n\mathbf{S}_n^0\end{aligned}$$

where \mathbf{S}_n^0 is estimated as

$$\hat{\mathbf{S}}_n = \frac{1}{n} \sum_{t=1}^n \sum_{s=1}^n (\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \otimes \mathbf{z}_t)(\mathbf{q}(\mathbf{y}_s, \mathbf{x}_s, \boldsymbol{\theta}) \otimes \mathbf{z}_s)'$$

Note that $\hat{\mathbf{S}}_n$ is a $gk \times gk$ matrix. Because $\text{Var}(\hat{\mathbf{S}}_n)$ does not decrease with increasing n , you consider estimators of \mathbf{S}_n^0 of the form:

$$\begin{aligned}\hat{\mathbf{S}}_n(l(n)) &= \sum_{\tau=-n+1}^{n-1} \hat{w}\left(\frac{\tau}{l(n)}\right) \mathbf{D} \hat{\mathbf{S}}_{n,\tau} \mathbf{D} \\ \hat{\mathbf{S}}_{n,\tau} &= \begin{cases} \sum_{t=1+\tau}^n [\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}^\#) \otimes \mathbf{z}_t][\mathbf{q}(\mathbf{y}_{t-\tau}, \mathbf{x}_{t-\tau}, \boldsymbol{\theta}^\#) \otimes \mathbf{z}_{t-\tau}]' & \tau \geq 0 \\ (\hat{\mathbf{S}}_{n,-\tau})' & \tau < 0 \end{cases} \\ \hat{w}\left(\frac{\tau}{l(n)}\right) &= \begin{cases} w\left(\frac{\tau}{l(n)}\right) & l(n) > 0 \\ \delta_{\tau,0} & l(n) = 0 \end{cases}\end{aligned}$$

where $l(n)$ is a scalar function that computes the bandwidth parameter, $w(\cdot)$ is a scalar valued kernel, and the Kronecker delta function, $\delta_{i,j}$, is 1 if $i = j$ and 0 otherwise. The diagonal matrix \mathbf{D} is used for a small sample degrees of freedom correction (Gallant 1987). The initial $\boldsymbol{\theta}^\#$ used for the estimation of $\hat{\mathbf{S}}_n$ is obtained from a 2SLS estimation of the system. The degrees of freedom correction is handled by the VARDEF= option as it is for the \mathbf{S} matrix estimation.

The following kernels are supported by PROC MODEL. They are listed with their default bandwidth functions.

Bartlett: KERNEL=BART

$$\begin{aligned}w(x) &= \begin{cases} 1 - |x| & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(n) &= \frac{1}{2}n^{1/3}\end{aligned}$$

Parzen: KERNEL=PARZEN

$$w(x) = \begin{cases} 1 - 6|x|^2 + 6|x|^3 & 0 \leq |x| \leq \frac{1}{2} \\ 2(1 - |x|)^3 & \frac{1}{2} \leq |x| \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

$$l(n) = n^{1/5}$$

Quadratic spectral: KERNEL=QS

$$w(x) = \frac{25}{12\pi^2 x^2} \left(\frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right)$$

$$l(n) = \frac{1}{2}n^{1/5}$$

Figure 19.23 Kernels for Smoothing

Details of the properties of these and other kernels are given in Andrews (1991). Kernels are selected with the KERNEL= option; KERNEL=PARZEN is the default. The general form of the KERNEL= option is

KERNEL= (PARZEN | QS | BART, c, e)

where the $e \geq 0$ and $c \geq 0$ are used to compute the bandwidth parameter as

$$l(n) = cn^e$$

The bias of the standard error estimates increases for large bandwidth parameters. A warning message is produced for bandwidth parameters greater than $n^{\frac{1}{3}}$. For a discussion of the computation of the optimal $l(n)$, refer to Andrews (1991).

The “Newey-West” kernel (Newey and West 1987) corresponds to the Bartlett kernel with bandwidth parameter $l(n) = L + 1$. That is, if the “lag length” for the Newey-West kernel is L , then the corresponding MODEL procedure syntax is `KERNEL=(bart, L+1, 0)`.

Andrews and Monahan (1992) show that using prewhitening in combination with GMM can improve confidence interval coverage and reduce over rejection of t statistics at the cost of inflating the variance and MSE of the estimator. Prewhitening can be performed by using the `%AR` macros.

For the special case that the errors are not serially correlated—that is,

$$E(e_t \otimes \mathbf{z}_t)(e_s \otimes \mathbf{z}_s) = 0 \quad t \neq s$$

the estimate for \mathbf{S}_n^0 reduces to

$$\hat{\mathbf{S}}_n = \frac{1}{n} \sum_{t=1}^n [\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \otimes \mathbf{z}_t][\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \otimes \mathbf{z}_t]'$$

The option `KERNEL=(kernel,0,)` is used to select this type of estimation when using GMM.

Covariance of GMM estimators

The covariance of GMM estimators, given a general weighting matrix \mathbf{V}_G^{-1} , is

$$[(\mathbf{YX})' \mathbf{V}_G^{-1} (\mathbf{YX})]^{-1} (\mathbf{YX})' \mathbf{V}_G^{-1} \hat{\mathbf{V}} \mathbf{V}_G^{-1} (\mathbf{YX}) [(\mathbf{YX})' \mathbf{V}_G^{-1} (\mathbf{YX})]^{-1}$$

By default or when `GENGMMV` is specified, this is the covariance of GMM estimators.

If the weighting matrix is the same as $\hat{\mathbf{V}}$, then the covariance of GMM estimators becomes

$$[(\mathbf{YX})' \hat{\mathbf{V}}^{-1} (\mathbf{YX})]^{-1}$$

If `NOGENGMMV` is specified, this is used as the covariance estimators.

Testing Overidentifying Restrictions

Let r be the number of unique instruments times the number of equations. The value r represents the number of orthogonality conditions imposed by the GMM method. Under the assumptions of the GMM method, $r - p$ linearly independent combinations of the orthogonality should be close to zero. The GMM estimates are computed by setting these combinations to zero. When r exceeds the number of parameters to be estimated, the `OBJECTIVE*N`, reported at the end of the estimation, is an asymptotically valid statistic to test the null hypothesis that the overidentifying restrictions of the model are valid. The `OBJECTIVE*N` is distributed as a chi-square with $r - p$ degrees of freedom (Hansen 1982, p. 1049). When the GMM method is selected, the value of the overidentifying restrictions test statistic, also known as Hansen’s J test statistic, and its associated number of degrees of freedom are reported together with the probability under the null hypothesis.

Iterated Generalized Method of Moments (ITGMM)

Iterated generalized method of moments is similar to the iterated versions of 2SLS, SUR, and 3SLS. The variance matrix for GMM estimation is reestimated at each iteration with the parameters determined by the GMM estimation. The iteration terminates when the variance matrix for the equation errors change less than the CONVERGE= value. Iterated generalized method of moments is selected by the ITGMM option on the FIT statement. For some indication of the small sample properties of ITGMM, see Ferson and Foerster (1993).

Simulated Method of Moments (SMM)

The SMM method uses simulation techniques in model inference and estimation. It is appropriate for estimating models in which integrals appear in the objective function, and these integrals can be approximated by simulation. There might be various reasons for integrals to appear in an objective function (for example, transformation of a latent model into an observable model, missing data, random coefficients, heterogeneity, and so on).

This simulation method can be used with all the estimation methods except full information maximum likelihood (FIML) in PROC MODEL. SMM, also known as simulated generalized method of moments (SGMM), is the default estimation method because of its nice properties.

Estimation Details

A general nonlinear model can be described as

$$\epsilon_t = \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})$$

where $\mathbf{q} \in R^g$ is a real vector valued function of $\mathbf{y}_t \in R^g$, $\mathbf{x}_t \in R^l$, $\boldsymbol{\theta} \in R^p$; g is the number of equations; l is the number of exogenous variables (lagged endogenous variables are considered exogenous here); p is the number of parameters; and t ranges from 1 to n . ϵ_t is an unobservable disturbance vector with the following properties:

$$\begin{aligned} E(\epsilon_t) &= 0 \\ E(\epsilon_t \epsilon_t') &= \Sigma \end{aligned}$$

In many cases, it is not possible to write $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})$ in a closed form. Instead \mathbf{q} is expressed as an integral of a function \mathbf{f} ; that is,

$$\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) = \int \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}, \mathbf{u}_t) dP(\mathbf{u})$$

where $\mathbf{f} \in R^g$ is a real vector valued function of $\mathbf{y}_t \in R^g$, $\mathbf{x}_t \in R^l$, $\boldsymbol{\theta} \in R^p$, and $\mathbf{u}_t \in R^m$, m is the number of stochastic variables with a known distribution $P(\mathbf{u})$. Since the distribution of \mathbf{u} is completely known, it is possible to simulate artificial draws from this distribution. Using such independent draws \mathbf{u}_{ht} , $h = 1, \dots, H$, and the strong law of large numbers, \mathbf{q} can be approximated by

$$\frac{1}{H} \sum_{h=1}^H \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}, \mathbf{u}_{ht}).$$

Simulated Generalized Method of Moments (SGMM)

Generalized method of moments (GMM) is widely used to obtain efficient estimates for general model systems. When the moment conditions are not readily available in closed forms but can be approximated by simulation, simulated generalized method of moments (SGMM) can be used. The SGMM estimators have the nice property of being asymptotically consistent and normally distributed even if the number of draws H is fixed (see McFadden 1989; Pakes and Pollard 1989).

Consider the nonlinear model

$$\begin{aligned}\epsilon_t &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) = \frac{1}{H} \sum_{h=1}^H \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \theta, \mathbf{u}_{ht}) \\ \mathbf{z}_t &= \mathbf{Z}(\mathbf{x}_t)\end{aligned}$$

where $\mathbf{z}_t \in R^k$ is a vector of k instruments and ϵ_t is an unobservable disturbance vector that can be serially correlated and nonstationary. In the case of no instrumental variables, \mathbf{z}_t is 1. $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)$ is the vector of moment conditions, and it is approximated by simulation.

In general, theory suggests the following orthogonality condition

$$E(\epsilon_t \otimes \mathbf{z}_t) = 0$$

which states that the expected crossproducts of the unobservable disturbances, ϵ_t , and functions of the observable variables are set to 0. The sample means of the crossproducts are

$$\begin{aligned}\mathbf{m}_n &= \frac{1}{n} \sum_{t=1}^n \mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \theta) \\ \mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \theta) &= \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \otimes \mathbf{z}_t\end{aligned}$$

where $\mathbf{m}(\mathbf{y}_t, \mathbf{x}_t, \theta) \in R^{gk}$. The case where $gk > p$, where p is the number of parameters, is considered here. An estimate of the true parameter vector θ^0 is the value of $\hat{\theta}$ that minimizes

$$S(\theta, V) = [n\mathbf{m}_n(\theta)]' \mathbf{V}^{-1} [n\mathbf{m}_n(\theta)] / n$$

where

$$\mathbf{V} = \text{Cov}(\mathbf{m}(\theta^0), \mathbf{m}(\theta^0)').$$

The steps for SGMM are as follows:

1. Start with a positive definite $\hat{\mathbf{V}}$ matrix. This $\hat{\mathbf{V}}$ matrix can be estimated from a consistent estimator of θ . If $\hat{\theta}$ is a consistent estimator, then \mathbf{u}_t for $t = 1, \dots, n$ can be simulated H' number of times. A consistent estimator of \mathbf{V} is obtained as

$$\hat{\mathbf{V}} = \frac{1}{n} \sum_{t=1}^n \left[\frac{1}{H'} \sum_{h=1}^{H'} \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \hat{\theta}, \mathbf{u}_{ht}) \otimes \mathbf{z}_t \right] \left[\frac{1}{H'} \sum_{h=1}^{H'} \mathbf{f}(\mathbf{y}_t, \mathbf{x}_t, \hat{\theta}, \mathbf{u}_{ht}) \otimes \mathbf{z}_t \right]'$$

H' must be large so that this is an consistent estimator of \mathbf{V} .

2. Simulate H number of \mathbf{u}_t for $t = 1, \dots, n$. As shown by Gourieroux and Monfort (1993), the number of simulations H does not need to be very large. For $H = 10$, the SGMM estimator achieves 90% of the

efficiency of the corresponding GMM estimator. Find $\hat{\theta}$ that minimizes the quadratic product of the moment conditions again with the weight matrix being $\hat{\mathbf{V}}^{-1}$.

$$\min_{\theta} [n\mathbf{m}_n(\theta)]' \hat{\mathbf{V}}^{-1} [n\mathbf{m}_n(\theta)] / n$$

3. The covariance matrix of $\sqrt{n}\theta$ is given as (Gourieroux and Monfort 1993)

$$\Sigma_1^{-1} \mathbf{D} \hat{\mathbf{V}}^{-1} \mathbf{V}(\hat{\theta}) \hat{\mathbf{V}}^{-1} \mathbf{D}' \Sigma_1^{-1} + \frac{1}{H} \Sigma_1^{-1} \mathbf{D} \hat{\mathbf{V}}^{-1} E[\mathbf{z} \otimes \text{Var}(\mathbf{f}|\mathbf{x}) \otimes \mathbf{z}] \hat{\mathbf{V}}^{-1} \mathbf{D}' \Sigma_1^{-1}$$

where $\Sigma_1 = \mathbf{D} \hat{\mathbf{V}}^{-1} \mathbf{D}$, \mathbf{D} is the matrix of partial derivatives of the residuals with respect to the parameters, $\mathbf{V}(\hat{\theta})$ is the covariance of moments from estimated parameters $\hat{\theta}$, and $\text{Var}(\mathbf{f}|\mathbf{x})$ is the covariance of moments for each observation from simulation. The first term is the variance-covariance matrix of the exact GMM estimator, and the second term accounts for the variation contributed by simulating the moments.

Implementation in PROC MODEL

In PROC MODEL, if the user specifies the GMM and NDRAW options in the FIT statement, PROC MODEL first fits the model by using N2SLS and computes $\hat{\mathbf{V}}$ by using the estimates from N2SLS and H' simulation. If NO2SLS is specified in the FIT statement, $\hat{\mathbf{V}}$ is read from VDATA= data set. If the user does not provide a $\hat{\mathbf{V}}$ matrix, the initial starting value of θ is used as the estimator for computing the $\hat{\mathbf{V}}$ matrix in step 1. If ITGMM option is specified instead of GMM, then PROC MODEL iterates from step 1 to step 3 until the \mathbf{V} matrix converges.

The consistency of the parameter estimates is not affected by the variance correction shown in the second term in step 3. The correction on the variance of parameter estimates is not computed by default. To add the adjustment, use ADJSMMV option on the FIT statement. This correction is of the order of $\frac{1}{H}$ and is small even for moderate H .

The following example illustrates how to use SMM to estimate a simple regression model. Suppose the model is

$$y = a + bx + u, u \sim iid N(0, s^2).$$

First, consider the problem in a GMM context. The first two moments of y are easily derived:

$$\begin{aligned} E(y) &= a + bx \\ E(y^2) &= (a + bx)^2 + s^2 \end{aligned}$$

Rewrite the moment conditions in the form similar to the discussion above:

$$\begin{aligned} \epsilon_{1t} &= y_t - (a + bx_t) \\ \epsilon_{2t} &= y_t^2 - (a + bx_t)^2 - s^2 \end{aligned}$$

Then you can estimate this model by using GMM with following statements:

```
proc model data=a;
  parms a b s;
  instrument x;
```

```

eq.m1 = y-(a+b*x);
eq.m2 = y*y - (a+b*x)**2 - s*s;
bound s > 0;
fit m1 m2 / gmm;
run;

```

Now suppose you do not have the closed form for the moment conditions. Instead you can simulate the moment conditions by generating H number of simulated samples based on the parameters. Then the simulated moment conditions are

$$\epsilon_{1t} = \frac{1}{H} \sum_{h=1}^H \{y_t - (a + bx_t + su_{t,h})\}$$

$$\epsilon_{2t} = \frac{1}{H} \sum_{h=1}^H \{y_t^2 - (a + bx_t + su_{t,h})^2\}$$

This model can be estimated by using SGMM with the following statements:

```

proc model data=_tmpdata;
  parms a b s;
  instrument x;
  ysim = (a+b*x) + s * rannor( 98711 );
  eq.m1 = y-ysim;
  eq.m2 = y*y - ysim*ysim;
  bound s > 0;
  fit m1 m2 / gmm ndraw=10;
run;

```

You can use the following MOMENT statement instead of specifying the two moment equations above:

```
moment ysim=(1, 2);
```

In cases where you require a large number of moment equations, using the MOMENT statement to specify them is more efficient.

Note that the NDRAW= option tells PROC MODEL that this is a simulation-based estimation. Thus, the random number function RANNOR returns random numbers in estimation process. During the simulation, 10 draws of $m1$ and $m2$ are generated for each observation, and the averages enter the objective functions just as the equations specified previously.

Other Estimation Methods

The simulation method can be used not only with GMM and ITGMM, but also with OLS, ITOLS, SUR, ITSUR, N2SLS, IT2SLS, N3SLS, and IT3SLS. These simulation-based methods are similar to the corresponding methods in PROC MODEL; the only difference is that the objective functions include the average of the H simulations.

Full Information Maximum Likelihood Estimation (FIML)

A different approach to the simultaneous equation bias problem is the full information maximum likelihood (FIML) estimation method (Amemiya 1977).

Compared to the instrumental variables methods (2SLS and 3SLS), the FIML method has these advantages and disadvantages:

- FIML does not require instrumental variables.
- FIML requires that the model include the full equation system, with as many equations as there are endogenous variables. With 2SLS or 3SLS, you can estimate some of the equations without specifying the complete system.
- FIML assumes that the equations errors have a multivariate normal distribution. If the errors are not normally distributed, the FIML method might produce poor results. 2SLS and 3SLS do not assume a specific distribution for the errors.
- The FIML method is computationally expensive.

The full information maximum likelihood estimators of θ and σ are the $\hat{\theta}$ and $\hat{\sigma}$ that minimize the negative log-likelihood function:

$$\begin{aligned} l_n(\theta, \sigma) = & \frac{ng}{2} \ln(2\pi) - \sum_{t=1}^n \ln \left(\left| \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)}{\partial \mathbf{y}_t'} \right| \right) + \frac{n}{2} \ln(|\Sigma(\sigma)|) \\ & + \frac{1}{2} \text{tr} \left(\Sigma(\sigma)^{-1} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \mathbf{q}'(\mathbf{y}_t, \mathbf{x}_t, \theta) \right) \end{aligned}$$

The option FIML requests full information maximum likelihood estimation. If the errors are distributed normally, FIML produces efficient estimators of the parameters. If instrumental variables are not provided, the starting values for the estimation are obtained from a SUR estimation. If instrumental variables are provided, then the starting values are obtained from a 3SLS estimation. The log-likelihood value and the l_2 norm of the gradient of the negative log-likelihood function are shown in the estimation summary.

FIML Details

To compute the minimum of $l_n(\theta, \sigma)$, this function is *concentrated* using the relation

$$\Sigma(\theta) = \frac{1}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \mathbf{q}'(\mathbf{y}_t, \mathbf{x}_t, \theta)$$

This results in the concentrated negative log-likelihood function discussed in Davidson and MacKinnon (1993):

$$l_n(\theta) = \frac{ng}{2} (1 + \ln(2\pi)) - \sum_{t=1}^n \ln \left| \frac{\partial}{\partial \mathbf{y}_t'} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \right| + \frac{n}{2} \ln |\Sigma(\theta)|$$

The gradient of the negative log-likelihood function is

$$\begin{aligned}\frac{\partial}{\partial \theta_i} l_n(\boldsymbol{\theta}) &= \sum_{t=1}^n \nabla_i(t) \\ \nabla_i(t) &= -\text{tr} \left(\left(\frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \mathbf{y}'_t} \right)^{-1} \frac{\partial^2 \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \mathbf{y}'_t \partial \theta_i} \right) \\ &+ \frac{1}{2} \text{tr} \left(\boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \frac{\partial \boldsymbol{\Sigma}(\boldsymbol{\theta})}{\partial \theta_i} \right. \\ &\quad \left. [I - \boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'] \right) \\ &+ \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}') \boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{\partial \theta_i}\end{aligned}$$

where

$$\frac{\partial \boldsymbol{\Sigma}(\boldsymbol{\theta})}{\partial \theta_i} = \frac{2}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \theta_i}$$

The estimator of the variance-covariance of $\hat{\boldsymbol{\theta}}$ (COVB) for FIML can be selected with the COVBEST= option with the following arguments:

CROSS selects the crossproducts estimator of the covariance matrix (Gallant 1987, p. 473):

$$C = \left(\frac{1}{n} \sum_{t=1}^n \nabla(t) \nabla'(t) \right)^{-1}$$

where $\nabla(t) = [\nabla_1(t), \nabla_2(t), \dots, \nabla_p(t)]'$. This is the default.

GLS selects the generalized least squares estimator of the covariance matrix. This is computed as (Dagenais 1978)

$$C = [\hat{\mathbf{Z}}' (\boldsymbol{\Sigma}(\boldsymbol{\theta})^{-1} \otimes I) \hat{\mathbf{Z}}]^{-1}$$

where $\hat{\mathbf{Z}} = (\hat{Z}_1, \hat{Z}_2, \dots, \hat{Z}_p)$ is $ng \times p$ and each \hat{Z}_i column vector is obtained from stacking the columns of

$$\mathbf{U} \frac{1}{n} \sum_{t=1}^n \left(\frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \mathbf{y}} \right)^{-1} \frac{\partial^2 \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})'}{\partial \mathbf{y}'_n \partial \theta_i} - Q_i$$

\mathbf{U} is an $n \times g$ matrix of residuals and q_i is an $n \times g$ matrix $\frac{\partial \mathbf{Q}}{\partial \theta_i}$.

FDA selects the inverse of concentrated likelihood Hessian as an estimator of the covariance matrix. The Hessian is computed numerically, so for a large problem this is computationally expensive.

The HESSIAN= option controls which approximation to the Hessian is used in the minimization procedure. Alternate approximations are used to improve convergence and execution time. The choices are as follows:

CROSS	The crossproducts approximation is used.
GLS	The generalized least squares approximation is used (default).
FDA	The Hessian is computed numerically by finite differences.

HESSIAN=GLS has better convergence properties in general, but COVBEST=CROSS produces the most pessimistic standard error bounds. When the HESSIAN= option is used, the default estimator of the variance-covariance of $\hat{\theta}$ is the inverse of the Hessian selected.

Multivariate t Distribution Estimation

The multivariate t distribution is specified by using the ERRORMODEL statement with the T option. Other method specifications (FIML and OLS, for example) are ignored when the ERRORMODEL statement is used for a distribution other than normal.

The probability density function for the multivariate t distribution is

$$P_q = \frac{\Gamma(\frac{df+m}{2})}{(\pi * df)^{\frac{m}{2}} * \Gamma(\frac{df}{2}) |\Sigma(\sigma)|^{\frac{1}{2}}} * \left(1 + \frac{\mathbf{q}'(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta}) \Sigma(\sigma)^{-1} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})}{df} \right)^{-\frac{df+m}{2}}$$

where m is the number of equations and df is the degrees of freedom.

The maximum likelihood estimators of θ and σ are the $\hat{\theta}$ and $\hat{\sigma}$ that minimize the negative log-likelihood function:

$$\begin{aligned} l_n(\boldsymbol{\theta}, \sigma) = & - \sum_{t=1}^n \ln \left(\frac{\Gamma(\frac{df+m}{2})}{(\pi * df)^{\frac{m}{2}} * \Gamma(\frac{df}{2})} * \left(1 + \frac{q_t' \Sigma^{-1} q_t}{df} \right)^{-\frac{df+m}{2}} \right) \\ & + \frac{n}{2} * \ln(|\Sigma|) - \sum_{t=1}^n \ln \left(\left| \frac{\partial q_t}{\partial \mathbf{y}_t'} \right| \right) \end{aligned}$$

The ERRORMODEL statement is used to request the t distribution maximum likelihood estimation. An OLS estimation is done to obtain initial parameter estimates and MSE.var estimates. Use NOOLS to turn off this initial estimation. If the errors are distributed normally, t distribution estimation produces results similar to FIML.

The multivariate model has a single shared degrees-of-freedom parameter, which is estimated. The degrees-of-freedom parameter can also be set to a fixed value. The log-likelihood value and the l_2 norm of the gradient of the negative log-likelihood function are shown in the estimation summary.

t Distribution Details

Since a variance term is explicitly specified by using the ERRORMODEL statement, $\Sigma(\theta)$ is estimated as a correlation matrix and $\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \boldsymbol{\theta})$ is normalized by the variance. The gradient of the negative log-likelihood function with respect to the degrees of freedom is

$$\begin{aligned} \frac{\partial l_n}{\partial df} = & \frac{nm}{2 df} - \frac{n}{2} \frac{\Gamma'(\frac{df+m}{2})}{\Gamma(\frac{df+m}{2})} + \frac{n}{2} \frac{\Gamma'(\frac{df}{2})}{\Gamma(\frac{df}{2})} + \\ & 0.5 \log \left(1 + \frac{\mathbf{q}' \Sigma^{-1} \mathbf{q}}{df} \right) - \frac{0.5(df+m)}{(1 + \frac{\mathbf{q}' \Sigma^{-1} \mathbf{q}}{df})} \frac{\mathbf{q}' \Sigma^{-1} \mathbf{q}}{df^2} \end{aligned}$$

The gradient of the negative log-likelihood function with respect to the parameters is

$$\frac{\partial l_n}{\partial \theta_i} = \frac{0.5(df + m)}{(1 + \mathbf{q}'\Sigma^{-1}\mathbf{q}/df)} \left[\frac{(2 \mathbf{q}'\Sigma^{-1} \frac{\partial \mathbf{q}}{\partial \theta_i})}{df} + \mathbf{q}'\Sigma^{-1} \frac{\partial \Sigma}{\partial \theta_i} \Sigma^{-1} \mathbf{q} \right] - \frac{n}{2} \text{trace}(\Sigma^{-1} \frac{\partial \Sigma}{\partial \theta_i})$$

where

$$\frac{\partial \Sigma(\theta)}{\partial \theta_i} = \frac{2}{n} \sum_{t=1}^n \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)'}{\partial \theta_i}$$

and

$$\mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) = \frac{\epsilon(\theta)}{\sqrt{h(\theta)}} \in R^{m \times n}$$

The estimator of the variance-covariance of $\hat{\theta}$ (COVB) for the t distribution is the inverse of the likelihood Hessian. The gradient is computed analytically, and the Hessian is computed numerically.

Empirical Distribution Estimation and Simulation

The following SAS statements fit a model that uses least squares as the likelihood function, but represent the distribution of the residuals with an empirical cumulative distribution function (CDF). The plot of the empirical probability distribution is shown in [Figure 19.24](#).

```
data t; /* Sum of two normals */
  format date monyy.;
  do t = 0 to 9.9 by 0.1;
    date = intnx( 'month', '1jun90'd, (t*10)-1 );
    y = 0.1 * (rannor(123)-10) +
        .5 * (rannor(123)+10);
    output;
  end;
run;

ods select Model.Likelihood.ResidSummary
           Model.Likelihood.ParameterEstimates;

proc model data=t time=t itprint;
  dependent y;
  parm a 5;

  y = a;
  obj = resid.y * resid.y;
  errormodel y ~ general( obj )
  cdf=(empirical=(tails=( normal percent=10)));

  fit y / outsn=s out=r;
  id date;

  solve y / data=t (where=(date='1aug98'd))
        residdata=r sdata=s
        random=200 seed=6789 out=monte ;
run;
```

```
proc kde data=monte;
  univar y / plots=density;
run;
```

Figure 19.24 Empirical PDF Plot

For simulation, if the CDF for the model is not built in to the procedure, you can use the `CDF=EMPIRICAL()` option. This uses the sorted residual data to create an empirical CDF. For computing the inverse CDF, the program needs to know how to handle the tails. For continuous data, the tail distribution is generally poorly determined. To counter this, the `PERCENT=` option specifies the percentage of the observations to use in constructing each tail. The default for the `PERCENT=` option is 10.

A normal distribution or a t distribution is used to extrapolate the tails to infinity. The standard errors for this extrapolation are obtained from the data so that the empirical CDF is continuous.

Properties of the Estimates

All of the methods are consistent. Small sample properties might not be good for nonlinear models. The tests and standard errors reported are based on the convergence of the distribution of the estimates to a normal distribution in large samples.

These nonlinear estimation methods reduce to the corresponding linear systems regression methods if the model is linear. If this is the case, PROC MODEL produces the same estimates as PROC SYSLIN.

Except for GMM, the estimation methods assume that the equation errors for each observation are identically and independently distributed with a 0 mean vector and positive definite covariance matrix Σ consistently estimated by S . For FIML, the errors need to be normally distributed. There are no other assumptions concerning the distribution of the errors for the other estimation methods.

The consistency of the parameter estimates relies on the assumption that the S matrix is a consistent estimate of Σ . These standard error estimates are asymptotically valid, but for nonlinear models they might not be reliable for small samples.

The S matrix used for the calculation of the covariance of the parameter estimates is the best estimate available for the estimation method selected. For S -iterated methods, this is the most recent estimation of Σ . For OLS and 2SLS, an estimate of the S matrix is computed from OLS or 2SLS residuals and used for the calculation of the covariance matrix. For a complete list of the S matrix used for the calculation of the covariance of the parameter estimates, see [Table 19.2](#).

Missing Values

An observation is excluded from the estimation if any variable used for FIT tasks is missing, if the weight for the observation is not greater than 0 when weights are used, or if a DELETE statement is executed by the model program. Variables used for FIT tasks include the equation errors for each equation, the instruments, if any, and the derivatives of the equation errors with respect to the parameters estimated. Note that variables can become missing as a result of computational errors or calculations with missing values.

The number of usable observations can change when different parameter values are used; some parameter values can be invalid and cause execution errors for some observations. PROC MODEL keeps track of the number of usable and missing observations at each pass through the data, and if the number of missing observations counted during a pass exceeds the number that was obtained using the previous parameter vector, the pass is terminated and the new parameter vector is considered infeasible. PROC MODEL never takes a step that produces more missing observations than the current estimate does.

The values used to compute the Durbin-Watson, R^2 , and other statistics of fit are from the observations used in calculating the objective function and do not include any observation for which any needed variable was missing (residuals, derivatives, and instruments).

Details on the Covariance of Equation Errors

There are several S matrices that can be involved in the various estimation methods and in forming the estimate of the covariance of parameter estimates. These S matrices are estimates of Σ , the true covariance of the equation errors. Apart from the choice of instrumental or noninstrumental methods, many of the methods provided by PROC MODEL differ in the way the various S matrices are formed and used.

All of the estimation methods result in a final estimate of Σ , which is included in the output if the COVS option is specified. The final S matrix of each method provides the initial S matrix for any subsequent estimation.

This estimate of the covariance of equation errors is defined as

$$S = D(R'R)D$$

where $\mathbf{R} = (\mathbf{r}_1, \dots, \mathbf{r}_g)$ is composed of the equation residuals computed from the current parameter estimates in an $n \times g$ matrix and \mathbf{D} is a diagonal matrix that depends on the VARDEF= option.

For VARDEF=N, the diagonal elements of \mathbf{D} are $1/\sqrt{n}$, where n is the number of nonmissing observations. For VARDEF=WGT, n is replaced with the sum of the weights. For VARDEF=WDF, n is replaced with the sum of the weights minus the model degrees of freedom. For the default VARDEF=DF, the i th diagonal element of \mathbf{D} is $1/\sqrt{n - df_i}$, where df_i is the degrees of freedom (number of parameters) for the i th equation. Binkley and Nelson (1984) show the importance of using a degrees-of-freedom correction in estimating Σ . Their results indicate that the DF method produces more accurate confidence intervals for N3SLS parameter estimates in the linear case than the alternative approach they tested. VARDEF=N is always used for the computation of the FIML estimates.

For the fixed \mathbf{S} methods, the OUTSUSED= option writes the \mathbf{S} matrix used in the estimation to a data set. This \mathbf{S} matrix is either the estimate of the covariance of equation errors matrix from the preceding estimation, or a prior Σ estimate read in from a data set when the SDATA= option is specified. For the diagonal \mathbf{S} methods, all of the off-diagonal elements of the \mathbf{S} matrix are set to 0 for the estimation of the parameters and for the OUTSUSED= data set, but the output data set produced by the OUTS= option contains the off-diagonal elements. For the OLS and N2SLS methods, there is no previous estimate of the covariance of equation errors matrix, and the option OUTSUSED= saves an identity matrix unless a prior Σ estimate is supplied by the SDATA= option. For FIML, the OUTSUSED= data set contains the \mathbf{S} matrix computed with VARDEF=N. The OUTS= data set contains the \mathbf{S} matrix computed with the selected VARDEF= option. Both versions of the \mathbf{S} matrix appear in the printed output for FIML.

If the COVS option is used, the method is not \mathbf{S} -iterated, \mathbf{S} is not an identity, and the OUTSUSED= matrix is included in the printed output.

For the methods that iterate the covariance of equation errors matrix, the \mathbf{S} matrix is iteratively re-estimated from the residuals produced by the current parameter estimates. This \mathbf{S} matrix estimate iteratively replaces the previous estimate until both the parameter estimates and the estimate of the covariance of equation errors matrix converge. The final OUTS= matrix and OUTSUSED= matrix are thus identical for the \mathbf{S} -iterated methods.

Nested Iterations

By default, for \mathbf{S} -iterated methods, the \mathbf{S} matrix is held constant until the parameters converge once. Then the \mathbf{S} matrix is reestimated. One iteration of the parameter estimation algorithm is performed, and the \mathbf{S} matrix is again reestimated. This latter process is repeated until convergence of both the parameters and the \mathbf{S} matrix. Since the objective of the minimization depends on the \mathbf{S} matrix, this has the effect of chasing a moving target.

When the NESTIT option is specified, iterations are performed to convergence for the structural parameters with a fixed \mathbf{S} matrix. The \mathbf{S} matrix is then reestimated, the parameter iterations are repeated to convergence, and so on until both the parameters and the \mathbf{S} matrix converge. This has the effect of fixing the objective function for the inner parameter iterations. It is more reliable, but usually more expensive, to nest the iterations.

R-Square Statistic

For unrestricted linear models with an intercept successfully estimated by OLS, R^2 is always between 0 and 1. However, nonlinear models do not necessarily encompass the dependent mean as a special case and can

produce negative R^2 statistics. Negative R^2 statistics can also be produced even for linear models when an estimation method other than OLS is used and no intercept term is in the model.

R^2 is defined for normalized equations as

$$R^2 = 1 - \frac{SSE}{SSA - \bar{y}^2 \times n}$$

where SSA is the sum of the squares of the actual y 's and \bar{y} are the actual means. R^2 cannot be computed for models in general form because of the need for an actual Y .

Minimization Methods

PROC MODEL currently supports two methods for minimizing the objective function. These methods are described in the following sections.

GAUSS

The Gauss-Newton parameter-change vector for a system with g equations, n nonmissing observations, and p unknown parameters is

$$\Delta = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r}$$

where Δ is the change vector, \mathbf{X} is the stacked $ng \times p$ Jacobian matrix of partial derivatives of the residuals with respect to the parameters, and \mathbf{r} is an $ng \times 1$ vector of the stacked residuals. The components of \mathbf{X} and \mathbf{r} are weighted by the \mathbf{S}^{-1} matrix. When instrumental methods are used, \mathbf{X} and \mathbf{r} are the projections of the Jacobian matrix and residuals vector in the instruments space and not the Jacobian and residuals themselves. In the preceding formula, \mathbf{S} and \mathbf{W} are suppressed. If instrumental variables are used, then the change vector becomes:

$$\Delta = (\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{r}$$

This vector is computed at the end of each iteration. The objective function is then computed at the changed parameter values at the start of the next iteration. If the objective function is not improved by the change, the Δ vector is reduced by one-half and the objective function is reevaluated. The change vector will be halved up to MAXSUBITER= times until the objective function is improved. If the objective function cannot be improved after MAXSUBITER= times, the procedure switches to the MARQUARDT method described in the next section to further improve the objective function.

For FIML, the $\mathbf{X}'\mathbf{X}$ matrix is substituted with one of three choices for approximations to the Hessian. See the section “[Full Information Maximum Likelihood Estimation \(FIML\)](#)” on page 1092 in this chapter.

MARQUARDT

The Marquardt-Levenberg parameter change vector is

$$\Delta = (\mathbf{X}'\mathbf{X} + \lambda \text{diag}(\mathbf{X}'\mathbf{X}))^{-1}\mathbf{X}'\mathbf{r}$$

where Δ is the change vector, and \mathbf{X} and \mathbf{r} are the same as for the Gauss-Newton method, described in the preceding section. Before the iterations start, λ is set to a small value (1E-6). At each iteration, the objective function is evaluated at the parameters changed by Δ . If the objective function is not improved, λ is increased to 10λ and the step is tried again. λ can be increased up to MAXSUBITER= times to a maximum of 1E15 (whichever comes first) until the objective function is improved. For the start of the next iteration, λ is reduced to $\max(\lambda/10, 1E-10)$.

Convergence Criteria

There are a number of measures that could be used as convergence or stopping criteria. PROC MODEL computes five convergence measures labeled R, S, PPC, RPC, and OBJECT.

When an estimation technique that iterates estimates of Σ is used (that is, IT3SLS), two convergence criteria are used. The termination values can be specified with the CONVERGE=(p,s) option in the FIT statement. If the second value, s , is not specified, it defaults to p . The criterion labeled S (described later in the section) controls the convergence of the \mathbf{S} matrix. When S is less than s , the \mathbf{S} matrix has converged. The criterion labeled R is compared to the p -value to test convergence of the parameters.

The R convergence measure cannot be computed accurately in the special case of singular residuals (when all the residuals are close to 0) or in the case of a 0 objective value. When either the trace of the \mathbf{S} matrix computed from the current residuals (trace(S)) or the objective value is less than the value of the SINGULAR= option, convergence is assumed.

The various convergence measures are explained in the following:

R is the primary convergence measure for the parameters. It measures the degree to which the residuals are orthogonal to the Jacobian columns, and it approaches 0 as the gradient of the objective function becomes small. R is defined as the square root of

$$\frac{(r'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X}(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})\mathbf{X})^{-1}\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{W})r)}{(r'(\mathbf{S}^{-1} \otimes \mathbf{W})r)}$$

where \mathbf{X} is the Jacobian matrix and \mathbf{r} is the residuals vector. R is similar to the relative offset orthogonality convergence criterion proposed by Bates and Watts (1981).

In the univariate case, the R measure has several equivalent interpretations:

- the cosine of the angle between the residuals vector and the column space of the Jacobian matrix. When this cosine is 0, the residuals are orthogonal to the partial derivatives of the predicted values with respect to the parameters, and the gradient of the objective function is 0.
- the square root of the R^2 for the current linear pseudo-model in the residuals
- a norm of the gradient of the objective function, where the norming matrix is proportional to the current estimate of the covariance of the parameter estimates. Thus, using R, convergence is judged when the gradient becomes small in this norm.
- the prospective relative change in the objective function value expected from the next GAUSS step, assuming that the current linearization of the model is a good local approximation.

In the multivariate case, R is somewhat more complicated but is designed to go to 0 as the gradient of the objective becomes small and can still be given the previous interpretations for the aggregation of the equations weighted by \mathbf{S}^{-1} .

PPC

is the prospective parameter change measure. PPC measures the maximum relative change in the parameters implied by the parameter-change vector computed for the next iteration. At the k th iteration, PPC is the maximum over the parameters

$$\frac{|\theta_i^{k+1} - \theta_i^k|}{|\theta_i^k| + 10^{-6}}$$

where θ_i^k is the current value of the i th parameter and θ_i^{k+1} is the prospective value of this parameter after adding the change vector computed for the next iteration. The parameter with the maximum prospective relative change is printed with the value of PPC, unless the PPC is nearly 0.

RPC

is the retrospective parameter change measure. RPC measures the maximum relative change in the parameters from the previous iteration. At the k th iteration, RPC is the maximum over i of

$$\frac{|\theta_i^k - \theta_i^{k-1}|}{|\theta_i^{k-1}| + 10^{-6}}$$

where θ_i^k is the current value of the i th parameter and θ_i^{k-1} is the previous value of this parameter. The name of the parameter with the maximum retrospective relative change is printed with the value of RPC, unless the RPC is nearly 0.

OBJECT

measures the relative change in the objective function value between iterations:

$$\frac{|O^k - O^{k-1}|}{|O^{k-1}| + 10^{-6}}$$

where O^{k-1} is the value of the objective function (O^k) from the previous iteration.

S

measures the relative change in the \mathbf{S} matrix. S is computed as the maximum over i, j of

$$\frac{|S_{ij}^k - S_{ij}^{k-1}|}{|S_{ij}^{k-1}| + 10^{-6}}$$

where S^{k-1} is the previous \mathbf{S} matrix. The S measure is relevant only for estimation methods that iterate the \mathbf{S} matrix.

An example of the convergence criteria output is shown in [Figure 19.25](#).

Figure 19.25 Convergence Criteria Output

Final Convergence Criteria	
R	0.000737
PPC(b)	0.003943
RPC(b)	0.00968
Object	4.784E-6
Trace(S)	0.533325
Objective Value	0.522214

The Trace(S) is the trace (the sum of the diagonal elements) of the **S** matrix computed from the current residuals. This row is labeled MSE if there is only one equation.

Troubleshooting Convergence Problems

As with any nonlinear estimation routine, there is no guarantee that the estimation will be successful for a given model and data. If the equations are linear with respect to the parameters, the parameter estimates always converge in one iteration. The methods that iterate the **S** matrix must iterate further for the **S** matrix to converge. Nonlinear models might not necessarily converge.

Convergence can be expected only with fully identified parameters, adequate data, and starting values sufficiently close to solution estimates.

Convergence and the rate of convergence might depend primarily on the choice of starting values for the estimates. This does not mean that a great deal of effort should be invested in choosing starting values. First, try the default values. If the estimation fails with these starting values, examine the model and data and rerun the estimation using reasonable starting values. It is usually not necessary that the starting values be very good, just that they not be very bad; choose values that seem plausible for the model and data.

An Example of Requiring Starting Values

Suppose you want to regress a variable *Y* on a variable *X*, assuming that the variables are related by the following nonlinear equation:

$$y = a + bx^c + \epsilon$$

In this equation, *Y* is linearly related to a power transformation of *X*. The unknown parameters are *a*, *b*, and *c*. ϵ is an unobserved random error. The following SAS statements generate simulated data. In this simulation, *a* = 10, *b* = 2, and the use of the SQRT function corresponds to *c* = .5.

```
data test;
  do i = 1 to 20;
    x = 5 * ranuni(1234);
    y = 10 + 2 * sqrt(x) + .5 * rannor(1234);
    output;
  end;
run;
```

The following statements specify the model and give descriptive labels to the model parameters. Then the FIT statement attempts to estimate a , b , and c by using the default starting value 0.0001.

```
proc model data=test;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y;
run;
```

PROC MODEL prints model summary and estimation problem summary reports and then prints the output shown in [Figure 19.26](#).

Figure 19.26 Diagnostics for Convergence Failure

The MODEL Procedure									
OLS Estimation									
ERROR: The parameter estimates failed to converge for OLS after 100 iterations using CONVERGE=0.001 as the convergence criteria.									
The MODEL Procedure									
OLS Estimation									
	Iteration	N Obs	R	Objective	Subit	N	a	b	c
OLS	100	20	0.9627	3.9678	2	137.3822	-126.533	-0.00213	
Gauss Method Parameter Change Vector									
	a	b	c						
	-69369.08	69368.01	-1.16						

By using the default starting values, PROC MODEL is unable to take even the first step in iterating to the solution. The change in the parameters that the Gauss-Newton method computes is very extreme and makes the objective values worse instead of better. Even when this step is shortened by a factor of a million, the objective function is still worse, and PROC MODEL is unable to estimate the model parameters.

The problem is caused by the starting value of C . Using the default starting value $C=0.0001$, the first iteration attempts to compute better values of A and B by what is, in effect, a linear regression of Y on the 10,000th root of X , which is almost the same as the constant 1. Thus the matrix that is inverted to compute the changes is nearly singular and affects the accuracy of the computed parameter changes.

This is also illustrated by the next part of the output, which displays collinearity diagnostics for the crossproducts matrix of the partial derivatives with respect to the parameters, shown in [Figure 19.27](#).

Figure 19.27 Collinearity Diagnostics

Collinearity Diagnostics					
Number	Eigenvalue	Condition Number	-----Proportion of Variation-----		
			a	b	c
1	2.376793	1.0000	0.0000	0.0000	0.0000
2	0.623207	1.9529	0.0000	0.0000	0.0000
3	1.68475E-12	1187758	1.0000	1.0000	1.0000

This output shows that the matrix is singular and that the partials of A, B, and C with respect to the residual are collinear at the point (0.0001, 0.0001, 0.0001) in the parameter space. See the section “[Linear Dependencies](#)” on page 1111 for a full explanation of the collinearity diagnostics.

The MODEL procedure next prints the note shown in [Figure 19.28](#), which suggests that you try different starting values.

Figure 19.28 Estimation Failure Note

NOTE: The parameter estimation is abandoned. Check your model and data. If the model is correct and the input data are appropriate, try rerunning the parameter estimation using different starting values for the parameter estimates.

PROC MODEL continues as if the parameter estimates had converged.

PROC MODEL then produces the usual printout of results for the nonconverged parameter values. The estimation summary is shown in [Figure 19.29](#). The heading includes the reminder “(Not Converged)”.

Figure 19.29 Nonconverged Estimation Summary

The MODEL Procedure

Solved	20

The nonconverged estimation results are shown in Figure 19.30.

Figure 19.30 Nonconverged Results

The MODEL Procedure							
Nonlinear OLS Summary of Residual Errors (Not Converged)							
Equation	DF Model	DF Error	SSE	MSE	Root MSE	R-Square	Adj R-Sq
y	3	17	79.3551	4.6679	2.1605	-1.6812	-1.9966

Note that the R^2 statistic is negative. An $R^2 < 0$ results when the residual mean squared error for the model is larger than the variance of the dependent variable. Negative R^2 statistics might be produced when either the parameter estimates fail to converge correctly, as in this case, or when the correctly estimated model fits the data very poorly.

Controlling Starting Values

To fit the preceding model you must specify a better starting value for C. Avoid starting values of C that are either very large or close to 0. For starting values of A and B, you can specify values, use the default, or have PROC MODEL fit starting values for them conditional on the starting value for C.

Starting values are specified with the START= option of the FIT statement or in a PARMS statement. In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. When no starting values for the parameter estimates are specified with BY group processing, the default start value 0.0001 is used for each by group. Again, when no starting values are specified, and a model with a FIT statement is stored by the OUTMODEL=outmodel-filename option in a previous step, the outmodel-filename can be invoked in a subsequent PROC MODEL step by using the MODEL=outmodel-filename option with multiple estimation methods in the second step. In such

a case, the parameter estimates from the *outmodel-filename* are used directly as starting values for OLS, and OLS results from the second step provide starting values for the subsequent estimation method such as 2SLS or SUR, provided that NOOLS is not specified.

For example, the following statements estimate the model parameters by using the starting values A=0.0001, B=0.0001, and C=5.

```
proc model data=test;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y start=(c=5);
run;
```

Using these starting values, the estimates converge in 16 iterations. The results are shown in Figure 19.31. Note that since the START= option explicitly declares parameters, the parameter C is placed first in the table.

Figure 19.31 Converged Results

The MODEL Procedure							
Nonlinear OLS Summary of Residual Errors							
Equation	DF Model	DF Error	SSE	MSE	Root MSE	R-Square	Adj R-Sq
y	3	17	5.7359	0.3374	0.5809	0.8062	0.7834
Nonlinear OLS Parameter Estimates							
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t	Label		
c	0.327079	0.2892	1.13	0.2738	Power Transformation Parameter		
a	8.384311	3.3775	2.48	0.0238	Intercept		
b	3.505391	3.4858	1.01	0.3287	Coefficient of Transformed X		

Using the STARTITER Option

PROC MODEL can compute starting values for some parameters conditional on starting values you specify for the other parameters. You supply starting values for some parameters and specify the STARTITER option on the FIT statement.

For example, the following statements set C to 1 and compute starting values for A and B by estimating these parameters conditional on the fixed value of C. With C=1, this is equivalent to computing A and B by linear regression on X. A PARMS statement is used to declare the parameters in alphabetical order. The ITPRINT option is used to print the parameter values at each iteration.

```

proc model data=test;
  parms a b c;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y start=(c=1) / starttiter itprint;
run;

```

With better starting values, the estimates converge in only eight iterations. Counting the iteration required to compute the starting values for A and B, this is seven fewer than the 16 iterations required without the STARTITER option. The iteration history listing is shown in [Figure 19.32](#).

Figure 19.32 ITPRINT Listing

The MODEL Procedure										
OLS Estimation										
	Iteration	N	Obs	R	Objective	Subit	N	a	b	c
GRID	0	20	0.9989		162.9	0	0.00010	0.00010	1.00000	
GRID	1	20	0.0000		0.3464	0	10.96530	0.77007	1.00000	
	Iteration	N	Obs	R	Objective	Subit	N	a	b	c
OLS	0	20	0.3873		0.3464	0	10.96530	0.77007	1.00000	
OLS	1	20	0.3339		0.3282	2	10.75993	0.99433	0.83096	
OLS	2	20	0.3244		0.3233	1	10.46894	1.31205	0.66810	
OLS	3	20	0.3151		0.3197	1	10.11707	1.69149	0.54626	
OLS	4	20	0.2764		0.3110	1	9.74691	2.08492	0.46615	
OLS	5	20	0.2379		0.3040	0	9.06175	2.80546	0.36575	
OLS	6	20	0.0612		0.2879	0	8.51825	3.36746	0.33201	
OLS	7	20	0.0022		0.2868	0	8.39485	3.49449	0.32776	
OLS	8	20	0.0001		0.2868	0	8.38467	3.50502	0.32711	
NOTE: At OLS Iteration 8 CONVERGE=0.001 Criteria Met.										

The results produced in this case are almost the same as the results shown in [Figure 19.31](#), except that the PARMS statement causes the parameter estimates table to be ordered A, B, C instead of C, A, B. They are not exactly the same because the different starting values caused the iterations to converge at a slightly different place. This effect is controlled by changing the convergence criterion with the CONVERGE= option.

By default, the STARTITER option performs one iteration to find starting values for the parameters that are not given values. In this case, the model is linear in A and B, so only one iteration is needed. If A or B were nonlinear, you could specify more than one “starting values” iteration by specifying a number for the STARTITER= option.

Finding Starting Values by Grid Search

PROC MODEL can try various combinations of parameter values and use the combination that produces the smallest objective function value as starting values. (For OLS the objective function is the residual mean square.) This is known as a preliminary *grid search*. You can combine the STARTITER option with a grid search.

For example, the following statements try five different starting values for C: 1, 0.7, 0.5, 0.3, and 0. For each value of C, values for A and B are estimated. The combination of A, B, and C values that produce the smallest residual mean square is then used to start the iterative process.

```
proc model data=test;
  parms a b c;
  y = a + b * x ** c;
  label a = "Intercept"
        b = "Coefficient of Transformed X"
        c = "Power Transformation Parameter";
  fit y start=(c=1 .7 .5 .3 0) / startiter itprint;
run;
```

The iteration history listing is shown in Figure 19.33. Using the best starting values found by the grid search, the OLS estimation only requires two iterations. However, since the grid search required nine iterations, the total iterations in this case is 11.

Figure 19.33 ITPRINT Listing

The MODEL Procedure									
OLS Estimation									
	Iteration	N	Obs	R	Objective	Subit	a	b	c
GRID	0	20	0.9989		162.9	0	0.00010	0.00010	1.00000
GRID	1	20	0.0000		0.3464	0	10.96530	0.77007	1.00000
GRID	0	20	0.7587		0.7242	0	10.96530	0.77007	0.70000
GRID	1	20	0.0000		0.3073	0	10.41027	1.36141	0.70000
GRID	0	20	0.7079		0.5843	0	10.41027	1.36141	0.50000
GRID	1	20	0.0000		0.2915	0	9.69319	2.13103	0.50000
GRID	0	20	0.7747		0.7175	0	9.69319	2.13103	0.30000
GRID	1	20	0.0000		0.2869	0	8.04397	3.85767	0.30000
GRID	0	20	0.5518		2.1277	0	8.04397	3.85767	0.00000
GRID	1	20	0.0000		1.4799	0	8.04397	4.66255	0.00000
	Iteration	N	Obs	R	Objective	Subit	a	b	c
OLS	0	20	0.0189		0.2869	0	8.04397	3.85767	0.30000
OLS	1	20	0.0158		0.2869	0	8.35023	3.54145	0.32233
OLS	2	20	0.0006		0.2868	0	8.37468	3.51540	0.32622
NOTE: At OLS Iteration 2 CONVERGE=0.001 Criteria Met.									

Because no initial values for A or B were provided in the PARAMETERS statement or were read in with a PARMSDATA= or ESTDATA= option, A and B were given the default value of 0.0001 for the first iteration.

At the second grid point, $C=5$, the values of A and B obtained from the previous iterations are used for the initial iteration. If initial values are provided for parameters, the parameters start at those initial values at each grid point.

Guessing Starting Values from the Logic of the Model

Example 19.1, which uses a logistic growth curve model of the U.S. population, illustrates the need for reasonable starting values. This model can be written

$$pop = \frac{a}{1 + \exp(b - c(t - 1790))}$$

where t is time in years. The model is estimated by using decennial census data of the U.S. population in millions. If this simple but highly nonlinear model is estimated by using the default starting values, the estimation fails to converge.

To find reasonable starting values, first consider the meaning of a and c . Taking the limit as time increases, a is the limiting or maximum possible population. So, as a starting value for a , several times the most recent population known can be used—for example, one billion (1000 million).

Dividing the time derivative by the function to find the growth rate and taking the limit as t moves into the past, you can determine that c is the initial growth rate. You can examine the data and compute an estimate of the growth rate for the first few decades, or you can pick a number that sounds like a plausible population growth rate figure, such as 2%.

To find a starting value for b , let t equal the base year used, 1790, which causes c to drop out of the formula for that year, and then solve for the value of b that is consistent with the known population in 1790 and with the starting value of a . This yields $b = \ln(a/3.9 - 1)$ or about 5.5, where a is 1000 and 3.9 is roughly the population for 1790 given in the data. The estimates converge using these starting values.

Convergence Problems

When estimating nonlinear models, you might encounter some of the following convergence problems.

Unable to Improve

The optimization algorithm might be unable to find a step that improves the objective function. If this happens in the Gauss-Newton method, the step size is halved to find a change vector for which the objective improves. In the Marquardt method, λ is increased to find a change vector for which the objective improves. If, after $\text{MAXSUBITER} =$ step-size halvings or increases in λ , the change vector still does not produce a better objective value, the iterations are stopped and an error message is printed.

Failure of the algorithm to improve the objective value can be caused by a $\text{CONVERGE} =$ value that is too small. Look at the convergence measures reported at the point of failure. If the estimates appear to be approximately converged, you can accept the NOT CONVERGED results reported, or you can try rerunning the FIT task with a larger $\text{CONVERGE} =$ value.

If the procedure fails to converge because it is unable to find a change vector that improves the objective value, check your model and data to ensure that all parameters are identified and data values are reasonably scaled. Then, rerun the model with different starting values. Also, consider using the Marquardt method if the Gauss-Newton method fails; the Gauss-Newton method can get into trouble if the Jacobian matrix is nearly singular or ill-conditioned. Keep in mind that a nonlinear model may be well-identified and well-conditioned for parameter values close to the solution values but unidentified or numerically ill-conditioned for other parameter values. The choice of starting values can make a big difference.

Nonconvergence

The estimates might diverge into areas where the program overflows or the estimates might go into areas where function values are illegal or too badly scaled for accurate calculation. The estimation might also take steps that are too small or that make only marginal improvement in the objective function and thus fail to converge within the iteration limit.

When the estimates fail to converge, collinearity diagnostics for the Jacobian crossproducts matrix are printed if there are 20 or fewer parameters estimated. See the section “[Linear Dependencies](#)” on page 1111 for an explanation of these diagnostics.

Inadequate Convergence Criterion

If convergence is obtained, the resulting estimates approximate only a minimum point of the objective function. The statistical validity of the results is based on the exact minimization of the objective function, and for nonlinear models the quality of the results depends on the accuracy of the approximation of the minimum. This is controlled by the convergence criterion used.

There are many nonlinear functions for which the objective function is quite flat in a large region around the minimum point so that many quite different parameter vectors might satisfy a weak convergence criterion. By using different starting values, different convergence criteria, or different minimization methods, you can produce very different estimates for such models.

You can guard against this by running the estimation with different starting values and different convergence criteria and checking that the estimates produced are essentially the same. If they are not, use a smaller CONVERGE= value.

Local Minimum

You might have converged to a local minimum rather than a global one. This problem is difficult to detect because the procedure appears to have succeeded. You can guard against this by running the estimation with different starting values or with a different minimization technique. The START= option can be used to automatically perform a grid search to aid in the search for a global minimum.

Discontinuities

The computational methods assume that the model is a continuous and smooth function of the parameters. If this is not the case, the methods might not work.

If the model equations or their derivatives contain discontinuities, the estimation usually succeeds, provided that the final parameter estimates lie in a continuous interval and that the iterations do not produce parameter values at points of discontinuity or parameter values that try to cross asymptotes.

One common case of discontinuities causing estimation failure is that of an asymptotic discontinuity between the final estimates and the initial values. For example, consider the following model, which is basically linear but is written with one parameter in reciprocal form:

$$y = a + b * x1 + x2 / c;$$

By placing the parameter C in the denominator, a singularity is introduced into the parameter space at C=0. This is not necessarily a problem, but if the correct estimate of C is negative while the starting value is positive (or vice versa), the asymptotic discontinuity at 0 will lie between the estimate and the starting value. This means that the iterations have to pass through the singularity to get to the correct estimates. The situation is shown in [Figure 19.34](#).

Figure 19.34 Asymptotic Discontinuity

Because of the incorrect sign of the starting value, the C estimate goes off towards positive infinity in a vain effort to get past the asymptote and onto the correct arm of the hyperbola. As the computer is required to work with ever closer approximations to infinity, the numerical calculations break down and an “objective function was not improved” convergence failure message is printed. At this point, the iterations terminate with an extremely large positive value for C . When the sign of the starting value for C is changed, the estimates converge quickly to the correct values.

Linear Dependencies

In some cases, the Jacobian matrix might not be of full rank; parameters might not be fully identified for the current parameter values with the current data. When linear dependencies occur among the derivatives of the model, some parameters appear with a standard error of 0 and with the word **BIASED** printed in place of the t statistic. When this happens, collinearity diagnostics for the Jacobian crossproducts matrix are printed if the **DETAILS** option is specified and there are twenty or fewer parameters estimated. Collinearity diagnostics are also printed out automatically when a minimization method fails, or when the **COLLIN** option is specified.

For each parameter, the proportion of the variance of the estimate accounted for by each *principal component* is printed. The principal components are constructed from the eigenvalues and eigenvectors of the correlation matrix (scaled covariance matrix). When collinearity exists, a principal component is associated with proportion of the variance of more than one parameter. The numbers reported are proportions so they remain between 0 and 1. If two or more parameters have large proportion values associated with the same principal component, then two problems can occur: the computation of the parameter estimates are slow

or nonconvergent; and the parameter estimates have inflated variances (Belsley, Kuh, and Welsch 1980, p. 105–117).

For example, the following cubic model is fit to a quadratic data set:

```
proc model data=test3;
  exogenous x1;
  parms b1 a1 c1 ;
  y1 = a1 * x1 + b1 * x1 * x1 + c1 * x1 * x1 *x1;
  fit y1 / collin;
run;
```

The collinearity diagnostics are shown in Figure 19.35.

Figure 19.35 Collinearity Diagnostics

The MODEL Procedure					
Collinearity Diagnostics					
Number	Eigenvalue	Condition Number	-----Proportion of Variation-----		
			b1	a1	c1
1	2.942920	1.0000	0.0001	0.0004	0.0002
2	0.056638	7.2084	0.0001	0.0357	0.0148
3	0.000442	81.5801	0.9999	0.9639	0.9850

Notice that the proportions associated with the smallest eigenvalue are almost 1. For this model, removing any of the parameters decreases the variances of the remaining parameters.

In many models, the collinearity might not be clear cut. Collinearity is not necessarily something you remove. A model might need to be reformulated to remove the redundant parameterization, or the limitations on the estimability of the model can be accepted. The GINV=G4 option can be helpful to avoid problems with convergence for models containing collinearities.

Collinearity diagnostics are also useful when an estimation does not converge. The diagnostics provide insight into the numerical problems and can suggest which parameters need better starting values. These diagnostics are based on the approach of Belsley, Kuh, and Welsch (1980).

Iteration History

The options ITPRINT, ITDETAILS, XPX, I, and ITALL specify a detailed listing of each iteration of the minimization process.

ITPRINT Option

The ITPRINT information is selected whenever any iteration information is requested.

The following information is displayed for each iteration:

N	is the number of usable observations.
Objective	is the corrected objective function value.
Trace(S)	is the trace of the S matrix.
subit	is the number of subiterations required to find a λ or a damping factor that reduces the objective function.
R	is the R convergence measure.

The estimates for the parameters at each iteration are also printed.

ITDETAILS Option

The additional values printed for the ITDETAILS option are:

Theta	is the angle in degrees between Δ , the parameter change vector, and the negative gradient of the objective function.
Phi	is the directional derivative of the objective function in the Δ direction scaled by the objective function.
Stepsize	is the value of the damping factor used to reduce Δ if the Gauss-Newton method is used.
Lambda	is the value of λ if the Marquardt method is used.
Rank(XPX)	is the rank of the $X'X$ matrix (output if the projected Jacobian crossproducts matrix is singular).

The definitions of PPC and R are explained in the section “[Convergence Criteria](#)” on page 1100. When the values of PPC are large, the parameter associated with the criteria is displayed in parentheses after the value.

XPX and I Options

The XPX and the I options select the printing of the augmented $X'X$ matrix and the augmented $X'X$ matrix after a *sweep* operation (Goodnight 1979) has been performed on it. An example of the output from the following statements is shown in [Figure 19.36](#).

```
proc model data=test2;
  y1 = a1 * x2 * x2 - exp( d1*x1);
  y2 = a2 * x1 * x1 + b2 * exp( d2*x2);
  fit y1 y2 / itall XPX I ;
run;
```

Figure 19.36 XPX and I Options Output

The MODEL Procedure						
OLS Estimation						
Cross Products for System At OLS Iteration 0						
	a1	d1	a2	b2	d2	Residual
a1	1839468	-33818.35	0.0	0.00	0.000000	3879959
d1	-33818	1276.45	0.0	0.00	0.000000	-76928
a2	0	0.00	42925.0	1275.15	0.154739	470686
b2	0	0.00	1275.2	50.01	0.003867	16055
d2	0	0.00	0.2	0.00	0.000064	2
Residual	3879959	-76928.14	470686.3	16055.07	2.329718	24576144
XPX Inverse for System At OLS Iteration 0						
	a1	d1	a2	b2	d2	Residual
a1	0.000001	0.000028	0.000000	0.0000	0.00	2
d1	0.000028	0.001527	0.000000	0.0000	0.00	-9
a2	0.000000	0.000000	0.000097	-0.0025	-0.08	6
b2	0.000000	0.000000	-0.002455	0.0825	0.95	172
d2	0.000000	0.000000	-0.084915	0.9476	15746.71	11931
Residual	1.952150	-8.546875	5.823969	171.6234	11930.89	10819902

The first matrix, labeled “Cross Products,” for OLS estimation is

$$\begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{r} \\ \mathbf{r}'\mathbf{X} & \mathbf{r}'\mathbf{r} \end{bmatrix}$$

The column labeled Residual in the output is the vector $\mathbf{X}'\mathbf{r}$, which is the gradient of the objective function. The diagonal scalar value $\mathbf{r}'\mathbf{r}$ is the objective function uncorrected for degrees of freedom. The second matrix, labeled “XPX Inverse,” is created through a sweep operation on the augmented $\mathbf{X}'\mathbf{X}$ matrix to get:

$$\begin{bmatrix} (\mathbf{X}'\mathbf{X})^{-1} & (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r} \\ (\mathbf{X}'\mathbf{r})'(\mathbf{X}'\mathbf{X})^{-1} & \mathbf{r}'\mathbf{r} - (\mathbf{X}'\mathbf{r})'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{r} \end{bmatrix}$$

Note that the residual column is the change vector used to update the parameter estimates at each iteration. The corner scalar element is used to compute the R convergence criteria.

ITALL Option

The ITALL option, in addition to causing the output of all of the preceding options, outputs the \mathbf{S} matrix, the inverse of the \mathbf{S} matrix, the CROSS matrix, and the swept CROSS matrix. An example of a portion of the CROSS matrix for the preceding example is shown in Figure 19.37.

Computer Resource Requirements

If you are estimating large systems, you need to be aware of how PROC MODEL uses computer resources (such as memory and the CPU) so they can be used most efficiently.

Saving Time with Large Data Sets

If your input data set has many observations, the FIT statement performs a large number of model program executions. A pass through the data is made at least once for each iteration and the model program is executed once for each observation in each pass. If you refine the starting estimates by using a smaller data set, the final estimation with the full data set might require fewer iterations.

For example, you could use

```
proc model;
  /* Model goes here */
  fit / data=a(obs=25);
  fit / data=a;
```

where OBS=25 selects the first 25 observations in A. The second FIT statement produces the final estimates using the full data set and starting values from the first run.

Fitting the Model in Sections to Save Space and Time

If you have a very large model (with several hundred parameters, for example), the procedure uses considerable space and time. You might be able to save resources by breaking the estimation process into several steps and estimating the parameters in subsets.

You can use the FIT statement to select for estimation only the parameters for selected equations. Do not break the estimation into too many small steps; the total computer time required is minimized by compromising between the number of FIT statements that are executed and the size of the crossproducts matrices that must be processed.

When the parameters are estimated for selected equations, the entire model program must be executed even though only a part of the model program might be needed to compute the residuals for the equations selected for estimation. If the model itself can be broken into sections for estimation (and later combined for simulation and forecasting), then more resources can be saved.

For example, to estimate the following four equation model in two steps, you could use

```
proc model data=a outmodel=part1;
  parms a0-a2 b0-b2 c0-c3 d0-d3;
  y1 = a0 + a1*y2 + a2*x1;
  y2 = b0 + b1*y1 + b2*x2;
  y3 = c0 + c1*y1 + c2*y4 + c3*x3;
  y4 = d0 + d1*y1 + d2*y3 + d3*x4;
  fit y1 y2;
  fit y3 y4;
  fit y1 y2 y3 y4;
run;
```

You should try estimating the model in pieces to save time only if there are more than 14 parameters; the preceding example takes more time, not less, and the difference in memory required is trivial.

Memory Requirements for Parameter Estimation

PROC MODEL is a large program, and it requires much memory. Memory is also required for the SAS System, various data areas, the model program and associated tables and data vectors, and a few crossproducts matrices. For most models, the memory required for PROC MODEL itself is much larger than that required for the model program, and the memory required for the model program is larger than that required for the crossproducts matrices.

The number of bytes needed for two crossproducts matrices, four **S** matrices, and three parameter covariance matrices is

$$8 \times (2 + k + m + g)^2 + 16 \times g^2 + 12 \times (p + 1)^2$$

plus lower-order terms, where m is the number of unique nonzero derivatives of each residual with respect to each parameter, g is the number of equations, k is the number of instruments, and p is the number of parameters. This formula is for the memory required for 3SLS. If you are using OLS, a reasonable estimate

of the memory required for large problems (greater than 100 parameters) is to divide the value obtained from the formula in half.

Consider the following model program.

```
proc model data=test2 details;
  exogenous x1 x2;
  parms b1 100 a1 a2 b2 2.5 c2 55;
  y1 = a1 * y2 + b1 * x1 * x1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2;
  fit y1 y2 / n3sls memoryuse;
  inst b1 b2 c2 x1 ;
run;
```

The DETAILS option prints the storage requirements information shown in [Figure 19.38](#).

Figure 19.38 Storage Requirements Information

The MODEL Procedure	
Storage Requirements for this Problem	
Order of XPX Matrix	6
Order of S Matrix	2
Order of Cross Matrix	13
Total Nonzero Derivatives	5
Distinct Variable Derivatives	5
Size of Cross matrix	728

The matrix $X'X$ augmented by the residual vector is called the XPX matrix in the output, and it has the size $m + 1$. The order of the S matrix, 2 for this example, is the value of g . The CROSS matrix is made up of the k unique instruments, a constant column that represents the intercept terms, followed by the m unique Jacobian variables plus a constant column that represents the parameters with constant derivatives, followed by the g residuals.

The size of two CROSS matrices in bytes is

$$8 \times (2 + k + m + g)^2 + 2 + k + m + g$$

Note that the CROSS matrix is symmetric, so only the diagonal and the upper triangular part of the matrix is stored. For examples of the CROSS and XPX matrices see the section “[Iteration History](#)” on page 1112.

The MEMORYUSE Option

The MEMORYUSE option in the FIT, SOLVE, MODEL, or RESET statement can be used to request a comprehensive memory usage summary.

[Figure 19.39](#) shows an example of the output produced by the MEMORYUSE option.

Figure 19.39 MEMORYUSE Option Output for FIT Task

Memory Usage Summary (in bytes)	
Symbols	15652
Strings	2593
Lists	2412
Arrays	2208
Statements	2448
Opcodes	1840
Parsing	6180
Executable	12717
Block option	0
Cross reference	0
Flow analysis	336
Derivatives	28640
Data vector	368
Cross matrix	1480
X'X matrix	590
S matrix	144
GMM memory	0
Jacobian	0
Work vectors	702
Overhead	14214

Total	92524

Definitions of the memory components follow:

symbols	memory used to store information about variables in the model
strings	memory used to store the variable names and labels
lists	space used to hold lists of variables
arrays	memory used by ARRAY statements
statements	memory used for the list of programming statements in the model
opcodes	memory used to store the code compiled to evaluate the expression in the model program
parsing	memory used in parsing the SAS statements
executable	the compiled model program size
block option	memory used by the BLOCK option
cross ref.	memory used by the XREF option
flow analysis	memory used to compute the interdependencies of the variables
derivatives	memory used to compute and store the analytical derivatives
data vector	memory used for the program data vector
cross matrix	memory used for one or more copies of the CROSS matrix
X'X matrix	memory used for one or more copies of the X'X matrix
S matrix	memory used for the covariance matrix
GMM memory	additional memory used for the GMM and ITGMM methods
Jacobian	memory used for the Jacobian matrix for SOLVE and FIML
work vectors	memory used for miscellaneous work vectors
overhead	other miscellaneous memory

Testing for Normality

The NORMAL option in the FIT statement performs multivariate and univariate tests of normality.

The three multivariate tests provided are Mardia's skewness test and kurtosis test (Mardia 1970) and the Henze-Zirkler $T_{n,\beta}$ test (Henze and Zirkler 1990). The two univariate tests provided are the Shapiro-Wilk W test and the Kolmogorov-Smirnov test. (For details on the univariate tests, refer to "Goodness-of-Fit Tests" section in "The UNIVARIATE Procedure" chapter in the *Base SAS Procedures Guide*.) The null hypothesis for all these tests is that the residuals are normally distributed.

For a random sample X_1, \dots, X_n , $X_i \in \mathbb{R}^d$, where d is the dimension of X_i and n is the number of observations, a measure of multivariate skewness is

$$b_{1,d} = \frac{1}{n^2} \sum_{i=1}^n \sum_{j=1}^n [(X_i - \mu)' S^{-1} (X_j - \mu)]^3$$

where S is the sample covariance matrix of \mathbf{X} . For weighted regression, both S and $(X_i - \mu)$ are computed by using the weights supplied by the WEIGHT statement or the _WEIGHT_ variable.

Mardia showed that under the null hypothesis $\frac{n}{6} b_{1,d}$ is asymptotically distributed as $\chi^2(d(d+1)(d+2)/6)$. For small samples, Mardia's skewness test statistic is calculated with a small sample correction formula, given by $\frac{nk}{6} b_{1,d}$ where the correction factor k is given by $k = (d+1)(n+1)(n+3)/n(((n+1)(d+1))-6)$. Mardia's skewness test statistic in PROC MODEL uses this small sample corrected formula.

A measure of multivariate kurtosis is given by

$$b_{2,d} = \frac{1}{n} \sum_{i=1}^n [(X_i - \mu)' S^{-1} (X_i - \mu)]^2$$

Mardia showed that under the null hypothesis, $b_{2,d}$ is asymptotically normally distributed with mean $d(d+2)$ and variance $8d(d+2)/n$.

The Henze-Zirkler test is based on a nonnegative functional $D(.,.)$ that measures the distance between two distribution functions and has the property that

$$D(N_d(0, I_d), Q) = 0$$

if and only if

$$Q = N_d(0, I_d)$$

where $N_d(\mu, \Sigma_d)$ is a d -dimensional normal distribution.

The distance measure $D(.,.)$ can be written as

$$D_\beta(P, Q) = \int_{\mathbb{R}^d} |\hat{P}(t) - \hat{Q}(t)|^2 \varphi_\beta(t) dt$$

where $\hat{P}(t)$ and $\hat{Q}(t)$ are the Fourier transforms of P and Q , and $\varphi_\beta(t)$ is a weight or a kernel function. The density of the normal distribution $N_d(0, \beta^2 I_d)$ is used as $\varphi_\beta(t)$

$$\varphi_\beta(t) = (2\pi\beta^2)^{-\frac{d}{2}} \exp\left(\frac{-|t|^2}{2\beta^2}\right), t \in \mathbb{R}^d$$

where $|t| = (t't)^{0.5}$.

The parameter β depends on n as

$$\beta_d(n) = \frac{1}{\sqrt{2}} \left(\frac{2d+1}{4} \right)^{1/(d+4)} n^{1/(d+4)}$$

The test statistic computed is called $T_\beta(d)$ and is approximately distributed as a lognormal. The lognormal distribution is used to compute the null hypothesis probability.

$$T_\beta(d) = \frac{1}{n^2} \sum_{j=1}^n \sum_{k=1}^n \exp\left(-\frac{\beta^2}{2} |Y_j - Y_k|^2\right) - 2(1 + \beta^2)^{-d/2} \frac{1}{n} \sum_{j=1}^n \exp\left(-\frac{\beta^2}{2(1 + \beta^2)} |Y_j|^2\right) + (1 + 2\beta^2)^{-d/2}$$

where

$$|Y_j - Y_k|^2 = (X_j - X_k)' \mathbf{S}^{-1} (X_j - X_k)$$

$$|Y_j|^2 = (X_j - \bar{X})' \mathbf{S}^{-1} (X_j - \bar{X})$$

Monte Carlo simulations suggest that $T_\beta(d)$ has good power against distributions with heavy tails.

The Shapiro-Wilk W test is computed only when the number of observations (n) is less than 2000 while computation of the Kolmogorov-Smirnov test statistic requires at least 2000 observations.

The following is an example of the output produced by the NORMAL option.

```
proc model data=test2;
  y1 = a1 * x2 * x2 - exp( d1*x1);
  y2 = a2 * x1 * x1 + b2 * exp( d2*x2);
  fit y1 y2 / normal ;
run;
```

Figure 19.40 Normality Test Output

The MODEL Procedure			
Normality Test			
Equation	Test Statistic	Value	Prob
y1	Shapiro-Wilk W	0.37	<.0001
y2	Shapiro-Wilk W	0.84	<.0001
System	Mardia Skewness	286.4	<.0001
	Mardia Kurtosis	31.28	<.0001
	Henze-Zirkler T	7.09	<.0001

Heteroscedasticity

One of the key assumptions of regression is that the variance of the errors is constant across observations. If the errors have constant variance, the errors are called *homoscedastic*. Typically, residuals are plotted to assess this assumption. Standard estimation methods are inefficient when the errors are *heteroscedastic* or have nonconstant variance.

Heteroscedasticity Tests

The MODEL procedure provides two tests for heteroscedasticity of the errors: White's test and the modified Breusch-Pagan test.

Both White's test and the Breusch-Pagan are based on the residuals of the fitted model. For systems of equations, these tests are computed separately for the residuals of each equation.

The residuals of an estimation are used to investigate the heteroscedasticity of the true disturbances.

The WHITE option tests the null hypothesis

$$H_0 : \sigma_i^2 = \sigma^2 \text{ for all } i$$

White's test is general because it makes no assumptions about the form of the heteroscedasticity (White 1980). Because of its generality, White's test might identify specification errors other than heteroscedasticity (Thursby 1982). Thus, White's test might be significant when the errors are homoscedastic but the model is misspecified in other ways.

White's test is equivalent to obtaining the error sum of squares for the regression of squared residuals on a constant and all the unique variables in $\mathbf{J} \otimes \mathbf{J}$, where the matrix \mathbf{J} is composed of the partial derivatives of the equation residual with respect to the estimated parameters. White's test statistic W is computed as follows:

$$W = nR^2$$

where R^2 is the correlation coefficient obtained from the above regression. The statistic is asymptotically distributed as chi-squared with $P-1$ degrees of freedom, where P is the number of regressors in the regression, including the constant and n is the total number of observations. In the example given below, the regressors are constant, income, income*income, income*income*income, and income*income*income*income. income*income occurs twice and one is dropped. Hence, $P=5$ with degrees of freedom, $P-1=4$.

Note that White's test in the MODEL procedure is different than White's test in the REG procedure requested by the SPEC option. The SPEC option produces the test from Theorem 2 on page 823 of White (1980). The WHITE option, on the other hand, produces the statistic discussed in Greene (1993).

The null hypothesis for the modified Breusch-Pagan test is homoscedasticity. The alternate hypothesis is that the error variance varies with a set of regressors, which are listed in the BREUSCH= option.

Define the matrix \mathbf{Z} to be composed of the values of the variables listed in the BREUSCH= option, such that $z_{i,j}$ is the value of the j th variable in the BREUSCH= option for the i th observation. The null hypothesis of the Breusch-Pagan test is

$$\sigma_i^2 = \sigma^2(\alpha_0 + \alpha' z_i) \qquad H_0 : \alpha = \mathbf{0}$$

where σ_i^2 is the error variance for the i th observation and α_0 and α are regression coefficients.

The test statistic for the Breusch-Pagan test is

$$bp = \frac{1}{v}(\mathbf{u} - \bar{u}\mathbf{i})' \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \mathbf{Z}'(\mathbf{u} - \bar{u}\mathbf{i})$$

where $\mathbf{u} = (e_1^2, e_2^2, \dots, e_n^2)$, \mathbf{i} is a $n \times 1$ vector of ones, and

$$v = \frac{1}{n} \sum_{i=1}^n (e_i^2 - \frac{\mathbf{e}'\mathbf{e}}{n})^2$$

This is a modified version of the Breusch-Pagan test, which is less sensitive to the assumption of normality than the original test (Greene 1993, p. 395).

The statements in the following example produce the output in [Figure 19.41](#):

```
proc model data=schools;
  parms const inc inc2;

  exp = const + inc * income + inc2 * income * income;
  incsq = income * income;

  fit exp / white breusch=(1 income incsq);
run;
```

Figure 19.41 Output for Heteroscedasticity Tests

The MODEL Procedure					
Heteroscedasticity Test					
Equation	Test	Statistic	DF	Pr > ChiSq	Variables
exp	White's Test	21.16	4	0.0003	Cross of all vars
	Breusch-Pagan	15.83	2	0.0004	1, income, incsq

Correcting for Heteroscedasticity

There are two methods for improving the efficiency of the parameter estimation in the presence of heteroscedastic errors. If the error variance relationships are known, weighted regression can be used or an error model can be estimated. For details about error model estimation, see the section “[Error Covariance Structure Specification](#)” on page 1132. If the error variance relationship is unknown, GMM estimation can be used.

Weighted Regression

The WEIGHT statement can be used to correct for the heteroscedasticity. Consider the following model, which has a heteroscedastic error term:

$$y_t = 250(e^{-0.2t} - e^{-0.8t}) + \sqrt{(9/t)}\epsilon_t$$

The data for this model is generated with the following SAS statements.

```

data test;
  do t=1 to 25;
    y = 250 * (exp( -0.2 * t ) - exp( -0.8 * t )) +
      sqrt( 9 / t ) * rannor(1);
    output;
  end;
run;

```

If this model is estimated with OLS, as shown in the following statements, the estimates shown in [Figure 19.42](#) are obtained for the parameters.

```

proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  fit y;
run;

```

Figure 19.42 Unweighted OLS Estimates

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
b1	0.200977	0.00101	198.60	<.0001
b2	0.826236	0.00853	96.82	<.0001

If both sides of the model equation are multiplied by \sqrt{t} , the model has a homoscedastic error term. This multiplication or weighting is done through the WEIGHT statement. The WEIGHT statement variable operates on the squared residuals as

$$\epsilon_t' \epsilon_t = \text{weight} \times q_t' q_t$$

so that the WEIGHT statement variable represents the square of the model multiplier. The following PROC MODEL statements corrects the heteroscedasticity with a WEIGHT statement:

```

proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  fit y;
  weight t;
run;

```

Note that the WEIGHT statement follows the FIT statement. The weighted estimates are shown in [Figure 19.43](#).

Figure 19.43 Weighted OLS Estimates

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
b1	0.200503	0.000844	237.53	<.0001
b2	0.816701	0.0139	58.71	<.0001

The weighted OLS estimates are identical to the output produced by the following PROC MODEL example:

```
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  _weight_ = t;
  fit y;
run;
```

If the WEIGHT statement is used in conjunction with the `_WEIGHT_` variable, the two values are multiplied together to obtain the weight used.

The WEIGHT statement and the `_WEIGHT_` variable operate on all the residuals in a system of equations. If a subset of the equations needs to be weighted, the residuals for each equation can be modified through the `RESID.` variable for each equation. The following example demonstrates the use of the `RESID.` variable to make a homoscedastic error term:

```
proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  resid.y = resid.y * sqrt(t);
  fit y;
run;
```

These statements produce estimates of the parameters and standard errors that are identical to the weighted OLS estimates. The reassignment of the `RESID.Y` variable must be done after `Y` is assigned; otherwise it would have no effect. Also, note that the residual (`RESID.Y`) is multiplied by \sqrt{t} . Here the multiplier is acting on the residual before it is squared.

GMM Estimation

If the form of the heteroscedasticity is unknown, generalized method of moments estimation (GMM) can be used. The following PROC MODEL statements use GMM to estimate the example model used in the preceding section:

```

proc model data=test;
  parms b1 0.1 b2 0.9;
  y = 250 * ( exp( -b1 * t ) - exp( -b2 * t ) );
  fit y / gmm;
  instruments b1 b2;
run;

```

GMM is an instrumental method, so instrument variables must be provided.

GMM estimation generates estimates for the parameters shown in Figure 19.44.

Figure 19.44 GMM Estimation for Heteroscedasticity

The MODEL Procedure				
Nonlinear GMM Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
b1	0.200487	0.000800	250.69	<.0001
b2	0.822148	0.0148	55.39	<.0001

Heteroscedasticity-Consistent Covariance Matrix Estimation

Homoscedasticity is required for ordinary least squares regression estimates to be efficient. A nonconstant error variance, heteroscedasticity, causes the OLS estimates to be inefficient, and the usual OLS covariance matrix, $\hat{\Sigma}$, is generally invalid:

$$\hat{\Sigma} = \sigma^2(\mathbf{X}'\mathbf{X})^{-1}$$

When the variance of the errors of a classical linear model

$$Y = \mathbf{X}\beta + \epsilon$$

is not constant across observations (heteroscedastic), so that $\sigma_i^2 \neq \sigma_j^2$ for some $j > 1$, the OLS estimator

$$\hat{\beta}_{OLS} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'Y$$

is unbiased but it is inefficient. Models that take into account the changing variance can make more efficient use of the data. When the variances, σ_i^2 , are known, generalized least squares (GLS) can be used and the estimator

$$\hat{\beta}_{GLS} = (\mathbf{X}'\mathbf{\Omega}\mathbf{X})^{-1}\mathbf{X}'\mathbf{\Omega}^{-1}Y$$

where

$$\mathbf{\Omega} = \begin{bmatrix} \sigma_1^2 & 0 & 0 & 0 \\ 0 & \sigma_2^2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \sigma_T^2 \end{bmatrix}$$

is unbiased and efficient. However, GLS is unavailable when the variances, σ_t^2 , are unknown.

To solve this problem White (1980) proposed a heteroscedastic consistent-covariance matrix estimator (HC-CME)

$$\hat{\Sigma} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\hat{\Omega}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}$$

that is consistent as well as unbiased, where

$$\hat{\Omega}_0 = \begin{bmatrix} \epsilon_1^2 & 0 & 0 & 0 \\ 0 & \epsilon_2^2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \epsilon_T^2 \end{bmatrix}$$

and $\epsilon_t = Y_t - \mathbf{X}_t\beta_{OLS}$.

This estimator is considered somewhat unreliable in finite samples. Therefore, Davidson and MacKinnon (1993) propose three different modifications to estimating $\hat{\Omega}$. The first solution is to simply multiply ϵ_t^2 by $\frac{n}{n-df}$, where n is the number of observations and df is the number of explanatory variables, so that

$$\hat{\Omega}_1 = \begin{bmatrix} \frac{n}{n-df} \epsilon_1^2 & 0 & 0 & 0 \\ 0 & \frac{n}{n-df} \epsilon_2^2 & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \frac{n}{n-df} \epsilon_n^2 \end{bmatrix}$$

The second solution is to define

$$\hat{\Omega}_2 = \begin{bmatrix} \frac{\epsilon_1^2}{1-\hat{h}_1} & 0 & 0 & 0 \\ 0 & \frac{\epsilon_2^2}{1-\hat{h}_2} & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \frac{\epsilon_n^2}{1-\hat{h}_n} \end{bmatrix}$$

where $\hat{h}_t = \mathbf{X}_t(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}_t'$.

The third solution, called the “jackknife,” is to define

$$\hat{\Omega}_3 = \begin{bmatrix} \frac{\epsilon_1^2}{(1-\hat{h}_1)^2} & 0 & 0 & 0 \\ 0 & \frac{\epsilon_2^2}{(1-\hat{h}_2)^2} & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \frac{\epsilon_n^2}{(1-\hat{h}_n)^2} \end{bmatrix}$$

MacKinnon and White (1985) investigated these three modified HCCMEs, including the original HCCME, based on finite-sample performance of pseudo- t statistics. The original HCCME performed the worst. The first modification performed better. The second modification performed even better than the first, and the third modification performed the best. They concluded that the original HCCME should never be used in finite sample estimation, and that the second and third modifications should be used over the first modification if the diagonals of $\hat{\Omega}$ are available.

Seemingly Unrelated Regression HCCME

Extending the discussion to systems of g equations, the HCCME for SUR estimation is

$$(\tilde{\mathbf{X}}'\tilde{\mathbf{X}})^{-1}\tilde{\mathbf{X}}'\hat{\mathbf{\Omega}}\tilde{\mathbf{X}}(\tilde{\mathbf{X}}'\tilde{\mathbf{X}})^{-1}$$

where $\tilde{\mathbf{X}}$ is a $ng \times k$ matrix with the first g rows representing the first observation, the next g rows representing the second observation, and so on. $\hat{\mathbf{\Omega}}$ is now a $ng \times ng$ block diagonal matrix with typical block $g \times g$

$$\hat{\mathbf{\Omega}}_i = \begin{bmatrix} \psi_{1,i} & \psi_{1,i} & \psi_{1,i} & \psi_{2,i} & \dots & \psi_{1,i} & \psi_{g,i} \\ \psi_{2,i} & \psi_{1,i} & \psi_{2,i} & \psi_{2,i} & \dots & \psi_{2,i} & \psi_{g,i} \\ \vdots & & \vdots & & \vdots & & \vdots \\ \psi_{g,i} & \psi_{1,i} & \psi_{g,i} & \psi_{2,i} & \dots & \psi_{g,i} & \psi_{g,i} \end{bmatrix}$$

where

$$\psi_{j,i} = \epsilon_{j,i} \quad HC_0$$

or

$$\psi_{j,i} = \sqrt{\frac{n}{n-df}} \epsilon_{j,i} \quad HC_1$$

or

$$\psi_{j,i} = \epsilon_{j,i} / \sqrt{1 - \hat{h}_i} \quad HC_2$$

or

$$\psi_{j,i} = \epsilon_{j,i} / (1 - \hat{h}_i) \quad HC_3$$

Two- and Three-Stage Least Squares HCCME

For two- and three-stage least squares, the HCCME for a g equation system is

$$\text{Cov} F(\hat{\mathbf{\Omega}}) \text{Cov}$$

where

$$\text{Cov} = \left(\frac{1}{n} \mathbf{X}'(\mathbf{I} \otimes \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}')\mathbf{X} \right)^{-1}$$

is the normal covariance matrix without the \mathbf{S} matrix and

$$F(\mathbf{\Omega}) = \frac{1}{n} \sum_i^g \sum_j^g \mathbf{X}_i' \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \mathbf{Z}' \hat{\mathbf{\Omega}}_{ij} \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \mathbf{Z}' \mathbf{X}_j$$

where \mathbf{X}_j is a $n \times p$ matrix with the j th equations regressors in the appropriate columns and zeros everywhere else.

$$\hat{\Omega}_{ij} = \begin{bmatrix} \psi_{i,1}\psi_{j,1} & 0 & 0 & 0 \\ 0 & \psi_{i,2}\psi_{j,2} & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \psi_{i,n}\psi_{j,n} \end{bmatrix}$$

For 2SLS $\hat{\Omega}_{ij} = 0$ when $i \neq j$. The ϵ_t used in $\hat{\Omega}$ is computed by using the parameter estimates obtained from the instrumental variables estimation.

The leverage value for the i th equation used in the HCCME=2 and HCCME=3 methods is computed as conditional on the first stage as

$$h_{ti} = \mathbf{Z}_t'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{X}_i(\mathbf{X}'(\mathbf{I} \otimes \mathbf{Z}(\mathbf{Z}' * \mathbf{Z})^{-1}\mathbf{Z}')\mathbf{X})^{-1}\mathbf{X}_i'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}_t'$$

for 2SLS and

$$h_{ti} = \mathbf{Z}_t'(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{X}_i(\mathbf{X}'(\mathbf{S}^{-1} \otimes \mathbf{Z}(\mathbf{Z}' * \mathbf{Z})^{-1}\mathbf{Z}')\mathbf{X})^{-1}\mathbf{X}_i'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}_t' / \mathbf{S}_{ii}$$

for 3SLS.

Testing for Autocorrelation

The GODFREY= option in the FIT statement produces the Godfrey Lagrange multiplier test for serially correlated residuals for each equation (Godfrey 1978a and 1978b). n is the maximum autoregressive order, and specifies that Godfrey's tests be computed for lags 1 through n . The default number of lags is four.

The tests are performed separately for each equation estimated by the FIT statement. When a nonlinear model is estimated, the test is computed by using a linearized model.

The following is an example of the output produced by the GODFREY=3 option:

Figure 19.45 Autocorrelation Test Output

Godfrey Test Output			
The MODEL Procedure			
Godfrey's Serial Correlation Test			
Equation	Alternative	LM	Pr > LM
y	1	6.63	0.0100
	2	6.89	0.0319
	3	6.96	0.0732

The three variations of the test reported by the GODFREY=3 option are designed to have power against different alternative hypothesis. Thus, if the residuals in fact have only first-order autocorrelation, the lag 1 test has the most power for rejecting the null hypothesis of uncorrelated residuals. If the residuals have

second- but not higher-order autocorrelation, the lag 2 test might be more likely to reject; the same is true for third-order autocorrelation and the lag 3 test.

The null hypothesis of Godfrey's tests is that the equation residuals are white noise. However, if the equation includes autoregressive error model of order p (AR(p),) then the lag i test, when considered in terms of the structural error, is for the null hypothesis that the structural errors are from an AR(p) process versus the alternative hypothesis that the errors are from an AR($p + i$) process.

The alternative ARMA(p, i) process is locally equivalent to the alternative AR($p + i$) process with respect to the null model AR(p). Thus, the GODFREY= option results are also a test of AR(p) errors against the alternative hypothesis of ARMA(p, i) errors. See Godfrey (1978a and 1978b) for more detailed information.

Transformation of Error Terms

In PROC MODEL you can control the form of the error term. By default, the error term is assumed to be additive. This section demonstrates how to specify nonadditive error terms and discusses the effects of these transformations.

Models with Nonadditive Errors

The estimation methods used by PROC MODEL assume that the error terms of the equations are independently and identically distributed with zero means and finite variances. Furthermore, the methods assume that the RESID.*name* equation variable for normalized form equations or the EQ.*name* equation variable for general form equations contains an estimate of the error term of the true stochastic model whose parameters are being estimated. Details on RESID.*name* and EQ.*name* equation variables are in the section “[Equation Translations](#)” on page 1225.

To illustrate these points, consider the common loglinear model

$$y = \alpha x^\beta \quad (1)$$

$$\ln y = a + b \ln(x) \quad (2)$$

where $a = \log(\alpha)$ and $b = \beta$. Equation (2) is called the *log form* of the equation in contrast to equation (1), which is called the *level form* of the equation. Using the SYSLIN procedure, you can estimate equation (2) by specifying

```
proc syslin data=in;
  model logy=logx;
run;
```

where LOGY and LOGX are the logs of Y and X computed in a preceding DATA step. The resulting values for INTERCEPT and LOGX correspond to a and b in equation (2).

Using the MODEL procedure, you can try to estimate the parameters in the level form (and avoid the DATA step) by specifying

```
proc model data=in;
  parms alpha beta;
  y = alpha * x ** beta;
  fit y;
run;
```

where ALPHA and BETA are the parameters in equation (1).

Unfortunately, at least one of the preceding is wrong; an ambiguity results because equations (1) and (2) contain no explicit error term. The SYSLIN and MODEL procedures both deal with additive errors; the residual used (the estimate of the error term in the equation) is the difference between the predicted and actual values (of LOGY for PROC SYSLIN and of Y for PROC MODEL in this example). If you perform the regressions discussed previously, PROC SYSLIN estimates equation (3) while PROC MODEL estimates equation (4).

$$\ln y = a + b \ln(x) + \epsilon \quad (3)$$

$$y = \alpha x^\beta + \xi \quad (4)$$

These are different statistical models. Equation (3) is the log form of equation (5)

$y = \alpha x^\beta \mu$ (5) where $\mu = e^\epsilon$. Equation (4), on the other hand, cannot be linearized because the error term ξ (different from μ) is additive in the level form.

You must decide whether your model is equation (4) or (5). If the model is equation (4), you should use PROC MODEL. If you linearize equation (1) without considering the error term and apply SYSLIN to MODEL LOGY=LOGX, the results will be wrong. On the other hand, if your model is equation (5) (in practice it usually is), and you want to use PROC MODEL to estimate the parameters in the *level* form, you must do something to account for the multiplicative error.

PROC MODEL estimates parameters by minimizing an objective function. The objective function is computed using either the RESID.-prefixed equation variable or the EQ.-prefixed equation variable. You must make sure that these prefixed equation variables are assigned an appropriate error term. If the model has additive errors that satisfy the assumptions, nothing needs to be done. In the case of equation (5), the error is nonadditive and the equation is in normalized form, so you must alter the value of RESID.Y.

The following assigns a valid estimate of μ to RESID.Y:

```
y = alpha * x ** beta;
resid.y = actual.y / pred.y;
```

However, $\mu = e^\epsilon$, and therefore μ , cannot have a mean of zero, and you cannot consistently estimate α and β by minimizing the sum of squares of an estimate of μ . Instead, you use $\epsilon = \ln \mu$.

```
proc model data=in;
  parms alpha beta;
  y = alpha * x ** beta;
  resid.y = log( actual.y / pred.y );
  fit y;
run;
```

If the model was expressed in general form, this transformation becomes

```
proc model data=in;
  parms alpha beta;
  EQ.trans = log( y / (alpha * x ** beta));
  fit trans;
run;
```

Both examples produce estimates of α and β of the level form that match the estimates of a and b of the log form. That is, $\text{ALPHA}=\exp(\text{INTERCEPT})$ and $\text{BETA}=\text{LOGX}$, where INTERCEPT and LOGX are the PROC SYSLIN parameter estimates from the MODEL $\text{LOGY}=\text{LOGX}$. The standard error reported for ALPHA is different from that for the INTERCEPT in the log form.

The preceding example is not intended to suggest that loglinear models should be estimated in level form but, rather, to make the following points:

- Nonlinear transformations of equations involve the error term of the equation, and this should be taken into account when transforming models.
- The RESID.-prefixed and the EQ.-prefixed equation variables for models estimated by the MODEL procedure must represent additive errors with zero means.
- You can use assignments to RESID.-prefixed and EQ.-prefixed equation variables to transform error terms.
- Some models do not have additive errors or zero means, and many such models can be estimated using the MODEL procedure. The preceding approach applies not only to multiplicative models but to any model that can be manipulated to isolate the error term.

Predicted Values of Transformed Models

Nonadditive or transformed errors affect the distribution of the predicted values, as well as the estimates. For the preceding loglinear example, the MODEL procedure produces consistent parameter estimates. However, the predicted values for Y computed by PROC MODEL are not unbiased estimates of the expected values of Y, although they do estimate the conditional median Y values.

In general, the predicted values produced for a model with nonadditive errors are not unbiased estimates of the conditional means of the endogenous value. If the model can be transformed to a model with additive errors by using a *monotonic* transformation, the predicted values estimate the conditional medians of the endogenous variable.

For transformed models in which the biasing factor is known, you can use programming statements to correct for the bias in the predicted values as estimates of the endogenous means. In the preceding log-linear case, the predicted values are biased by the factor $\exp(\sigma^2/2)$. You can produce approximately unbiased predicted values in this case by writing the model as

```
proc model data=in;
  parms alpha beta;
  y=alpha * x ** beta;
  resid.y = log( actual.y / pred.y );
  fit y;
run;
```

See Miller (1984) for a discussion of bias factors for predicted values of transformed models.

Note that models with transformed errors are not appropriate for Monte Carlo simulation that uses the SDATA= option. PROC MODEL computes the OUTS= matrix from the transformed RESID.-prefixed equation variables, while it uses the SDATA= matrix to generate multivariate normal errors, which are added to the predicted values. This method of computing errors is inconsistent when the equation variables have been transformed.

Error Covariance Structure Specification

One of the key assumptions of regression is that the variance of the errors is constant across observations. Correcting for heteroscedasticity improves the efficiency of the estimates.

Consider the following general form for models:

$$\begin{aligned} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) &= \boldsymbol{\varepsilon}_t \\ \boldsymbol{\varepsilon}_t &= H_t * \boldsymbol{\epsilon}_t \\ H_t &= \begin{bmatrix} \sqrt{h_{t,1}} & 0 & \dots & 0 \\ 0 & \sqrt{h_{t,2}} & \dots & 0 \\ & & \ddots & \\ 0 & 0 & \dots & \sqrt{h_{t,g}} \end{bmatrix} \\ \mathbf{h}_t &= \mathbf{g}(\mathbf{y}_t, \mathbf{x}_t, \phi) \end{aligned}$$

where $\boldsymbol{\epsilon}_t \sim N(0, \Sigma)$.

For models that are homoscedastic,

$$h_t = 1$$

If you have a model that is heteroscedastic with known form, you can improve the efficiency of the estimates by performing a weighted regression. The weight variable, using this notation, would be $1/\sqrt{h_t}$.

If the errors for a model are heteroscedastic and the functional form of the variance is known, the model for the variance can be estimated along with the regression function.

To specify a functional form for the variance, assign the function to an `H.var` variable where `var` is the equation variable. For example, if you want to estimate the scale parameter for the variance of a simple regression model

$$y = a * x + b$$

you can specify

```
proc model data=s;
  y = a * x + b;
  h.y = sigma**2;
fit y;
```

Consider the same model with the following functional form for the variance:

$$h_t = \sigma^2 * x^{2*\alpha}$$

This would be written as

```
proc model data=s;
  y = a * x + b;
  h.y = sigma**2 * x**(2*alpha);
fit y;
```

There are three ways to model the variance in the MODEL procedure: feasible generalized least squares, generalized method of moments, and full information maximum likelihood.

Feasible GLS

A simple approach to estimating a variance function is to estimate the mean parameters θ by using some auxiliary method, such as OLS, and then use the residuals of that estimation to estimate the parameters ϕ of the variance function. This scheme is called *feasible GLS*. It is possible to use the residuals from an auxiliary method for the purpose of estimating ϕ because in many cases the residuals consistently estimate the error terms.

For all estimation methods except GMM and FIML, using the H.var syntax specifies that feasible GLS is used in the estimation. For feasible GLS, the mean function is estimated by the usual method. The variance function is then estimated using pseudo-likelihood (PL) function of the generated residuals. The objective function for the PL estimation is

$$p_n(\sigma, \theta) = \sum_{i=1}^n \left(\frac{(y_i - f(x_i, \hat{\beta}))^2}{\sigma^2 h(z_i, \theta)} + \log[\sigma^2 h(z_i, \theta)] \right)$$

Once the variance function has been estimated, the mean function is reestimated by using the variance function as weights. If an S-iterated method is selected, this process is repeated until convergence (iterated feasible GLS).

Note that feasible GLS does not yield consistent estimates when one of the following is true:

- The variance is unbounded.
- There is too much serial dependence in the errors (the dependence does not fade with time).
- There is a combination of serial dependence and lag dependent variables.

The first two cases are unusual, but the third is much more common. Whether iterated feasible GLS avoids consistency problems with the last case is an unanswered research question. For more information see Davidson and MacKinnon (1993, pp. 298–301) or Gallant (1987, pp. 124–125) and Amemiya (1985, pp. 202–203).

One limitation is that parameters cannot be shared between the mean equation and the variance equation. This implies that certain GARCH models, cross-equation restrictions of parameters, or testing of combinations of parameters in the mean and variance component are not allowed.

Generalized Method of Moments

In GMM, normally the first moment of the mean function is used in the objective function.

$$\begin{aligned} \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta) &= \epsilon_t \\ \mathbf{E}(\epsilon_t) &= 0 \end{aligned}$$

To add the second moment conditions to the estimation, add the equation

$$\mathbf{E}(\epsilon_t * \epsilon_t - h_t) = 0$$

to the model. For example, if you want to estimate σ for linear example above, you can write

```

proc model data=s;
  y = a * x + b;
  eq.two = resid.y**2 - sigma**2;
fit y two/ gmm;
instruments x;
run;

```

This is a popular way to estimate a continuous-time interest rate processes (see Chan et al. 1992). The H.var syntax automatically generates this system of equations.

To further take advantage of the information obtained about the variance, the moment equations can be modified to

$$\begin{aligned} \mathbf{E}(\varepsilon_t / \sqrt{h_t}) &= 0 \\ \mathbf{E}(\varepsilon_t * \varepsilon_t - h_t) &= 0 \end{aligned}$$

For the above example, this can be written as

```

proc model data=s;
  y = a * x + b;
  eq.two = resid.y**2 - sigma**2;
  resid.y = resid.y / sigma;
fit y two/ gmm;
instruments x;
run;

```

Note that, if the error model is misspecified in this form of the GMM model, the parameter estimates might be inconsistent.

Full Information Maximum Likelihood

For FIML estimation of variance functions, the concentrated likelihood below is used as the objective function. That is, the mean function is coupled with the variance function and the system is solved simultaneously.

$$\begin{aligned} l_n(\phi) &= \frac{ng}{2}(1 + \ln(2\pi)) - \sum_{t=1}^n \ln \left(\left| \frac{\partial \mathbf{q}(\mathbf{y}_t, \mathbf{x}_t, \theta)}{\partial \mathbf{y}_t} \right| \right) \\ &\quad + \frac{1}{2} \sum_{t=1}^n \sum_{i=1}^g (\ln(h_{t,i}) + \mathbf{q}_i(\mathbf{y}_t, \mathbf{x}_t, \theta)^2 / h_{t,i}) \end{aligned}$$

where g is the number of equations in the system.

The HESSIAN=GLS option is not available for FIML estimation that involves variance functions. The matrix used when HESSIAN=CROSS is specified is a crossproducts matrix that has been enhanced by the dual quasi-Newton approximation.

Examples

You can specify a GARCH(1,1) model as follows:

```
proc model data=modloc.usd_jpy;

    /* Mean model -----*/
    jpyret = intercept ;

    /* Variance model -----*/
    h.jpyret = arch0
              + arch1 * xlag( resid.jpyret ** 2, mse.jpyret )
              + garch1 * xlag(h.jpyret, mse.jpyret) ;

    bounds arch0 arch1 garch1 >= 0;

    fit jpyret / method=marquardt fiml;
run;
```

Note that the BOUNDS statement is used to ensure that the parameters are positive, a requirement for GARCH models.

EGARCH models are used because there are no restrictions on the parameters. You can specify a EGARCH(1,1) model as follows:

```
proc model data=sasuser.usd_dem ;

    /* Mean model -----*/
    demret = intercept ;

    /* Variance model -----*/
    if ( _OBS_ =1 ) then
        h.demret = exp( earch0 + egarch1 * log(mse.demret) );
    else
        h.demret = exp( earch0 + earch1 * zlag( g
                                                + egarch1 * log(zlag(h.demret))) );
        g = - theta * nresid.demret + abs( nresid.demret ) - sqrt(2/3.1415);

    fit demret / method=marquardt fiml maxiter=100 converge=1.0e-6;
run;
```

Ordinary Differential Equations

Ordinary differential equations (ODEs) are also called *initial value problems* because a time zero value for each first-order differential equation is needed. The following is an example of a first-order system of ODEs:

$$\begin{aligned} y' &= -0.1y + 2.5z^2 \\ z' &= -z \\ y_0 &= 0 \\ z_0 &= 1 \end{aligned}$$

Note that you must provide an initial value for each ODE.

As a reminder, any n -order differential equation can be modeled as a system of first-order differential equations. For example, consider the differential equations

$$\begin{aligned} y'' &= by' + cy \\ y_0 &= 0 \\ y'_0 &= 1 \end{aligned}$$

which can be written as the system of differential equations

$$\begin{aligned} y' &= z \\ z' &= by' + cy \\ y_0 &= 0 \\ z_0 &= 1 \end{aligned}$$

This differential system can be simulated as follows:

```
data t;
  time=0; output;
  time=1; output;
  time=2; output;
run;

proc model data=t ;
  dependent y 0 z 1;
  parm b -2 c -4;

  dert.y = z;
  dert.z = b * dert.y + c * y;

  solve y z / dynamic solveprint;
run;
```

The preceding statements produce the output shown in [Figure 19.46](#). These statements produce additional output, which is not shown.

Figure 19.46 Simulation Results for Differential System

The differential variables are distinguished by the derivative with respect to time (DERT.) prefix. Once you define the DERT. variable, you can use it on the right-hand side of another equation. The differential equations must be expressed in normal form; implicit differential equations are not allowed, and other terms on the left-hand side are not allowed.

The TIME variable is the *implied with respect to* variable for all DERT. variables. The TIME variable is also the only variable that must be in the input data set.

You can provide initial values for the differential equations in the data set, in the declaration statement (as in the previous example), or in statements in the program. Using the previous example, you can specify the initial values as

```
proc model data=t ;
  dependent y z ;
  parm b -2 c -4;

  if ( time=0 ) then
    do;
      y=0;
      z=1;
    end;
  else
    do;
      dert.y = z;
      dert.z = b * dert.y + c * y;
    end;
```

```

end;

solve y z / dynamic solveprint;
run;

```

If you do not provide an initial value, 0 is used.

DYNAMIC and STATIC Simulation

Note that, in the previous example, the DYNAMIC option is specified in the SOLVE statement. The DYNAMIC and STATIC options work the same for differential equations as they do for dynamic systems. In the differential equation case, the DYNAMIC option makes the initial value needed at each observation the computed value from the previous iteration. For a static simulation, the data set must contain values for the integrated variables. For example, if DERT.Y and DERT.Z are the differential variables, you must include Y and Z in the input data set in order to do a static simulation of the model.

If the simulation is dynamic, the initial values for the differential equations are obtained from the data set, if they are available. If the variable is not in the data set, you can specify the initial value in a declaration statement. If you do not specify an initial value, the value of 0.0 is used.

A dynamic solution is obtained by solving one initial value problem for all the data. A graph of a simple dynamic simulation is shown in Figure 19.47. If the time variable for the current observation is less than the time variable for the previous observation, the integration is restarted from this point. This allows for multiple samples in one data file.

Figure 19.47 Dynamic Solution

In a static solution, $n-1$ initial value problems are solved using the first $n-1$ data values as initial values.

The equations are integrated using the i th data value as an initial value to the $i+1$ data value. Figure 19.48 displays a static simulation of noisy data from a simple differential equation. The static solution does not propagate errors in initial values as the dynamic solution does.

Figure 19.48 Static Solution

For estimation, the DYNAMIC and STATIC options in the FIT statement perform the same functions as they do in the SOLVE statement. Components of differential systems that have missing values or are not in the data set are simulated dynamically. For example, often in multiple compartment kinetic models, only one compartment is monitored. The differential equations that describe the unmonitored compartments are simulated dynamically.

For estimation, it is important to have accurate initial values for ODEs that are not in the data set. If an accurate initial value is not known, the initial value can be made an unknown parameter and estimated. This allows for errors in the initial values but increases the number of parameters to estimate by the number of equations.

Estimation of Differential Equations

Consider the kinetic model for the accumulation of mercury (Hg) in mosquito fish (Matis, Miller, and Allen 1991, p. 177). The model for this process is the one-compartment constant infusion model shown in Figure 19.49.

Figure 19.49 One-Compartment Constant Infusion Model

The differential equation that models this process is

$$\begin{aligned}\frac{dconc}{dt} &= k_u - k_e conc \\ conc_0 &= 0\end{aligned}$$

The analytical solution to the model is

$$conc = (k_u/k_e)(1 - \exp(-k_e t))$$

The data for the model are

```
data fish;
  input day conc;
datalines;
0.0 0.0
1.0 0.15
2.0 0.2
3.0 0.26
4.0 0.32
6.0 0.33
;
```

To fit this model in differential form, use the following statements:

```
proc model data=fish;
  parm ku ke;

  dert.conc = ku - ke * conc;

  fit conc / time=day;
run;
```

The results from this estimation are shown in [Figure 19.50](#).

Figure 19.50 Static Estimation Results for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.180159	0.0312	5.78	0.0044
ke	0.524661	0.1181	4.44	0.0113

To perform a dynamic estimation of the differential equation, add the DYNAMIC option to the FIT statement.

```
proc model data=fish;
  parm ku .3 ke .3;

  dert.conc = ku - ke * conc;

  fit conc / time = day dynamic;
run;
```

The equation DERT.CONC is integrated from $conc(0) = 0$. The results from this estimation are shown in Figure 19.51.

Figure 19.51 Dynamic Estimation Results for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.167109	0.0170	9.84	0.0006
ke	0.469033	0.0731	6.42	0.0030

To perform a dynamic estimation of the differential equation and estimate the initial value, use the following statements:

```
proc model data=fish;
  parm ku .3 ke .3 conc0 0;

  dert.conc = ku - ke * conc;

  fit conc initial=(conc = conc0) / time = day dynamic;
run;
```

The INITIAL= option in the FIT statement is used to associate the initial value of a differential equation with a parameter. The results from this estimation are shown in Figure 19.52.

Figure 19.52 Dynamic Estimation with Initial Value for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.164408	0.0230	7.14	0.0057
ke	0.45949	0.0943	4.87	0.0165
conc0	0.003798	0.0174	0.22	0.8414

Finally, to estimate the fish model by using the analytical solution, use the following statements:

```
proc model data=fish;
  parm ku .3 ke .3;

  conc = (ku/ ke)*( 1 -exp(-ke * day));

  fit conc;
run;
```

The results from this estimation are shown in [Figure 19.53](#).

Figure 19.53 Analytical Estimation Results for Fish Model

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
ku	0.167109	0.0170	9.84	0.0006
ke	0.469033	0.0731	6.42	0.0030

A comparison of the results among the four estimations reveals that the two dynamic estimations and the analytical estimation give nearly identical results (identical to the default precision). The two dynamic estimations are identical because the estimated initial value (0.00013071) is very close to the initial value used in the first dynamic estimation (0). Note also that the static model did not require an initial guess for the parameter values. Static estimation, in general, is more forgiving of bad initial values.

The form of the estimation that is preferred depends mostly on the model and data. If a very accurate initial value is known, then a dynamic estimation makes sense. If, additionally, the model can be written analytically, then the analytical estimation is computationally simpler. If only an approximate initial value is known and not modeled as an unknown parameter, the static estimation is less sensitive to errors in the initial value.

The form of the error in the model is also an important factor in choosing the form of the estimation. If the error term is additive and independent of previous error, then the dynamic mode is appropriate. If, on the

other hand, the errors are cumulative, a static estimation is more appropriate. See the section “[Monte Carlo Simulation](#)” on page 1188 for an example.

Auxiliary Equations

Auxiliary equations can be used with differential equations. These are equations that need to be satisfied with the differential equations at each point between each data value. They are automatically added to the system, so you do not need to specify them in the SOLVE or FIT statement.

Consider the following example.

The Michaelis-Menten equations describe the kinetics of an enzyme-catalyzed reaction. The enzyme is E, and S is called the *substrate*. The enzyme first reacts with the substrate to form the enzyme-substrate complex ES, which then breaks down in a second step to form enzyme and products P.

The reaction rates are described by the following system of differential equations:

$$\frac{d[ES]}{dt} = k_1([E] - [ES])[S] - k_2[ES] - k_3[ES]$$

$$\frac{d[S]}{dt} = -k_1([E] - [ES])[S] + k_2[ES]$$

$$[E] = [E]_{tot} - [ES]$$

The first equation describes the rate of formation of ES from E + S. The rate of formation of ES from E + P is very small and can be ignored. The enzyme is in either the complexed or the uncomplexed form. So if the total $([E]_{tot})$ concentration of enzyme and the amount bound to the substrate is known, $[E]$ can be obtained by conservation.

In this example, the conservation equation is an auxiliary equation and is coupled with the differential equations for integration.

Time Variable

You must provide a time variable in the data set. The name of the time variable defaults to TIME. You can use other variables as the time variable by specifying the TIME= option in the FIT or SOLVE statement. The time intervals need not be evenly spaced. If the time variable for the current observation is less than the time variable for the previous observation, the integration is restarted.

Differential Equations and Goal Seeking

Consider the following differential equation

$$y' = a * x$$

and the data set

```
data t2;
  y=0; time=0; output;
  y=2; time=1; output;
  y=3; time=2; output;
run;
```

The problem is to find values for X that satisfy the differential equation and the data in the data set. Problems of this kind are sometimes referred to as *goal-seeking problems* because they require you to search for values of X that satisfy the goal of Y.

This problem is solved with the following statements:

```
proc model data=t2;
  independent x 0;
  dependent y;
  parm a 5;
  dert.y = a * x;
  solve x / out=goaldata;
run;

proc print data=goaldata;
run;
```

The output from the PROC PRINT statement is shown in [Figure 19.54](#).

Figure 19.54 Dynamic Solution

Obs	_TYPE_	_MODE_	_ERRORS_	x	y	time
1	PREDICT	SIMULATE	0	0.0	0	0
2	PREDICT	SIMULATE	0	0.8	2	1
3	PREDICT	SIMULATE	0	-0.4	3	2

Note that an initial value of 0 is provided for the X variable because it is undetermined at TIME = 0.

In the preceding goal-seeking example, X is treated as a linear function between each set of data points (see [Figure 19.55](#)).

Figure 19.55 Form of X Used for Integration in Goal Seeking

If you integrate $y' = ax$ manually, you have

$$\begin{aligned}
 x(t) &= \frac{t_f - t}{t_f - t_o} x_o + \frac{t - t_o}{t_f - t_o} x_f \\
 y_f - y_o &= \int_{t_o}^{t_f} ax(t) dt \\
 &= a \frac{1}{t_f - t_o} \left(t(t_f x_o - t_o x_f) + \frac{1}{2} t^2 (x_f - x_o) \right) \Big|_{t_o}^{t_f}
 \end{aligned}$$

For observation 2, this reduces to

$$\begin{aligned}
 y_f - y_o &= \frac{1}{2} a * x_f \\
 2 &= 2.5 * x_f
 \end{aligned}$$

So $x = 0.8$ for this observation.

Goal seeking for the TIME variable is not allowed.

Restrictions and Bounds on Parameters

Using the BOUNDS and RESTRICT statements, PROC MODEL can compute optimal estimates subject to equality or inequality constraints on the parameter estimates.

Equality restrictions can be written as a vector function:

$$h(\theta) = 0$$

Inequality restrictions are either active or inactive. When an inequality restriction is active, it is treated as an equality restriction. All inactive inequality restrictions can be written as a vector function:

$$F(\theta) \geq 0$$

Strict inequalities, such as $(f(\theta) > 0)$, are transformed into inequalities as $f(\theta) \times (1 - \epsilon) - \epsilon \geq 0$, where the tolerance ϵ is controlled by the EPSILON= option in the FIT statement and defaults to 10^{-8} . The i th inequality restriction becomes active if $F_i < 0$ and remains active until its Lagrange multiplier becomes negative. Lagrange multipliers are computed for all the nonredundant equality restrictions and all the active inequality restrictions.

For the following, assume the vector $\mathbf{h}(\theta)$ contains all the current active restrictions. The constraint matrix \mathbf{A} is

$$\mathbf{A}(\hat{\theta}) = \frac{\partial \mathbf{h}(\hat{\theta})}{\partial \hat{\theta}}$$

The covariance matrix for the restricted parameter estimates is computed as

$$\mathbf{Z}(\mathbf{Z}'\mathbf{H}\mathbf{Z})^{-1}\mathbf{Z}'$$

where \mathbf{H} is Hessian or approximation to the Hessian of the objective function $((\mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{X})$ for OLS), and \mathbf{Z} is the last $(np - nc)$ columns of \mathbf{Q} . \mathbf{Q} is from an LQ factorization of the constraint matrix, nc is the number of active constraints, and np is the number of parameters. See Gill, Murray, and Wright (1981) for more details on LQ factorization. The covariance column in Table 19.2 summarizes the Hessian approximation used for each estimation method.

The covariance matrix for the Lagrange multipliers is computed as

$$(\mathbf{A}\mathbf{H}^{-1}\mathbf{A}')^{-1}$$

The p -value reported for a restriction is computed from a beta distribution rather than a t distribution because the numerator and the denominator of the t ratio for an estimated Lagrange multiplier are not independent.

The Lagrange multipliers for the active restrictions are printed with the parameter estimates. The Lagrange multiplier estimates are computed using the relationship

$$\mathbf{A}'\lambda = \mathbf{g}$$

where the dimensions of the constraint matrix \mathbf{A} are the number of constraints by the number of parameters, λ is the vector of Lagrange multipliers, and \mathbf{g} is the gradient of the objective function at the final estimates.

The final gradient includes the effects of the estimated \mathbf{S} matrix. For example, for OLS the final gradient would be:

$$\mathbf{g} = \mathbf{X}'(\text{diag}(\mathbf{S})^{-1} \otimes \mathbf{I})\mathbf{r}$$

where \mathbf{r} is the residual vector. Note that when nonlinear restrictions are imposed, the convergence measure R might have values greater than one for some iterations.

Tests on Parameters

In general, the hypothesis tested can be written as

$$H_0 : \mathbf{h}(\theta) = 0$$

where $\mathbf{h}(\theta)$ is a vector-valued function of the parameters θ given by the r expressions specified on the TEST statement.

Let $\hat{\mathbf{V}}$ be the estimate of the covariance matrix of $\hat{\theta}$. Let $\hat{\theta}$ be the unconstrained estimate of θ and $\tilde{\theta}$ be the constrained estimate of θ such that $h(\tilde{\theta}) = 0$. Let

$$\mathbf{A}(\theta) = \partial h(\theta) / \partial \theta \big|_{\hat{\theta}}$$

Let r be the dimension of $h(\theta)$ and n be the number of observations. Using this notation, the test statistics for the three kinds of tests are computed as follows.

The Wald test statistic is defined as

$$W = h'(\hat{\theta}) \left(\mathbf{A}(\hat{\theta}) \hat{\mathbf{V}} \mathbf{A}'(\hat{\theta}) \right)^{-1} h(\hat{\theta})$$

The Wald test is not invariant to reparameterization of the model (Gregory and Veall 1985; Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

The Lagrange multiplier test statistic is

$$R = \lambda' \mathbf{A}(\tilde{\theta}) \tilde{\mathbf{V}} \mathbf{A}'(\tilde{\theta}) \lambda$$

where λ is the vector of Lagrange multipliers from the computation of the restricted estimate $\tilde{\theta}$.

The Lagrange multiplier test statistic is equivalent to Rao's efficient score test statistic:

$$R = (\partial L(\tilde{\theta}) / \partial \theta)' \tilde{\mathbf{V}} (\partial L(\tilde{\theta}) / \partial \theta)$$

where L is the log-likelihood function for the estimation method used. For SUR, 3SLS, GMM, and iterated versions of these methods, the likelihood function is computed as

$$L = \text{Objective} \times Nobs / 2$$

For OLS and 2SLS, the Lagrange multiplier test statistic is computed as:

$$R = [(\partial \hat{S}(\tilde{\theta}) / \partial \theta)' \tilde{\mathbf{V}} (\partial \hat{S}(\tilde{\theta}) / \partial \theta)] / \hat{S}(\tilde{\theta})$$

where $\hat{S}(\tilde{\theta})$ is the corresponding objective function value at the constrained estimate.

The likelihood ratio test statistic is

$$T = 2 \left(L(\hat{\theta}) - L(\tilde{\theta}) \right)$$

where $\tilde{\theta}$ represents the constrained estimate of θ and L is the concentrated log-likelihood value.

For OLS and 2SLS, the likelihood ratio test statistic is computed as:

$$T = (n - nparms) \times (\hat{S}(\tilde{\theta}) - \hat{S}(\hat{\theta})) / \hat{S}(\hat{\theta})$$

This test statistic is an approximation from

$$T = n \times \log \left(1 + \frac{rF}{n - nparms} \right)$$

when the value of $rF/(n - nparms)$ is small (Greene 2004, p. 421).

The likelihood ratio test is not appropriate for models with nonstationary serially correlated errors (Gallant 1987, p. 139). The likelihood ratio test should not be used for dynamic systems, for systems with lagged dependent variables, or with the FIML estimation method unless certain conditions are met (see Gallant 1987, p. 479).

For each kind of test, under the null hypothesis the test statistic is asymptotically distributed as a χ^2 random variable with r degrees of freedom, where r is the number of expressions in the TEST statement. The p -values reported for the tests are computed from the $\chi^2(r)$ distribution and are only asymptotically valid. When both RESTRICT and TEST statements are used in a PROC MODEL step, test statistics are computed by taking into account the constraints imposed by the RESTRICT statement.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation to its small sample distribution than the other two tests. However, the Wald test has the least computational cost, since it does not require computation of the constrained estimate $\tilde{\theta}$.

The following is an example of using the TEST statement to perform a likelihood ratio test for a compound hypothesis.

```
test a*exp(-k) = 1-k, d = 0 , / 1r;
```

It is important to keep in mind that although individual t tests for each parameter are printed by default into the parameter estimates table, they are only asymptotically valid for nonlinear models. You should be cautious in drawing any inferences from these t tests for small samples.

Hausman Specification Test

Hausman's specification test, or m -statistic, can be used to test hypotheses in terms of bias or inconsistency of an estimator. This test was also proposed by Wu (1973). Hausman's m -statistic is as follows.

Given two estimators, $\hat{\beta}_0$ and $\hat{\beta}_1$, where under the null hypothesis both estimators are consistent but only $\hat{\beta}_0$ is asymptotically efficient and under the alternative hypothesis only $\hat{\beta}_1$ is consistent, the m -statistic is

$$m = \hat{q}'(\hat{\mathbf{V}}_1 - \hat{\mathbf{V}}_0)^{-1}\hat{q}$$

where $\hat{\mathbf{V}}_1$ and $\hat{\mathbf{V}}_0$ represent consistent estimates of the asymptotic covariance matrices of $\hat{\beta}_1$ and $\hat{\beta}_0$ respectively, and

$$q = \hat{\beta}_1 - \hat{\beta}_0$$

The m -statistic is then distributed χ^2 with k degrees of freedom, where k is the rank of the matrix $(\hat{V}_1 - \hat{V}_0)$. A generalized inverse is used, as recommended by Hausman and Taylor (1982).

In the MODEL procedure, Hausman's m -statistic can be used to determine if it is necessary to use an instrumental variables method rather than a more efficient OLS estimation. Hausman's m -statistic can also be used to compare 2SLS with 3SLS for a class of estimators for which 3SLS is asymptotically efficient (similarly for OLS and SUR).

Hausman's m -statistic can also be used, in principle, to test the null hypothesis of normality when comparing 3SLS to FIML. Because of the poor performance of this form of the test, it is not offered in the MODEL procedure. See Fair (1984, pp. 246–247) for a discussion of why Hausman's test fails for common econometric models.

To perform a Hausman's specification test, specify the HAUSMAN option in the FIT statement. The selected estimation methods are compared using Hausman's m -statistic.

In the following example, Hausman's test is used to check the presence of measurement error. Under H_0 of no measurement error, OLS is efficient, while under H_1 , 2SLS is consistent. In the following code, OLS and 2SLS are used to estimate the model, and Hausman's test is requested.

```
proc model data=one out=fiml2;
    endogenous y1 y2;

    y1 = py2 * y2 + px1 * x1 + interc;
    y2 = py1* y1 + pz1 * z1 + d2;

    fit y1 y2 / ols 2sls hausman;
    instruments x1 z1;
run;
```

The output specified by the HAUSMAN option produces the results shown in Figure 19.56.

Figure 19.56 Hausman's Specification Test Results

The MODEL Procedure				
Hausman's Specification Test Results				
Efficient under H0	Consistent under H1	DF	Statistic	Pr > ChiSq
OLS	2SLS	6	13.86	0.0313

Figure 19.56 indicates that 2SLS is preferred over OLS at 5% level of significance. In this case, the null hypothesis of no measurement error is rejected. Hence, the instrumental variable estimator is required for this example due to the presence of measurement error.

Chow Tests

The Chow test is used to test for break points or structural changes in a model. The problem is posed as a partitioning of the data into two parts of size n_1 and n_2 . The null hypothesis to be tested is

$$H_0 : \beta_1 = \beta_2 = \beta$$

where β_1 is estimated by using the first part of the data and β_2 is estimated by using the second part.

The test is performed as follows (see Davidson and MacKinnon 1993, p. 380).

1. The p parameters of the model are estimated.
2. A second linear regression is performed on the residuals, \hat{u} , from the nonlinear estimation in step one.

$$\hat{u} = \hat{\mathbf{X}}b + \text{residuals}$$

where $\hat{\mathbf{X}}$ is Jacobian columns that are evaluated at the parameter estimates. If the estimation is an instrumental variables estimation with matrix of instruments \mathbf{W} , then the following regression is performed:

$$\hat{u} = \mathbf{P}_{\mathbf{W}^*}\hat{\mathbf{X}}b + \text{residuals}$$

where $\mathbf{P}_{\mathbf{W}^*}$ is the projection matrix.

3. The restricted SSE (RSSE) from this regression is obtained. An SSE for each subsample is then obtained by using the same linear regression.
4. The F statistic is then

$$f = \frac{(RSSE - SSE_1 - SSE_2)/p}{(SSE_1 + SSE_2)/(n - 2p)}$$

This test has p and $n - 2p$ degrees of freedom.

Chow's test is not applicable if $\min(n_1, n_2) < p$, since one of the two subsamples does not contain enough data to estimate β . In this instance, the *predictive Chow test* can be used. The predictive Chow test is defined as

$$f = \frac{(RSSE - SSE_1) \times (n_1 - p)}{SSE_1 \times n_2}$$

where $n_1 > p$. This test can be derived from the Chow test by noting that the $SSE_2 = 0$ when $n_2 \leq p$ and by adjusting the degrees of freedom appropriately.

You can select the Chow test and the predictive Chow test by specifying the `CHOW=arg` and the `PCHOW=arg` options in the FIT statement, where *arg* is either the number of observations in the first sample or a parenthesized list of first sample sizes. If the size of the one of the two groups in which the sample is partitioned is less than the number of parameters, then a predictive Chow test is automatically used. These tests statistics are not produced for GMM and FIML estimations.

The following is an example of the use of the Chow test.

```

data exp;
  x=0;
  do time=1 to 100;
    if time=50 then x=1;
    y = 35 * exp( 0.01 * time ) + rannor( 123 ) + x * 5;
    output;
  end;
run;

proc model data=exp;
  parm zo 35 b;
  dert.z = b * z;
  y=z;
  fit y init=(z=zo) / chow =(40 50 60) pchow=90;
run;

```

The data set introduces an artificial structural change into the model (the structural change effects the intercept parameter). The output from the requested Chow tests are shown in [Figure 19.57](#).

Figure 19.57 Chow's Test Results

The MODEL Procedure					
Structural Change Test					
Test	Break Point	Num DF	Den DF	F Value	Pr > F

Chow	50	2	96	101.37	<.0001
Chow	60	2	96	26.43	<.0001
Predictive Chow	90	11	87	1.86	0.0566

Profile Likelihood Confidence Intervals

Wald-based and likelihood-ratio-based confidence intervals are available in the MODEL procedure for computing a confidence interval on an estimated parameter. A confidence interval on a parameter θ can be constructed by inverting a Wald-based or a likelihood-ratio-based test.

The approximate $100(1 - \alpha) \%$ Wald confidence interval for a parameter θ is

$$\hat{\theta} \pm z_{1-\alpha/2} \hat{\sigma}$$

where z_p is the 100 p th percentile of the standard normal distribution, $\hat{\theta}$ is the maximum likelihood estimate of θ , and $\hat{\sigma}$ is the standard error estimate of $\hat{\theta}$.

A likelihood-ratio-based confidence interval is derived from the χ^2 distribution of the generalized likelihood ratio test. The approximate $1 - \alpha$ confidence interval for a parameter θ is

$$\theta : 2[l(\hat{\theta}) - l(\theta)] \leq q_{1,1-\alpha} = 2l^*$$

where $q_{1,1-\alpha}$ is the $(1 - \alpha)$ quantile of the χ^2 with one degree of freedom, and $l(\theta)$ is the log likelihood as a function of one parameter. The endpoints of a confidence interval are the zeros of the function $l(\theta) - l^*$. Computing a likelihood-ratio-based confidence interval is an iterative process. This process must be performed twice for each parameter, so the computational cost is considerable. Using a modified form of the algorithm recommended by Venzon and Moolgavkar (1988), you can determine that the cost of each endpoint computation is approximately the cost of estimating the original system.

To request confidence intervals on estimated parameters, specify the PRL= option in the FIT statement. By default, the PRL option produces 95% likelihood ratio confidence limits. The coverage of the confidence interval is controlled by the ALPHA= option in the FIT statement.

The following is an example of the use of the confidence interval options.

```
data exp;
  do time = 1 to 20;
    y = 35 * exp( 0.01 * time ) + 5*rannor( 123 );
  output;
  end;
run;

proc model data=exp;
  parm zo 35 b;
  dert.z = b * z;
  y=z;
  fit y init=(z=zo) / prl=both;
  test zo = 40.475437 ,/ lr;
run;
```

The output from the requested confidence intervals and the TEST statement are shown in [Figure 19.58](#)

Figure 19.58 Confidence Interval Estimation

The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
zo	36.58933	1.9471	18.79	<.0001
b	0.006497	0.00464	1.40	0.1780
Test Results				
Test	Type	Statistic	Pr > ChiSq	Label
Test0	L.R.	3.81	0.0509	zo = 40.475437

Figure 19.58 continued

Parameter Wald			
95% Confidence Intervals			
Parameter	Value	Lower	Upper
zo	36.5893	32.7730	40.4056
b	0.00650	-0.00259	0.0156

Parameter Likelihood Ratio			
95% Confidence Intervals			
Parameter	Value	Lower	Upper
zo	36.5893	32.8381	40.4921
b	0.00650	-0.00264	0.0157

In this example the parameter value used in the likelihood ratio test, $z_o = 40.475437$, is close to the upper bound computed for the likelihood ratio confidence interval, $z_o \leq 40.4921$. This coincidence is not germane to the analysis however, since the likelihood ratio test is a test of the null hypothesis $H_0 : z_o = 40.475437$ and the confidence interval can be viewed as a test of the null hypothesis $H_0 : 32.8381 \leq z_o \leq 40.4921$.

Choice of Instruments

Several of the estimation methods supported by PROC MODEL are instrumental variables methods. There is no standard method for choosing instruments for nonlinear regression. Few econometric textbooks discuss the selection of instruments for nonlinear models. See Bowden and Turkington (1984, pp. 180–182) for more information.

The purpose of the instrumental projection is to purge the regressors of their correlation with the residual. For nonlinear systems, the regressors are the partials of the residuals with respect to the parameters.

Possible instrumental variables include the following:

- any variable in the model that is independent of the errors
- lags of variables in the system
- derivatives with respect to the parameters, if the derivatives are independent of the errors
- low-degree polynomials in the exogenous variables
- variables from the data set or functions of variables from the data set

Selected instruments must not have any of the following characteristics:

- depend on any variable endogenous with respect to the equations estimated
- depend on any of the parameters estimated
- be lags of endogenous variables if there is serial correlation of the errors

If the preceding rules are satisfied and there are enough observations to support the number of instruments used, the results should be consistent and the efficiency loss held to a minimum.

You need at least as many instruments as the maximum number of parameters in any equation, or some of the parameters cannot be estimated. Note that *number of instruments* means linearly independent instruments. If you add an instrument that is a linear combination of other instruments, it has no effect and does not increase the effective number of instruments.

You can, however, use too many instruments. In order to get the benefit of instrumental variables, you must have more observations than instruments. Thus, there is a trade-off; the instrumental variables technique completely eliminates the simultaneous equation bias only in large samples. In finite samples, the larger the excess of observations over instruments, the more the bias is reduced. Adding more instruments might improve the efficiency, but after some point efficiency declines as the excess of observations over instruments becomes smaller and the bias grows.

The instruments used in an estimation are printed out at the beginning of the estimation. For example, the following statements produce the instruments list shown in Figure 19.59.

```
proc model data=test2;
  exogenous x1 x2;
  parms b1 a1 a2 b2 2.5 c2 55;
  y1 = a1 * y2 + b1 * exp(x1);
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2;
  fit y1 y2 / n2s1s;
  inst b1 b2 c2 x1 ;
run;
```

Figure 19.59 Instruments Used Message

```

The MODEL Procedure

The 2 Equations to Estimate

      y1 = F(b1, a1(y2))
      y2 = F(a2(y1), b2, c2)
Instruments  1 x1 @y1/@b1 @y2/@b2 @y2/@c2

```

This states that an intercept term, the exogenous variable X1, and the partial derivatives of the equations with respect to B1, B2, and C2, were used as instruments for the estimation.

Examples

Suppose that Y1 and Y2 are endogenous variables, that X1 and X2 are exogenous variables, and that A, B, C, D, E, F, and G are parameters. Consider the following model:

```
y1 = a + b * x1 + c * y2 + d * lag(y1);
y2 = e + f * x2 + g * y1;
fit y1 y2;
instruments exclude=(c g);
```

The INSTRUMENTS statement produces X1, X2, LAG(Y1), and an intercept as instruments.

In order to estimate the Y1 equation by itself, it is necessary to include X2 explicitly in the instruments since F, in this case, is not included in the following estimation:

```
y1 = a + b * x1 + c * y2 + d * lag(y1);
y2 = e + f * x2 + g * y1;
fit y1;
instruments x2 exclude=(c);
```

This produces the same instruments as before. You can list the parameter associated with the lagged variable as an instrument instead of using the EXCLUDE= option. Thus, the following is equivalent to the previous example:

```
y1 = a + b * x1 + c * y2 + d * lag(y1);
y2 = e + f * x2 + g * y1;
fit y1;
instruments x1 x2 d;
```

For an example of declaring instruments when estimating a model involving identities, consider Klein's Model I:

```
proc model data=klien;
  endogenous c p w i x wsum k y;
  exogenous wp g t year;
  parms c0-c3 i0-i3 w0-w3;
  a: c = c0 + c1 * p + c2 * lag(p) + c3 * wsum;
  b: i = i0 + i1 * p + i2 * lag(p) + i3 * lag(k);
  c: w = w0 + w1 * x + w2 * lag(x) + w3 * year;
  x = c + i + g;
  y = c + i + g-t;
  p = x-w-t;
  k = lag(k) + i;
  wsum = w + wp;
run;
```

The three equations to estimate are identified by the labels A, B, and C. The parameters associated with the predetermined terms are C2, I2, I3, W2, and W3 (and the intercepts, which are automatically added to the instruments). In addition, the system includes five identities that contain the predetermined variables G, T, LAG(K), and WP. Thus, the INSTRUMENTS statement can be written as

```
lagk = lag(k);
instruments c2 i2 i3 w2 w3 g t wp lagk;
```

where LAGK is a program variable used to hold LAG(K). However, this is more complicated than it needs to be. Except for LAG(K), all the predetermined terms in the identities are exogenous variables, and LAG(K) is already included as the coefficient of I3. There are also more parameters for predetermined terms than for endogenous terms, so you might prefer to use the EXCLUDE= option. Thus, you can specify the same instruments list with the simpler statement

```
instruments _exog_ exclude=(c1 c3 i1 w1);
```

To illustrate the use of polynomial terms as instrumental variables, consider the following model:

$$y1 = a + b * \exp(c * x1) + d * \log(x2) + e * \exp(f * y2);$$

The parameters are A, B, C, D, E, and F, and the right-hand-side variables are X1, X2, and Y2. Assume that X1 and X2 are exogenous (independent of the error), while Y2 is endogenous. The equation for Y2 is not specified, but assume that it includes the variables X1, X3, and Y1, with X3 exogenous, so the exogenous variables of the full system are X1, X2, and X3. Using as instruments quadratic terms in the exogenous variables, the model is specified to PROC MODEL as follows:

```
proc model;
  parms a b c d e f;
  y1 = a + b * exp( c * x1 ) + d * log( x2 ) + e * exp( f * y2 );
  instruments inst1-inst9;
  inst1 = x1; inst2 = x2; inst3 = x3;
  inst4 = x1 * x1; inst5 = x1 * x2; inst6 = x1 * x3;
  inst7 = x2 * x2; inst8 = x2 * x3; inst9 = x3 * x3;
  fit y1 / 2sls;
run;
```

It is not clear what degree polynomial should be used. There is no way to know how good the approximation is for any degree chosen, although the first-stage R^2 s might help the assessment.

First-Stage R-Squares

When the FSRSQ option is used on the FIT statement, the MODEL procedure prints a column of first-stage R^2 (FSRSQ) statistics along with the parameter estimates. The FSRSQ measures the fraction of the variation of the derivative column associated with the parameter that remains after projection through the instruments.

Ideally, the FSRSQ should be very close to 1.00 for exogenous derivatives. If the FSRSQ is small for an endogenous derivative, it is unclear whether this reflects a poor choice of instruments or a large influence of the errors in the endogenous right-hand-side variables. When the FSRSQ for one or more parameters is small, the standard errors of the parameter estimates are likely to be large.

Note that you can make all the FSRSQs larger (or 1.00) by including more instruments, because of the disadvantage discussed previously. The FSRSQ statistics reported are unadjusted R^2 s and do not include a degrees-of-freedom correction.

Autoregressive Moving-Average Error Processes

Autoregressive moving-average error processes (ARMA errors) and other models that involve lags of error terms can be estimated by using FIT statements and simulated or forecast by using SOLVE statements. ARMA models for the error process are often used for models with autocorrelated residuals. The %AR macro can be used to specify models with autoregressive error processes. The %MA macro can be used to specify models with moving-average error processes.

Autoregressive Errors

A model with first-order autoregressive errors, AR(1), has the form

$$y_t = f(x_t, \theta) + \mu_t$$

$$\mu_t = \phi \mu_{t-1} + \epsilon_t$$

while an AR(2) error process has the form

$$\mu_t = \phi_1 \mu_{t-1} + \phi_2 \mu_{t-2} + \epsilon_t$$

and so forth for higher-order processes. Note that the ϵ_t 's are independent and identically distributed and have an expected value of 0.

An example of a model with an AR(2) component is

$$y = \alpha + \beta x_1 + \mu_t$$

$$\mu_t = \phi_1 \mu_{t-1} + \phi_2 \mu_{t-2} + \epsilon_t$$

You would write this model as

```
proc model data=in;
  parms a b p1 p2;
  y = a + b * x1 + p1 * zlag1(y - (a + b * x1)) +
      p2 * zlag2(y - (a + b * x1));
  fit y;
run;
```

or equivalently using the %AR macro as

```
proc model data=in;
  parms a b;
  y = a + b * x1;
  %ar( y, 2 );
  fit y;
run;
```

Moving-Average Models

A model with first-order moving-average errors, MA(1), has the form

$$y_t = f(x_t) + \mu_t$$

$$\mu_t = \epsilon_t - \theta_1 \epsilon_{t-1}$$

where ϵ_t is identically and independently distributed with mean zero. An MA(2) error process has the form

$$\mu_t = \epsilon_t - \theta_1 \epsilon_{t-1} - \theta_2 \epsilon_{t-2}$$

and so forth for higher-order processes.

For example, you can write a simple linear regression model with MA(2) moving-average errors as

```
proc model data=inma2;
  parms a b ma1 ma2;
  y = a + b * x + ma1 * zlag1( resid.y ) +
      ma2 * zlag2( resid.y );
  fit;
run;
```

where MA1 and MA2 are the moving-average parameters.

Note that RESID.Y is automatically defined by PROC MODEL as

```
pred.y = a + b * x + ma1 * zlag1( resid.y ) +
      ma2 * zlag2( resid.y );
resid.y = pred.y - actual.y;
```

Note that RESID.Y is negative of ϵ_t .

The ZLAG function must be used for MA models to truncate the recursion of the lags. This ensures that the lagged errors start at zero in the lag-priming phase and do not propagate missing values when lag-priming period variables are missing, and it ensures that the future errors are zero rather than missing during simulation or forecasting. For details about the lag functions, see the section “[Lag Logic](#)” on page 1230.

This model written using the %MA macro is as follows:

```
proc model data=inma2;
  parms a b;
  y = a + b * x;
  %ma(y, 2);
  fit;
run;
```

General Form for ARMA Models

The general ARMA(p, q) process has the following form

$$\mu_t = \phi_1 \mu_{t-1} + \dots + \phi_p \mu_{t-p} + \epsilon_t - \theta_1 \epsilon_{t-1} - \dots - \theta_q \epsilon_{t-q}$$

An ARMA(p, q) model can be specified as follows:

```
yhat = ... compute structural predicted value here ... ;
yarma = ar1 * zlag1( y - yhat ) + ... /* ar part */
      + ar(p) * zlag(p)( y - yhat )
      + ma1 * zlag1( resid.y ) + ... /* ma part */
      + ma(q) * zlag(q)( resid.y );
y = yhat + yarma;
```

where AR i and MA j represent the autoregressive and moving-average parameters for the various lags. You can use any names you want for these variables, and there are many equivalent ways that the specification could be written.

Vector ARMA processes can also be estimated with PROC MODEL. For example, a two-variable AR(1) process for the errors of the two endogenous variables Y1 and Y2 can be specified as follows:

```

y1hat = ... compute structural predicted value here ... ;

y1      = y1hat + ar1_1 * zlag1( y1 - y1hat )    /* ar part y1,y1 */
          + ar1_2 * zlag1( y2 - y2hat ); /* ar part y1,y2 */

y21hat = ... compute structural predicted value here ... ;

y2      = y2hat + ar2_2 * zlag1( y2 - y2hat )    /* ar part y2,y2 */
          + ar2_1 * zlag1( y1 - y1hat ); /* ar part y2,y1 */

```

Convergence Problems with ARMA Models

ARMA models can be difficult to estimate. If the parameter estimates are not within the appropriate range, a moving-average model's residual terms grow exponentially. The calculated residuals for later observations can be very large or can overflow. This can happen either because improper starting values were used or because the iterations moved away from reasonable values.

Care should be used in choosing starting values for ARMA parameters. Starting values of 0.001 for ARMA parameters usually work if the model fits the data well and the problem is well-conditioned. Note that an MA model can often be approximated by a high-order AR model, and vice versa. This can result in high collinearity in mixed ARMA models, which in turn can cause serious ill-conditioning in the calculations and instability of the parameter estimates.

If you have convergence problems while estimating a model with ARMA error processes, try to estimate in steps. First, use a FIT statement to estimate only the structural parameters with the ARMA parameters held to zero (or to reasonable prior estimates if available). Next, use another FIT statement to estimate the ARMA parameters only, using the structural parameter values from the first run. Since the values of the structural parameters are likely to be close to their final estimates, the ARMA parameter estimates might now converge. Finally, use another FIT statement to produce simultaneous estimates of all the parameters. Since the initial values of the parameters are now likely to be quite close to their final joint estimates, the estimates should converge quickly if the model is appropriate for the data.

AR Initial Conditions

The initial lags of the error terms of $AR(p)$ models can be modeled in different ways. The autoregressive error startup methods supported by SAS/ETS procedures are the following:

CLS	conditional least squares (ARIMA and MODEL procedures)
ULS	unconditional least squares (AUTOREG, ARIMA, and MODEL procedures)
ML	maximum likelihood (AUTOREG, ARIMA, and MODEL procedures)
YW	Yule-Walker (AUTOREG procedure only)
HL	Hildreth-Lu, which deletes the first p observations (MODEL procedure only)

See Chapter 8, “[The AUTOREG Procedure](#),” for an explanation and discussion of the merits of various $AR(p)$ startup methods.

The CLS, ULS, ML, and HL initializations can be performed by PROC MODEL. For $AR(1)$ errors, these initializations can be produced as shown in [Table 19.3](#). These methods are equivalent in large samples.

Table 19.3 Initializations Performed by PROC MODEL: AR(1) ERRORS

Method	Formula
conditional least squares	$Y = YHAT + AR1 * ZLAG1(Y - YHAT);$
unconditional least squares	$Y = YHAT + AR1 * ZLAG1(Y - YHAT);$ IF _OBS_=1 THEN $RESID.Y = \sqrt{1 - AR1^2} * RESID.Y;$
maximum likelihood	$Y = YHAT + AR1 * ZLAG1(Y - YHAT);$ $W = (1 - AR1^2)^{-1/(2 * _NUSED_)};$ IF _OBS_=1 THEN $W = W * \sqrt{1 - AR1^2};$ $RESID.Y = W * RESID.Y;$
Hildreth-Lu	$Y = YHAT + AR1 * LAG1(Y - YHAT);$

MA Initial Conditions

The initial lags of the error terms of $MA(q)$ models can also be modeled in different ways. The following moving-average error start-up paradigms are supported by the ARIMA and MODEL procedures:

ULS	unconditional least squares
CLS	conditional least squares
ML	maximum likelihood

The conditional least squares method of estimating moving-average error terms is not optimal because it ignores the start-up problem. This reduces the efficiency of the estimates, although they remain unbiased. The initial lagged residuals, extending before the start of the data, are assumed to be 0, their unconditional expected value. This introduces a difference between these residuals and the generalized least squares residuals for the moving-average covariance, which, unlike the autoregressive model, persists through the data set. Usually this difference converges quickly to 0, but for nearly noninvertible moving-average processes the convergence is quite slow. To minimize this problem, you should have plenty of data, and the moving-average parameter estimates should be well within the invertible range.

This problem can be corrected at the expense of writing a more complex program. Unconditional least squares estimates for the $MA(1)$ process can be produced by specifying the model as follows:

```

yhat = ... compute structural predicted value here ... ;
if _obs_ = 1 then do;
  h = sqrt( 1 + mal ** 2 );
  y = yhat;
  resid.y = ( y - yhat ) / h;
end;
else do;
  g = mal / zlag1( h );
  h = sqrt( 1 + mal ** 2 - g ** 2 );
  y = yhat + g * zlag1( resid.y );
  resid.y = ( ( y - yhat ) - g * zlag1( resid.y ) ) / h;
end;

```

Moving-average errors can be difficult to estimate. You should consider using an $AR(p)$ approximation to the moving-average process. A moving-average process can usually be well-approximated by an autoregressive process if the data have not been smoothed or differenced.

The %AR Macro

The SAS macro %AR generates programming statements for PROC MODEL for autoregressive models. The %AR macro is part of SAS/ETS software, and no special options need to be set to use the macro. The autoregressive process can be applied to the structural equation errors or to the endogenous series themselves.

The %AR macro can be used for the following types of autoregression:

- univariate autoregression
- unrestricted vector autoregression
- restricted vector autoregression

Univariate Autoregression

To model the error term of an equation as an autoregressive process, use the following statement after the equation:

```
%ar( varname, nlags )
```

For example, suppose that Y is a linear function of X1, X2, and an AR(2) error. You would write this model as follows:

```
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 2 )
  fit y / list;
run;
```

The calls to %AR must come *after* all of the equations that the process applies to.

The preceding macro invocation, %AR(y,2), produces the statements shown in the LIST output in [Figure 19.60](#).

Figure 19.60 LIST Option Output for an AR(2) Model

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	2338:4	PRED.y = a + b * x1 + c * x2;
1	2338:4	RESID.y = PRED.y - ACTUAL.y;
1	2338:4	ERROR.y = PRED.y - y;
2	2339:14	_PRED__y = PRED.y;
3	2339:15	_OLD_PRED.y = PRED.y + y_l1
		* ZLAG1(y - _PRED__y) + y_l2
		* ZLAG2(y - _PRED__y);
3	2339:15	PRED.y = _OLD_PRED.y;
3	2339:15	RESID.y = PRED.y - ACTUAL.y;
3	2339:15	ERROR.y = PRED.y - y;

The `_PRED__` prefixed variables are temporary program variables used so that the lags of the residuals are the correct residuals and not the ones redefined by this equation. Note that this is equivalent to the statements explicitly written in the section “[General Form for ARMA Models](#)” on page 1158.

You can also restrict the autoregressive parameters to zero at selected lags. For example, if you wanted autoregressive parameters at lags 1, 12, and 13, you can use the following statements:

```
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 13, , 1 12 13 )
  fit y / list;
run;
```

These statements generate the output shown in [Figure 19.61](#).

Figure 19.61 LIST Option Output for an AR Model with Lags at 1, 12, and 13

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	2347:4	PRED.y = a + b * x1 + c * x2;
1	2347:4	RESID.y = PRED.y - ACTUAL.y;
1	2347:4	ERROR.y = PRED.y - y;
2	2348:14	_PRED__y = PRED.y;
3	2348:15	_OLD_PRED.y = PRED.y + y_l1 * ZLAG1(y -
		_PRED__y) + y_l12 * ZLAG12(y -
		_PRED__y) + y_l13 * ZLAG13(
		y - _PRED__y);
3	2348:15	PRED.y = _OLD_PRED.y;
3	2348:15	RESID.y = PRED.y - ACTUAL.y;
3	2348:15	ERROR.y = PRED.y - y;

There are variations on the conditional least squares method, depending on whether observations at the start of the series are used to “warm up” the AR process. By default, the %AR conditional least squares method uses all the observations and assumes zeros for the initial lags of autoregressive terms. By using the M= option, you can request that %AR use the unconditional least squares (ULS) or maximum-likelihood (ML) method instead. For example,

```
proc model data=in;
  y = a + b * x1 + c * x2;
  %ar( y, 2, m=uls )
  fit y;
run;
```

Discussions of these methods is provided in the section “AR Initial Conditions” on page 1159.

By using the M=CLSn option, you can request that the first n observations be used to compute estimates of the initial autoregressive lags. In this case, the analysis starts with observation $n + 1$. For example:

```
proc model data=in;
  y = a + b * x1 + c * x2;
  %ar( y, 2, m=cls2 )
  fit y;
run;
```

You can use the %AR macro to apply an autoregressive model to the endogenous variable, instead of to the error term, by using the TYPE=V option. For example, if you want to add the five past lags of Y to the equation in the previous example, you could use %AR to generate the parameters and lags by using the following statements:

```
proc model data=in;
  parms a b c;
  y = a + b * x1 + c * x2;
  %ar( y, 5, type=v )
  fit y / list;
run;
```

The preceding statements generate the output shown in Figure 19.62.

Figure 19.62 LIST Option Output for an AR model of Y

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	2370:4	PRED.y = a + b * x1 + c * x2;
1	2370:4	RESID.y = PRED.y - ACTUAL.y;
1	2370:4	ERROR.y = PRED.y - y;
2	2371:15	_OLD_PRED.y = PRED.y + y_l1 * ZLAG1(y) + y_l2 * ZLAG2(y) + y_l3 * ZLAG3(y) + y_l4 * ZLAG4(y) + y_l5 * ZLAG5(y);
2	2371:15	PRED.y = _OLD_PRED.y;
2	2371:15	RESID.y = PRED.y - ACTUAL.y;
2	2371:15	ERROR.y = PRED.y - y;

This model predicts Y as a linear combination of $X1$, $X2$, an intercept, and the values of Y in the most recent five periods.

Unrestricted Vector Autoregression

To model the error terms of a set of equations as a vector autoregressive process, use the following form of the %AR macro after the equations:

```
%ar( process_name, nlags, variable_list )
```

The *process_name* value is any name that you supply for %AR to use in making names for the autoregressive parameters. You can use the %AR macro to model several different AR processes for different sets of equations by using different process names for each set. The process name ensures that the variable names used are unique. Use a short *process_name* value for the process if parameter estimates are to be written to an output data set. The %AR macro tries to construct parameter names less than or equal to eight characters, but this is limited by the length of *process_name*, which is used as a prefix for the AR parameter names.

The *variable_list* value is the list of endogenous variables for the equations.

For example, suppose that errors for equations $Y1$, $Y2$, and $Y3$ are generated by a second-order vector autoregressive process. You can use the following statements:

```
proc model data=in;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 2, y1 y2 y3 )
  fit y1 y2 y3;
run;
```

which generate the following for $Y1$ and similar code for $Y2$ and $Y3$:

```
y1 = pred.y1 + name1_1_1*zlag1(y1-name_y1) +
      name1_1_2*zlag1(y2-name_y2) +
      name1_1_3*zlag1(y3-name_y3) +
      name2_1_1*zlag2(y1-name_y1) +
      name2_1_2*zlag2(y2-name_y2) +
      name2_1_3*zlag2(y3-name_y3) ;
```

Only the conditional least squares (M=CLS or M=CLSn) method can be used for vector processes.

You can also use the same form with restrictions that the coefficient matrix be 0 at selected lags. For example, the following statements apply a third-order vector process to the equation errors with all the coefficients at lag 2 restricted to 0 and with the coefficients at lags 1 and 3 unrestricted:

```
proc model data=in;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 3, y1 y2 y3, 1 3 )
  fit y1 y2 y3;
```

You can model the three series Y_1 – Y_3 as a vector autoregressive process in the variables instead of in the errors by using the `TYPE=V` option. If you want to model Y_1 – Y_3 as a function of past values of Y_1 – Y_3 and some exogenous variables or constants, you can use `%AR` to generate the statements for the lag terms. Write an equation for each variable for the nonautoregressive part of the model, and then call `%AR` with the `TYPE=V` option. For example,

```
proc model data=in;
  parms a1-a3 b1-b3;
  y1 = a1 + b1 * x;
  y2 = a2 + b2 * x;
  y3 = a3 + b3 * x;
  %ar( name, 2, y1 y2 y3, type=v )
  fit y1 y2 y3;
run;
```

The nonautoregressive part of the model can be a function of exogenous variables, or it can be intercept parameters. If there are no exogenous components to the vector autoregression model, including no intercepts, then assign zero to each of the variables. There must be an assignment to each of the variables before `%AR` is called.

```
proc model data=in;
  y1=0;
  y2=0;
  y3=0;
  %ar( name, 2, y1 y2 y3, type=v )
  fit y1 y2 y3;
run;
```

This example models the vector $Y=(Y_1 \ Y_2 \ Y_3)'$ as a linear function only of its value in the previous two periods and a white noise error vector. The model has $18=(3 \times 3 + 3 \times 3)$ parameters.

Syntax of the %AR Macro

There are two cases of the syntax of the `%AR` macro. When restrictions on a vector AR process are not needed, the syntax of the `%AR` macro has the general form

%AR (name , nlag < ,endolist < , laglist >> < ,M= method > < ,TYPE= V>) ;

where

<i>name</i>	specifies a prefix for <code>%AR</code> to use in constructing names of variables needed to define the AR process. If the <i>endolist</i> is not specified, the endogenous list defaults to <i>name</i> , which must be the name of the equation to which the AR error process is to be applied. The <i>name</i> value cannot exceed 32 characters.
<i>nlag</i>	is the order of the AR process.
<i>endolist</i>	specifies the list of equations to which the AR process is to be applied. If more than one name is given, an unrestricted vector process is created with the structural residuals of all the equations included as regressors in each of the equations. If not specified, <i>endolist</i> defaults to <i>name</i> .
<i>laglist</i>	specifies the list of lags at which the AR terms are to be added. The coefficients of the terms at lags not listed are set to 0. All of the listed lags must be less than or equal to

nlag, and there must be no duplicates. If not specified, the *laglist* defaults to all lags 1 through *nlag*.

- M=method** specifies the estimation method to implement. Valid values of M= are CLS (conditional least squares estimates), ULS (unconditional least squares estimates), and ML (maximum likelihood estimates). M=CLS is the default. Only M=CLS is allowed when more than one equation is specified. The ULS and ML methods are not supported for vector AR models by %AR.
- TYPE=V** specifies that the AR process is to be applied to the endogenous variables themselves instead of to the structural residuals of the equations.

Restricted Vector Autoregression

You can control which parameters are included in the process, restricting to 0 those parameters that you do not include. First, use %AR with the DEFER option to declare the variable list and define the dimension of the process. Then, use additional %AR calls to generate terms for selected equations with selected variables at selected lags. For example,

```
proc model data=d;
  y1 = ... equation for y1 ...;
  y2 = ... equation for y2 ...;
  y3 = ... equation for y3 ...;
  %ar( name, 2, y1 y2 y3, defer )
  %ar( name, y1, y1 y2 )
  %ar( name, y2 y3, , 1 )
  fit y1 y2 y3;
run;
```

The error equations produced are as follows:

```
y1 = pred.y1 + name1_1_1*zlag1(y1-name_y1) +
      name1_1_2*zlag1(y2-name_y2) + name2_1_1*zlag2(y1-name_y1) +
      name2_1_2*zlag2(y2-name_y2) ;
y2 = pred.y2 + name1_2_1*zlag1(y1-name_y1) +
      name1_2_2*zlag1(y2-name_y2) + name1_2_3*zlag1(y3-name_y3) ;
y3 = pred.y3 + name1_3_1*zlag1(y1-name_y1) +
      name1_3_2*zlag1(y2-name_y2) + name1_3_3*zlag1(y3-name_y3) ;
```

This model states that the errors for Y1 depend on the errors of both Y1 and Y2 (but not Y3) at both lags 1 and 2, and that the errors for Y2 and Y3 depend on the previous errors for all three variables, but only at lag 1.

%AR Macro Syntax for Restricted Vector AR

An alternative use of %AR is allowed to impose restrictions on a vector AR process by calling %AR several times to specify different AR terms and lags for different equations.

The first call has the general form

```
%AR( name, nlag, endlst , DEFER ) ;
```

where

<i>name</i>	specifies a prefix for %AR to use in constructing names of variables needed to define the vector AR process.
<i>nlag</i>	specifies the order of the AR process.
<i>endolist</i>	specifies the list of equations to which the AR process is to be applied.
DEFER	specifies that %AR is not to generate the AR process but is to wait for further information specified in later %AR calls for the same <i>name</i> value.

The subsequent calls have the general form

```
%AR( name, eqlist, varlist, laglist, TYPE= )
```

where

<i>name</i>	is the same as in the first call.
<i>eqlist</i>	specifies the list of equations to which the specifications in this %AR call are to be applied. Only names specified in the <i>endolist</i> value of the first call for the <i>name</i> value can appear in the list of equations in <i>eqlist</i> .
<i>varlist</i>	specifies the list of equations whose lagged structural residuals are to be included as regressors in the equations in <i>eqlist</i> . Only names in the <i>endolist</i> of the first call for the <i>name</i> value can appear in <i>varlist</i> . If not specified, <i>varlist</i> defaults to <i>endolist</i> .
<i>laglist</i>	specifies the list of lags at which the AR terms are to be added. The coefficients of the terms at lags not listed are set to 0. All of the listed lags must be less than or equal to the value of <i>nlag</i> , and there must be no duplicates. If not specified, <i>laglist</i> defaults to all lags 1 through <i>nlag</i> .

The %MA Macro

The SAS macro %MA generates programming statements for PROC MODEL for moving-average models. The %MA macro is part of SAS/ETS software, and no special options are needed to use the macro. The moving-average error process can be applied to the structural equation errors. The syntax of the %MA macro is the same as the %AR macro except there is no TYPE= argument.

When you are using the %MA and %AR macros combined, the %MA macro must follow the %AR macro. The following SAS/IML statements produce an ARMA(1, (1 3)) error process and save it in the data set MADAT2.

```
proc iml;
  phi = { 1 .2 };
  theta = { 1 .3 0 .5 };
  y = armasim( phi, theta, 0, .1, 200, 32565 );
  create madat2 from y[colname='y'];
  append from y;
quit;
```

The following PROC MODEL statements are used to estimate the parameters of this model by using maximum likelihood error structure:

```

title 'Maximum Likelihood ARMA(1, (1 3))';
proc model data=madat2;
  y=0;
  %ar( y, 1, , M=m1 )
  %ma( y, 3, , 1 3, M=m1 ) /* %MA always after %AR */
  fit y;
run;
title;

```

The estimates of the parameters produced by this run are shown in [Figure 19.63](#).

Figure 19.63 Estimates from an ARMA(1, (1 3)) Process

Maximum Likelihood ARMA(1, (1 3))							
The MODEL Procedure							
Nonlinear OLS Summary of Residual Errors							
Equation	DF Model	DF Error	SSE	MSE	Root MSE	R-Square	Adj R-Sq
y	3	197	2.6383	0.0134	0.1157	-0.0067	-0.0169
RESID.y		197	1.9957	0.0101	0.1007		
Nonlinear OLS Parameter Estimates							
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t	Label		
y_l1	-0.10067	0.1187	-0.85	0.3973	AR(y) y lag1 parameter		
y_m1	-0.1934	0.0939	-2.06	0.0408	MA(y) y lag1 parameter		
y_m3	-0.59384	0.0601	-9.88	<.0001	MA(y) y lag3 parameter		

Syntax of the %MA Macro

There are two cases of the syntax for the %MA macro. When restrictions on a vector MA process are not needed, the syntax of the %MA macro has the general form

```
%MA ( name , nlag < , endolist < , laglist > > < , M= method > ) ;
```

where

name specifies a prefix for %MA to use in constructing names of variables needed to define the MA process and is the default *endolist*.

nlag is the order of the MA process.

endolist specifies the equations to which the MA process is to be applied. If more than one name is given, CLS estimation is used for the vector process.

<i>laglist</i>	specifies the lags at which the MA terms are to be added. All of the listed lags must be less than or equal to <i>nlag</i> , and there must be no duplicates. If not specified, the <i>laglist</i> defaults to all lags 1 through <i>nlag</i> .
<i>M=method</i>	specifies the estimation method to implement. Valid values of <i>M=</i> are CLS (conditional least squares estimates), ULS (unconditional least squares estimates), and ML (maximum likelihood estimates). <i>M=CLS</i> is the default. Only <i>M=CLS</i> is allowed when more than one equation is specified in the <i>endolist</i> .

%MA Macro Syntax for Restricted Vector Moving-Average

An alternative use of %MA is allowed to impose restrictions on a vector MA process by calling %MA several times to specify different MA terms and lags for different equations.

The first call has the general form

```
%MA( name , nlag , endolist , DEFER ) ;
```

where

<i>name</i>	specifies a prefix for %MA to use in constructing names of variables needed to define the vector MA process.
<i>nlag</i>	specifies the order of the MA process.
<i>endolist</i>	specifies the list of equations to which the MA process is to be applied.
DEFER	specifies that %MA is not to generate the MA process but is to wait for further information specified in later %MA calls for the same <i>name</i> value.

The subsequent calls have the general form

```
%MA( name, eqlist, varlist, laglist )
```

where

<i>name</i>	is the same as in the first call.
<i>eqlist</i>	specifies the list of equations to which the specifications in this %MA call are to be applied.
<i>varlist</i>	specifies the list of equations whose lagged structural residuals are to be included as regressors in the equations in <i>eqlist</i> .
<i>laglist</i>	specifies the list of lags at which the MA terms are to be added.

Distributed Lag Models and the %PDL Macro

In the following example, the variable *y* is modeled as a linear function of *x*, the first lag of *x*, the second lag of *x*, and so forth:

$$y_t = a + b_0x_t + b_1x_{t-1} + b_2x_{t-2} + b_3x_{t-3} + \dots + b_nx_{t-n}$$

Models of this sort can introduce a great many parameters for the lags, and there may not be enough data to compute accurate independent estimates for them all. Often, the number of parameters is reduced by assuming that the lag coefficients follow some pattern. One common assumption is that the lag coefficients follow a polynomial in the lag length

$$b_i = \sum_{j=0}^d \alpha_j (i)^j$$

where d is the degree of the polynomial used. Models of this kind are called *Almon lag models*, *polynomial distributed lag models*, or *PDLs* for short. For example, Figure 19.64 shows the lag distribution that can be modeled with a low-order polynomial. Endpoint restrictions can be imposed on a PDL to require that the lag coefficients be 0 at the 0th lag, or at the final lag, or at both.

Figure 19.64 Polynomial Distributed Lags

For linear single-equation models, SAS/ETS software includes the PDLREG procedure for estimating PDL models. See Chapter 21, “[The PDLREG Procedure](#),” for a more detailed discussion of polynomial distributed lags and an explanation of endpoint restrictions.

Polynomial and other distributed lag models can be estimated and simulated or forecast with PROC MODEL. For polynomial distributed lags, the %PDL macro can generate the needed programming statements automatically.

The %PDL Macro

The SAS macro %PDL generates the programming statements to compute the lag coefficients of polynomial distributed lag models and to apply them to the lags of variables or expressions.

To use the %PDL macro in a model program, you first call it to declare the lag distribution; later, you call it again to apply the PDL to a variable or expression. The first call generates a PARMS statement for the polynomial parameters and assignment statements to compute the lag coefficients. The second call generates an expression that applies the lag coefficients to the lags of the specified variable or expression. A PDL can be declared only once, but it can be used any number of times (that is, the second call can be repeated).

The initial declaratory call has the general form

```
%PDL ( pdlname, nlags, degree , R=code , OUTEST=dataset );
```

where *pdlname* is a name (up to 32 characters) that you give to identify the PDL, *nlags* is the lag length, and *degree* is the degree of the polynomial for the distribution. The *R=code* is optional for endpoint restrictions. The value of *code* can be FIRST (for upper), LAST (for lower), or BOTH (for both upper and lower endpoints). See Chapter 21, “[The PDLREG Procedure](#),” for a discussion of endpoint restrictions. The option *OUTEST=dataset* creates a data set that contains the estimates of the parameters and their covariance matrix.

The later calls to apply the PDL have the general form

```
%PDL( pdlname, expression )
```

where *pdlname* is the name of the PDL and *expression* is the variable or expression to which the PDL is to be applied. The *pdlname* given must be the same as the name used to declare the PDL.

The following statements produce the output in [Figure 19.65](#):

```
proc model data=in list;
  parms int pz;
  %pdl(xpdl,5,2);
  y = int + pz * z + %pdl(xpdl,x);
  %ar(y,2,M=ULS);
  id i;
fit y / out=model1 outresid converge=1e-6;
run;
```

Figure 19.65 %PDL Macro Estimates

The MODEL Procedure					
Nonlinear OLS Estimates					
Term	Estimate	Approx Std Err	t Value	Approx Pr > t	Label
XPDL_L0	1.568788	0.0935	16.77	<.0001	PDL(XPDL,5,2) coefficient for lag0
XPDL_L1	0.564917	0.0328	17.22	<.0001	PDL(XPDL,5,2) coefficient for lag1
XPDL_L2	-0.05063	0.0593	-0.85	0.4155	PDL(XPDL,5,2) coefficient for lag2
XPDL_L3	-0.27785	0.0517	-5.37	0.0004	PDL(XPDL,5,2) coefficient for lag3
XPDL_L4	-0.11675	0.0368	-3.17	0.0113	PDL(XPDL,5,2) coefficient for lag4
XPDL_L5	0.43267	0.1362	3.18	0.0113	PDL(XPDL,5,2) coefficient for lag5

This second example models two variables, Y1 and Y2, and uses two PDLs:

```
proc model data=in;
  parms int1 int2;
  %pdl( logxpdl, 5, 3 )
  %pdl( zpdl, 6, 4 )
  y1 = int1 + %pdl( logxpdl, log(x) ) + %pdl( zpdl, z );
  y2 = int2 + %pdl( zpdl, z );
  fit y1 y2;
run;
```

A (5,3) PDL of the log of X is used in the equation for Y1. A (6,4) PDL of Z is used in the equations for both Y1 and Y2. Since the same ZPDL is used in both equations, the lag coefficients for Z are the same for the Y1 and Y2 equations, and the polynomial parameters for ZPDL are shared by the two equations. See [Example 19.5](#) for a complete example and comparison with PDLREG.

Input Data Sets

DATA= Input Data Set

For FIT tasks, the DATA= option specifies which input data set to use in estimating parameters. Variables in the model program are looked up in the DATA= data set and, if found, their attributes (type, length, label, and format) are set to be the same as those in the DATA= data set (if not defined otherwise within PROC MODEL).

ESTDATA= Input Data Set

The ESTDATA= option specifies an input data set that contains an observation that gives values for some or all of the model parameters. The data set can also contain observations that give the rows of a covariance matrix for the parameters.

Parameter values read from the ESTDATA= data set provide initial starting values for parameters estimated. Observations that provide covariance values, if any are present in the ESTDATA= data set, are ignored.

The ESTDATA= data set is usually created by the OUTEST= option in a previous FIT statement. You can also create an ESTDATA= data set with a SAS DATA step program. The data set must contain a numeric variable for each parameter to be given a value or covariance column. The name of the variable in the ESTDATA= data set must match the name of the parameter in the model. Parameters with names longer than 32 characters cannot be set from an ESTDATA= data set. The data set must also contain a character variable _NAME_ of length 32. _NAME_ has a blank value for the observation that gives values to the parameters. _NAME_ contains the name of a parameter for observations that define rows of the covariance matrix.

More than one set of parameter estimates and covariances can be stored in the ESTDATA= data set if the observations for the different estimates are identified by the variable _TYPE_. _TYPE_ must be a character variable of length 8. The TYPE= option is used to select for input the part of the ESTDATA= data set for which the _TYPE_ value matches the value of the TYPE= option.

In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used.

The following SAS statements generate the ESTDATA= data set shown in [Figure 19.66](#). The second FIT statement uses the TYPE= option to select the estimates from the GMM estimation as starting values for the FIML estimation.

```
/* Generate test data */
data gmm2;
  do t=1 to 50;
    x1 = sqrt(t) ;
    x2 = rannor(10) * 10;

MISSING=PAIRWISE | DELETE

When missing values are encountered for any one of the equations in a system of equations, the default action is to drop that observation for all of the equations. The new **MISSING=PAIRWISE** option in the **FIT** statement provides a different method of handling missing values that avoids losing data for nonmissing equations for the observation. This is especially useful for SUR estimation on equations with unequal numbers of observations.

The option **MISSING=PAIRWISE** specifies that missing values are tracked on an equation-by-equation basis. The **MISSING=DELETE** option specifies that the entire observation is omitted from the analysis when any equation has a missing predicted or actual value for the equation. The default is **MISSING=DELETE**.

When you specify the **MISSING=PAIRWISE** option, the **S** matrix is computed as

$$\mathbf{S} = \mathbf{D}(\mathbf{R}'\mathbf{R})\mathbf{D}$$

where **D** is a diagonal matrix that depends on the **VARDEF=** option, the matrix **R** is $(\mathbf{r}_1, \dots, \mathbf{r}_g)$, and \mathbf{r}_i is the vector of residuals for the i th equation with r_{ij} replaced with zero when r_{ij} is missing.

For **MISSING=PAIRWISE**, the calculation of the diagonal element $d_{i,i}$ of **D** is based on n_i , the number of nonmissing observations for the i th equation, instead of on n . Similarly, for **VARDEF=WGT** or **WDF**, the calculation is based on the sum of the weights for the nonmissing observations for the i th equation instead of

on the sum of the weights for all observations. See the description of the VARDEF= option for the definition of **D**.

The degrees-of-freedom correction for a shared parameter is computed by using the average number of observations used in its estimation.

The MISSING=PAIRWISE option is not valid for the GMM and FIML estimation methods.

For the instrumental variables estimation methods (2SLS, 3SLS), when an instrument is missing for an observation, that observation is dropped for all equations, regardless of the MISSING= option.

PARMSDATA= Input Data Set

The option PARMSDATA= reads values for all parameters whose names match the names of variables in the PARMSDATA= data set. Values for any or all of the parameters in the model can be reset by using the PARMSDATA= option. The PARMSDATA= option goes in the PROC MODEL statement, and the data set is read before any FIT or SOLVE statements are executed.

In PROC MODEL, you have several options to specify starting values for the parameters to be estimated. When more than one option is specified, the options are implemented in the following order of precedence (from highest to lowest): the START= option, the PARMS statement initialization value, the ESTDATA= option, and the PARMSDATA= option. If no options are specified for the starting value, the default value of 0.0001 is used. Together, the OUTPARMS= and PARMSDATA= options enable you to change part of a model and recompile the new model program without the need to reestimate equations that were not changed.

Suppose you have a large model with parameters estimated and you now want to replace one equation, Y, with a new specification. Although the model program must be recompiled with the new equation, you don't need to reestimate all the equations, just the one that changed.

Using the OUTPARMS= and PARMSDATA= options, you could do the following:

```
proc model model=oldmod outparms=temp; run;
proc model outmodel=newmod parmsdata=temp data=in;
    ... include new model definition with changed y eq. here ...
    fit y;
run;
```

The model file NEWMOD then contains the new model and its estimated parameters plus the old models with their original parameter values.

SDATA= Input Data Set

The SDATA= option allows a cross-equation covariance matrix to be input from a data set. The **S** matrix read from the SDATA= data set, specified in the FIT statement, is used to define the objective function for the OLS, N2SLS, SUR, and N3SLS estimation methods and is used as the initial **S** for the methods that iterate the **S** matrix.

Most often, the SDATA= data set has been created by the OUTS= or OUTSUSED= option in a previous FIT statement. The OUTS= and OUTSUSED= data sets from a FIT statement can be read back in by a FIT statement in the same PROC MODEL step.

You can create an input SDATA= data set by using the DATA step. PROC MODEL expects to find a character variable _NAME_ in the SDATA= data set as well as variables for the equations in the estimation

or solution. For each observation with a `_NAME_` value that matches the name of an equation, PROC MODEL fills the corresponding row of the **S** matrix with the values of the names of equations found in the data set. If a row or column is omitted from the data set, a 1 is placed on the diagonal for the row or column. Missing values are ignored, and since the **S** matrix is symmetric, you can include only a triangular part of the **S** matrix in the `SDATA=` data set with the omitted part indicated by missing values. If the `SDATA=` data set contains multiple observations with the same `_NAME_`, the last values supplied for the `_NAME_` are used. The structure of the expected data set is further described in the section “[OUTS= Data Set](#)” on page 1180.

Use the `TYPE=` option in the PROC MODEL or FIT statement to specify the type of estimation method used to produce the **S** matrix you want to input.

The following SAS statements are used to generate an **S** matrix from a GMM and a 3SLS estimation and to store that estimate in the data set GMMS:

```
proc model data=gmm2 ;
    exogenous x1 x2;
    parms a1 a2 b1 2.5 b2 c2 55 d1;
    inst b1 b2 c2 x1 x2;
    y1 = a1 * y2 + b1 * x1 * x1 + d1;
    y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

    fit y1 y2 / 3sls gmm kernel=(qs,1,0.2)
               outest=gmmest outs=gmmms;
run;

proc print data=gmmms;
run;
```

The data set GMMS is shown in [Figure 19.67](#).

Figure 19.67 `SDATA=` Data Set

Obs	<code>_NAME_</code>	<code>_TYPE_</code>	<code>_NUSED_</code>	y1	y2
1	y1	3SLS	50	27.1032	38.1599
2	y2	3SLS	50	38.1599	74.6253
3	y1	GMM	50	27.6248	32.2811
4	y2	GMM	50	32.2811	58.8387

VDATA= Input data set

The `VDATA=` option enables a variance matrix for GMM estimation to be input from a data set. When the `VDATA=` option is used in the PROC MODEL or FIT statement, the matrix that is input is used to define the objective function and is used as the initial **V** for the methods that iterate the **V** matrix.

Normally the `VDATA=` matrix is created from the `OUTV=` option in a previous FIT statement. Alternately an input `VDATA=` data set can be created by using the DATA step. Each row and column of the **V** matrix is associated with an equation and an instrument. The position of each element in the **V** matrix can then be indicated by an equation name and an instrument name for the row of the element and an equation name

and an instrument name for the column. Each observation in the VDATA= data set is an element in the **V** matrix. The row and column of the element are indicated by four variables (EQ_ROW, INST_ROW, EQ_COL, and INST_COL) that contain the equation name or instrument name. The variable name for an element is VALUE. Missing values are set to 0. Because the variance matrix is symmetric, only a triangular part of the matrix needs to be input.

The following SAS statements are used to generate a **V** matrix estimation from GMM and to store that estimate in the data set GMMV:

```
proc model data=gmm2;
  exogenous x1 x2;
  parms a1 a2 b1 b2 2.5 c2 55 d1;
  inst b1 b2 c2 x1 x2;
  y1 = a1 * y2 + b1 * x1 * x1 + d1;
  y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

  fit y1 y2 / gmm outv=gmmv;
run;

proc print data=gmmv(obs=15);
run;
```

The data set GMM2 was generated by the example in the preceding ESTDATA= section. The **V** matrix stored in GMMV is selected for use in an additional GMM estimation by the following FIT statement:

```
fit y1 y2 / gmm vdata=gmmv;
run;
```

A partial listing of the GMMV data set is shown in Figure 19.68. There are a total of 78 observations in this data set. The **V** matrix is 12 by 12 for this example.

Output Data Sets

OUT= Data Set

For normalized form equations, the OUT= data set specified in the FIT statement contains residuals, actuals, and predicted values of the dependent variables computed from the parameter estimates. For general form equations, actual values of the endogenous variables are copied for the residual and predicted values.

The variables in the data set are as follows:

- BY variables
- RANGE variable
- ID variables
- `_ESTYPE_`, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- `_TYPE_`, a character variable of length 8 that identifies the type of observation: RESIDUAL, PREDICT, or ACTUAL
- `_WEIGHT_`, the weight of the observation in the estimation. The `_WEIGHT_` value is 0 if the observation was not used. It is equal to the product of the `_WEIGHT_` model program variable and the variable named in the WEIGHT statement, if any, or 1 if weights were not used.
- the WEIGHT statement variable if used
- the model variables. The dependent variables for the normalized form equations in the estimation contain residuals, actuals, or predicted values, depending on the `_TYPE_` variable, whereas the model variables that are not associated with estimated equations always contain actual values from the input data set.
- any other variables named in the OUTVARS statement. These can be program variables computed by the model program, CONTROL variables, parameters, or special variables in the model program.

The following SAS statements are used to generate and print an OUT= data set:

```
proc model data=gmm2;
    exogenous x1 x2;
    parms a1 a2 b2 b1 2.5 c2 55 d1;
    inst b1 b2 c2 x1 x2;
    y1 = a1 * y2 + b1 * x1 * x1 + d1;
    y2 = a2 * y1 + b2 * x2 * x2 + c2 / x2 + d1;

    fit y1 y2 / 3sls gmm out=resid outall ;
run;

proc print data=resid(obs=20);
run;
```

The data set GMM2 was generated by the example in the preceding ESTDATA= section above. A partial listing of the RESID data set is shown in [Figure 19.69](#).

OUTEST= Data Set

The OUTEST= data set contains parameter estimates and, if requested, estimates of the covariance of the parameter estimates.

The variables in the data set are as follows:

- BY variables
- _NAME_, a character variable of length 32, blank for observations that contain parameter estimates or a parameter name for observations that contain covariances
- _TYPE_, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- _STATUS_, variable that gives the convergence status of estimation. _STATUS_ = 0 when convergence criteria are met, = 1 when estimation converges with a note, = 2 when estimation converges with a warning, and = 3 when estimation fails to converge
- _NUSED_, the number of observations used in estimation
- the parameters estimated

If the COVOUT option is specified, an additional observation is written for each row of the estimate of the covariance matrix of parameter estimates, with the _NAME_ values that contain the parameter names for the rows. Parameter names longer than 32 characters are truncated.

OUTPARMS= Data Set

The option OUTPARMS= writes all the parameter estimates to an output data set. This output data set contains one observation and is similar to the OUTEST= data set, but it contains all the parameters, is not associated with any FIT task, and contains no covariances. The OUTPARMS= option is used in the PROC MODEL statement, and the data set is written at the end, after any FIT or SOLVE steps have been performed.

OUTS= Data Set

The OUTS= SAS data set contains the estimate of the covariance matrix of the residuals across equations. This matrix is formed from the residuals that are computed by using the parameter estimates.

The variables in the OUTS= data set are as follows:

- BY variables
- _NAME_, a character variable that contains the name of the equation
- _TYPE_, a character variable of length 8 that identifies the estimation method: OLS, SUR, N2SLS, N3SLS, ITOLS, ITSUR, IT2SLS, IT3SLS, GMM, ITGMM, or FIML
- variables with the names of the equations in the estimation

Each observation contains a row of the covariance matrix. The data set is suitable for use with the SDATA= option in a subsequent FIT or SOLVE statement. (See the section “[Tests on Parameters](#)” on page 1147 in this chapter for an example of the SDATA= option.)

OUTSUSED= Data Set

The OUTSUSED= SAS data set contains the covariance matrix of the residuals across equations that is used to define the objective function. The form of the OUTSUSED= data set is the same as that for the OUTS= data set.

Note that OUTSUSED= is the same as OUTS= for the estimation methods that iterate the **S** matrix (ITOLS, IT2SLS, ITSUR, and IT3SLS). If the SDATA= option is specified in the FIT statement, OUTSUSED= is the same as the SDATA= matrix read in for the methods that do not iterate the **S** matrix (OLS, SUR, N2SLS, and N3SLS).

OUTV= Data Set

The OUTV= data set contains the estimate of the variance matrix, **V**. This matrix is formed from the instruments and the residuals that are computed by using the final parameter estimates obtained from the estimation method chosen.

An estimate of **V** obtained from 2SLS is used in GMM estimation. Hence if you input the dataset obtained from the OUTV statement in 2SLS into the VDATA statement while fitting GMM, you get the same result by fitting GMM directly without specifying the VDATA option.

ODS Table Names

PROC MODEL assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 19.4 ODS Tables Produced in PROC MODEL

ODS Table Name	Description	Option
ODS Tables Created by the FIT Statement		
AugGMMCovariance	Crossproducts matrix	GMM ITALL
ChowTest	Structural change test	CHOW=
CollinDiagnostics	Collinearity diagnostics	
ConfInterval	Profile likelihood confidence intervals	PRL=
ConvCrit	Convergence criteria for estimation	default
ConvergenceStatus	Convergence status	default
CorrB	Correlations of parameters	COVB/CORRB
CorrResiduals	Correlations of residuals	CORRS/COVS

Table 19.4 (continued)

ODS Table Name	Description	Option
SortAdjacencyMatrix	Sorted adjacency graph	GRAPH
TransitiveClosure	Transitive closure graph	GRAPH

The AugGMMCovariance table is the \mathbf{V} matrix augmented with the moment vector at iteration zero, produced when the ITALL option is used with the GMM option. If the \mathbf{V} matrix to be used in GMM is read in by the VDATA option, then AugGMMCovariance would be the same matrix augmented with the moment vectors. The GMMCovariance ODS output is produced only when you read in a covariance matrix to be used in the GMM method. This table is produced by using DETAILS option with the GMM option.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the MODEL procedure.

ODS Graph Names

PROC MODEL assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when you use ODS. The names are listed in Table 19.5.

To request these graphs, ODS Graphics must be enabled.

Table 19.5 ODS Graphics Produced by PROC MODEL

ODS Graph Name	Plot Description
ACFPlot	Autocorrelation of residuals
ActualByPredicted	Predicted versus actual plot
BlockDependencyPlot	Simulation dependency analysis
CooksD	Cook’s D plot
DiagnosticsPanel	Panel of all plots
IACFPlot	Inverse autocorrelation of residuals
QQPlot	Q-Q plot of residuals
PACFPlot	Partial autocorrelation of residuals
ResidualHistogram	Histogram of the residuals
StudentResidualPlot	Studentized residual plot

Details: Simulation by the MODEL Procedure

The *solution*, given the vector \mathbf{k} , of the following nonlinear system of equations is the vector \mathbf{u} that satisfies this equation:

$$\mathbf{q}(\mathbf{u}, \mathbf{k}, \boldsymbol{\theta}) = 0$$

A *simulation* is a set of solutions \mathbf{u}_t for a specific sequence of vectors \mathbf{k}_t .

Model simulation can be performed to do the following:

- check how well the model predicts the actual values over the historical period
- investigate the sensitivity of the solution to changes in the input values or parameters
- examine the dynamic characteristics of the model
- check the stability of the simultaneous solution
- estimate the statistical distribution of the predicted values of the nonlinear model using Monte Carlo methods

By combining the various solution modes with different input data sets, model simulation can answer many different questions about the model. This section presents details of model simulation and solution.

Solution Modes

The following solution modes are commonly used:

- The *dynamic simultaneous forecast* mode is used for forecasting with the model. Collect the historical data on the model variables, the future assumptions of the exogenous variables, and any prior information on the future endogenous values, and combine them in a SAS data set. Use the FORECAST option in the SOLVE statement.
- The *dynamic simultaneous simulation* mode is often called *ex post simulation*, *historical simulation*, or *ex post forecasting*. Use the DYNAMIC option. This mode is the default.

- The *static simultaneous simulation* mode can be used to examine the within-period performance of the model without the complications of previous period errors. Use the `STATIC` option.
- The `NAHEAD=n` *dynamic simultaneous simulation* mode can be used to see how well n -period-ahead forecasting would have performed over the historical period. Use the `NAHEAD=n` option.

The different solution modes are explained in detail in the following sections.

Dynamic and Static Simulations

In model simulation, either solved values or actual values from the data set can be used to supply lagged values of an endogenous variable. A *dynamic* solution refers to a solution obtained by using only solved values for the lagged values. Dynamic mode is used both for forecasting and for simulating the dynamic properties of the model.

A *static* solution refers to a solution obtained by using the actual values when available for the lagged endogenous values. Static mode is used to simulate the behavior of the model without the complication of previous period errors. Dynamic simulation is the default.

If you want to use static values for lags only for the first n observations, and dynamic values thereafter, specify the `START=n` option. For example, if you want a dynamic simulation to start after observation twenty-four, specify `START=24` on the `SOLVE` statement. If the model being simulated had a value lagged for four time periods, then this value would start using dynamic values when the simulation reached observation number 28.

n -Period-Ahead Forecasting

Suppose you want to regularly forecast 12 months ahead and produce a new forecast each month as more data becomes available. n -period-ahead forecasting allows you to test how well you would have done over time if you had been using your model to forecast one year ahead.

To see how well a model predicts n time periods in the future, perform an n -period-ahead forecast on real data and compare the forecast values with the actual values.

n -period-ahead forecasting refers to using dynamic values for the lagged endogenous variables only for lags 1 through $n-1$. For example, one-period-ahead forecasting, specified by the `NAHEAD=1` option in the `SOLVE` statement, is the same as if a static solution had been requested. Specifying `NAHEAD=2` produces a solution that uses dynamic values for lag one and static, actual, values for longer lags.

The following example is a two-year-ahead dynamic simulation. The output is shown in [Figure 19.70](#).

```

data yearly;
  input year x1 x2 x3 y1 y2 y3;
  datalines;
84 4 9 0 7 4 5
85 5 6 1 1 27 4
86 3 8 2 5 8 2
87 2 10 3 0 10 10
88 4 7 6 20 60 40
89 5 4 8 40 40 40
90 3 2 10 50 60 60
91 2 5 11 40 50 60
;
run;

proc model data=yearly outmodel=yearlyModel;
  endogenous y1 y2 y3;
  exogenous x1 x2 x3;

  y1 = 2 + 3*x1 - 2*x2 + 4*x3;
  y2 = 4 + lag2( y3 ) + 2*y1 + x1;
  y3 = lag3( y1 ) + y2 - x2;

  solve y1 y2 y3 / nahead=2 out=c;
run;

proc print data=c;
run;

The C data set is shown in [Figure 19.71](#):

Figure 19.71 C Data Set

Obs	_TYPE_	_MODE_	_LAG_	_ERRORS_	y1	y2	y3	x1	x2	x3
1	PREDICT	SIMULATE	0	0	0	10	7	2	10	3
2	PREDICT	SIMULATE	1	0	24	58	52	4	7	6
3	PREDICT	SIMULATE	1	0	41	101	102	5	4	8
4	PREDICT	SIMULATE	1	0	47	141	139	3	2	10
5	PREDICT	SIMULATE	1	0	42	130	145	2	5	11

The preceding two-year-ahead simulation can be emulated without using the NAHEAD= option by the following PROC MODEL statements:

```
proc model data=yearly model=yearlyModel;
  range year = 87 to 88;
  solve y1 y2 y3 / dynamic solveprint;
run;

  range year = 88 to 89;
  solve y1 y2 y3 / dynamic solveprint;
run;

  range year = 89 to 90;
  solve y1 y2 y3 / dynamic solveprint;
run;

  range year = 90 to 91;
  solve y1 y2 y3 / dynamic solveprint;
```

The totals shown under “Observations Processed” in [Figure 19.70](#) are equal to the sum of the four individual runs.

Simulation and Forecasting

You can perform a simulation of your model or use the model to produce forecasts. *Simulation* refers to the determination of the endogenous or dependent variables as a function of the input values of the other variables, even when actual data for some of the solution variables are available in the input data set. The

simulation mode is useful for verifying the fit of the model parameters. Simulation is selected by the SIMULATE option in the SOLVE statement. Simulation mode is the default.

In forecast mode, PROC MODEL solves only for those endogenous variables that are missing in the data set. The actual value of an endogenous variable is used as the solution value whenever nonmissing data for it is available in the input data set. Forecasting is selected by the FORECAST option in the SOLVE statement.

For example, an econometric forecasting model can contain an equation to predict future tax rates, but tax rates are usually set in advance by law. Thus, for the first year or so of the forecast, the predicted tax rate should really be exogenous. Or, you might want to use a prior forecast of a certain variable from a short-run forecasting model to provide the predicted values for the earlier periods of a longer-range forecast of a long-run model. A common situation in forecasting is when historical data needed to fill the initial lags of a dynamic model are available for some of the variables but have not yet been obtained for others. In this case, the forecast must start in the past to supply the missing initial lags. Clearly, you should use the actual data that are available for the lags. In all the preceding cases, the forecast should be produced by running the model in the FORECAST mode; simulating the model over the future periods would not be appropriate.

Monte Carlo Simulation

The accuracy of the forecasts produced by PROC MODEL depends on four sources of error (Pindyck and Rubinfeld 1981, 405–406):

- The system of equations contains an implicit random error term ϵ

$$g(y, x, \hat{\theta}) = \epsilon$$

where y , x , g , $\hat{\theta}$, and ϵ are vector valued.

- The estimated values of the parameters, $\hat{\theta}$, are themselves random variables.
- The exogenous variables might have been forecast themselves and therefore might contain errors.
- The system of equations might be incorrectly specified; the model only approximates the process modeled.

The RANDOM= option is used to request Monte Carlo (or stochastic) simulations to generate confidence intervals for errors that arise from the first two sources. The Monte Carlo simulations can be performed with ϵ , θ , or both vectors represented as random variables. The SEED= option is used to control the random number generator for the simulations. SEED=0 forces the random number generator to use the system clock as its seed value.

In Monte Carlo simulations, repeated simulations are performed on the model for random perturbations of the parameters and the additive error term. The random perturbations follow a multivariate normal distribution with expected value of 0 and covariance described by a covariance matrix of the parameter estimates in the case of θ , or a covariance matrix of the equation residuals for the case of ϵ . PROC MODEL can generate both covariance matrices or you can provide them.

The ESTDATA= option specifies a data set that contains an estimate of the covariance matrix of the parameter estimates to use for computing perturbations of the parameters. The ESTDATA= data set is usually created by the FIT statement with the OUTEST= and OUTCOV options. When the ESTDATA= option is

specified, the matrix read from the ESTDATA= data set is used to compute vectors of random shocks or perturbations for the parameters. These random perturbations are computed at the start of each repetition of the solution and added to the parameter values. The perturbed parameters are fixed throughout the solution range. If the covariance matrix of the parameter estimates is not provided, the parameters are not perturbed.

The SDATA= option specifies a data set that contains the covariance matrix of the residuals to use for computing perturbations of the equations. The SDATA= data set is usually created by the FIT statement with the OUTS= option. When SDATA= is specified, the matrix read from the SDATA= data set is used to compute vectors of random shocks or perturbations for the equations. These random perturbations are computed at each observation. The simultaneous solution satisfies the model equations plus the random shocks. That is, the solution is not a perturbation of a simultaneous solution of the structural equations; rather, it is a simultaneous solution of the stochastic equations by using the simulated errors. If the SDATA= option is not specified, the random shocks are not used.

The different random solutions are identified by the _REP_ variable in the OUT= data set. An unperturbed solution with _REP_=0 is also computed when the RANDOM= option is used. RANDOM= n produces $n + 1$ solution observations for each input observation in the solution range. If the RANDOM= option is not specified, the SDATA= and ESTDATA= options are ignored, and no Monte Carlo simulation is performed.

PROC MODEL does not have an automatic way of modeling the exogenous variables as random variables for Monte Carlo simulation. If the exogenous variables have been forecast, the error bounds for these variables should be included in the error bounds generated for the endogenous variables. If the models for the exogenous variables are included in PROC MODEL, then the error bounds created from a Monte Carlo simulation contain the uncertainty due to the exogenous variables.

Alternatively, if the distribution of the exogenous variables is known, the built-in random number generator functions can be used to perturb these variables appropriately for the Monte Carlo simulation. For example, if you know the forecast of an exogenous variable, X , has a standard error of 5.2 and the error is normally distributed, then the following statements can be used to generate random values for X :

```
x_new = x + 5.2 * rannor(456);
```

During a Monte Carlo simulation, the random number generator functions produce one value at each observation. It is important to use a different seed value for all the random number generator functions in the model program; otherwise, the perturbations will be correlated. For the unperturbed solution, _REP_=0, the random number generator functions return 0.

PROC UNIVARIATE can be used to create confidence intervals for the simulation (see the Monte Carlo simulation example in the section “[Getting Started: MODEL Procedure](#)” on page 1018).

Multivariate t Distribution Simulation

To perform a Monte Carlo analysis of models that have residuals distributed as a multivariate t , use the ERRORMODEL statement with either the $\sim t(\text{variance}, df)$ option or with the CDF= $t(\text{variance}, df)$ option. The CDF= option specifies the distribution that is used for simulation so that the estimation can be done for one set of distributional assumptions and the simulation for another.

The following is an example of estimating and simulating a system of equations with t distributed errors by using the ERRORMODEL statement.

```

/* generate simulation data set */
data five;
  set xfrate end=last;
  if last then do;
    todate = date +5;
    do date = date to todate;
      output;
    end;
  end;
run;

```

The preceding DATA step generates the data set to request a five-days-ahead forecast. The following statements estimate and forecast the three forward-rate models of the following form.

$$\begin{aligned}
 rate_t &= rate_{t-1} + \mu * rate_{t-1} + v \\
 v &= \sigma * rate_{t-1} * \epsilon \\
 \epsilon &\sim N(0, 1)
 \end{aligned}$$

```

title "Daily Multivariate Geometric Brownian Motion Model "
      "of D-Mark/USDollar Forward Rates";

proc model data=xfrate;

  parms df 15;          /* Give initial value to df */

  demusd1m = lag(demusd1m) + mulm * lag(demusd1m);
  var_demusd1m = sigma1m ** 2 * lag(demusd1m **2);
  demusd3m = lag(demusd3m) + mu3m * lag(demusd3m);
  var_demusd3m = sigma3m ** 2 * lag(demusd3m ** 2);
  demusd6m = lag(demusd6m) + mu6m * lag(demusd6m);
  var_demusd6m = sigma6m ** 2 * lag(demusd6m ** 2);

  /* Specify the error distribution */
  errormodel demusd1m demusd3m demusd6m
    ~ t( var_demusd1m var_demusd3m var_demusd6m, df );

  /* output normalized S matrix */
  fit demusd1m demusd3m demusd6m / outsn=s;
run;

  /* forecast five days in advance */
  solve demusd1m demusd3m demusd6m /
    data=five sdata=s random=1500 out=monte;
  id date;
run;

  /* select out the last date ---*/
  data monte; set monte;
  if date = '10dec95'd then output;
run;

title "Distribution of demusd1m Five Days Ahead";

```

```

proc univariate data=monte noprint;
  var demusd1m;
  histogram demusd1m /
    normal(noprint color=red)
    kernel(noprint color=blue) cfill=ligr;
run;

```

The Monte Carlo simulation specified in the preceding example draws from a multivariate t distribution with constant degrees of freedom and forecasted variance, and it computes future states of DEMUSD1M, DEMUSD3M, and DEMUSD6M. The OUTSN= option in the FIT statement is used to specify the data set for the normalized Σ matrix. That is, the Σ matrix is created by crossing the normally distributed residuals. The normally distributed residuals are created from the t distributed residuals by using the normal inverse CDF and the t CDF. This matrix is a correlation matrix.

The distribution of DEMUSD1M on the fifth day is shown in the Figure 19.72. The two curves overlaid on the graph are a kernel density estimation and a normal distribution fit to the results.

Figure 19.72 Distribution of DEMUSD1M

Alternate Distribution Simulation

As an alternate to the normal distribution, the `ERRORMODEL` statement can be used in a simulation to specify other distributions. The distributions available for simulation are Cauchy, chi-squared, F , Poisson, t , and uniform. An empirical distribution can also be used if the residuals are specified by using the `RESIDDATA=` option in the `SOLVE` statement.

Except for the t distribution, all of these alternate distributions are univariate but can be used together in a multivariate simulation. The `ERRORMODEL` statement applies to solved for equations only. That is, the normal form or general form equation referred to by the `ERRORMODEL` statement must be one of the equations you have selected in the `SOLVE` statement.

In the following example, two Poisson distributed variables are used to simulate the calls that arrive at and leave a call center.

```
data s;      /* Covariance between arriving and leaving */
    arriving = 1; leaving = 0.7; _name_ = "arriving";
    output;
    arriving = 0.7; leaving = 1.0; _name_ = "leaving";
    output;
run;

data calls;
    date = '20mar2001'd;
    output;
run;
```

The first DATA step generates a data set that contains a covariance matrix for the `ARRIVING` and `LEAVING` variables. The covariance is

$$\begin{vmatrix} 1 & .7 \\ .7 & 1 \end{vmatrix}$$

The following statements create the number of waiting clients data:

```
proc model data=calls;
    arriving = 0;
    errormodel arriving ~ poisson( 10 );
    leaving = 4;
    errormodel leaving ~ poisson( 11 );

    waiting = arriving - leaving;
    if waiting < 0 then waiting=0;
    outvars waiting;

    solve arriving leaving / random=500 sdata=s out=sim;
run;

title "Distribution of Clients Waiting";
proc univariate data=sim noprint;
    var waiting ;
    histogram waiting / cfill=ligr;
run;
```

The distribution of number of waiting clients is shown in Figure 19.73.

Figure 19.73 Distribution of Number of Clients Waiting

Mixtures of Distributions—Copulas

The theory of copulas is what enables the MODEL procedure to combine and simulate multivariate distributions with different marginals. This section provides a brief overview of copulas.

Modeling a system of variables accurately is a difficult task. The underlying, ideal, distributional assumptions for each variable are usually different from each other. An individual variable might be best modeled as a t distribution or as a Poisson process. The correlation of the various variables are very important to estimate as well. A joint estimation of a set of variables would make it possible to estimate a correlation structure but would restrict the modeling to single, simple multivariate distribution (for example, the normal). Even with a simple multivariate distribution, the joint estimation would be computationally difficult and would have to deal with issues of missing data.

By using the MODEL procedure `ERRORMODEL` statement, you can combine and simulate from models of different distributions. The covariance matrix for the combined model is constructed by using the copula

induced by the multivariate normal distribution. A copula is a function that couples joint distributions to their marginal distributions.

By default, the copula used in the MODEL procedure is based on the multivariate normal. This particular multivariate normal has zero mean and covariance matrix \mathbf{R} . The user provides \mathbf{R} , which can be created by using the following steps:

1. Each model is estimated separately and their residuals are saved.
2. The residuals for each model are converted to a normal distribution by using their CDFs, $F_i(\cdot)$, using the relationship $\Phi^{-1}(F(\epsilon_{it}))$.
3. These normal residuals are crossed to create a covariance matrix \mathbf{R} .

If the model of interest can be estimated jointly, such as multivariate T, then the OUTSN= option can be used to generate the correct covariance matrix.

A draw from this mixture of distributions is created by using the following steps that are performed automatically by the MODEL procedure.

1. Independent $N(0, 1)$ variables are generated.
2. These variables are transformed to a correlated set by using the covariance matrix \mathbf{R} .
3. These correlated normals are transformed to a uniform by using $\Phi()$.
4. $F^{-1}()$ is used to compute the final sample value.

Alternate Copulas

The Gaussian, t , and the normal mixture copula are available in the MODEL procedure. These copulas support asymmetric parameters and can use alternate estimation methods for creating the base covariance matrix.

The normal (Gaussian) copula is the default. A draw from a Gaussian copula is obtained from

$$\mathbf{x} = \mathbf{A}\mathbf{z}$$

where $\mathbf{z} \in R^d$ is a vector of independent random normal(0, 1) draws, $\mathbf{A} \in R^{d \times d}$ is the square root of the covariance matrix, \mathbf{R} . For the normal mixture and t copula, a draw is created as

$$\mathbf{x} = w\boldsymbol{\gamma} + \sqrt{w}\mathbf{A}\mathbf{z}$$

where w is a scalar random variable and $\boldsymbol{\gamma} \in R^d$ is a vector of asymmetry parameters. $\boldsymbol{\gamma}$ is specified in the SDATA= data set. If $W \sim \text{inverse gamma}(df/2, df/2)$, then \mathbf{x} is multivariate t or skewed t if $\boldsymbol{\gamma}$ is provided. When NORMALMIX is specified, w is distributed as a step function with each of the n positive variances, $v_1 \dots v_n$, having probability $p_1 \dots p_n$.

The covariance matrix $\mathbf{R} = \mathbf{A}'\mathbf{A}$ is specified with the SDATA= option. The vector of asymmetry parameters, $\boldsymbol{\gamma}$, defaults to zero or is specified in the SDATA= data set with _TYPE_=ASYM. The ASYM option specifies that the nonzero asymmetry vector, $\boldsymbol{\gamma}$, is to be used.

The actual draw for an individual variable, y_i , depends on the marginal distribution of the variable, \tilde{F} , and the chosen copula F as

$$y_i = \tilde{F}_i^{-1}(F(x_i))$$

Archimedean Copulas

The three Archimedean copulas available in the MODEL procedure are the Clayton, Gumbel, and Frank copulas. Archimedean copulas require only a single parameter, θ , to define the joint distribution's covariance structure for a simulation problem. Therefore, a covariance matrix is not required to perform simulations that use Archimedean copulas, and the SDATA= option does not have to be specified for these simulations. For more information about Archimedean copulas, including the functional forms of the Clayton, Gumbel, and Frank copulas, see the section “Archimedean Copulas” in Chapter 10, “[The COPULA Procedure \(Experimental\)](#).”

Asymmetrical Copula Example

In this example, an asymmetrical t copula is used to correlate two uniform distributions. The asymmetrical parameter is varied over a range of values to demonstrate its effect. The resulting graphs is produced by using ODS graphics.

```
data histdata;
  do asym = -1.3 to 1.1 by .3;
    date='01aug2007'd;
    y = .5;
    z = .5;
    output;
  end;
run ;

/* Add the asymmetric parameter to cov mat */
data asym;
  do asym = -1.3 to 1.1 by .3;
    y = asym;
    z = 0;
    _name_ = " ";
    _type_ = "asym";
    output;
    y = 1;
    z = .65;
    _name_ = "y";
    _type_ = "cov";
    output;
    y = .65;
    z = 1;
    _name_ = "z";
    _type_ = "cov";
    output;
  end;
run;
```

```

proc model out=sim(where=(_REP_ > 0)) data=histdata sdata=asym;
  y = 0;
  errormodel y ~ Uniform(0,1);

  z = 0;
  errormodel z ~ Uniform(0,1);

  solve y z / random=500 seed=12345 copula=(t(5) asym );
  by asym;
run;

```

To produce a panel plot of this joint distribution, use the following SAS/GRAPH statements.

```

ods graphics on / height=800 width=800;
proc template;
  define statgraph myplot.panel;
    BeginGraph;
      entrytitle halign=left halign=center
        textattrs=GRAPHTITLETEXT "t Copula with a Range of Asymmetry";

      layout datapanel classvars=(asym) / rows=3 columns=3
        order=rowmajor height=1024 width=1420
        rowaxisopts=(griddisplay=on label=' ')
        columnaxisopts=(griddisplay=on label=' ');
      layout prototype;
        scatterplot x=z y=y ;
      endlayout;
    endlayout;
  EndGraph;
end;
run;

proc sgrender data=sim template='myplot.panel';
run;

```

Figure 19.74 *t* Copula with Asymmetry

Quasi-Random Number Generators

Traditionally high-discrepancy pseudo-random number generators are used to generate innovations in Monte Carlo simulations. Loosely translated, a high-discrepancy pseudo-random number generator is one in which there is very little correlation between the current number generated and the past numbers generated. This property is ideal if indeed independence of the innovations is required. If, on the other hand, the efficient spanning of a multidimensional space is desired, a low discrepancy, quasi-random number generator can be used. A quasi-random number generator produces numbers that have no random component.

A simple one-dimensional quasi-random sequence is the van der Corput sequence. Given a prime number r ($r \geq 2$), any integer has a unique representation in terms of base r . A number in the interval $[0,1)$ can be created by inverting the representation base power by base power. For example, consider $r=3$ and $n=1$, 1 in base 3 is

$$1_{10} = 1 \cdot 3^0 = 1_3$$

When the powers of 3 are inverted,

$$\phi(1) = \frac{1}{3}$$

Also, 11 in base 3 is

$$11_{10} = 1 \cdot 3^2 + 2 \cdot 3^0 = 102_3$$

When the powers of 3 are inverted,

$$\phi(11) = \frac{1}{9} + 2 \cdot \frac{1}{3} = \frac{7}{9}$$

The first 10 numbers in this sequence $\phi(1) \dots \phi(10)$ are provided below

$$0, \frac{1}{3}, \frac{2}{3}, \frac{1}{9}, \frac{4}{9}, \frac{7}{9}, \frac{2}{9}, \frac{5}{9}, \frac{8}{9}, \frac{1}{27}$$

As the sequence proceeds, it fills in the gaps in a uniform fashion.

Several authors have expanded this idea to many dimensions. Two versions supported by the MODEL procedure are the Sobol sequence (QUASI=SOBOL) and the Faure sequence (QUASI=FAURE). The Sobol sequence is based on binary numbers and is generally computationally faster than the Faure sequence. The Faure sequence uses the dimensionality of the problem to determine the number base to use to generate the sequence. The Faure sequence has better distributional properties than the Sobol sequence for dimensions greater than 8.

As an example of the difference between a pseudo-random number and a quasi-random number, consider simulating a bivariate normal with 100 draws.

Figure 19.75 Kernel Density of a Bivariate Normal produced by 100 Faure-Random Draws

Figure 19.76 Kernel Density of a Bivariate Normal produced by 100 Pseudo-Random Draws

Solution Mode Output

The following SAS statements dynamically forecast the solution to a nonlinear equation:

```
proc model data=sashelp.citimon;
  parameters a 0.010708 b -0.478849 c 0.929304;
  lhur = 1/(a * ip) + b + c * lag(lhur);
  solve lhur / out=sim forecast dynamic;
run;
```

The first page of output produced by the SOLVE step is shown in [Figure 19.77](#). This is the summary description of the model. The error message states that the simulation was aborted at observation 144 because of missing input values.

Figure 19.77 Solve Step Summary Output

```

Variables Solved For	LHUR

This solution summary table includes the names of the input data set and the output data set followed by a description of the model. The table also indicates that the solution method defaulted to Newton's method. The remaining output is defined as follows.

Maximum CC	is the maximum convergence value accepted by the Newton procedure. This number is always less than the value for the CONVERGE= option.
Maximum Iterations	is the maximum number of Newton iterations performed at each observation and each replication of Monte Carlo simulations.
Total Iterations	is the sum of the number of iterations required for each observation and each Monte Carlo simulation.
Average Iterations	is the average number of Newton iterations required to solve the system at each step.
Solved	is the number of observations used times the number of random replications selected plus one, for Monte Carlo simulations. The one additional simulation is the original unperturbed solution. For simulations that do not involve Monte Carlo, this number is the number of observations used.

Summary Statistics

The STATS and THEIL options are used to select goodness-of-fit statistics. Actual values must be provided in the input data set for these statistics to be printed. When the RANDOM= option is specified, the statistics do not include the unperturbed (_REP_=0) solution.

STATS Option Output

The following statements show the addition of the STATS and THEIL options to the model in the previous section:

```
proc model data=sashelp.citimon;
  parameters a 0.010708 b -0.478849 c 0.929304;
  lhur= 1/(a * ip) + b + c * lag(lhur) ;
  solve lhur / out=sim dynamic stats theil;
  range date to '01nov91'd;
run;
```

The STATS output in Figure 19.80 and the THEIL output in Figure 19.81 are generated.

Figure 19.80 STATS Output

The number of observations (Nobs), the number of observations with both predicted and actual values nonmissing (N), and the mean and standard deviation of the actual and predicted values of the determined variables are printed first. The next set of columns in the output are defined as follows:

$$\text{Mean Error} \quad \frac{1}{N} \sum_{j=1}^N (\hat{y}_j - y_j)$$

$$\text{Mean \% Error} \quad \frac{100}{N} \sum_{j=1}^N (\hat{y}_j - y_j)/y_j$$

$$\text{Mean Abs Error} \quad \frac{1}{N} \sum_{j=1}^N |\hat{y}_j - y_j|$$

$$\text{Mean Abs \% Error} \quad \frac{100}{N} \sum_{j=1}^N |(\hat{y}_j - y_j)/y_j|$$

$$\text{RMS Error} \quad \sqrt{\frac{1}{N} \sum_{j=1}^N (\hat{y}_j - y_j)^2}$$

$$\text{RMS \% Error} \quad 100 \sqrt{\frac{1}{N} \sum_{j=1}^N ((\hat{y}_j - y_j)/y_j)^2}$$

$$\text{R-square} \quad 1 - SSE/CSSA$$

$$SSA \quad \sum_{j=1}^N (y_j)^2$$

$$CSSA \quad SSA - \left(\sum_{j=1}^N y_j \right)^2$$

\hat{y} predicted value

y actual value

When the RANDOM= option is specified, the statistics do not include the unperturbed (_REP_=0) solution.

THEIL Option Output

The THEIL option specifies that Theil forecast error statistics be computed for the actual and predicted values and for the relative changes from lagged values. Mathematically, the quantities are

$$\hat{y}c = (\hat{y} - \text{lag}(y))/\text{lag}(y)$$

$$yc = (y - \text{lag}(y))/\text{lag}(y)$$

where $\hat{y}c$ is the relative change for the predicted value and yc is the relative change for the actual value.

Figure 19.81 THEIL Output

Theil Forecast Error Statistics

				Bias (UM)	Reg (UR)	Dist (UD)	Var (US)	Covar (UC)
LHUR	142	0.0126	-0.08	0.09	0.85	0.06	0.43	0.47

Theil Relative Change Forecast Error Statistics			
Variable	Inequality Coef		Label
	U1	U	
LHUR	4.1226	0.8348	UNEMPLOYMENT RATE: ALL WORKERS, 16 YEARS

The columns have the following meaning:

Corr (R) is the correlation coefficient, ρ , between the actual and predicted values.

$$\rho = \frac{\text{cov}(y, \hat{y})}{\sigma_a \sigma_p}$$

where σ_p and σ_a are the standard deviations of the predicted and actual values.

Bias (UM) is an indication of systematic error and measures the extent to which the average values of the actual and predicted deviate from each other.

$$\frac{(E(y) - E(\hat{y}))^2}{\frac{1}{N} \sum_{t=1}^N (y_t - \hat{y}_t)^2}$$

Reg (UR) is defined as $(\sigma_p - \rho * \sigma_a)^2 / MSE$. Consider the regression

$$y = \alpha + \beta \hat{y}$$

If $\hat{\beta} = 1$, UR will equal zero.

Dist (UD) is defined as $(1 - \rho^2)\sigma_a\sigma_a / MSE$ and represents the variance of the residuals obtained by regressing y_c on \hat{y}_c .

Var (US) is the variance proportion. US indicates the ability of the model to replicate the degree of variability in the endogenous variable.

$$US = \frac{(\sigma_p - \sigma_a)^2}{MSE}$$

Covar (UC) represents the remaining error after deviations from average values and average variabilities have been accounted for.

$$UC = \frac{2(1 - \rho)\sigma_p\sigma_a}{MSE}$$

U1 is a statistic that measures the accuracy of a forecast defined as follows:

$$U1 = \frac{\sqrt{MSE}}{\sqrt{\frac{1}{N} \sum_{t=1}^N (y_t)^2}}$$

U is the Theil's inequality coefficient defined as follows:

$$U = \frac{\sqrt{MSE}}{\sqrt{\frac{1}{N} \sum_{t=1}^N (y_t)^2 + \frac{1}{N} \sum_{t=1}^N (\hat{y}_t)^2}}$$

MSE is the mean square error. In the case of the relative change Theil statistics, the MSE is computed as follows:

$$MSE = \frac{1}{N} \sum_{t=1}^N (\hat{y}_t - y_t)^2$$

More information about these statistics can be found in the references Maddala (1977, 344–347) and Pindyck and Rubinfeld (1981, 364–365).

Goal Seeking: Solving for Right-Hand-Side Variables

The process of computing input values that are needed to produce target results is often called *goal seeking*. To compute a goal-seeking solution, use a SOLVE statement that lists the variables you want to solve for and provide a data set that contains values for the remaining variables.

Consider the following demand model for packaged rice

$$\text{quantity demanded} = \alpha_1 + \alpha_2 \text{price}^{2/3} + \alpha_3 \text{income}$$

where *price* is the price of the package and *income* is disposable personal income. The only variable the company has control over is the price it charges for rice. This model is estimated by using the following simulated data and PROC MODEL statements:

```
data demand;
  do t=1 to 40;
    price = (rannor(10) +5) * 10;
    income = 8000 * t ** (1/8);
    demand = 7200 - 1054 * price ** (2/3) +
              7 * income + 100 * rannor(1);
    output;
  end;
run;

data goal;
  demand = 85000;
  income = 12686;
run;
```

The goal is to find the price the company would have to charge to meet a sales target of 85,000 units. To do this, a data set is created with a DEMAND variable set to 85000 and with an INCOME variable set to 12686, the last income value.

The desired price is then determined by using the following PROC MODEL statements:

```
proc model data=demand
  outmodel=demandModel;
  demand = a1 - a2 * price ** (2/3) + a3 * income;
  fit demand / outest=demest;
  solve price / estdata=demest data=goal solveprint;
run;
```

The SOLVEPRINT option prints the solution values, number of iterations, and final residuals at each observation. The SOLVEPRINT output from this solve is shown in [Figure 19.82](#).

Figure 19.82 Goal Seeking, SOLVEPRINT Output

The MODEL Procedure						
Single-Equation Simulation						
Observation	1	Iterations	6	CC	0.000000	ERROR.demand 0.000000

Figure 19.82 continued

Solution Values	
	price
	33.59016

The output indicates that it took six Newton iterations to determine the PRICE of 33.5902, which makes the DEMAND value within 16E-11 of the goal of 85,000 units.

Consider a more ambitious goal of 100,000 units. The output shown in Figure 19.83 indicates that the sales target of 100,000 units is not attainable according to this model.

```
data goal;
  demand = 100000;
  income = 12686;
run;

proc model model=demandModel;
  solve price / estdata=demest data=goal solveprint;
run;
```

Figure 19.83 Goal Seeking, Convergence Failure

The MODEL Procedure				
Single-Equation Simulation				
ERROR: Could not reduce norm of residuals in 10 subiterations.				
ERROR: The solution failed because 1 equations are missing or have extreme values for observation 1 at NEWTON iteration 1.				
Observation	1	Iteration	1	CC
		Missing	1	-1.000000
The MODEL Procedure				
Single-Equation Simulation				
--- Listing of Program Data Vector ---				
N:	12	ACTUAL.demand:	100000	ERROR.demand:
PRED.demand:	.	a1:	7126.437997	a2:
a3:	6.992694	demand:	100000	income:
price:	-0.000172			12686
@PRED.demand/@pri:	.			

The program data vector with the error note indicates that even after 10 subiterations, the norm of the residuals could not be reduced. The sales target of 100,000 units are unattainable with the given model. You might need to reformulate your model or collect more data to more accurately reflect the market response.

Numerical Solution Methods

If the SINGLE option is not used, PROC MODEL computes values that simultaneously satisfy the model equations for the variables named in the SOLVE statement. PROC MODEL provides three iterative methods, Newton, Jacobi, and Seidel, for computing a simultaneous solution of the system of nonlinear equations.

Single-Equation Solution

For normalized form equation systems, the solution either can simultaneously satisfy all the equations or can be computed for each equation separately, by using the actual values of the solution variables in the current period to compute each predicted value. By default, PROC MODEL computes a simultaneous solution. The SINGLE option in the SOLVE statement selects single-equation solutions.

Single-equation simulations are often used to produce residuals (which estimate the random terms of the stochastic equations) rather than the predicted values themselves. If the input data and range are the same as those used for parameter estimation, a static single-equation simulation reproduces the residuals of the estimation.

Newton's Method

The NEWTON option in the SOLVE statement requests Newton's method to simultaneously solve the equations for each observation. Newton's method is the default solution method. Newton's method is an iterative scheme that uses the derivatives of the equations with respect to the solution variables, \mathbf{J} , to compute a change vector as

$$\Delta \mathbf{y}^i = \mathbf{J}^{-1} \mathbf{q}(\mathbf{y}^i, \mathbf{x}, \boldsymbol{\theta})$$

PROC MODEL builds and solves \mathbf{J} by using efficient sparse matrix techniques. The solution variables \mathbf{y}^i at the i th iteration are then updated as

$$\mathbf{y}^{i+1} = \mathbf{y}^i + d \times \Delta \mathbf{y}^i$$

where d is a damping factor between 0 and 1 chosen iteratively so that

$$\|\mathbf{q}(\mathbf{y}^{i+1}, \mathbf{x}, \boldsymbol{\theta})\| < \|\mathbf{q}(\mathbf{y}^i, \mathbf{x}, \boldsymbol{\theta})\|$$

The number of subiterations that are allowed for finding a suitable d is controlled by the MAXSUBITER= option. The number of iterations of Newton's method that are allowed for each observation is controlled by MAXITER= option. See Ortega and Rheinbolt (1970) for more details.

Optimization Method

The OPTIMIZE option in the SOLVE statement requests that an optimization algorithm be used to minimize a norm of the errors in equations subject to constraints on the solution variables. The OPTIMIZE method is the only solution method that supports constraints on solution variables that are specified using the BOUNDS and RESTRICT statements. Constraints are ignored by the other solution methods. The OPTIMIZE method performs the following optimization:

$$\begin{array}{ll} \text{minimize} & \|\mathbf{q}(\mathbf{y}, \mathbf{x}, \boldsymbol{\theta})\| \\ \text{subject to} & \mathbf{y}_l \leq \mathbf{y} \leq \mathbf{y}_u \\ \text{and} & f(\mathbf{y}) \geq 0 \end{array}$$

The norm used in the minimization process is

$$\|q(y, x, \theta)\| = q(y, x, \theta)' \text{diag}(S)^{-1} q(y, x, \theta)$$

where the S matrix is the covariance of equation errors that is specified by the `SDATA=` option in the `SOLVE` statement. If no `SDATA=` option is specified, the identity matrix is used. Both strict inequality and inequality constraints on the solution variables can be imposed using the `BOUNDS` or `RESTRICT` statement. For bounded problems, each lower and upper strict inequality is transformed into an inequality by using the equations

$$y_l = (y_{\text{lower strict}} + \epsilon)/(1 - \epsilon)$$

$$y_u = (y_{\text{upper strict}} - \epsilon)/(1 + \epsilon)$$

When strict inequality expressions are imposed using the `RESTRICT` statement, these expressions are transformed into an inequality by using the equation

$$f(y) = (f_{\text{strict}}(y) + \epsilon)/(1 - \epsilon)$$

where $f_{\text{strict}}(y)$ is a nonlinear strict inequality constraint. The tolerance ϵ is controlled by the `EPSILON=` option in the `SOLVE` statement and defaults to 10^{-8} . To achieve the best performance from the minimization algorithm, both the first and second analytic derivatives of the equation errors with respect to the solution variables are used to compute the gradient and second derivatives of the objective function, $\|q(y, x, \theta)\|$. Analytic derivatives of the restriction expressions that are used to specify constraints are also used in the minimization. The gradient of the objective function is

$$\nabla \|q(y, x, \theta)\| = 2 J' \text{diag}(S)^{-1} q(y, x, \theta)$$

The matrix of second derivatives of the objective function with respect to the solution variables is

$$\frac{\partial^2 \|q(y, x, \theta)\|}{\partial y^2} = 2 \left(J' \text{diag}(S)^{-1} J + \sum_{k=1}^d \frac{\partial^2 q_k(y, x, \theta)}{\partial y^2} \text{diag}(S)^{-1} q_k(y, x, \theta) \right)$$

where d is the number of equations.

The algorithm that is used to find a minimum of $\|q(y, x, \theta)\|$ subject to bounds on the solution variables employs the interior point technique for nonlinear optimization problems. For further information about this optimization method, see Chapter 7, “The Nonlinear Programming Solver” (*SAS/OR User’s Guide: Mathematical Programming*).

When constraints are active in a solution, the minimum value of the objective function, $\|q(y, x, \theta)\|$, is typically greater than 0. The diagnostic quantities that are produced by the `OUTOBJVALS` and `OUTVIOLATIONS` options are available to help identify and characterize solutions that have active bounds constraints. The following program contains a boundary constraint that becomes active in steps 6, 8, 10, 12, 13, and 16 of a Monte Carlo simulation:

```

proc model data=d sdata=s;
  dependent rate stock;
  parms theta    0.2
        kappa    0.002
        sigma    0.4
        sinit    1
        vol      .1;
  id i;

  bounds rate >= 0;

  rate    = zlag(rate) + kappa*(theta - zlag(rate));
  h.rate  = sigma**2 * zlag(rate);
  eq.stock = log(stock/sinit) - (rate + vol*vol/2);
  h.stock = vol**2;

  solve / optimize converge=1e-6 seed=1 random=1 out=o outobjvals outviolations;
quit;

proc print data=o(where=( _objval_>1e-6 ));
run;

```

Figure 19.84 shows how the OUTOBJVALS option can be used to identify simulation steps with an active bounds constraint, and how the OUTVIOLATIONS option can be used to determine that the RATE equation is not satisfied for those steps.

Jacobi Method

The JACOBI option in the SOLVE statement selects a matrix-free alternative to Newton's method. This method is the traditional nonlinear Jacobi method found in the literature. The Jacobi method as implemented in PROC MODEL substitutes predicted values for the endogenous variables and iterates until a fixed point is reached. Then necessary derivatives are computed only for the diagonal elements of the jacobian, **J**.

If the normalized form equation is

$$y = f(y, x, \theta)$$

the Jacobi iteration has the form

$$y^{i+1} = f(y^i, x, \theta)$$

Seidel Method

The Seidel method is an order-dependent alternative to the Jacobi method. You select the Seidel method by specifying the SEIDEL option in the SOLVE statement. The Seidel method is like the Jacobi method, except that in the Seidel method the model is further edited to substitute the predicted values into the solution variables immediately after they are computed. The Seidel method thus differs from the other methods in that the values of the solution variables are not fixed within an iteration. With the other methods, the order of the equations in the model program makes no difference, but the Seidel method might work much differently when the equations are specified in a different sequence. This fixed-point method is the traditional nonlinear Seidel method found in the literature.

The iteration has the form

$$y_j^{i+1} = f(\hat{y}^i, x, \theta)$$

where y_j^{i+1} is the j th equation variable at the i th iteration and

$$\hat{y}^i = (y_1^{i+1}, y_2^{i+1}, y_3^{i+1}, \dots, y_{j-1}^{i+1}, y_j^i, y_{j+1}^i, \dots, y_g^i)'$$

If the model is recursive, and if the equations are in recursive order, the Seidel method converges at once. If the model is block-recursive, the Seidel method might converge faster if the equations are grouped by block and the blocks are placed in block-recursive order. The BLOCK option can be used to determine the block-recursive form.

Jacobi and Seidel Methods with General Form Equations

Jacobi and Seidel solution methods support general form equations.

There are two cases where derivatives are (automatically) computed. The first case is for equations with the solution variable on the right-hand side and on the left-hand side of the equation

$$y^i = f(x, y^i)$$

In this case the derivative of `ERROR.y` with respect to y is computed, and the new y approximation is computed as

$$y^{i+1} = y^i - \frac{f(x, y^i) - y^i}{\partial(f(x, y^i) - y^i)/\partial y}$$

The second case is a system of equations that contains one or more `EQ.var` equations. In this case, the MODEL procedure assigns a unique solution variable to each equation if such an assignment exists. Use the DETAILS option in the SOLVE statement to print a listing of the assigned variables.

Once the assignment is made, the new y approximation is computed as

$$y^{i+1} = y^i - \frac{f(\mathbf{x}, \mathbf{y}^i) - y^i}{\partial(f(\mathbf{x}, \mathbf{y}^i) - y^i)/\partial y}$$

If k is the number of general form equations, then k derivatives are required.

The convergence properties of the Jacobi and Seidel solution methods remain significantly poorer than the default Newton's method.

Comparison of Methods

Newton's method is the default and should work better than the others for most small- to medium-sized models. The Seidel method is always faster than the Jacobi for recursive models with equations in recursive order. For very large models and some highly nonlinear smaller models, the Jacobi or Seidel methods can sometimes be faster. Newton's method uses more memory than the Jacobi or Seidel methods.

Both the Newton's method and the Jacobi method are order-invariant in the sense that the order in which equations are specified in the model program has no effect on the operation of the iterative solution process. In order-invariant methods, the values of the solution variables are fixed for the entire execution of the model program. Assignments to model variables are automatically changed to assignments to corresponding equation variables. Only after the model program has completed execution are the results used to compute the new solution values for the next iteration.

Troubleshooting Problems

In solving a simultaneous nonlinear dynamic model you might encounter some of the following problems.

Missing Values

For SOLVE tasks, there can be no missing parameter values. Missing right-hand-side variables result in missing left-hand-side variables for that observation.

Unstable Solutions

A solution might exist but be unstable. An unstable system can cause the Jacobi and Seidel methods to diverge.

Explosive Dynamic Systems

A model might have well-behaved solutions at each observation but be dynamically unstable. The solution might oscillate wildly or grow rapidly with time.

Propagation of Errors

During the solution process, solution variables can take on values that cause computational errors. For example, a solution variable that appears in a LOG function might be positive at the solution but might be given a negative value during one of the iterations. When computational errors occur, missing values are generated and propagated, and the solution process might collapse.

Convergence Problems

The following items can cause convergence problems:

- There are illegal function values (for example $\sqrt{-1}$).
- There are local minima in the model equation.
- No solution exists.
- Multiple solutions exist.
- Initial values are too far from the solution.
- The CONVERGE= value is too small.

When PROC MODEL fails to find a solution to the system, the current iteration information and the program data vector are printed. The simulation halts if actual values are not available for the simulation to proceed. Consider the following program, which produces the output shown in [Figure 19.85](#):

```
data test1;
  do t=1 to 50;
    x1 = sqrt(t) ;
    y = .;
    output;
  end;

proc model data=test1;
  exogenous x1 ;
  control a1 -1 b1 -29 c1 -4 ;
  y = a1 * sqrt(y) + b1 * x1 * x1 + c1 * lag(x1);
  solve y / out=sim forecast dynamic ;
run;
```

Figure 19.85 SOLVE Convergence Problems

b1:          -29      c1:      -4      x1:      1.41421
y:          -0.00109
@PRED.y/@y:      .      @ERROR.y/@y:      .

NOTE: Check for missing input data or uninitialized lags.
      (Note that the LAG and DIF functions return missing values for the
      initial lag starting observations. This is a change from the 1982 and earlier
      versions of SAS/ETS which returned zero for uninitialized lags.)
NOTE: Simulation aborted.

```

At the first observation, a solution to the following equation is attempted:

$$y = -\sqrt{y} - 62$$

There is no solution to this problem. The iterative solution process got as close as it could to making Y negative while still being able to evaluate the model. This problem can be avoided in this case by altering the equation.

In other models, the problem of missing values can be avoided by either altering the data set to provide better starting values for the solution variables or by altering the equations.

You should be aware that, in general, a nonlinear system can have any number of solutions and the solution found might not be the one that you want. When multiple solutions exist, the solution that is found is usually determined by the starting values for the iterations. If the value from the input data set for a solution variable is missing, the starting value for it is taken from the solution of the last period (if nonmissing) or else the solution estimate is started at 0.

Iteration Output

The iteration output, produced by the ITPRINT option, is useful in determining the cause of a convergence problem. The ITPRINT option forces the printing of the solution approximation and equation errors at each iteration for each observation. A portion of the ITPRINT output from the following statements is shown in Figure 19.86.

```

proc model data=test1;
  exogenous x1 ;
  control a1 -1 b1 -29 c1 -4 ;
  y = a1 * sqrt(abs(y)) + b1 * x1 * x1 + c1 * lag(x1);
  solve y / out=sim forecast dynamic itprint;
run;

```

For each iteration, the equation with the largest error is listed in parentheses after the Newton convergence criteria measure. From this output you can determine which equation or equations in the system are not converging well.

Numerical Integration

The differential equation system is numerically integrated to obtain a solution for the derivative variables at each data point. The integration is performed by evaluating the provided model at multiple points between each data point. The integration method used is a variable order, variable step-size backward difference scheme; for more detailed information, see Aiken (1985) and Byrne and Hindmarsh (1975). The step size or time step is chosen to satisfy a *local truncation error* requirement. The term *truncation error* comes from the fact that the integration scheme uses a truncated series expansion of the integrated function to do the integration. Because the series is truncated, the integration scheme is within the truncation error of the true value.

To further improve the accuracy of the integration, the total integration time is broken up into small intervals (time steps or step sizes), and the integration scheme is applied to those intervals. The integration at each time step uses the values computed at the previous time step so that the truncation error tends to accumulate. It is usually not possible to estimate the global error with much precision. The best that can be done is to monitor and to control the local truncation error, which is the truncation error committed at each time step relative to

$$d = \max_{0 \leq t \leq T} (\|y(t)\|_{\infty}, 1)$$

where $y(t)$ is the integrated variable. Furthermore, the $y(t)$ s are dynamically scaled to within two orders of magnitude of one to keep the error monitoring well-behaved.

The local truncation error requirement defaults to 1.0E-9. You can specify the LTEBOUND= option to modify that requirement. The LTEBOUND= option is a relative measure of accuracy, so a value smaller than 1.0E-10 is usually not practical. A larger bound increases the speed of the simulation and estimation but decreases the accuracy of the results. If the LTEBOUND= option is set too small, the integrator is not able to take time steps small enough to satisfy the local truncation error requirement and still have enough machine precision to compute the results. Since the integrations are scaled to within 1.0E-2 of one, the simulated values should be correct to at least seven decimal places.

There is a default minimum time step of 1.0E-14. This minimum time step is controlled by the MINTIMESTEP= option and the machine epsilon. If the minimum time step is smaller than the machine epsilon times the final time value, the minimum time step is increased automatically.

For the points between each observation in the data set, the values for nonintegrated variables in the data set are obtained from a linear interpolation from the two closest points. Lagged variables can be used with integrations, but their values are discrete and are not interpolated between points. Lagging, therefore, can then be used to input step functions into the integration.

The derivatives necessary for estimation (the gradient with respect to the parameters) and goal seeking (the Jacobian) are computed by numerically integrating analytical derivatives. The accuracy of the derivatives is controlled by the same integration techniques mentioned previously.

Limitations

There are limitations to the types of differential equations that can be solved or estimated. One type is an explosive differential equation (finite escape velocity) for which the following differential equation is an example:

$$y' = a \times y, a > 0$$

If this differential equation is integrated too far in time, y exceeds the maximum value allowed on the computer, and the integration terminates.

Likewise, differential systems that are singular cannot be solved or estimated in general. For example, consider the following differential system:

$$\begin{aligned} x' &= -y' + 2x + 4y + \exp(t) \\ y' &= -x' + y + \exp(4*t) \end{aligned}$$

This system has an analytical solution, but an accurate numerical solution is very difficult to obtain. The reason is that y' and x' cannot be isolated on the left-hand side of the equation. If the equation is modified slightly to

$$\begin{aligned} x' &= -y' + 2x + 4y + \exp(t) \\ y' &= x' + y + \exp(4t) \end{aligned}$$

the system is nonsingular, but the integration process could still fail or be extremely slow. If the MODEL procedure encounters either system, a warning message is issued.

This system can be rewritten as the following recursive system, which can be estimated and simulated successfully with the MODEL procedure:

$$\begin{aligned} x' &= 0.5y + 0.5\exp(4t) + x + 1.5y - 0.5\exp(t) \\ y' &= x' + y + \exp(4t) \end{aligned}$$

Petzold (1982) mentions a class of differential algebraic equations that, when integrated numerically, could produce incorrect or misleading results. An example of such a system is

$$\begin{aligned} y_2'(t) &= y_1(t) + g_1(t) \\ 0 &= y_2(t) + g_2(t) \end{aligned}$$

The analytical solution to this system depends on g and its derivatives at the current time only and not on its initial value or past history. You should avoid systems of this and other similar forms mentioned in Petzold (1982).

SOLVE Data Sets

SDATA= Input Data Set

The SDATA= option reads a cross-equation covariance matrix from a data set. The covariance matrix read from the SDATA= data set specified in the SOLVE statement is used to generate random equation errors when the RANDOM= option specifies Monte Carlo simulation.

Typically, the SDATA= data set is created by the OUTS= option in a previous FIT statement. (The OUTS= data set from a FIT statement can be read back in by a SOLVE statement in the same PROC MODEL step.)

You can create an input SDATA= data set by using the DATA step. PROC MODEL expects to find a character variable `_NAME_` in the SDATA= data set as well as variables for the equations in the estimation or solution. For each observation with a `_NAME_` value that matches the name of an equation, PROC MODEL fills the corresponding row of the **S** matrix with the values of the names of equations found in the data set. If a row or column is omitted from the data set, an identity matrix row or column is assumed. Missing values are ignored. Since the **S** matrix is symmetric, you can include only a triangular part of the **S** matrix in the SDATA= data set with the omitted part indicated by missing values. If the SDATA= data set contains multiple observations with the same `_NAME_`, the last values supplied for the `_NAME_` variable are used. The section “[OUTS= Data Set](#)” on page 1180 contains more details on the format of this data set.

Use the TYPE= option to specify the type of estimation method used to produce the **S** matrix you want to input.

ESTDATA= Input Data Set

The ESTDATA= option specifies an input data set that contains an observation with values for some or all of the model parameters. It can also contain observations with the rows of a covariance matrix for the parameters.

When the ESTDATA= option is used, parameter values are set from the first observation. If the RANDOM= option is used and the ESTDATA= data set contains a covariance matrix, the covariance matrix of the parameter estimates is read and used to generate pseudo-random shocks to the model parameters for Monte Carlo simulation. These random perturbations have a multivariate normal distribution with the covariance matrix read from the ESTDATA= data set.

The ESTDATA= data set is usually created by the OUTEST= option in a FIT statement. The OUTEST= data set contains the parameter estimates produced by the FIT statement and also contains the estimated covariance of the parameter estimates if the OUTCOV option is used. This OUTEST= data set can be read in by the ESTDATA= option in a SOLVE statement.

You can also create an ESTDATA= data set with a SAS DATA step program. The data set must contain a numeric variable for each parameter to be given a value or covariance column. The name of the variable in the ESTDATA= data set must match the name of the parameter in the model. Parameters with names longer than 32 characters cannot be set from an ESTDATA= data set. The data set must also contain a character variable `_NAME_` of length 32. `_NAME_` has a blank value for the observation that gives values to the parameters. `_NAME_` contains the name of a parameter for observations that define rows of the covariance matrix.

More than one set of parameter estimates and covariances can be stored in the ESTDATA= data set if the observations for the different estimates are identified by the variable `_TYPE_`. `_TYPE_` must be a character

variable of length eight. The TYPE= option is used to select for input the part of the ESTDATA= data set for which the value of the _TYPE_ variable matches the value of the TYPE= option.

OUT= Data Set

The OUT= data set contains solution values, residual values, and actual values of the solution variables.

The OUT= data set contains the following variables:

- BY variables
- RANGE variable
- ID variables
- _TYPE_, a character variable of length eight that identifies the type of observation. The _TYPE_ variable can be PREDICT, RESIDUAL, ACTUAL, or ERROR.
- _MODE_, a character variable of length eight that identifies the solution mode. _MODE_ takes the value FORECAST or SIMULATE.
- if lags are used, a numeric variable, _LAG_, that contains the number of dynamic lags that contribute to the solution. The value of _LAG_ is always zero for STATIC mode solutions. _LAG_ is set to a missing value for lag-starting observations.
- if the RANDOM= option is used, _REP_, a numeric variable that contains the replication number. For example, if RANDOM=10, each input observation results in eleven output observations with _REP_ values 0 through 10. The observations with _REP_=0 are from the unperturbed solution. (The random-number generator functions are suppressed, and the parameter and endogenous perturbations are zero when _REP_=0.)
- _ERRORS_, a numeric variable that contains the number of errors that occurred during the execution of the program for the last iteration for the observation. If the solution failed to converge, this is counted as one error, and the _ERRORS_ variable is made negative.
- solution and other variables. The solution variables contain solution or predicted values for _TYPE_=PREDICT observations, residuals for _TYPE_=RESIDUAL observations, or actual values for _TYPE_=ACTUAL observations. The other model variables, and any other variables read from the input data set, are always actual values from the input data set.
- any other variables named in the OUTVARS statement. These can be program variables computed by the model program, CONTROL variables, parameters, or special variables in the model program. Compound variable names longer than 32 characters are truncated in the OUT= data set.

By default, only the predicted values are written to the OUT= data set. The OUTRESID, OUTACTUAL, and OUTERROR options are used to add the residual, actual, and ERROR. values, respectively, to the data set.

For examples of the OUT= data set, see [Example 19.6](#).

DATA= Input Data Set

The input data set should contain all of the exogenous variables and should supply nonmissing values for them for each period to be solved.

Solution variables can be supplied in the input data set and are used as follows:

- to supply initial lags. For example, if the lag length of the model is three, three observations are read in to feed the lags before any solutions are computed.
- to evaluate the goodness of fit. Goodness-of-fit measures are computed based on the difference between the solved values and the actual values supplied from the data set.
- to supply starting values for the iterative solution. If the value from the input data set for a solution variable is missing, the starting value for it is taken from the solution of the last period (if nonmissing) or else the solution estimate is started at zero.
- for STATIC mode solutions, actual values from the data set are used by the lagging functions for the solution variables.
- for FORECAST mode solutions, actual values from the data set are used as the solution values when nonmissing.

Programming Language Overview: MODEL Procedure

Variables in the Model Program

Variable names are alphanumeric but must start with a letter. The length is limited to 32 characters.

PROC MODEL uses several classes of variables, and different variable classes are treated differently. The variable class is controlled by *declaration statements*: the VAR, ENDOGENOUS, and EXOGENOUS statements for model variables, the PARAMETERS statement for parameters, and the CONTROL statement for control class variables. These declaration statements have several valid abbreviations. Various *internal variables* are also made available to the model program to allow communication between the model program and the procedure. RANGE, ID, and BY variables are also available to the model program. Those variables not declared as any of the preceding classes are *program variables*.

Some classes of variables can be lagged; that is, their value at each observation is remembered, and previous values can be referred to by the lagging functions. Other classes have only a single value and are not affected by lagging functions. For example, parameters have only one value and are not affected by lagging functions; therefore, if P is a parameter, $DIF_n(P)$ is always 0, and $LAG_n(P)$ is always the same as P for all values of n .

The different variable classes and their roles in the model are described in the following.

Model Variables

Model variables are declared by VAR, ENDOGENOUS, or EXOGENOUS statements, or by FIT and SOLVE statements. The model variables are the variables that the model is intended to explain or predict.

PROC MODEL enables you to use expressions on the left-hand side of the equal sign to define model equations. For example, a log-linear model for Y can be written as

$$\log(y) = a + b * x;$$

Previously, only a variable name was allowed on the left-hand side of the equal sign.

The text on the left-hand side of the equation serves as the equation name used to identify the equation in printed output, in the OUT= data sets, and in FIT or SOLVE statements. To refer to equations specified by using left-hand side expressions (in the FIT statement, for example), place the left-hand side expression in quotes. For example, the following statements fit a log-linear model to the dependent variable Y:

```
proc model data=in;
    log( y ) = a + b * x;
    fit "log(y)";
run;
```

The estimation and simulation is performed by transforming the models into general form equations. No actual or predicted value is available for general form equations, so no R^2 or adjusted R^2 is computed.

Equation Variables

An equation variable is one of several special variables used by PROC MODEL to control the evaluation of model equations. An equation variable name consists of one of the prefixes EQ, RESID, ERROR, PRED, or ACTUAL, followed by a period and the name of a model equation.

Equation variable names can appear in parts of the PROC MODEL printed output, and they can be used in the model program. For example, RESID-prefixed variables can be used in LAG functions to define equations with moving-average error terms. See the section “[Autoregressive Moving-Average Error Processes](#)” on page 1156 for details.

The meaning of these prefixes is detailed in the section “[Equation Translations](#)” on page 1225.

Parameters

Parameters are variables that have the same value for each observation. Parameters can be given values or can be estimated by fitting the model to data. During the SOLVE stage, parameters are treated as constants. If no estimation is performed, the SOLVE stage uses the initial value provided in the ESTDATA= data set, the MODEL= file, or in the PARAMETER statement, as the value of the parameter.

The PARAMETERS statement declares the parameters of the model. Parameters are not lagged, and they cannot be changed by the model program.

Control Variables

Control variables supply constant values to the model program that can be used to control the model in various ways. The **CONTROL** statement declares control variables and specifies their values. A control variable is like a parameter except that it has a fixed value and is not estimated from the data.

Control variables are not reinitialized before each pass through the data and can thus be used to retain values between passes. You can use control variables to vary the program logic. Control variables are not affected by lagging functions.

For example, if you have two versions of an equation for a variable *Y*, you could put both versions in the model and, by using a **CONTROL** statement to select one of them, produce two different solutions to explore the effect the choice of equation has on the model, as shown in the following statements:

```
select (case);
  when (1) y = ...first version of equation... ;
  when (2) y = ...second version of equation... ;
end;

control case 1;
solve / out=case1;
run;

control case 2;
solve / out=case2;
run;
```

RANGE, ID, and BY Variables

The **RANGE** statement controls the range of observations in the input data set that is processed by **PROC MODEL**. The **ID** statement lists variables in the input data set that are used to identify observations in the printout and in the output data set. The **BY** statement can be used to make **PROC MODEL** perform a separate analysis for each **BY** group. The variable in the **RANGE** statement, the **ID** variables, and the **BY** variables are available for the model program to examine, but their values should not be changed by the program. The **BY** variables are not affected by lagging functions.

Internal Variables

You can use several internal variables in the model program to communicate with the procedure. For example, if you want **PROC MODEL** to list the values of all the variables when more than 10 iterations are performed and the procedure is past the 20th observation, you can write

```
if _obs_ > 20 then if _iter_ > 10 then _list_ = 1;
```

Internal variables are not affected by lagging functions, and they cannot be changed by the model program except as noted. The following internal variables are available. The variables are all numeric except where noted.

ERRORS is a flag that is set to 0 at the start of program execution and is set to a nonzero value whenever an error occurs. The program can also set the **_ERRORS_** variable.

<code>_ITER_</code>	is the iteration number. For FIT tasks, the value of <code>_ITER_</code> is negative for preliminary grid-search passes. The iterative phase of the estimation starts with iteration 0. After the estimates have converged, a final pass is made to collect statistics with <code>_ITER_</code> set to a missing value. Note that at least one pass, and perhaps several subiteration passes as well, is made for each iteration. For SOLVE tasks, <code>_ITER_</code> counts the iterations used to compute the simultaneous solution of the system.
<code>_LAG_</code>	is the number of dynamic lags that contribute to the solution at the current observation. <code>_LAG_</code> is always 0 for FIT tasks and for STATIC solutions. <code>_LAG_</code> is set to a missing value during the lag starting phase.
<code>_LIST_</code>	is a list flag that is set to 0 at the start of program execution. The program can set <code>_LIST_</code> to a nonzero value to request a listing of the values of all the variables in the program after the program has finished executing.
<code>_METHOD_</code>	is the solution method in use for SOLVE tasks. <code>_METHOD_</code> is set to a blank value for FIT tasks. <code>_METHOD_</code> is a character-valued variable. Values are NEWTON, JACOBI, SIEDEL, or ONEPASS.
<code>_MODE_</code>	takes the value ESTIMATE for FIT tasks and the value SIMULATE or FORECAST for SOLVE tasks. <code>_MODE_</code> is a character-valued variable.
<code>_NMISS_</code>	is the number of missing or otherwise unusable observations during the model estimation. For FIT tasks, <code>_NMISS_</code> is initially set to 0; at the start of each iteration, <code>_NMISS_</code> is set to the number of unusable observations for the previous iteration. For SOLVE tasks, <code>_NMISS_</code> is set to a missing value.
<code>_NUSED_</code>	is the number of nonmissing observations used in the estimation. For FIT tasks, PROC MODEL initially sets <code>_NUSED_</code> to the number of parameters; at the start of each iteration, <code>_NUSED_</code> is reset to the number of observations used in the previous iteration. For SOLVE tasks, <code>_NUSED_</code> is set to a missing value.
<code>_OBS_</code>	counts the observations being processed. <code>_OBS_</code> is negative or 0 for observations in the lag starting phase.
<code>_REP_</code>	is the replication number for Monte Carlo simulation when the RANDOM= option is specified in the SOLVE statement. <code>_REP_</code> is 0 when the RANDOM= option is not used and for FIT tasks. When <code>_REP_=0</code> , the random-number generator functions always return 0.
<code>_WEIGHT_</code>	is the weight of the observation. For FIT tasks, <code>_WEIGHT_</code> provides a weight for the observation in the estimation. <code>_WEIGHT_</code> is initialized to 1.0 at the start of execution for FIT tasks. For SOLVE tasks, <code>_WEIGHT_</code> is ignored.

Program Variables

Variables not in any of the other classes are called program variables. Program variables are used to hold intermediate results of calculations. Program variables are reinitialized to missing values before each observation is processed. Program variables can be lagged. The RETAIN statement can be used to give program variables initial values and enable them to keep their values between observations.

Character Variables

PROC MODEL supports both numeric and character variables. Character variables are not involved in the model specification but can be used to label observations, to write debugging messages, or for documentation purposes. All variables are numeric unless they are the following.

- character variables in a DATA= SAS data set
- program variables assigned a character value
- declared to be character by a LENGTH or ATTRIB statement

Equation Translations

Equations written in normalized form are always automatically converted to general form equations. For example, when a normalized form equation such as

$$y = a + b \cdot x;$$

is encountered, it is translated into the equations

```
PRED.y = a + b*x;
RESID.y = PRED.y - ACTUAL.y;
ERROR.y = PRED.y - y;
```

If the same system is expressed as the following general form equation, then this equation is used unchanged.

$$EQ.y = y - (a + b \cdot x);$$

This makes it easy to solve for arbitrary variables and to modify the error terms for autoregressive or moving average models.

Use the LIST option to see how this transformation is performed. For example, the following statements produce the listing shown in [Figure 19.87](#).

```
proc model data=line list;
  y = a1 + b1*x1 + c1*x2;
  fit y;
run;
```

Figure 19.87 LIST Output

The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	4104:4	PRED.y = a1 + b1 * x1 + c1 * x2;
1	4104:4	RESID.y = PRED.y - ACTUAL.y;
1	4104:4	ERROR.y = PRED.y - y;

PRED.Y is the predicted value of Y, and ACTUAL.Y is the value of Y in the data set. The predicted value minus the actual value, RESID.Y, is then the error term, ϵ , for the original Y equation. Note that the residuals obtained from the OUTRESID option in the OUT=dataset for both the FIT and SOLVE statements are defined as *actual – predicted*, the negative of RESID.Y. See the section “[Syntax: MODEL Procedure](#)” on page 1032 for details. ACTUAL.Y and Y have the same value for parameter estimation. For solve tasks, ACTUAL.Y is still the value of Y in the data set but Y becomes the solved value; the value that satisfies $\text{PRED.Y} - Y = 0$.

The following are the equation variable definitions.

- EQ.** The value of an EQ.-prefixed equation variable (normally used to define a general form equation) represents the failure of the equation to hold. When the EQ.*name* variable is 0, the *name* equation is satisfied.
- RESID.** The RESID.*name* variables represent the stochastic parts of the equations and are used to define the objective function for the estimation process. A RESID.-prefixed equation variable is like an EQ.-prefixed variable but makes it possible to use or transform the stochastic part of the equation. The RESID. equation is used in place of the ERROR. equation for model solutions if it has been reassigned or used in the equation.
- ERROR.** An ERROR.*name* variable is like an EQ.-prefixed variable, except that it is used only for model solution and does not affect parameter estimation.
- PRED.** For a normalized form equation (specified by assignment to a model variable), the PRED.*name* equation variable holds the predicted value, where *name* is the name of both the model variable and the corresponding equation. (PRED.-prefixed variables are not created for general form equations.)
- ACTUAL.** For a normalized form equation (specified by assignment to a model variable), the ACTUAL.*name* equation variable holds the value of the *name* model variable read from the input data set.
- DETR.** The DETR.*name* variable defines a differential equation. Once defined, it might be used on the right-hand side of another equation.
- H.** The H.*name* variable specifies the functional form for the variance of the named equation.
- GMM_H.** This is created for H.*vars* and is the moment equation for the variance for GMM. This variable is used only for GMM.

GMM_H.name = RESID.name2 - H.name;**

MSE. The `MSE.y` variable contains the value of the mean squared error for `y` at each iteration. An `MSE.` variable is created for each dependent/endogenous variable in the model. These variables can be used to specify the missing lagged values in the estimation and simulation of GARCH type models.

```
demret = intercept ;
h.demret = arch0 +
            arch1 * xlag( resid.demret ** 2, mse.demret) +
            garch1 * xlag(h.demret, mse.demret) ;
```

NRESID. This is created for `H.vars` and is the normalized residual of the variable `<name>`. The formula is

```
NRESID.name = RESID.name / sqrt(H.name) ;
```

The three equation variable prefixes, `RESID.`, `ERROR.`, and `EQ.` allow for control over the objective function for the `FIT`, the `SOLVE`, or both the `FIT` and the `SOLVE` stages. For `FIT` tasks, `PROC MODEL` looks first for a `RESID.name` variable for each equation. If defined, the `RESID.`-prefixed equation variable is used to define the objective function for the parameter estimation process. Otherwise, `PROC MODEL` looks for an `EQ.`-prefixed variable for the equation and uses it instead.

For `SOLVE` tasks, `PROC MODEL` looks first for an `ERROR.name` variable for each equation. If defined, the `ERROR.`-prefixed equation variable is used for the solution process. Otherwise, `PROC MODEL` looks for an `EQ.`-prefixed variable for the equation and uses it instead. To solve the simultaneous equation system, `PROC MODEL` computes values of the solution variables (the model variables being solved for) that make all of the `ERROR.name` and `EQ.name` variables close to 0.

Derivatives

Nonlinear modeling techniques require the calculation of derivatives of certain variables with respect to other variables. The `MODEL` procedure includes an analytic differentiator that determines the model derivatives and generates program code to compute these derivatives. When parameters are estimated, the `MODEL` procedure takes the derivatives of the equation with respect to the parameters. When the model is solved, Newton's method requires the derivatives of the equations with respect to the variables solved for.

`PROC MODEL` uses exact mathematical formulas for derivatives of non-user-defined functions. For other functions, numerical derivatives are computed and used.

The differentiator differentiates the entire model program, including the conditional logic and flow of control statements. Delayed definitions, as when the `LAG` of a program variable is referred to before the variable is assigned a value, are also differentiated correctly.

The differentiator includes optimization features that produce efficient code for the calculation of derivatives. However, when flow of control statements such as `GOTO` statements are used, the optimization process is impeded, and less efficient code for derivatives might be produced. Optimization is also reduced by conditional statements, iterative `DO` loops, and multiple assignments to the same variable.

The table of derivatives is printed with the `LISTDER` option. The code generated for the computation of the derivatives is printed with the `LISTCODE` option.

Derivative Variables

When the differentiator needs to generate code to evaluate the expression for the derivative of a variable, the result is stored in a special derivative variable. Derivative variables are not created when the derivative expression reduces to a previously computed result, a variable, or a constant. The names of derivative variables, which might sometimes appear in the printed output, have the form *@obj/@wrt*, where *obj* is the variable whose derivative is being taken and *wrt* is the variable that the differentiation is with respect to. For example, the derivative variable for the derivative of *Y* with respect to *X* is named *@Y/@X*.

The derivative variables can be accessed or used as part of the model program using the GETDER() function.

GETDER(*x*, *a*) the derivative of *x* with respect to *a*.

GETDER(*x*, *a*, *b*) the second derivative of *x* with respect to *a* and *b*.

The main purpose of the GETDER() function is for surfacing the derivatives so they can be stored in a data set for further processing. Only derivatives that are implied by the problem are available to the GETDER() function. When derivatives are requested that aren't already created, a missing value will be returned. The derivative of the GETDER() function is always zero so the results of the GETDER() function shouldn't be used in any of the equations in the FIT or the SOLVE statement.

The following example adds the gradient of the PRED.y value with respect to the parameters to the OUT= data set.

```
proc model data=line ;
  y = a1 + b1**2 *x1 + c1*x2;
  Dy_a1 = getder(PRED.y, a1);
  Dy_b1 = getder(PRED.y, b1);
  Dy_c1 = getder(PRED.y, c1);
  outvars Dy_a1 Dy_b1 Dy_c1;
  fit y / out=grad;
run;
```

Mathematical Functions

The following is a brief summary of SAS functions that are useful for defining models. Additional functions and details are in *SAS Language: Reference*. Information about creating new functions can be found in *SAS/BASE Software: Procedure Reference*, Chapter 18, "The FCMP Procedure."

ABS(<i>x</i>)	the absolute value of <i>x</i>
ARCOS(<i>x</i>)	the arccosine in radians of <i>x</i> ; <i>x</i> should be between -1 and 1 .
ARSIN(<i>x</i>)	the arcsine in radians of <i>x</i> ; <i>x</i> should be between -1 and 1 .
ATAN(<i>x</i>)	the arctangent in radians of <i>x</i>
COS(<i>x</i>)	the cosine of <i>x</i> ; <i>x</i> is in radians.
COSH(<i>x</i>)	the hyperbolic cosine of <i>x</i>
EXP(<i>x</i>)	e^x
LOG(<i>x</i>)	the natural logarithm of <i>x</i>

LOG10(x)	the log base ten of x
LOG2(x)	the log base two of x
SIN(x)	the sine of x ; x is in radians.
SINH(x)	the hyperbolic sine of x
SQRT(x)	the square root of x
TAN(x)	the tangent of x ; x is in radians and is not an odd multiple of $\pi/2$.
TANH(x)	the hyperbolic tangent of x

Random-Number Functions

The MODEL procedure provides several functions for generating random numbers for Monte Carlo simulation. These functions use the same generators as the corresponding SAS DATA step functions.

The following random number functions are supported: RANBIN, RANCAU, RAND, RANEXP, RANGAM, RANNOR, RANPOI, RANTBL, RANTRI, and RANUNI. For more information, refer to *SAS Language: Reference*.

Each reference to a random number function sets up a separate pseudo-random sequence. Note that this means that two calls to the same random function with the same seed produce identical results. This is different from the behavior of the random number functions used in the SAS DATA step. For example, the following statements produce identical values for X and Y, but Z is from an independent pseudo-random sequence:

```
x=rannor(123);
y=rannor(123);
z=rannor(567);
q=rand('BETA', 1, 12);
```

For FIT tasks, all random number functions always return 0. For SOLVE tasks, when Monte Carlo simulation is requested, a random number function computes a new random number on the first iteration for an observation (if it is executed on that iteration) and returns that same value for all later iterations of that observation. When Monte Carlo simulation is not requested, random number functions always return 0.

Functions across Time

PROC MODEL provides four types of special built-in functions that refer to the values of variables and expressions in previous time periods. These functions have the following forms where n represents the number of periods, x is any expression, and the argument i is a variable or expression that gives the lag length ($0 \leq i \leq n$). If the index value i is omitted, the maximum lag length n is used.

LAG n ($< i, > x$) returns the i th lag of x , where n is the maximum lag;

DIF n (x) is the difference of x at lag n

ZLAG n ($< i, > x$) returns the i th lag of x , where n is the maximum lag, with missing lags replaced with zero

- XLAGn** (*x*, *y*) returns the *n*th lag of *x* if *x* is nonmissing, or *y* if *x* is missing
- ZDIFn** (*x*) is the difference with lag length truncated and missing values converted to zero; *x* is the variable or expression to compute the moving average of
- MOVAVGn**(*x*) is the moving average if X_t denotes the observation at time point *t*, to ensure compatibility with the number *n* of observations used to calculate the moving average MOVAVGn, the following definition is used:

$$MOVAVGn(X_t) = \frac{X_t + X_{t-1} + X_{t-2} + \dots + X_{t-n+1}}{n}$$

The moving average calculation for SAS 9.1 and earlier releases is as follows:

$$MOVAVGn(X_t) = \frac{X_t + X_{t-1} + X_{t-2} + \dots + X_{t-n}}{n + 1}$$

Missing values of *x* are omitted in computing the average.

If you do not specify *n*, the number of periods is assumed to be one. For example, LAG(*X*) is the same as LAG1(*X*). No more than four digits can be used with a lagging function; that is, LAG9999 is the greatest LAG function, ZDIF9999 is the greatest ZDIF function, and so on.

The LAG functions get values from previous observations and make them available to the program. For example, LAG(*X*) returns the value of the variable *X* as it was computed in the execution of the program for the preceding observation. The expression LAG2(*X*+2**Y*) returns the value of the expression *X*+2**Y*, computed by using the values of the variables *X* and *Y* that were computed by the execution of the program for the observation two periods ago.

The DIF functions return the difference between the current value of a variable or expression and the value of its LAG. For example, DIF2(*X*) is a short way of writing *X*–LAG2(*X*), and DIF15(SQRT(2**Z*)) is a short way of writing SQRT(2**Z*)–LAG15(SQRT(2**Z*)).

The ZLAG and ZDIF functions are like the LAG and DIF functions, but they are not counted in the determination of the program lag length, and they replace missing values with 0s. The ZLAG function returns the lagged value if the lagged value is nonmissing, or 0 if the lagged value is missing. The ZDIF function returns the differenced value if the differenced value is nonmissing, or 0 if the value of the differenced value is missing. The ZLAG function is especially useful for models with ARMA error processes. See the next section for details.

Lag Logic

The LAG and DIF lagging functions in the MODEL procedure are different from the queuing functions with the same names in the DATA step. Lags are determined by the final values that are set for the program variables by the execution of the model program for the observation. This can have upsetting consequences for programs that take lags of program variables that are given different values at various places in the program, as shown in the following statements:

```
temp = x + w;
t     = lag( temp );
temp = q - r;
s     = lag( temp );
```

The expression `LAG(TEMP)` always refers to `LAG(Q-R)`, never to `LAG(X+W)`, since `Q-R` is the final value assigned to the variable `TEMP` by the model program. If `LAG(X+W)` is wanted for `T`, it should be computed as `T=LAG(X+W)` and not `T=LAG(TEMP)`, as in the preceding example.

Care should also be exercised in using the `DIF` functions with program variables that might be reassigned later in the program. For example, the program

```
temp = x ;
s     = dif( temp );
temp = 3 * y;
```

computes values for `S` equivalent to

```
s = x - lag( 3 * y );
```

Note that in the preceding examples, `TEMP` is a program variable, *not* a model variable. If it were a model variable, the assignments to it would be changed to assignments to a corresponding equation variable.

Note that whereas `LAG1(LAG1(X))` is the same as `LAG2(X)`, `DIF1(DIF1(X))` is *not* the same as `DIF2(X)`. The `DIF2` function is the difference between the current period value at the point in the program where the function is executed and the final value at the end of execution two periods ago; `DIF2` is not the second difference. In contrast, `DIF1(DIF1(X))` is equal to `DIF1(X)-LAG1(DIF1(X))`, which equals `X-2*LAG1(X)+LAG2(X)`, which is the second difference of `X`.

More information about the differences between `PROC MODEL` and the `DATA` step `LAG` and `DIF` functions is found in Chapter 3, “[Working with Time Series Data](#).”

Lag Lengths

The lag length of the model program is the number of lags needed for any relevant equation. The program lag length controls the number of observations used to initialize the lags.

`PROC MODEL` keeps track of the use of lags in the model program and automatically determines the lag length of each equation and of the model as a whole. `PROC MODEL` sets the program lag length to the maximum number of lags needed to compute any equation to be estimated, solved, or needed to compute any instrument variable used.

In determining the lag length, the `ZLAG` and `ZDIF` functions are treated as always having a lag length of 0. For example, if `Y` is computed as

```
y = lag2( x + zdif3( temp ) );
```

then `Y` has a lag length of 2 (regardless of how `TEMP` is defined). If `Y` is computed as

```
y = zlag2( x + dif3( temp ) );
```

then `Y` has a lag length of 0.

This is so that `ARMA` errors can be specified without causing the loss of additional observations to the lag starting phase and so that recursive lag specifications, such as moving-average error terms, can be used. Recursive lags are not permitted unless the `ZLAG` or `ZDIF` functions are used to truncate the lag length. For example, the following statement produces an error message:

```
t = a + b * lag( t );
```

The program variable T depends recursively on its own lag, and the lag length of T is therefore undefined.

In the following equation RESID.Y depends on the predicted value for the Y equation but the predicted value for the Y equation depends on the LAG of RESID.Y, and thus, the predicted value for the Y equation depends recursively on its own lag.

```
y = yhat + ma * lag( resid.y );
```

The lag length is infinite, and PROC MODEL prints an error message and stops. Since this kind of specification is allowed, the recursion must be truncated at some point. The ZLAG and ZDIF functions do this.

The following equation is valid and results in a lag length for the Y equation equal to the lag length of YHAT:

```
y = yhat + ma * zlag( resid.y );
```

Initially, the lags of RESID.Y are missing, and the ZLAG function replaces the missing residuals with 0s, their unconditional expected values.

The ZLAG0 function can be used to zero out the lag length of an expression. ZLAG0(*x*) returns the current period value of the expression *x*, if nonmissing, or else returns 0, and prevents the lag length of *x* from contributing to the lag length of the current statement.

Initializing Lags

At the start of each pass through the data set or BY group, the lag variables are set to missing values and an initialization is performed to fill the lags. During this phase, observations are read from the data set, and the model variables are given values from the data. If necessary, the model is executed to assign values to program variables that are used in lagging functions. The results for variables used in lag functions are saved. These observations are not included in the estimation or solution.

If, during the execution of the program for the lag starting phase, a lag function refers to lags that are missing, the lag function returns missing. Execution errors that occur while starting the lags are not reported unless requested. The modeling system automatically determines whether the program needs to be executed during the lag starting phase.

If L is the maximum lag length of any equation being fit or solved, then the first L observations are used to prime the lags. If a BY statement is used, the first L observations in the BY group are used to prime the lags. If a RANGE statement is used, the first L observations prior to the first observation requested in the RANGE statement are used to prime the lags. Therefore, there should be at least L observations in the data set.

Initial values for the lags of model variables can also be supplied in VAR, ENDOGENOUS, and EXOGENOUS statements. This feature provides initial lags of solution variables for dynamic solution when initial values for the solution variable are not available in the input data set. For example, the statement

```
var x 2 3 y 4 5 z 1;
```

feeds the initial lags exactly like these values in an input data set:

Lag	X	Y	Z
2	3	5	.
1	2	4	1

If initial values for lags are available in the input data set and initial lag values are also given in a declaration statement, the values in the VAR, ENDOGENOUS, or EXOGENOUS statements take priority.

The RANGE statement is used to control the range of observations in the input data set that are processed by PROC MODEL. In the following statement, '01jan1924' specifies the starting period of the range, and '01dec1943' specifies the ending period:

```
range date = '01jan1924'd to '01dec1943'd;
```

The observations in the data set immediately prior to the start of the range are used to initialize the lags.

Language Differences

For the most part, PROC MODEL programming statements work the same as they do in the DATA step as documented in *SAS Language: Reference*. However, there are several differences that should be noted.

DO Statement Differences

The DO statement in PROC MODEL does not allow a character index variable. Thus, the following DO statement is not valid in PROC MODEL, although it is supported in the DATA step:

```
do i = 'A', 'B', 'C'; /* invalid PROC MODEL code */
```

IF Statement Differences

The IF statement in PROC MODEL does not allow a character-valued condition. For example, the following IF statement is not supported by PROC MODEL:

```
if 'this' then statement;
```

Comparisons of character values are supported in IF statements, so the following IF statement is acceptable:

```
if 'this' < 'that' then statement;
```

PROC MODEL allows for embedded conditionals in expressions. For example the following two statements are equivalent:

```
flag = if time = 1 or time = 2 then conc+30/5 + dose*time
      else if time > 5 then (0=1) else (patient * flag);
```

```
if time = 1 or time = 2 then flag= conc+30/5 + dose*time;
else if time > 5 then flag=(0=1); else flag=patient*flag;
```

Note that the ELSE operator involves only the first object or token after it so that the following assignments are not equivalent:

```
total = if sum > 0 then sum else sum + reserve;
total = if sum > 0 then sum else (sum + reserve);
```

The first assignment makes TOTAL always equal to SUM plus RESERVE.

PUT Statement Differences

The PUT statement, mostly used in PROC MODEL for program debugging, supports only some of the features of the DATA step PUT statement. It also has some new features that the DATA step PUT statement does not support.

The PROC MODEL PUT statement does not support line pointers, factored lists, iteration factors, overprinting, the `_INFILE_` option, or the colon (`:`) format modifier.

The PROC MODEL PUT statement does support expressions, but an expression must be enclosed in parentheses. For example, the following statement prints the square root of `x`:

```
put (sqrt(x));
```

Subscripted array names must be enclosed in parentheses. For example, the following statement prints the *i*th element of the array `A`:

```
put (a i);
```

However, the following statement is an error:

```
put a i;
```

The PROC MODEL PUT statement supports the print item `_PDV_` to print a formatted listing of all the variables in the program. For example, the following statement prints a much more readable listing of the variables than does the `_ALL_` print item:

```
put _pdv_;
```

To print all the elements of the array `A`, use the following statement:

```
put a;
```

To print all the elements of `A` with each value labeled by the name of the element variable, use the following statement:

```
put a=;
```

ABORT Statement Difference

In the MODEL procedure, the ABORT statement does not allow any arguments.

SELECT/WHEN/OTHERWISE Statement Differences

The WHEN and OTHERWISE statements allow more than one target statement. That is, DO groups are not necessary for multiple statement WHENs. For example in PROC MODEL, the following syntax is valid:

```
select;
  when (exp1)
    stmt1;
    stmt2;
  when (exp2)
    stmt3;
    stmt4;
end;
```

The ARRAY Statement

ARRAY *arrayname* < {*dimensions*} > < \$ [*length*] > < *variables and constants* > ; ;

The ARRAY statement is used to associate a name with a list of variables and constants. The array name can then be used with subscripts in the model program to refer to the items in the list.

In PROC MODEL, the ARRAY statement does not support all the features of the DATA step ARRAY statement. Implicit indexing cannot be used; all array references must have explicit subscript expressions. Only exact array dimensions are allowed; lower-bound specifications are not supported. A maximum of six dimensions is allowed.

On the other hand, the ARRAY statement supported by PROC MODEL does allow both variables and constants to be used as array elements. You cannot make assignments to constant array elements. Both dimension specification and the list of elements are optional, but at least one must be supplied. When the list of elements is not given or fewer elements than the size of the array are listed, array variables are created by suffixing element numbers to the array name to complete the element list.

The following are valid PROC MODEL array statements:

```
array x[120];           /* array X of length 120          */
array q[2,2];           /* Two dimensional array Q          */
array b[4] va vb vc vd; /* B[2] = VB, B[4] = VD            */
array x x1-x30;         /* array X of length 30, X[7] = X7  */
array a[5] (1 2 3 4 5); /* array A initialized to 1,2,3,4,5 */
```

RETAIN Statement

RETAIN *variables initial-values* ;

The RETAIN statement causes a program variable to hold its value from a previous observation until the variable is reassigned. The RETAIN statement can be used to initialize program variables.

The RETAIN statement does not work for model variables, parameters, or control variables because the values of these variables are under the control of PROC MODEL and not programming statements. Use the PARS and CONTROL statements to initialize parameters and control variables. Use the VAR, ENDOGENOUS, or EXOGENOUS statement to initialize model variables.

Storing Programs in Model Files

Models can be saved in and recalled from SAS catalog files as well as XML-based data sets. SAS catalogs are special files that can store many kinds of data structures as separate units in one SAS file. Each separate unit is called an entry, and each entry has an entry type that identifies its structure to the SAS system. Starting with SAS 9.2, model files are being stored as SAS data sets instead of being stored as members of a SAS catalog as in earlier releases. This makes MODEL files more readily extendable in the future and enables Java-based applications to read the MODEL files directly. You can choose between the two formats by specifying a global CMPMODEL option in an OPTIONS statement. Details are given below.

In general, to save a model, use the OUTMODEL=*name* option in the PROC MODEL statement, where *name* is specified as *libref.catalog.entry*, *libref.entry*, or *entry* for catalog entry and, starting with SAS 9.2, *libref.datasetname* or *datasetname* for XML-based SAS datasets. The *libref*, *catalog*, *datasetnames* and *entry* names must be valid SAS names no more than 32 characters long. The *catalog* name is restricted to seven characters on the CMS operating system. If not given, the *catalog* name defaults to MODELS, and the *libref* defaults to WORK. The entry type is always MODEL. Thus, OUTMODEL=X writes the model to the file WORK.MODELS.X.MODEL in the SAS catalog or creates a WORK.X XML-based dataset in the WORK library depending on the format chosen by using the CMPMODEL= option. By default, both these formats are chosen.

The CMPMODEL= option can be used in an OPTIONS statement to modify the behavior when reading and writing MODEL files. The values allowed are CMPMODEL= BOTH | XML | CATALOG. For example, the following statements restore the previous behavior:

```
options cmpmodel=catalog;
```

The CMPMODEL= option defaults to BOTH in SAS 9.2 and is intended for transitional use. If CMPMODEL=BOTH, the MODEL procedure writes both formats; when loading model files PROC MODEL attempts to load the XML version first and the CATALOG version second (if the XML version is not found). If CMPMODEL=XML, the MODEL procedure reads and writes only the XML format. If CMPMODEL=CATALOG, only the catalog format is used.

The MODEL= option is used to read in a model. A list of model files can be specified in the MODEL= option, and a range of names with numeric suffixes can be given, as in MODEL=(MODEL1–MODEL10). When more than one model file is given, the list must be placed in parentheses, as in MODEL=(A B C), except in case of a single name. If more than one model file is specified, the files are combined in the order listed in the MODEL= option.

The MODEL procedure continues to read and write catalog MODEL files, and model files created by previous releases of SAS/ETS continue to work, so you should experience no direct impact from this change.

When the MODEL= option is specified in the PROC MODEL statement and model definition statements are also given later in the PROC MODEL step, the model files are read in first, in the order listed, and the model program specified in the PROC MODEL step is appended after the model program read from the MODEL= files. The class that is assigned to a variable, when multiple model files are used, is the last declaration of that variable. For example, if Y1 is declared endogenous in the model file M1 and exogenous in the model file M2, the following statement causes Y1 to be declared exogenous:

```
proc model model=(m1 m2);
```

The INCLUDE statement can be used to append model code to the current model code. In contrast, when the MODEL= option is specified in the RESET statement, the current model is deleted before the new model is read.

By default, no model file is output if the PROC MODEL step performs any FIT or SOLVE tasks, or if the MODEL= option or the NOSTORE option is specified. However, to ensure compatibility with previous versions of SAS/ETS software, if the PROC MODEL step does nothing but compile the model program, no input model file is read, and the NOSTORE option is not used, then a model file is written. This model file is the default input file for a later PROC SYSLIN or PROC SIMLIN step. The default output model filename in this case is WORK.MODELS._MODEL_.MODEL.

If FIT statements are used to estimate model parameters, the parameter estimates that are written to the output model file are the estimates from the last estimation performed for each parameter.

Macro Return Codes (SYSINFO)

The MODEL procedure stores a return code in the automatic macro variable SYSINFO upon completion of the PROC MODEL step. In the event any FIT or SOLVE task fails to converge during the completion of a PROC MODEL step, the value 1 is stored in the SYSINFO macro variable. Any subsequent SAS step resets the value of SYSINFO.

Diagnostics and Debugging

PROC MODEL provides several features to aid in finding errors in the model program. These debugging features are not usually needed; most models can be developed without them.

The example model program that follows is used in the following sections to illustrate the diagnostic and debugging capabilities. This example is the estimation of a segmented model.

```

```

Program Listing

The LIST option produces a listing of the model program. The statements are printed one per line with the original line number and column position of the statement.

The program listing from the example program is shown in [Figure 19.88](#).

Figure 19.88 LIST Output for Segmented Model

QUADRATIC MODEL WITH PLATEAU		
The MODEL Procedure		
Listing of Compiled Program Code		
Stmt	Line:Col	Statement as Parsed
1	4150:4	x0 = (-0.5 * b) / c;
2	4151:4	if x < x0 then
3	4152:7	PRED.y = a + b * x + c * x * x;
3	4152:7	RESID.y = PRED.y - ACTUAL.y;
3	4152:7	ERROR.y = PRED.y - y;
4	4153:4	else
5	4154:7	PRED.y = a + b * x0 + c * x0 * x0;
5	4154:7	RESID.y = PRED.y - ACTUAL.y;
5	4154:7	ERROR.y = PRED.y - y;

The LIST option also shows the model translations that PROC MODEL performs. LIST output is useful for understanding the code generated by the %AR and the %MA macros.

Cross-Reference

The XREF option produces a cross-reference listing of the variables in the model program. The XREF listing is usually used in conjunction with the LIST option. The XREF listing does not include derivative (@-prefixed) variables. The XREF listing does not include generated assignments to equation variables, PRED., RESID., and ERROR.-prefixed variables, unless the DETAILS option is used.

The cross-reference from the example program is shown in [Figure 19.89](#).

Figure 19.89 XREF Output for Segmented Model

Compiler Listing

The LISTCODE option lists the model code and derivatives tables produced by the compiler. This listing is useful only for debugging and should not normally be needed.

LISTCODE prints the operator and operands of each operation generated by the compiler for each model program statement. Many of the operands are temporary variables generated by the compiler and given names such as #temp1. When derivatives are taken, the code listing includes the operations generated for the derivatives calculations. The derivatives tables are also listed.

A LISTCODE option prints the transformed equations from the example shown in [Figure 19.90](#) and [Figure 19.91](#).

Figure 19.90 LISTCODE Output for Segmented Model—Statements as Parsed

Analyzing the Structure of Large Models

PROC MODEL provides several features to aid in analyzing the structure of the model program. These features summarize properties of the model in various forms.

Simulation Dependency Analysis

During the development of model programs for simulation, misspecification of the equations or variables that compose the systems of nonlinear equations is common. These misspecification errors can occur both in the original formulation of the model and in the encoding of the model into PROC MODEL statements. For large systems these errors can be difficult and time consuming to isolate and repair. Similarly, the process of becoming familiar with an existing simulation model that is encoded in PROC MODEL can be laborious when available documentation is insufficient to understand the model's implementation. To address these issues, the ANALYZESEP= option can be applied to SOLVE steps to produce graphical analyses of a model's structure.

The graphical output that is produced by the ANALYZESEP= option displays the results of two separate, hierarchical analyses that are both based on the dependence of equations on solve variables in the nonlinear system of equations. First, the system is partitioned to identify which equations overdetermine solve variables, which equations underdetermine solve variables, and which equations consistently determine solve variables. These three partitions of equations and their corresponding three partitions of solve variables are identified in the graphical output and listing produced by the ANALYZESEP= option. Second, each partition from the first analysis is analyzed to identify subpartitions of equations and solve variables such that all the solve variables within each subpartition depend either directly or indirectly on one another. In the graphical output the subpartitions are represented as blocks in a dependency matrix. The subpartition blocks are ordered so that the matrix of dependencies has a block upper-triangular form.

The first-level partitioning of the system into underdetermined, overdetermined, and consistent systems of equations and variables uses a Dulmage-Mendelsohn (DM) decomposition to define the three partitions, following the work by Dulmage and Mendelsohn (1958) and Pothén and Fan (1990). The overdetermining equations in a DM decomposition are the set of all equations that do not have dependent variables on the diagonal of any dependency matrix that contains the maximum possible number of entries on the diagonal. The dependency matrices for a problem consist of the set of pairs of orderings of the problem's equations and solve variables. Correspondingly, the DM decomposition defines underdetermined variables as the set of all variables that do not appear on the diagonal of any dependency matrix that contains the maximum number of entries on the diagonal. Therefore, the DM decomposition is canonical in the sense that its partitioning of the system is invariant to the order equations and variables are specified in the model program. The following PROC MODEL statements illustrate how to partition a simple model with five equations and five unknowns:

```
proc model data=_null_;
  endo a b c d e;

  f(a)      = 0;
  g(a,b)    = 0;
  h(a,b)    = 0;
  i(b,d)    = 0;
  j(c,d,e)  = 0;

  solve / analyzedep=(block);
quit;
```

Figure 19.92 Block Dependency Analysis

Figure 19.93 Block Partitions

Equation and Variable Blocks		
Type	Block	Symbols
Underdetermined	Eq 1	$j(c,d,e)$
	Var 1	$c\ e$
Consistent	Eq 2	$i(b,d)$
	Var 2	d
Overdetermined	Eq 3	$f(a)\ g(a,b)\ h(a,b)$
	Var 3	$a\ b$

Figure 19.92 and Figure 19.93 illustrate which equations and variables belong to each block and which blocks are in each partition. The cells that are marked “Nonzero” in the plot represent a dependency between blocks that are above the diagonal in the dependency matrix. The exact functional forms of the equations

in this example are not shown; however, the dependency analysis here reveals that this model is structurally singular because it contains overdetermined and underdetermined components. Some modification of the model specification is necessary before a SOLVE step can be executed.

For large systems of equations, the graphical output that the ANALYZE DEP= option produces can be used as a starting point to explore dependency relationships when the models' programming statement listings and dependency tables are too long to read and comprehend. For example, one econometric model of U.S. agriculture involves thousand of equation and variable dependencies whose structure is difficult to interpret in textual listings of the model. If you examine the block triangular form of its dependency matrix in [Figure 19.94](#), one pattern of dependencies that becomes apparent is the vertical grouping of block dependencies in the middle of the plot. [Figure 19.95](#) shows the dependency matrix for this important subpartition of equations and variables responsible for coupling the vertical grouping of blocks.

Figure 19.94 Block Triangular Form of U.S. Agriculture Model

Figure 19.95 Important Component in U.S. Agriculture Model

Compared to the BLOCK and GRAPH options, the ANALYZEDEP= option has the following advantages:

- shows which equations and solve variables are overdetermined, consistent, and underdetermined
- works with any combination of normal form and general form equations
- can display dependency matrices involving many more equations and variables
- can be limited to a subset of the equations and variables in the model

The following Klein's model program is used to introduce the LISTDEP, BLOCK, and GRAPH options:

```
proc model out=m data=klein listdep graph block;
  endogenous c p w i x wsum k y;
  exogenous wp g t year;
  parms c0-c3 i0-i3 w0-w3;
  a: c = c0 + c1 * p + c2 * lag(p) + c3 * wsum;
  b: i = i0 + i1 * p + i2 * lag(p) + i3 * lag(k);
  c: w = w0 + w1 * x + w2 * lag(x) + w3 * year;
  x = c + i + g;
  y = c + i + g-t;
  p = x-w-t;
  k = lag(k) + i;
  wsum = w + wp;
  id year;
quit;
```

Dependency List

The LISTDEP option produces a dependency list for each variable in the model program. For each variable, a list of variables that depend on it and a list of variables it depends on is given. The dependency list produced by the example program is shown in [Figure 19.96](#).

BLOCK Listing

The BLOCK option prints an analysis of the program variables based on the assignments in the model program. The output produced by the example is shown in [Figure 19.97](#).

Figure 19.97 The BLOCK Output for Klein's Model

```

                        The MODEL Procedure
                        Model Structure Analysis
(Based on Assignments to Endogenous Model Variables)

Exogenous Variables      wp g t year
Endogenous Variables     c p w i x wsum k y

                        Block Structure of the System

                        Block 1      c p w i x wsum

                        Dependency Structure of the System

Block 1      Depends On All_Exogenous
k            Depends On Block 1 All_Exogenous
y            Depends On Block 1 All_Exogenous

```

One use for the block output is to put a model in recursive form. Simulations of the model can be done with the SEIDEL method, which is efficient if the model is recursive and if the equations are in recursive order. By examining the block output, you can determine how to reorder the model equations for the most efficient simulation.

Adjacency Graph

The GRAPH option displays the same information as the BLOCK option with the addition of an adjacency graph. An X in a column in an adjacency graph indicates that the variable associated with the row depends on the variable associated with the column. The output produced by the example is shown in [Figure 19.98](#).

The first and last graphs are straightforward. The middle graph represents the dependencies of the nonexogenous variables after transitive closure has been performed (that is, A depends on B, and B depends on C, so A depends on C). The preceding transitive closure matrix indicates that K and Y do not directly or indirectly depend on each other.

Examples: MODEL Procedure

Example 19.1: OLS Single Nonlinear Equation

This example illustrates the use of the MODEL procedure for nonlinear ordinary least squares (OLS) regression. The model is a logistic growth curve for the population of the United States. The data is the population in millions recorded at ten-year intervals starting in 1790 and ending in 2000. For an explanation of the starting values given by the START= option, see the section “[Troubleshooting Convergence Problems](#)” on page 1102. Portions of the output from the following statements are shown in [Output 19.1.1](#) through [Output 19.1.3](#).

```

Output 19.1.3 Logistic Growth Curve Estimates

Logistic Growth Curve Model of U.S. Population						
The MODEL Procedure						
Nonlinear OLS Summary of Residual Errors						
Equation	DF Model	DF Error	SSE	MSE	R-Square	Adj R-Sq
pop	3	18	345.6	19.2020	0.9972	0.9969
Nonlinear OLS Parameter Estimates						
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t	Label	
a	387.9307	30.0404	12.91	<.0001	Maximum Population	
b	3.990385	0.0695	57.44	<.0001	Location Parameter	
c	0.022703	0.00107	21.22	<.0001	Initial Growth Rate	

The adjusted R^2 value indicates the model fits the data well. There are only 21 observations and the model is nonlinear, so significance tests on the parameters are only approximate. The significance tests and associated approximate probabilities indicate that all the parameters are significantly different from 0.

The FIT statement included the options OUT=RESID and OUTRESID so that the residuals from the estimation are saved to the data set RESID. The residuals are plotted to check for heteroscedasticity by using PROC SGPlot as follows.

```

title2 "Residuals Plot";
proc sgplot data=resid;
  refline 0;
  scatter x=year y=pop / markerattrs=(symbol=circlefilled);
  xaxis values=(1780 to 2000 by 20);
run;

```

The plot is shown in [Output 19.1.4](#).

Output 19.1.4 Residual for Population Model (Actual–Predicted)

The residuals do not appear to be independent, and the model could be modified to explain the remaining nonrandom errors.

Example 19.2: A Consumer Demand Model

This example shows the estimation of a system of nonlinear consumer demand equations based on the translog functional form by using seemingly unrelated regression (SUR). Expenditure shares and corresponding normalized prices are given for three goods.

Since the shares add up to one, the system is singular; therefore, one equation is omitted from the estimation process. The choice of which equation to omit is arbitrary. The nonlinear system is first estimated in unrestricted form by the following statements:

```

title1 'Consumer Demand--Translog Functional Form';
title2 'Asymmetric Model';

proc model data=tlog1;
  endogenous share1 share2;
  parms a1 a2 b11 b12 b13 b21 b22 b23 b31 b32 b33;

  bm1 = b11 + b21 + b31;
  bm2 = b12 + b22 + b32;
  bm3 = b13 + b23 + b33;
  lp1 = log(p1);
  lp2 = log(p2);
  lp3 = log(p3);
  share1 = ( a1 + b11 * lp1 + b12 * lp2 + b13 * lp3 ) /
            ( -1 + bm1 * lp1 + bm2 * lp2 + bm3 * lp3 );
  share2 = ( a2 + b21 * lp1 + b22 * lp2 + b23 * lp3 ) /
            ( -1 + bm1 * lp1 + bm2 * lp2 + bm3 * lp3 );

  fit share1 share2
    start=( a1 -.14 a2 -.45 b11 .03 b12 .47 b22 .98 b31 .20
            b32 1.11 b33 .71 ) / outsused=smatrix sur;
run;

```

A portion of the printed output produced by this example is shown in [Output 19.2.1](#) through [Output 19.2.3](#).

Hypothesis testing requires that the **S** matrix from the unrestricted model be imposed on the restricted model, as explained in the section “[Tests on Parameters](#)” on page 1147. The **S** matrix saved in the data set **SMATRIX** is requested by the **SDATA=** option.

A chi-square test is used to see if the hypothesis of symmetry is accepted or rejected. $(Oc - Ou)$ has a chi-square distribution asymptotically, where Oc is the constrained **OBJECTIVE*N** and Ou is the unconstrained

OBJECTIVE*N. The degrees of freedom is equal to the difference in the number of free parameters in the two models.

In this example, O_u is 76.9697 and O_c is 78.4097, resulting in a difference of 1.44 with 3 degrees of freedom. You can obtain the probability value by using the following statements:

```
data _null_;
  /* probchi( reduced-full, n-restrictions )*/
  p = 1-probchi( 1.44, 3 );
  put p=;
run;
```

The output from this DATA step run is $p = 0.6961858724$. With this p -value you cannot reject the hypothesis of symmetry. This test is asymptotically valid.

Example 19.3: Vector AR(1) Estimation

This example shows the estimation of a two-variable vector AR(1) error process for the Grunfeld model (Grunfeld and Griliches 1960) by using the %AR macro. First, the full model is estimated. Second, the model is estimated with the restriction that the errors are univariate AR(1) instead of a vector process. The following statements produce [Output 19.3.1](#) through [Output 19.3.5](#).

```
data grunfeld;
  input year gei gef gec whi whf whc;
  label gei = 'Gross Investment GE'
        gec = 'Capital Stock Lagged GE'
        gef = 'Value of Outstanding Shares GE Lagged'
        whi = 'Gross Investment WH'
        whc = 'Capital Stock Lagged WH'
        whf = 'Value of Outstanding Shares Lagged WH';
datalines;
1935      33.1      1170.6      97.8      12.93      191.5      1.8
1936      45.0      2015.8     104.4      25.90      516.0       .8
1937      77.2      2803.3     118.0      35.05      729.0      7.4

... more lines ...

title1 'Example of Vector AR(1) Error Process Using Grunfeld's Model';
/* Note: GE stands for General Electric
        WH stands for Westinghouse      */

proc model outmodel=grunmod;
  var gei whi gef gec whf whc;
  parms ge_int ge_f ge_c wh_int wh_f wh_c;
  label ge_int = 'GE Intercept'
        ge_f   = 'GE Lagged Share Value Coef'
        ge_c   = 'GE Lagged Capital Stock Coef'
        wh_int = 'WH Intercept'
        wh_f   = 'WH Lagged Share Value Coef'
        wh_c   = 'WH Lagged Capital Stock Coef';
  gei = ge_int + ge_f * gef + ge_c * gec;
  whi = wh_int + wh_f * whf + wh_c * whc;
run;
```

The preceding PROC MODEL step defines the structural model and stores it in the model file named GRUNMOD.

The following PROC MODEL step reads in the model, adds the vector autoregressive terms using %AR, and requests SUR estimation by using the FIT statement.

```
title2 'With Unrestricted Vector AR(1) Error Process';

proc model data=grunfeld model=grunmod;
  %ar( ar, 1, gei whi )
  fit gei whi / sur;
run;
```

The final PROC MODEL step estimates the restricted model, as shown in the following statements:

```
title2 'With restricted AR(1) Error Process';

proc model data=grunfeld model=grunmod;
  %ar( gei, 1 )
  %ar( whi, 1)
  fit gei whi / sur;
run;
```

The model stored in [Example 19.3](#) is read in by using the MODEL= option and the moving-average terms are added using the %MA macro.

The MA(1) model using maximum likelihood is estimated by using the following statements:

```
title2 'MA(1) Error Process Using Maximum Likelihood ';

proc model data=grunfeld model=grunmod;
  %ma(gei,1, m=ml);
  %ma(whi,1, m=ml);
  fit whi gei;
run;
```

For comparison, the model is estimated by using PROC ARIMA as follows:

```
title2 'PROC ARIMA Using Maximum Likelihood ';

proc arima data=grunfeld;
  identify var=whi cross=(whf whc) noprint;
  estimate q=1 input=(whf whc) method=ml;
run;
```

PROC ARIMA does not estimate systems, so only one equation is evaluated.

The estimation results are shown in [Output 19.4.3](#) and [Output 19.4.4](#). The small differences in the parameter values between PROC MODEL and PROC ARIMA can be eliminated by tightening the convergence criteria for both procedures.

Example 19.5: Polynomial Distributed Lags by Using %PDL

This example shows the use of the %PDL macro for polynomial distributed lag models. Simulated data is generated so that Y is a linear function of six lags of X, with the lag coefficients following a quadratic

polynomial. The model is estimated by using a fourth-degree polynomial, both with and without endpoint constraints. The example uses simulated data generated from the following model:

$$y_t = 10 + \sum_{z=0}^6 f(z)x_{t-z} + \epsilon$$

$$f(z) = -5z^2 + 1.5z$$

The LIST option prints the model statements added by the %PDL macro. The following statements generate simulated data as shown:

```

/*-----*/
/*  Generate Simulated Data for a Linear Model with a PDL on X  */
/*      y = 10 + x(6,2) + e                                     */
/*      pdl(x) = -5.*(lg)**2 + 1.5*(lg) + 0.                    */
/*-----*/
data pdl;
  pdl2=-5.; pdl1=1.5; pdl0=0;
  array zz(i) z0-z6;
  do i=1 to 7;
    z=i-1;
    zz=pdl2*z**2 + pdl1*z + pdl0;
  end;
  do n=-11 to 30;
    x =10*ranuni(1234567)-5;
    pdl=z0*x + z1*x11 + z2*x12 + z3*x13 + z4*x14 + z5*x15 + z6*x16;
    e =10*rannor(1234567);
    y =10+pdl+e;
    if n>=1 then output;
    x16=x15; x15=x14; x14=x13; x13=x12; x12=x11; x11=x;
  end;
run;

title1 'Polynomial Distributed Lag Example';
title3 'Estimation of PDL(6,4) Model-- No Endpoint Restrictions';

proc model data=pdl;
  parms int; /* declare the intercept parameter */
  %pdl( xpdl, 6, 4 ) /* declare the lag distribution */
  y = int + %pdl( xpdl, x ); /* define the model equation */
  fit y / list; /* estimate the parameters */
run;

```

The LIST output for the model without endpoint restrictions is shown in [Output 19.5.1](#). The first seven statements in the generated program are the polynomial expressions for lag parameters XPDL_L0 through XPDL_L6. The estimated parameters are INT, XPDL_0, XPDL_1, XPDL_2, XPDL_3, and XPDL_4.

XPDL_3	-9.3535	1.7602	-5.31	<.0001	PDL(XPDL, 6, 4) parameter for (L)**3		
XPDL_4	1.032421	0.1471	7.02	<.0001	PDL(XPDL, 6, 4) parameter for (L)**4		

Note that XPDL_0 and XPDL_1 are not shown in the estimate summary. They were used to satisfy the endpoint restrictions analytically by the generated %PDL macro code. Their values can be determined by back substitution.

To estimate the PDL model with one or more of the polynomial terms dropped, specify the largest degree of the polynomial desired with the %PDL macro and use the DROP= option in the FIT statement to remove the unwanted terms. The dropped parameters should be set to 0. The following PROC MODEL statements demonstrate estimation with a PDL of degree 2 without the 0th order term.

```

title3 'Estimation of PDL(6,2) Model-- With XPDL_0 Dropped';

proc model data=pd1 list;
  parms int;                      /* declare the intercept parameter */
  %pdl( xpd1, 6, 2 )              /* declare the lag distribution */
  y = int + %pdl( xpd1, x );      /* define the model equation */
  xpd1_0 =0;
  fit y drop=xpd1_0;              /* estimate the parameters */
run;

```

The results from this estimation are shown in [Output 19.5.4](#).

Output 19.5.4 PROC MODEL Results That Specify %PDL(XPDL, 6, 2)

Example 19.6: General Form Equations

Data for this example are generated. General form equations are estimated and forecast by using PROC MODEL. The system is a basic supply and demand model.

The following statements specify the form of the model:

```

title1 "General Form Equations for Supply-Demand Model";

proc model outmodel=model;
  var price quantity income unitcost;
  parms d0-d2 s0-s2;
  eq.demand=d0+d1*price+d2*income-quantity;
  eq.supply=s0+s1*price+s2*unitcost-quantity;
run;

```

Three data sets are used in this example. The first data set, HISTORY, is used to estimate the parameters of the model. The ASSUME data set is used to produce a forecast of PRICE and QUANTITY. Notice that the ASSUME data set does not need to contain the variables PRICE and QUANTITY. The HISTORY data set is shown as follows:

```
data history;
  input year income unitcost price quantity;
datalines;
1976    2221.87    3.31220    0.17903    266.714
1977    2254.77    3.61647    0.06757    276.049
1978    2285.16    2.21601    0.82916    285.858

... more lines ...
```

The ASSUME data set is shown as follows:

```
data assume;
  input year income unitcost;
datalines;
1986    2571.87    2.31220
1987    2609.12    2.45633
1988    2639.77    2.51647
1989    2667.77    1.65617
1990    2705.16    1.01601
;
```

The third data set, GOAL, used in a forecast of PRICE and UNITCOST as a function of INCOME and QUANTITY is as follows:

```
data goal;
  input year income quantity;
datalines;
1986    2571.87    371.4
1987    2721.08    416.5
1988    3327.05    597.3
1989    3885.85    764.1
1990    3650.98    694.3
;
```

The following statements fit the model to the HISTORY data set and solve the fitted model for the ASSUME data set.

```
proc model model=model outmodel=model;

/* estimate the model parameters */
  fit supply demand / data=history outest=est n2sls;
  instruments income unitcost year;
run;

/* produce forecasts for income and unitcost assumptions */
  solve price quantity / data=assume out=pq;
run;

title2 "Parameter Estimates for the System";
proc print data=est;
run;

title2 "Price Quantity Solution";
proc print data=pq;
run;
```

The model summary of the supply and demand model is shown as follows:

Example 19.7: Spring and Damper Continuous System

This model simulates the mechanical behavior of a spring and damper system shown in Figure 19.99.

Figure 19.99 Spring and Damper System Model

A mass is hung from a spring with spring constant K . The motion is slowed by a damper with damper constant C . The damping force is proportional to the velocity, while the spring force is proportional to the displacement.

This is actually a continuous system; however, the behavior can be approximated by a discrete time model. We approximate the differential equation

$$\frac{\partial \text{disp}}{\partial \text{time}} = \text{velocity}$$

with the difference equation

$$\frac{\Delta \text{disp}}{\Delta \text{time}} = \text{velocity}$$

This is rewritten as

$$\frac{\text{disp} - \text{LAG}(\text{disp})}{dt} = \text{velocity}$$

where dt is the time step used. In PROC MODEL, this is expressed with the program statement

```
disp = lag(disp) + vel * dt;
```

or

```
dert.disp = vel;
```

The first statement is simply a computing formula for Euler's approximation for the integral

$$disp = \int velocity \, dt$$

If the time step is small enough with respect to the changes in the system, the approximation is good. Although PROC MODEL does not have the variable step-size and error-monitoring features of simulators designed for continuous systems, the procedure is a good tool to use for less challenging continuous models.

The second form instructs the MODEL procedure to do the integration for you.

This model is unusual because there are no exogenous variables, and endogenous data are not needed. Although you still need a SAS data set to count the simulation periods, no actual data are brought in.

Since the variables DISP and VEL are lagged, initial values specified in the VAR statement determine the starting state of the system. The mass, time step, spring constant, and damper constant are declared and initialized by a CONTROL statement as shown in the following statements:

```
title1 'Simulation of Spring-Mass-Damper System';

/*- Data to drive the simulation time periods ---*/
data one;
  do n=1 to 100;
    output;
  end;
run;

proc model data=one outmodel=spring;
  var      force -200 disp 10 vel 0 accel -20 time 0;
  control  mass  9.2 c    1.5 dt  .1 k      20;
  force = -k * disp -c * vel;
  disp  = lag(disp) + vel * dt;
  vel   = lag(vel) + accel * dt;
  accel = force / mass;
  time  = lag(time) + dt;
run;
```

The displacement scale is zeroed at the point where the force of gravity is offset, so the acceleration of the gravity constant is omitted from the force equation. The control variable C and K represent the damper and the spring constants respectively.

The model is simulated three times, and the simulation results are written to output data sets. The first run uses the original initial conditions specified in the VAR statement. In the second run, the initial displacement is doubled; the results show that the period of the motion is unaffected by the amplitude. In the third run, the DERT. syntax is used to do the integration. Notice that the path of the displacement is close to the old path, indicating that the original time step is short enough to yield an accurate solution. These simulations are performed by the following statements:

```

proc model data=one model=spring;
  title2 "Simulation of the model for the base case";
  control run '1';
  solve / out=a;
run;

  title2 "Simulation of the model with twice the initial displacement";
  control run '2';
  var disp 20;
  solve / out=b;
run;

data two;
  do time = 0 to 10 by .2; output;end;
run;

title2 "Simulation of the model using the dert. syntax";
proc model data=two;
  var      force -200  disp  10  vel  0  accel -20  time 0;
  control  mass   9.2  c    1.5  dt   .1  k      20;
  control run '3' ;
  force = -k * disp -c * vel;
  dert.disp = vel ;
  dert.vel   = accel;
  accel = force / mass;
  solve / out=c;
  id time ;
run;

```

The output SAS data sets that contain the solution results are merged and the displacement time paths for the three simulations are plotted. The three runs are identified on the plot as 1, 2, and 3. The following statements produce [Output 19.7.1](#) through [Output 19.7.5](#).

```

data p;
  set a b c;
run;

title2 'Overlay Plot of All Three Simulations';
proc sgplot data=p;

Example 19.8: Nonlinear FIML Estimation

The data and model for this example were obtained from Bard (1974, p.133–138). The example is a two-equation econometric model used by Bodkin and Klein to fit U.S production data for the years 1909–1949. The model is the following:

$$g_1 = c_1 10^{c_2 z_4} (c_5 z_1^{-c_4} + (1 - c_5) z_2^{-c_4})^{-c_3/c_4} - z_3 = 0$$

$$g_2 = [c_5 / (1 - c_5)] (z_1 / z_2)^{(-1 - c_4)} - z_5 = 0$$

where z_1 is capital input, z_2 is labor input, z_3 is real output, z_4 is time in years with 1929 as year zero, and z_5 is the ratio of price of capital services to wage scale. The c_i 's are the unknown parameters. z_1 and z_2 are considered endogenous variables. A FIML estimation is performed by using the following statements:

```

data bodkin;
    input z1 z2 z3 z4 z5;
datalines;
1.33135 0.64629 0.4026 -20 0.24447
1.39235 0.66302 0.4084 -19 0.23454
1.41640 0.65272 0.4223 -18 0.23206
... more lines ...

title1 "Nonlinear FIML Estimation";

proc model data=bodkin;
    parms c1-c5;
    endogenous z1 z2;
    exogenous z3 z4 z5;

    eq.g1 = c1 * 10 ** (c2 * z4) * (c5*z1**(-c4)+
        (1-c5)*z2**(-c4))**(-c3/c4) - z3;
    eq.g2 = (c5/(1-c5))*(z1/z2)**(-1-c4) -z5;

    fit g1 g2 / fiml ;
run;

```

When FIML estimation is selected, the log likelihood of the system is output as the objective value. The results of the estimation are shown in [Output 19.8.1](#).

Example 19.9: Circuit Estimation

Consider the nonlinear circuit shown in Figure 19.100.

Figure 19.100 Nonlinear Resistor Capacitor Circuit

The theory of electric circuits is governed by Kirchhoff's laws: the sum of the currents flowing to a node is zero, and the net voltage drop around a closed loop is zero. In addition to Kirchhoff's laws, there are relationships between the current I through each element and the voltage drop V across the elements. For the circuit in Figure 19.100, the relationships are

$$C \frac{dV}{dt} = I$$

for the capacitor and

$$V = (R_1 + R_2(1 - \exp(-V)))I$$

for the nonlinear resistor. The following differential equation describes the current at node 2 as a function of time and voltage for this circuit:

$$C \frac{dV_2}{dt} - \frac{V_1 - V_2}{R_1 + R_2(1 - \exp(-V))} = 0$$

This equation can be written in the form

$$\frac{dV_2}{dt} = \frac{V_1 - V_2}{(R_1 + R_2(1 - \exp(-V)))C}$$

Consider the following data.

```

data circ;
  input v2 v1 time@@;
datalines;

;

```

You can estimate the parameters in the preceding equation by using the following SAS statements:

```

title1 'Circuit Model Estimation Example';

proc model data=circ mintimestep=1.0e-23;
  parm R2 2000 R1 4000 C 5.0e-13;
  dert.v2 = (v1-v2)/((r1 + r2*(1-exp( -(v1-v2)))) * C);
  fit v2;
run;

```

The results of the estimation are shown in [Output 19.9.1](#).

Output 19.9.1 Circuit Estimation

Circuit Model Estimation Example				
The MODEL Procedure				
Nonlinear OLS Parameter Estimates				
Parameter	Estimate	Approx Std Err	t Value	Approx Pr > t
R2	3002.471	1517.1	<-----	Biased
R1	4984.842	1466.8	<-----	Biased
C	5E-13	0	<-----	Biased
NOTE: The model was singular. Some estimates are marked 'Biased'.				

In this case, the model equation is such that there is linear dependency that causes biased results and inflated variances. The Jacobian matrix is singular or nearly singular, but eliminating one of the parameters is not a solution in this case.

Example 19.10: Systems of Differential Equations

The following is a simplified reaction scheme for the competitive inhibitors with recombinant human renin (Morelock et al. 1995).

Figure 19.101 Competitive Inhibition of Recombinant Human Renin

In Figure 19.101, E =enzyme, D =probe, and I =inhibitor.

The differential equations that describe this reaction scheme are as follows:

$$\begin{aligned}
 \frac{dD}{dt} &= k1r * ED - k1f * E * D \\
 \frac{dED}{dt} &= k1f * E * D - k1r * ED \\
 \frac{dE}{dt} &= k1r * ED - k1f * E * D + k2r * EI - k2f * E * I \\
 \frac{dEI}{dt} &= k2f * E * I - k2r * EI \\
 \frac{dI}{dt} &= k2r * EI - k2f * E * I
 \end{aligned}$$

For this system, the initial values for the concentrations are derived from equilibrium considerations (as a function of parameters) or are provided as known values.

The experiment used to collect the data was carried out in two ways; preincubation (type='disassoc') and no preincubation (type='assoc'). The data also contain repeated measurements. The data contain values for fluorescence F , which is a function of concentration. Since there are no direct data for the concentrations, all the differential equations are simulated dynamically.

The SAS statements used to fit this model are as follows:

```

title1 'Systems of Differential Equations Example';

proc sort data=fit;

Example 19.11: Monte Carlo Simulation

This example illustrates how the form of the error in a ODE model affects the results from a static and dynamic estimation. The differential equation studied is

$$\frac{dy}{dt} = a - ay$$

The analytical solution to this differential equation is

$$y = 1 - \exp(-at)$$

The first data set contains errors that are strictly additive and independent. The data for this estimation are generated by the following DATA step:

```
data drive1;
  a = 0.5;
  do iter=1 to 100;
    do time = 0 to 50;
      y = 1 - exp(-a*time) + 0.1 *rannor(123);
      output;
    end;
  end;
run;
```

The second data set contains errors that are cumulative in form.

```
data drive2;
  a = 0.5;
  yp = 1.0 + 0.01 *rannor(123);
  do iter=1 to 100;
    do time = 0 to 50;
      y = 1 - exp(-a)*(1 - yp);
      yp = y + 0.01 *rannor(123);
      output;
    end;
  end;
run;
```

The following statements perform the 100 static estimations for each data set:

```

title1 'Monte Carlo Simulation of ODE';

proc model data=drive1 noprint;
  parm a 0.5;
  dert.y = a - a * y;
  fit y / outest=est;
  by iter;
run;

```

Similar statements are used to produce 100 dynamic estimations with a fixed and an unknown initial value. The first value in the data set is used to simulate an error in the initial value. The following PROC UNIVARIATE statements process the estimations:

```

proc univariate data=est noprint;
  var a;
  output out=monte mean=mean p5=p5 p95=p95;
run;

proc print data=monte;
run;

```

The results of these estimations are summarized in [Table 19.6](#).

Table 19.6 Monte Carlo Summary, A=0.5

Estimation Type	Additive Error			Cumulative Error		
	mean	p95	p5	mean	p95	p5
static	0.77885	1.03524	0.54733	0.57863	1.16112	0.31334
dynamic fixed	0.48785	0.63273	0.37644	3.8546E24	8.88E10	-51.9249
dynamic unknown	0.48518	0.62452	0.36754	641704.51	1940.42	-25.6054

For this example model, it is evident that the static estimation is the least sensitive to misspecification.

Example 19.12: Cauchy Distribution Estimation

In this example a nonlinear model is estimated by using the Cauchy distribution. Then a simulation is done for one observation in the data.

The following DATA step creates the data for the model.

```

/* Generate a Cauchy distributed Y */
data c;
  format date monyy.;
  call streaminit(156789);
  do t=0 to 20 by 0.1;
    date=intnx('month', '01jun90'd, (t*10)-1);
    x=rand('normal');
    e=rand('cauchy') + 10 ;
    y=exp(4*x)+e;
    output;
  end;
run;

```

The model to be estimated is

$$y = e^{-a x} + \epsilon$$

$$\epsilon \sim \text{Cauchy}(nc)$$

That is, the residuals of the model are distributed as a Cauchy distribution with noncentrality parameter nc .

The log likelihood for the Cauchy distribution is

$$\text{ll} = -\log \pi(1 + (x - nc)^2)$$

The following SAS statements specify the model and the log-likelihood function.

```

title1 'Cauchy Distribution';

proc model data=c ;
  dependent y;
  parm a -2 nc 4;
  y=exp(-a*x);

  /* Likelihood function for the residuals */
  obj = log(constant('pi')*(1+(-resid.y-nc)**2));

  errormodel y ~ general(obj) cdf=cauchy(nc);

  fit y / outsn=s1 method=marquardt;
  solve y / sdata=s1 data=c(obs=1) random=1000
          seed=256789 out=out1;
run;

title 'Distribution of Y';
proc sgplot data=out1;
  histogram y;
run;

```

The FIT statement uses the OUTSN= option to output the Σ matrix for residuals from the normal distribution. The Σ matrix is 1×1 and has value 1.0 because it is a correlation matrix. The OUTS= matrix is the scalar 2989.0. Because the distribution is univariate (no covariances), the OUTS= option would produce the same simulation results. The simulation is performed by using the SOLVE statement.

The distribution of y is shown in the following output.

Output 19.12.1 Distribution of Y

Example 19.13: Switching Regression Example

Take the usual linear regression problem

$$y = \mathbf{X}\beta + u$$

where Y denotes the n column vector of the dependent variable, \mathbf{X} denotes the $(n \times k)$ matrix of independent variables, β denotes the k column vector of coefficients to be estimated, n denotes the number of observations ($i = 1, 2, \dots, n$), and k denotes the number of independent variables.

You can take this basic equation and split it into two regimes, where the i th observation on y is generated by one regime or the other:

$$y_i = \sum_{j=1}^k \beta_{1j} X_{ji} + u_{1i} = x_i' \beta_1 + u_{1i}$$

$$y_i = \sum_{j=1}^k \beta_{2j} X_{ji} + u_{2i} = x_i' \beta_2 + u_{2i}$$

where x_{hi} and x_{hj} are the i th and j th observations, respectively, on x_h . The errors, u_{1i} and u_{2i} , are assumed to be distributed normally and independently with mean zero and constant variance. The variance for the first regime is σ_1^2 , and the variance for the second regime is σ_2^2 . If $\sigma_1^2 \neq \sigma_2^2$ and $\beta_1 \neq \beta_2$, the regression system given previously is thought to be switching between the two regimes.

The problem is to estimate β_1 , β_2 , σ_1 , and σ_2 without knowing *a priori* which of the n values of the dependent variable, y , was generated by which regime. If it is known *a priori* which observations belong to which regime, a simple Chow test can be used to test $\sigma_1^2 = \sigma_2^2$ and $\beta_1 = \beta_2$.

Using Goldfeld and Quandt's D-method for switching regression, you can solve this problem. Assume that observations exist on some exogenous variables $z_{1i}, z_{2i}, \dots, z_{pi}$, where z determines whether the i th observation is generated from one equation or the other. The equations are given as follows:

$$y_i = x_i' \beta_1 + u_{1i} \quad \text{if } \sum_{j=1}^p \pi_j z_{ji} \leq 0$$

$$y_i = x_i' \beta_2 + u_{2i} \quad \text{if } \sum_{j=1}^p \pi_j z_{ji} > 0$$

where π_j are unknown coefficients to be estimated. Define $d(z_i)$ as a continuous approximation to a step function. Replacing the unit step function with a continuous approximation by using the cumulative normal integral enables a more practical method that produces consistent estimates.

$$d(z_i) = \frac{1}{\sqrt{2\pi}\sigma} \int_{-\infty}^{\sum \pi_j z_{ji}} \exp\left[-\frac{1}{2} \frac{\xi^2}{\sigma^2}\right] d\xi$$

D is the n dimensional diagonal matrix consisting of $d(z_i)$:

$$\mathbf{D} = \begin{bmatrix} d(z_1) & 0 & 0 & 0 \\ 0 & d(z_2) & 0 & 0 \\ 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & d(z_n) \end{bmatrix}$$

The parameters to estimate are now the k β_1 's, the k β_2 's, σ_1^2 , σ_2^2 , p π 's, and the σ introduced in the $d(z_i)$ equation. The σ can be considered as given *a priori*, or it can be estimated, in which case, the estimated magnitude provides an estimate of the success in discriminating between the two regimes (Goldfeld and Quandt 1976). Given the preceding equations, the model can be written as:

$$Y = (\mathbf{I} - \mathbf{D}) \mathbf{X} \beta_1 + \mathbf{D} \mathbf{X} \beta_2 + W$$

where $W = (\mathbf{I} - \mathbf{D})U_1 + \mathbf{D}U_2$, and W is a vector of unobservable and heteroscedastic error terms. The covariance matrix of W is denoted by $\mathbf{\Omega}$, where $\mathbf{\Omega} = (\mathbf{I} - \mathbf{D})^2\sigma_1^2 + \mathbf{D}^2\sigma_2^2$. The maximum likelihood parameter estimates maximize the following log-likelihood function.

$$\begin{aligned} \log L = & -\frac{n}{2} \log 2\pi - \frac{1}{2} \log |\mathbf{\Omega}| - \\ & \frac{1}{2} * [Y - (\mathbf{I} - \mathbf{D})\mathbf{X}\beta_1 - \mathbf{D}\mathbf{X}\beta_2]' \mathbf{\Omega}^{-1} [Y - (\mathbf{I} - \mathbf{D})\mathbf{X}\beta_1 - \mathbf{D}\mathbf{X}\beta_2] \end{aligned}$$

As an example, you now can use this switching regression likelihood to develop a model of housing starts as a function of changes in mortgage interest rates. The data for this example are from the U.S. Census Bureau and cover the period from January 1973 to March 1999. The hypothesis is that there are different coefficients on your model based on whether the interest rates are going up or down.

So the model for z_i is

$$z_i = p * (\text{rate}_i - \text{rate}_{i-1})$$

where rate_i is the mortgage interest rate at time i and p is a scale parameter to be estimated.

The regression model is

$$\begin{aligned} \text{starts}_i &= \text{intercept}_1 + \text{ar1} * \text{starts}_{i-1} + \text{djf1} * \text{decjanfeb} & z_i < 0 \\ \text{starts}_i &= \text{intercept}_2 + \text{ar2} * \text{starts}_{i-1} + \text{djf2} * \text{decjanfeb} & z_i \geq 0 \end{aligned}$$

where starts_i is the number of housing starts at month i and decjanfeb is a dummy variable that indicates that the current month is one of December, January, or February.

This model is written by using the following SAS statements:

```

title1 'Switching Regression Example';

proc model data=switch;
  parms sig1=10 sig2=10 int1 b11 b13 int2 b21 b23 p;
  bounds 0.0001 < sig1 sig2;

  decjanfeb = ( month(date) = 12 | month(date) <= 2 );

  a = p*dif(rate);          /* Upper bound of integral */
  d = probnorm(a);          /* Normal CDF as an approx of switch */

  /* Regime 1 */
  y1 = int1 + zlag(starts)*b11 + decjanfeb *b13 ;
  /* Regime 2 */
  y2 = int2 + zlag(starts)*b21 + decjanfeb *b23 ;
  /* Composite regression equation */
  starts = (1 - d)*y1 + d*y2;

  /* Resulting log-likelihood function */
  logL = (1/2)* ( log(2*3.1415) ) +
    log( (sig1**2)*((1-d)**2)+(sig2**2)*(d**2) )
    + (resid.starts*( 1/( (sig1**2)*((1-d)**2)+

```

```

      (sig2**2)*(d**2) ) *resid.starts) ) ;

errormodel starts ~ general(logL);

fit starts / method=marquardt converge=1.0e-5;

/* Test for significant differences in the parms */
test int1 = int2 ,/ lm;
test b11 = b21 ,/ lm;
test b13 = b23 ,/ lm;
test sig1 = sig2 ,/ lm;

run;

```

Four TEST statements are added to test the hypothesis that the parameters are the same in both regimes. The parameter estimates and ANOVA table from this run are shown in [Output 19.13.1](#).

Output 19.13.1 Parameter Estimates from the Switching Regression

Example 19.14: Simulating from a Mixture of Distributions

This example illustrates how to perform a multivariate simulation by using models that have different error distributions. Three models are used. The first model has t distributed errors. The second model is a GARCH(1,1) model with normally distributed errors. The third model has a noncentral Cauchy distribution.

The following SAS statements generate the data for this example. The t and the CAUCHY data sets use a common seed so that those two series are correlated.

```

/* set distribution parameters */
%let df = 7.5;
%let sig1 = .5;
%let var2 = 2.5;

data t;
  format date monyy.;
  do date='1jun2001'd to '1nov2002'd;
    /* t-distribution with df,sig1 */
    t = .05 * date + 5000 + &sig1*tinv(ranuni(1234),&df);
    output;
  end;
run;

data normal;
  format date monyy.;
  le = &var2;
  lv = &var2;
  do date='1jun2001'd to '1nov2002'd;
    /* Normal with GARCH error structure */
    v = 0.0001 + 0.2 * le**2 + .75 * lv;
    e = sqrt(v) * rannor(12345);
    normal = 25 + e;
    le = e;
    lv = v;
    output;
  end;
run;

```

```

data cauchy;
  format date monyy.;
  PI = 3.1415926;
  do date='1jun2001'd to '1nov2002'd;
    cauchy = -4 + tan((ranuni(1234) - 0.5) * PI);
    output;
  end;
run;

```

Since the multivariate joint likelihood is unknown, the models must be estimated separately. The residuals for each model are saved by using the OUT= option. Also, each model is saved by using the OUTMODEL= option. The ID statement is used to provide a variable in the residual data set to merge by. The XLAG function is used to model the GARCH(1,1) process. The XLAG function returns the lag of the first argument if it is nonmissing, otherwise it returns the second argument.

```

title1 't-distributed Errors Example';

proc model data=t outmod=tModel;
  parms df 10 vt 4;
  t = a * date + c;
  errormodel t ~ t( vt, df );
  fit t / out=tresid;
  id date;
run;

title1 'GARCH-distributed Errors Example';

proc model data=normal outmodel=normalModel;
  normal = b0 ;
  h.normal = arch0 + arch1 * xlag(resid.normal **2 , mse.normal)
    + GARCH1 * xlag(h.normal, mse.normal);

  fit normal /fiml out=nresid;
  id date;
run;

title1 'Cauchy-distributed Errors Example';

proc model data=cauchy outmod=cauchyModel;
  parms nc = 1;
  /* nc is noncentrality parm to Cauchy dist */
  cauchy = nc;
  obj = log(1+resid.cauchy**2 * 3.1415926);
  errormodel cauchy ~ general(obj) cdf=cauchy(nc);

  fit cauchy / out=cresid;
  id date;
run;

```

The simulation requires a covariance matrix created from normal residuals. The following DATA step statements use the inverse CDFs of the t and Cauchy distributions to convert the residuals to the normal distribution. The CORR procedure is used to create a correlation matrix that uses the converted residuals.

```

/* Merge and normalize the 3 residual data sets */
data c; merge tresid nresid cresid; by date;
    t = probit(cdf("T", t/sqrt(0.2789), 16.58 ));
    cauchy = probit(cdf("CAUCHY", cauchy, -4.0623));
run;

proc corr data=c out=s;
    var t normal cauchy;
run;

```

Now the models can be simulated together by using the MODEL procedure SOLVE statement. The data set created by the CORR procedure is used as the correlation matrix.

```

title1 'Simulating Equations with Different Error Distributions';

/* Create one observation driver data set */
data sim; merge t normal cauchy; by date;
data sim; set sim(firstobs = 519 );

proc model data=sim model=( tModel normalModel cauchyModel );
    errormodel t ~ t( vt, df );
    errormodel cauchy ~ cauchy(nc);
    solve t cauchy normal / random=2000 seed=1962 out=monte
        sdata=s(where=(_type_="CORR"));
run;

```

An estimation of the joint density of the t and Cauchy distribution is created by using the KDE procedure. Bounds are placed on the Cauchy dimension because of its fat tail behavior. The joint PDF is shown in [Output 19.14.1](#).

```

title "T and Cauchy Distribution";

proc kde data=monte;
    univar t          / out=t_dens;
    univar cauchy     / out=cauchy_dens;
    bivar t cauchy    / out=density
                    plots=all;
run;

```

Example 19.15: Simulated Method of Moments—Simple Linear Regression

This example illustrates how to use SMM to estimate a simple linear regression model for the following process:

$$y = a + bx + \epsilon, \epsilon \sim iid N(0, s^2)$$

In the following SAS statements, $ysim$ is simulated, and the first moment and the second moment of $ysim$ are compared with those of the observed endogenous variable y .

```
title "Simple regression model";

data regdata;
  do i=1 to 500;
    x = rannor( 1013 );
    Y = 2 + 1.5 * x + 1.5 * rannor( 1013 );
    output;
  end;
run;
```

```

proc model data=regdata;
  parms a b s;
  instrument x;

  ysim = (a+b*x) + s * rannor( 8003 );
  y = ysim;
  eq.ysq = y*y - ysim*ysim;

  fit y ysq / gmm ndraw;
  bound s > 0;
run;

```

Alternatively, the MOMENT statement can be used to specify the moments using the following syntax:

```

proc model data=regdata;
  parms a b s;
  instrument x;

  ysim = (a+b*x) + s * rannor( 8003 );
  y = ysim;
  moment y = (2);

  fit y / gmm ndraw;
  bound s > 0;
run;

```

The output of the MODEL procedure is shown in [Output 19.15.1](#):

Example 19.16: Simulated Method of Moments—AR(1) Process

This example illustrates how to use SMM to estimate an AR(1) regression model for the following process:

$$\begin{aligned}
 y_t &= a + bx_t + u_t \\
 u_t &= \alpha u_{t-1} + \epsilon_t \\
 \epsilon_t &\sim iid N(0, s^2)
 \end{aligned}$$

In the following SAS statements, *ysim* is simulated by using this model, and the endogenous variable *y* is set to be equal to *ysim*. The **MOMENT** statement creates two more moments for the estimation. One is the second moment, and the other is the first-order autocovariance. The **NPREOBS=10** option instructs **PROC MODEL** to run the simulation 10 times before *ysim* is compared to the first observation of *y*. Because the initial *zlag(u)* is zero, the first *ysim* is $a + b * x + s * \text{rannor}(8003)$. Without the **NPREOBS** option, this *ysim* is matched with the first observation of *y*. With **NPREOBS**, this *ysim* and the next nine *ysim* are thrown away, and the moment match starts with the eleventh *ysim* with the first observation of *y*. This way, the initial values do not exert a large influence on the simulated endogenous variables.

```

Example 19.17: Simulated Method of Moments—Stochastic Volatility Model

This example illustrates how to use SMM to estimate a stochastic volatility model as in Andersen and Sorensen (1996):

$$\begin{aligned}y_t &= \sigma_t z_t \\ \log(\sigma_t^2) &= a + b \log(\sigma_{t-1}^2) + s u_t \\ (z_t, u_t) &\sim iid N(0, I_2)\end{aligned}$$

This model is widely used in modeling the return process of stock prices and foreign exchange rates. This is called the stochastic volatility model because the volatility is stochastic as the random variable u_t appears in the volatility equation. The following SAS statements use three moments: absolute value, the second-order moment, and absolute value of the first-order autoregressive moment. Note the ADJSMMV option in the FIT statement to request the SMM covariance adjustment for the parameter estimates. Although these moments have closed form solution as shown by Andersen and Sorensen (1996), the simulation approach significantly simplifies the moment conditions.

```
%let nob=1000;

Example 19.18: Duration Data Model with Unobserved Heterogeneity

All of the previous three models actually have closed-form moment conditions, so the simulation approach is not necessarily required for the estimation. This example illustrates how to use SMM to estimate a model for which there is no closed-form solution for the moments and thus the traditional GMM method does not apply. The model is the duration data model with unobserved heterogeneity in [Gourieroux and Monfort \(1993\)](#):

$$y_i = -\exp(-bx_i - \sigma u_i) \log(v_i)$$

$$u_i \sim N(0, 1) \quad v_i \sim U[0, 1]$$

The SAS statements are:

```

Example 19.19: EMM Estimation of a Stochastic Volatility Model

The efficient method of moments (EMM), introduced by Bansal et al. (1993 and 1995) and Gallant and Tauchen (2001), can be considered a variant of SMM. The idea is to match the efficiency of the maximum likelihood (ML) estimation with the flexibility of the SMM procedure. ML itself can be interpreted as a method of moments procedure, where the *score vector*, the vector of derivatives of the log-likelihood function with respect to the parameters, provides the exactly identifying moment conditions. EMM employs an auxiliary (or pseudo) model that closely matches the true model. The score vector of the auxiliary model provides the moment conditions in the SMM step.

This example uses the SMM feature of PROC MODEL to estimate the simple stochastic volatility (SV) model of [Example 19.17](#) with the EMM method.

Suppose that your data are the time series $\{y_1, y_2, \dots, y_n\}$, and the model that you want to estimate, or the structural model, is characterized by the vector of parameters θ . For the SV model, θ is given by (a, b, s) .

The first step of the EMM method is to fit the data with an auxiliary model (or score generator) that has transition density $f(y_t|Y_{t-1}, \eta)$, parametrized by the pseudo parameter η , where $Y_{t-1} = \{y_{t-1}, \dots, y_1\}$. The auxiliary model must approximate the true data-generating process as closely as possible and be such that ML estimation is feasible.

The only identification requirement is that the dimension of the pseudo parameter η be greater than or equal to that of the structural parameter θ .

Andersen, Chung, and Sorensen (1999) showed that the GARCH(1,1) is an appropriate auxiliary model that leads to a good performance of the EMM estimator for the SV model.

The analytical expression for the GARCH(1,1) model with mean zero is

$$\begin{aligned} y_t &= \sigma_t z_t \\ \sigma_t^2 &= \omega + \alpha y_{t-1} + \beta \sigma_{t-1}^2 \end{aligned}$$

The pseudo parameter vector η is given by (ω, α, β) .

One advantage of such a class of models is that the conditional density of y_t is Gaussian—that is,

$$f(y_t|Y_{t-1}, \eta) \propto \frac{1}{\sigma_t} \exp\left(-\frac{y_t^2}{2\sigma_t^2}\right)$$

Therefore the score vector can easily be computed analytically.

The AUTOREG procedure provides the ML estimates, $\hat{\eta}_n$. The output is stored in the garchout data set, while the estimates are stored in the garchest data set.

```

title1 'Efficient Method of Moments for Stochastic Volatility Model';

/* estimate GARCH(1,1) model */
proc autoreg data=svdata(keep=y)
    outest=garchest
    noprint covout;
    model y = / noint garch=(q=1,p=1);
    output out=garchout cev=gsigmasq r=resid;
run;

```

If the pseudo model is close enough to the structural model, in a suitable sense, Gallant and Long (1997) showed that a consistent estimator of the asymptotic covariance matrix of the sample pseudo-score vector can be obtained from the formula

$$\hat{\mathbf{V}}_n = \frac{1}{n} \sum_{t=1}^n s_f(Y_t, \hat{\eta}_n) s_f(Y_t, \hat{\eta}_n)'$$

where $s_f(Y_t, \hat{\eta}_n) = (\partial/\partial\eta_n) \log f(y_t|Y_{t-1}, \hat{\eta}_n)$ denotes the score function of the auxiliary model computed at the ML estimates.

The ML estimates of the GARCH(1,1) model are used in the following SAS statements to compute the variance-covariance matrix $\hat{\mathbf{V}}_n$.

```

/* compute the V matrix */
data vvalues;
    set garchout(keep=y gsigmasq resid);

    /* compute scores of GARCH model */
    score_1 = (-1 + y**2/gsigmasq) / gsigmasq;
    score_2 = (-1 + y**2/gsigmasq)*lag(gsigmasq) / gsigmasq;
    score_3 = (-1 + y**2/gsigmasq)*lag(y**2) / gsigmasq;

    array score{*} score_1-score_3;
    array v_t{*} v_t_1-v_t_6;
    array v{*} v_1-v_6;

    /* compute external product of score vector */
    do i=1 to 3;
        do j=i to 3;
            v_t{j*(j-1)/2 + i} = score{i}*score{j};
        end;
    end;

```

```

/* average them over t */
do s=1 to 6;
    v{s}+ v_t{s}/&nobs;
end;
run;

```

The $\hat{\mathbf{V}}$ matrix must be formatted to be used with the VDATA= option of the MODEL procedure. See the section “VDATA= Input data set” on page 1176 for more information about the VDATA= data set.

```

/* Create a VDATA dataset acceptable to PROC MODEL */

/* Transpose the last obs in the dataset */
proc transpose data=vvalues(firstobs=&nobs keep=v_1-v_6)
    out=tempv;
run;

/* Add eq and inst labels */
data vhat;
    set tempv(drop=_name_);
    value = coll;
    drop coll;
    input _type_ $ eq_row $ eq_col $ inst_row $ inst_col $; *$;
    datalines;
        gmm m1 m1 1 1 /* intcpt is the only inst we use */
        gmm m1 m2 1 1
        gmm m2 m2 1 1
        gmm m1 m3 1 1
        gmm m2 m3 1 1
        gmm m3 m3 1 1
    ;

```

The last step of the EMM procedure is to estimate θ by using SMM, where the moment conditions are given by the scores of the auxiliary model.

Given a fixed value of the parameter vector θ and an arbitrarily large T , one can simulate a series $\{\hat{y}_1(\theta), \hat{y}_2(\theta), \dots, \hat{y}_T(\theta)\}$ from the structural model. The EMM estimator is the value $\hat{\theta}_n$ that minimizes the quantity

$$m_T(\theta, \hat{\eta}_n)' \hat{\mathbf{V}}_n^{-1} m_T(\theta, \hat{\eta}_n)$$

where

$$m_T(\theta, \hat{\eta}_n) = \frac{1}{T} \sum_{k=1}^T s_f(\hat{Y}_k(\theta), \hat{\eta}_n)$$

is the sample moment condition evaluated at the fixed estimated pseudo parameter $\hat{\eta}_n$. Note that the target function depends on the parameter θ only through the simulated series \hat{y}_k .

The following statements generate a data set that contains $T = 20,000$ replicates of the estimated pseudo parameter $\hat{\eta}_n$ and that is then input to the MODEL procedure. The EMM estimates are found by using the SMM option of the FIT statement. The $\hat{\mathbf{V}}_n$ matrix computed above serves as weighting matrix by using the VDATA= option, and the scores of the GARCH(1,1) auxiliary model evaluated at the ML estimates are the moment conditions in the GMM step.

Since the number of structural parameters to estimate (3) is equal to the number of moment equations (3) times the number of instruments (1), the model is exactly identified and the objective function has value zero at the minimum.

For simplicity, the starting values are set to the true values of the parameters.

```

/* USE SMM TO FIND EMM ESTIMATES */

/* Generate dataset of length T */
data emm;
    set garchest(obs=1 keep = _ah_0 _ah_1 _gh_1 _mse_);

Example 19.20: Illustration of ODS Graphics

This example illustrates graphical output from PROC MODEL. This is a continuation of the section “[Nonlinear Regression Analysis](#)” on page 1019. For information about the graphics available in the MODEL procedure, see the section “[ODS Graphics](#)” on page 1183.

The following statements show how to generate ODS Graphics plots with the MODEL procedure. The plots are displayed in [Output 19.20.1](#) and [Output 19.20.2](#). Note that the variable date in the ID statement is used to define the horizontal tick mark values when appropriate.

```

title1 'Example of Graphical Output from PROC MODEL';

proc model data=sashelp.citimon;
  lhur = 1/(a * ip + b) + c;
  fit lhur;
  id date;
run;

```

Output 19.20.1 Diagnostics Plots

Output 19.20.2 Diagnostics Plots

You can also obtain the plots in the diagnostics panel as separate graphs by specifying the PLOTS(UNPACK) option. These plots are displayed in [Output 19.20.3](#) through [Output 19.20.10](#).

```

title1 'Unpacked Graphical Output from PROC MODEL';

proc model data=sashelp.citimon plots(unpack);
  lhur = 1/(a * ip + b) + c;
  fit lhur;
  id date;
run;

```

Output 19.20.3 Studentized Residuals Plot

Output 19.20.4 Cook's D Plot

Output 19.20.5 Predicted versus Actual Plot

Output 19.20.6 Autocorrelation of Residuals Plot

Output 19.20.7 Partial Autocorrelation of Residuals Plot

Output 19.20.8 Inverse Autocorrelation of Residuals Plot

Output 19.20.9 Q-Q Plot of Residuals

Output 19.20.10 Histogram of Residuals

Overview: PANEL Procedure

The PANEL procedure analyzes a class of linear econometric models that commonly arise when time series and cross-sectional data are combined. This type of pooled data on time series cross-sectional bases is often referred to as panel data. Typical examples of panel data include observations over time on households, countries, firms, trade, and so on. For example, in the case of survey data on household income, the panel is created by repeatedly surveying the same households in different time periods (years).

The panel data models can be grouped into several categories depending on the structure of the error term. The PANEL procedure uses the following error structures and the corresponding methods to analyze data:

- one-way and two-way models
- fixed-effects and random-effects models
- autoregressive models
- moving average models

A one-way model depends only on the cross section to which the observation belongs. A two-way model depends on both the cross section and the time period to which the observation belongs.

Apart from the possible one-way or two-way nature of the effect, the other dimension of difference between the possible specifications is the nature of the cross-sectional or time-series effect. The models are referred to as fixed-effects models if the effects are nonrandom and as random-effects models otherwise.

If the effects are fixed, the models are essentially regression models with dummy variables that correspond to the specified effects. For fixed-effects models, ordinary least squares (OLS) estimation is the best linear unbiased estimator. Random-effects models use a two-stage approach. In the first stage, variance components are calculated by using methods described by Fuller and Battese (1974), Wansbeek and Kapteyn (1984), Wallace and Hussain (1969), or Nerlove (1971). In the second stage, variance components are used to standardize the data, and ordinary least squares (OLS) regression is performed.

Two types of models in the PANEL procedure accommodate an autoregressive structure: The Parks method estimates a first-order autoregressive model with contemporaneous correlation, and the dynamic panel estimator estimates an autoregressive model with lagged dependent variable.

The Da Silva method estimates a mixed variance-component moving-average error process. The regression parameters are estimated by using a two-step generalized least squares (GLS)-type estimator.

The PANEL procedure enhances the features that were implemented in the TSCSREG procedure. The following list shows the most important additions.

- New estimation methods include between estimators, pooled estimators, and dynamic panel estimators that use the generalized method of moments (GMM). The variance components for random-effects models can be calculated for both balanced and unbalanced panels by using the methods described by Fuller and Battese (1974), Wansbeek and Kapteyn (1984), Wallace and Hussain (1969), or Nerlove (1971).
- The CLASS statement creates classification variables that are used in the analysis.
- The TEST statement includes new options for Wald, Lagrange multiplier, and the likelihood ratio tests.
- The new RESTRICT statement specifies linear restrictions on the parameters.
- The FLATDATA statement enables the data to be in a compressed form.
- Several methods that produce heteroscedasticity-consistent covariance matrices (HCCME) are added because the presence of heteroscedasticity can result in inefficient and biased estimates of the variance-covariance matrix in the OLS framework.
- The LAG statement can generate a large number of missing values, depending on lag order. Typically, it is difficult to create lagged variables in the panel setting. If lagged variables are created in a DATA step, several programming steps that include loops are often needed. By including the LAG statement, the PANEL procedure makes the creation of lagged values easy. The missing values can be replaced with zeros, overall mean, time mean, or cross section mean by using the LAG, ZLAG, XLAG, SLAG, and CLAG statements.
- The OUTPUT statement enables you to output data and estimates that can be used in other analyses.

Getting Started: PANEL Procedure

This section demonstrates the use of the PANEL procedure.

Specifying the Input Data

The PANEL procedure is similar to other regression procedures in SAS. Suppose you want to regress the variable *Y* on regressors *X1* and *X2*. Cross sections are identified by the variable *STATE*, and time periods are identified by the variable *DATE*. The input data set used by PROC PANEL must be sorted by cross section and by time within each cross section. Therefore, the first step in PROC PANEL is to make sure that the input data set is sorted. The following statements sort the data set *A* appropriately:

```
proc sort data=a;
  by state date;
run;
```

The next step is to invoke the PANEL procedure and specify the cross section and time series variables in an ID statement. The following statements show the correct syntax:

```
proc panel data=a;
  id state date;
  model y = x1 x2;
run;
```

Alternatively, PROC PANEL has the capability to read “flat” data. Say that you are using the data set *A*, which has observations on states. Specifically, the data are composed of observations on *Y*, *X1*, and *X2*. Unlike the previous case, the data is not recorded with a PROC PANEL structure. Instead, you have all of a state’s information on a single row. You have variables to denote the name of the state (say *state*). The time observations for the *Y* variable are recorded horizontally. So the variable *Y_1* is the first period’s time observation, *Y_10* is the tenth period’s observation for some state. The same holds for the other variables. You have variables *X1_1* to *X1_10*, *X2_1* to *X2_10*, and *X3_1* to *X3_10* for others. With such data, PROC PANEL could be called by using the following syntax:

```
proc panel data=a;
  flatdata indid = state base = (Y X1 X2) tsname = t;
  id state t;
  model Y = X1 X2;
run;
```

See “[FLATDATA Statement](#)” on page 1346 and [Example 20.2](#) for more information about the use of the FLATDATA statement.

Specifying the Regression Model

The MODEL statement in PROC PANEL is specified like the MODEL statement in other SAS regression procedures: the dependent variable is listed first, followed by an equal sign, followed by the list of regressor variables, as shown in the following statements:

```
proc panel data=a;
    id state date;
    model y = x1 x2;
run;
```

The major advantage of using PROC PANEL is that you can incorporate a model for the structure of the random errors. It is important to consider what kind of error structure model is appropriate for your data and to specify the corresponding option in the MODEL statement.

The error structure options supported by the PANEL procedure are FIXONE, FIXONETIME, FIXTWO, RANONE, RANTWO, PARKS, DASILVA, GMM, and ITGMM (iterated GMM). See the section “[Details: PANEL Procedure](#)” on page 1363 for more information about these methods and the error structures they assume. The following statements fit a Fuller-Battese one-way random-effects model:

```
proc panel data=a;
    id state date;
    model y = x1 x2 / ranone vcomp=fb;
run;
```

You can specify more than one error structure option in the MODEL statement; the analysis is repeated using each specified method. You can use any number of MODEL statements to estimate different regression models or estimate the same model by using different options. See [Example 20.1](#) for more information.

To aid in model specification within this class of models, PROC PANEL provides two specification test statistics. The first is an F statistic that tests the null hypothesis that the fixed-effects parameters are all 0. The second is a Hausman m statistic that provides information about the appropriateness of the random-effects specification. The m statistic is based on the idea that, under the null hypothesis of no correlation between the effects variables and the regressors, OLS and GLS are consistent. However, OLS is inefficient. Hence, a test can be based on the result that the covariance of an efficient estimator with its difference from an inefficient estimator is 0. Rejection of the null hypothesis might suggest that the fixed-effects model is more appropriate.

The PANEL procedure also provides the Buse R square measure. This number is interpreted as a measure of the proportion of the transformed sum of squares of the dependent variable that is attributable to the influence of the independent variables. In the case of OLS estimation, the Buse R square measure is equivalent to the usual R square measure.

Unbalanced Data

For fixed-effects models, random-effects models, between estimators, and dynamic panel estimators, the PANEL procedure can process data with different numbers of time series observations across different cross

sections. The Parks and Da Silva methods cannot be used with unbalanced data. The missing time series observations are recognized by the absence of time series ID variable values in some of the cross sections in the input data set. Moreover, if an observation with a particular time series ID value and cross-sectional ID value is present in the input data set, but one or more of the model variables are missing, that time series point is treated as missing for that cross section.

Introductory Example

The following statements use the cost function data from Greene (1990) to estimate the variance components model. The variable PRODUCTION is the log of output in millions of kilowatt-hours, and COST is the log of cost in millions of dollars. Refer to Greene (1990) for details.

```
data greene;
  input firm year production cost @@;
datalines;
1 1955 5.36598 1.14867 1 1960 6.03787 1.45185
1 1965 6.37673 1.52257 1 1970 6.93245 1.76627

... more lines ...
```

You decide to fit the following model to the data:

$$C_{it} = \text{Intercept} + \beta P_{it} + v_i + e_t + \epsilon_{it} \quad i = 1, \dots, N; \quad t = 1, \dots, T$$

where C_{it} and P_{it} represent the cost and production, and v_i , e_t and ϵ_{it} are the cross-sectional, time series, and error variance components.

If you assume that the time and cross-sectional effects are random, you are left with four possible estimators for the variance components. You choose Fuller-Battese.

The following statements fit this model.

```
proc sort data=greene;
  by firm year;
run;

proc panel data=greene;
  model cost = production / rantwo vcomp = fb;
  id firm year;
run;
```

The PANEL procedure output is shown in [Figure 20.1](#). A model description is printed first, which reports the estimation method used and the number of cross sections and time periods. The variance components estimates are printed next. Finally, the table of regression parameter estimates shows the estimates, standard errors, and t tests.

Figure 20.1 The Variance Components Estimates

The PANEL Procedure					
Fuller and Battese Variance Components (RanTwo)					
Dependent Variable: cost					
Model Description					
Estimation Method	RanTwo				
Number of Cross Sections	6				
Time Series Length	4				
Fit Statistics					
SSE	0.3481	DFE	22		
MSE	0.0158	Root MSE	0.1258		
R-Square	0.8136				
Variance Component Estimates					
Variance Component for Cross Sections	0.046907				
Variance Component for Time Series	0.00906				
Variance Component for Error	0.008749				
Hausman Test for Random Effects					
DF	m Value	Pr > m			
1	26.46	<.0001			
Parameter Estimates					
Variable	DF	Estimate	Standard Error	t Value	Pr > t
Intercept	1	-2.99992	0.6478	-4.63	0.0001
production	1	0.746596	0.0762	9.80	<.0001

Syntax: PANEL Procedure

The following statements are used with the PANEL procedure.

```

PROC PANEL options ;
  BY variables ;
  CLASS options ;
  FLATDATA options ;
  ID cross-section-id time-series-id ;
  INSTRUMENTS options ;
  LAG options ;
  MODEL dependent = regressors < / options > ;
  RESTRICT equation1 < ,equation2... > ;
  TEST equation1 < ,equation2... > ;

```

Functional Summary

The statements and options used with the PANEL procedure are summarized in the following table.

Description	Statement	Option
Data Set Options		
Includes correlations in the OUTEST= data set	PANEL	CORROUT
Includes covariances in the OUTEST= data set	PANEL	COVOUT
Specifies the input data set	PANEL	DATA=
Specifies variables to keep but not transform	FLATDATA	KEEP=
Specifies the output data set for CLASS STATEMENT	CLASS	OUT =
Specifies the output data set	FLATDATA	OUT =
Specifies the name of an output SAS data set	OUTPUT	OUT=
Writes parameter estimates to an output data set	PANEL	OUTEST=
Writes the transformed series to an output data set	PANEL	OUTTRANS=
Requests that the procedure produce graphics via the Output Delivery System	PANEL	PLOTS=
Declaring the Role of Variables		
Specifies BY-group processing	BY	
Specifies the classification variables	CLASS	
Transfers the data into uncompressed form	FLATDATA	
Specifies the cross section and time ID variables	ID	
Declares instrumental variables	INSTRUMENTS	

Description	Statement	Option
Lag Generation		
Specifies output data set for lags where missing values are replaced with the cross section mean	CLAG	OUT=
Specifies output data set for lags with missing values included	LAG	OUT=
Specifies output data set for lags where missing values are replaced with the time period mean	SLAG	OUT=
Specifies output data set for lags where missing values are replaced with overall mean	XLAG	OUT=
Specifies output data set for lags where missing values are replaced with zero	ZLAG	OUT=
Printing Control Options		
Prints correlations of the estimates	MODEL	CORRB
Prints covariances of the estimates	MODEL	COVB
Suppresses printed output	MODEL	NOPRINT
Requests that the procedure produce graphics via the Output Delivery System	MODEL	PLOTS=
Prints fixed effects	MODEL	PRINTFIXED
Performs tests of linear hypotheses	TEST	
Model Estimation Options		
Requests the Breusch-Pagan test for one-way random effects	MODEL	BP
Requests the Breusch-Pagan test for two-way random effects	MODEL	BP2
Specifies the between-groups model	MODEL	BTWNG
Specifies the between-time-periods model	MODEL	BTWNT
Requests the clustered HCCME estimator for the variance-covariance matrix	MODEL	CLUSTER
Specifies the Da Silva method	MODEL	DASILVA
Specifies the one-way fixed-effects model	MODEL	FIXONE
Specifies the one-way fixed-effects model with respect to time	MODEL	FIXONETIME
Specifies the two-way fixed-effects model	MODEL	FIXTWO
Specifies the Moore-Penrose generalized inverse	MODEL	GINV = G4
Specifies the dynamic panel estimator model	MODEL	GMM
Requests the HAC estimator for the variance-covariance matrix	MODEL	HAC=
Requests the HCCME estimator for the variance-covariance matrix	MODEL	HCCME=
Specifies the order of the moving average error process for Da Silva method	MODEL	M=

Description	Statement	Option
Suppresses the intercept term	MODEL	NOINT
Specifies the Parks method	MODEL	PARKS
Prints the Φ matrix for Parks method	MODEL	PHI
Specifies the pooled model	MODEL	POOLED
Requests poolability tests for one-way fixed effects and pooled model	MODEL	POOLTEST
Specifies the one-way random-effects model	MODEL	RANONE
Specifies the two-way random-effects model	MODEL	RANTWO
Prints autocorrelation coefficients for Parks method	MODEL	RHO
Controls the check for singularity	MODEL	SINGULAR=
Specifies the method for panel unit root/stationarity test	MODEL	UROOTTEST=
Specifies the method for the variance components estimator	MODEL	VCOMP=
Specifies linear equality restrictions on the parameters	RESTRICT	
Specifies the TEST statement	TEST	WALD, LM, LR

PROC PANEL Statement

PROC PANEL *options* ;

The following options can be specified on the PROC PANEL statement.

DATA=SAS-data-set

names the input data set. The input data set must be sorted by cross section and by time period within cross section. If you omit the DATA= option, the most recently created SAS data set is used.

OUTEST=SAS-data-set

names an output data set to contain the parameter estimates. When the OUTEST= option is not specified, the OUTEST= data set is not created. See the section “[OUTEST= Data Set](#)” on page 1414 for details about the structure of the OUTEST= data set.

OUTTRANS=SAS-data-set

names an output data set to contain the transformed series for further analysis and computation of models with time observations greater than two. See the section “[OUTTRANS= Data Set](#)” on page 1416 for details about the structure of the OUTTRANS= data set.

OUTCOV

COVOUT

writes the standard errors and covariance matrix of the parameter estimates to the OUTEST= data set. See the section “[OUTEST= Data Set](#)” on page 1414 for details.

OUTCORR**CORROUT**

writes the correlation matrix of the parameter estimates to the OUTEST= data set. See the section “[OUTEST= Data Set](#)” on page 1414 for details.

PLOTS < (*global-plot-options* < (**NCROSS**=*value*) >) > < = (*specific-plot-options*) >

selects plots to be produced via the Output Delivery System. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*). The *global-plot-options* apply to all relevant plots generated by the PANEL procedure.

Global Plot Options

The following *global-plot-options* are supported:

ONLY

suppresses the default plots. Only the plots specifically requested are produced.

UNPACKPANEL**UNPACK**

displays each graph separately. (By default, some graphs can appear together in a single panel.)

NCROSS=*value*

specifies the number of cross sections to be combined into one time series plot.

Specific Plot Options

The following *specific-plot-options* are supported:

ACTSURFACE	produces a surface plot of actual values.
ALL	produces all appropriate plots.
FITPLOT	plots the predicted and actual values.
NONE	suppresses all plots.
PRESURFACE	produces a surface plot of predicted values.
QQ	produces a QQ plot of residuals.
RESIDSTACK RESSTACK	produces a stacked plot of residuals.
RESIDSURFACE	produces a surface plot of residual values.
RESIDUAL RES	plots the residuals.
RESIDUALHISTOGRAM RESIDHISTOGRAM	plots the histogram of residuals.

For more details, see the section “[Creating ODS Graphics](#)” on page 1413.

In addition, any of the following MODEL statement options can be specified in the PROC PANEL statement: CORRB, COVB, FIXONE, FIXONETIME, FIXTWO, BTWNG, BTWNT, POOLED, RANONE, RANTWO, FULLER, PARKS, DASILVA, NOINT, NOPRINT, PRINTFIXED, M=, PHI, RHO, VCOMP=, and SINGULAR=. When specified in the PROC PANEL statement, these options are equivalent to specifying the options for every MODEL statement. See the section “[MODEL Statement](#)” on page 1350 for a complete description of each of these options.

BY Statement

BY *variables* ;

A BY statement obtains separate analyses on observations in groups that are defined by the BY variables. When a BY statement appears, the input data set must be sorted both by the BY variables and by cross section and time period within the BY groups.

The following statements show an example:

```
proc sort data=a;
    by byvar1 byvar2 csid tsid;
run;

proc panel data=a;
    by byvar1 byvar2;
    id csid tsid;
    ...
run;
```

CLASS Statement

CLASS *variables* < / out= SAS-data-set > ;

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

In PROC PANEL, the CLASS statement enables you to output class variables to a data set that contains a copy of the original data.

FLATDATA Statement

FLATDATA *options* < / out= SAS-data-set > ;

The following options must be specified in the FLATDATA statement:

BASE=(*variable, variable, ..., variable*)

specifies the variables that are to be transformed into a proper PROC PANEL format. All variables to be transformed must be named according to the convention: `basename_timeperiod`. You supply just the `basename`, and the procedure extracts the appropriate variables to transform. If some year's data are missing for a variable, then PROC PANEL detects this and fills in with missing values.

INDID=*variable*

names the variable in the input data set that uniquely identifies each individual. The INDID variable can be a character or numeric variable.

KEEP=*(variable, variable, ..., variable)*

specifies the variables that are to be copied without any transformation. These variables remain constant with respect to time when the data are converted to PROC PANEL format. This is an optional item.

TSNAME=*name*

specifies a name for the generated time identifier. The name must satisfy the requirements for the name of a SAS variable. The name can be quoted, but it must not be the name of a variable in the input data set.

The following options can be specified on the FLATDATA statement after the slash (/):

OUT =*SAS-data-set*

saves the converted flat data set to a PROC PANEL formatted data set.

ID Statement

ID *cross-section-id time-series-id* ;

The ID statement is used to specify variables in the input data set that identify the cross section and time period for each observation.

When an ID statement is used, the PANEL procedure verifies that the input data set is sorted by the cross section ID variable and by the time series ID variable within each cross section. The PANEL procedure also verifies that the time series ID values are the same for all cross sections.

To make sure the input data set is correctly sorted, use PROC SORT to sort the input data set with a BY statement with the variables listed exactly as they are listed in the ID statement, as shown in the following statements:

```
proc sort data=a;
    by csid tsid;
run;

proc panel data=a;
    id csid tsid;
    ... etc. ...
run;
```

INSTRUMENTS Statement

INSTRUMENTS *options* ;

The INSTRUMENTS statement denotes which variables are used in the moment condition equations of the dynamic panel estimator. The following options can be used with the INSTRUMENTS statement.

CONSTANT

includes an intercept (column of ones) as an uncorrelated exogenous instrument.

DEPVAR

specifies that a dependent variable be used at an appropriate lag as an instrument.

CORRELATED=(*variable, variable, ..., variable*)

specifies a list of variables correlated with the error term. These variables are not used in forming moment conditions from level equations.

EXOGENOUS=(*variable, variable, ..., variable*)

specifies a list of variables that are not correlated with the error term.

PREDETERMINED=(*variable, variable, ..., variable*)

specifies a list of variables whose future realizations can be correlated with the error term but whose present and past realizations are not.

If a variable listed in the EXOGENOUS list is not included in the CORRELATED list, then it is considered to be uncorrelated to the error term. For example, in the following statements, the exogenous instruments are Z1, Z2 and X1. Z1 is an instrument that is correlated to the individual fixed effects.

```
proc panel data=a;
  inst exogenous=(Z1 Z2 X1)
    correlated = (Z1) constant depvar;
  model Y = X1 X2 X3 / gmm;
run;
```

For a detailed discussion of the model set up and the use of the INSTRUMENTS statement, see “[Dynamic Panel Estimator](#)” on page 1384.

Note that for each MODEL statement, one INSTRUMENT statement is required. In other words, if there are two models to be estimated by using GMM within one PANEL procedure, then there should be two INSTRUMENT statements. For example,

```
proc panel data=test;
  inst depvar pred=(x1 x2) exog=(x3 x4 x5) correlated=(x3 x4 x5);
  model y = y_1 x1 x2 / gmm maxband=6 nolevels ginv=g4 artest=5;
  inst pred=(x2 x4) exog=(x3 x5) correlated=(x3 x4);
  model y = y_1 x2 / gmm maxband=6 nolevels ginv=g4 artest=5;
  id cs ts;
run;
```

LAG, ZLAG, XLAG, SLAG, or CLAG Statement

LAG *var*₁ (*lag*₁ *lag*₂ ... *lag*_{*T*}) , ... , *var*_{*N*} (*lag*₁ *lag*₂ ... *lag*_{*T*}) < / **OUT**= *SAS-data-set* > ;

Generally, creating lags of variables in a panel setting is a tedious process in which you must generate many DATA step statements. The PANEL procedure now enables you to generate lags of any series without jumping across the boundary of any individual series. The LAG statement is a data set generation tool. Using the data created by a LAG statement requires a subsequent PROC PANEL call. You can specify more than one LAG statement in each call to PROC PANEL.

You must specify the OUT= option in the LAG statement. The output data set includes all variables in the input set, plus the lags that are denoted with the convention *var_lag*. The LAG statement tends to generate many missing values in the data. This can be problematic, because the number of usable observations diminishes with the lag length. Therefore, PROC PANEL offers the following alternatives to the LAG statement. The following statements can be used instead of LAG with otherwise identical syntax:

CLAG *var*₁ (*lag*₁ *lag*₂ ... *lag*_{*T*}) , ... , *var*_{*N*} (*lag*₁ *lag*₂ ... *lag*_{*T*}) < / **OUT**= *SAS-data-set* > ;

replaces missing values with the cross section mean for that variable in that cross section. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

SLAG *var*₁ (*lag*₁ *lag*₂ ... *lag*_{*T*}) , ... , *var*_{*N*} (*lag*₁ *lag*₂ ... *lag*_{*T*}) < / **OUT**= *SAS-data-set* > ;

replaces missing values with the time mean for that variable in that time period. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

XLAG *var*₁ (*lag*₁ *lag*₂ ... *lag*_{*T*}) , ... , *var*_{*N*} (*lag*₁ *lag*₂ ... *lag*_{*T*}) < / **OUT**= *SAS-data-set* > ;

replaces missing values with the overall mean for that variable. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

ZLAG *var*₁ (*lag*₁ *lag*₂ ... *lag*_{*T*}) , ... , *var*_{*N*} (*lag*₁ *lag*₂ ... *lag*_{*T*}) < / **OUT**= *SAS-data-set* > ;

replaces missing values with 0 for that variable. Missing values are replaced only if they are in the generated (lagged) series. Missing variables in the original variables are not changed.

Assume that data set A has been sorted by cross section and by time period within cross section (or that the FLATDATA statement has been specified) and that the variables are Y, X1, X2, and X3. The following PROC PANEL statements generate a series with lags 1 and 3 of the X1 variable; lags 3, 6, and 9 of the X2 variable; and lag 2 of the X3 variable.

```
proc panel data=A;
  id i t;
  lag X1(1 3) X2(3 6 9) X3(2) / out=A_lag;
run;
```

If you want a zeroing instead of missing values, then you specify the following:

```
proc panel data=A;
  id i t;
  zlag X1(1 3) X2(3 6 9) X3(2) / out=A_zlag;
run;
```

Similarly, you can specify XLAG to replace with overall means, SLAG to replace with time means, and CLAG to replace with cross section means.

MODEL Statement

MODEL *response* = *regressors* < / *options* > ;

The MODEL statement specifies the regression model and the error structure assumed for the regression residuals. The response variable on the left side of the equal sign is regressed on the independent variables listed after the equal sign. Any number of MODEL statements can be used. For each model statement, only one response variable can be specified on the left side of the equal sign.

The error structure is specified by the FULLER, PARKS, DASILVA, FIXONE, FIXONETIME, FIXTWO, RANONE, RANTWO, GMM, and ITGMM options. More than one of these options can be used, in which case the analysis is repeated for each error structure model specified.

Models can be given labels. Model labels are used in the printed output to identify the results for different models. If no label is specified, the response variable name is used as the label for the model. The model label is specified as follows:

label : MODEL ...;

The following *options* can be specified in the MODEL statement after a slash (/).

ARTEST=integer

specifies the maximum order of the test for the presence of AR effects in the residual in the dynamic panel model. The acceptable range of values for this option is 1 to $t - 3$.

ATOL=number

specifies the convergence criterion for iterated GMM when convergence of the method is determined by convergence in the weighting matrix. The convergence criterion must be positive. The default option is the BTOL= option unless the ATOL= option is specified. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

BANDOPT=TRAILING | CENTERED | LEADING

specifies which observations are included in the instrument list when the MAXBAND= option is specified. This option should be used only for exogenous instruments. BANDOPT=TRAILING is the default. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

BP

requests the Breusch-Pagan one-way test for random effects.

BP2

requests the Breusch-Pagan two-way test for random effects.

BTOL=number

specifies the convergence criterion for iterated GMM when convergence of the method is determined by convergence in the parameter matrix. The convergence criterion must be positive. The default is BTOL=1E-8. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

BTWNG

specifies that a between-groups model be estimated.

BTWNT

specifies that a between-time-periods model be estimated.

CLUSTER

specifies the cluster correction for the variance-covariance matrix. The cluster correction can be requested with HCCME=0, 1, 2 or 3.

CORRB**CORR**

prints the matrix of estimated correlations between the parameter estimates.

COVB**VAR**

prints the matrix of estimated covariances between the parameter estimates.

DASILVA

specifies that the model be estimated by using the Da Silva method, which assumes a mixed variance-component moving average model for the error structure. See the section “[Da Silva Method \(Variance-Component Moving Average Model\)](#)” on page 1382 for details.

FIXONE

specifies that a one-way fixed-effects model be estimated with the one-way model corresponding to cross-sectional effects only.

FIXONETIME

specifies that a one-way fixed-effects model be estimated with the one-way model corresponding to time effects only.

FIXTWO

specifies that a two-way fixed-effects model be estimated.

GINV= G2 | G4

specifies what type of generalized inverse to use. The default is a G2 inverse. The G4 inverse is generally more desirable except that it is a more numerically intensive methodology.

GMM

specifies that the model be estimated by using the dynamic panel estimator method, which allows for autoregressive processes. This is the single-step model. Note that with this option one INSTRUMENT statement is required for each MODEL statement. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

HAC < (hac-options) >

specifies the heteroscedasticity- and autocorrelation-consistent (HAC) covariance matrix estimator. This option is not available for between models and cannot be specified with the HCCME option. When you specify this option, you can also specify the following *hac-options* within parentheses:

KERNEL=*value*

specifies the type of kernel function. You can specify the following *values*:

BARTLETT	specifies the Bartlett kernel function.
PARZEN	specifies the Parzen kernel function.
QS	specifies the quadratic spectral kernel function.
TH	specifies the Turkey-Hanning kernel function.
TRUNCATED	specifies the truncated kernel function.

The default is **KERNEL=TRUNCATED**.

KERNELLB=*number*

specifies the lower bound of the kernel weight value. Any kernel weight less than this lower bound is regarded as 0, which accelerates the calculation for big samples, especially for the quadratic spectral kernel function. By default, **KERNELLB=0**.

BANDWIDTH=*value*

specifies the fixed bandwidth value or bandwidth selection method which is used in the kernel function. You can specify the following *values*:

ANDREWS91 | ANDREWS

specifies the Andrews(1991) bandwidth selection method.

NEWWEYWEST94<(C=*number*)>**NW94** <(C=*number*)>

specifies the Newey and West(1994) bandwidth selection method. The C= option can be specified within parentheses for the calculation of lag selection parameter; the default is C=12.

SAMPLESIZE<(option-list)>**SS**<(option-list)>

specifies that the bandwidth be calculated according to the following equation based on the sample size

$$b = \gamma T^r + c$$

where b is the bandwidth parameter, T is the sample size, and γ , r and c are values specified by the following options within parentheses and separated by commas.

GAMMA=*number*

specifies the coefficient γ in the equation. The default is $\gamma = 0.75$.

RATE=*number*

specifies the growth rate r in the equation. The default is $r = 0.3333$.

CONSTANT=*number*

specifies the constant c in the equation. The default is $c = 0.5$.

INT

specifies that the bandwidth parameter must be integer; that is, $b = \lfloor \gamma T^r + c \rfloor$, where $\lfloor x \rfloor$ denotes the largest integer less than or equal to x .

number

specifies the fixed value of the bandwidth parameter.

The default is BANDWIDTH=ANDREWS91.

PREWHITENING

specifies that prewhitening is required in the covariance calculation.

ADJUSTDF

specifies that the adjustment of degrees of freedom is required in the covariance calculation.

See the section “[Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrices](#)” on page 1396 for details.

HCCME= NO | *number*

specifies the type of HCCME variance-covariance matrix requested. If you specify HCCME=NO, the variance-covariance matrix is not corrected. The value *number* can be any integer from 0 to 4, inclusive. See the section “[Heteroscedasticity-Corrected Covariance Matrices](#)” on page 1393 for details. By default, HCCME=NO.

ITGMM

specifies that the model be estimated by using the dynamic panel estimator method, but that PROC PANEL keep updating the weighting matrix until either the parameter vector converges or the weighting matrix converges. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

ITPRINT

prints out the iteration history of the parameter and transformed sum of error squared.

M=*number*

specifies the order of the moving-average process in the Da Silva method. The value of the M=option must be less than $T - 1$. The default is M=1.

MAXBAND=*integer*

specifies the maximum number of time periods (per instrumental variable) that are allowed into the moment condition. The acceptable range of values for this option is 1 to $T - 1$. If BANDOPT=LEADING or CENTERED, then the default value of MAXBAND is 2. If BANDOPT=TRAILING, then the default value of MAXBAND is 1. If no BANDOPT option is specified such as when no exogenous instruments are used, then the default value of MAXBAND is 1. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

MAXITER=*integer*

specifies the maximum number of iterations allowed for the iterated GMM option. The default value is MAXITER=200. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

NEWKEYWEST=<(option-list)>

specifies the well-known Newey-West estimator, a special HAC estimator with (1) the Bartlett kernel, (2) the bandwidth parameter determined by the equation based on the sample size, $b = \lfloor \gamma T^r + c \rfloor$,

and (3) no adjustment for degrees of freedom and no prewhitening. By default the bandwidth parameter for Newey-West estimator is $\lfloor 0.75T^{0.3333} + 0.5 \rfloor$, as shown in the equation (15.17) in Stock and Watson (2002). When you specify COVEST=NEWKEYWEST, you can specify the following options in parentheses and separate them with commas:

GAMMA= *number*

specifies the coefficient γ in the equation. The default is $\gamma = 0.75$.

RATE= *number*

specifies the growth rate r in the equation. The default is $r = 0.3333$.

CONSTANT= *number*

specifies the constant c in the equation. The default is $c = 0.5$.

NOIFFS

specifies that the dynamic panel model be estimated without moment conditions from the difference equations. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

NOESTIM

limits the estimation of a FIXONE, FIXONETIME, RANONE model to the generation of the transformed series. This option is intended for use with an OUTTRANS= data set.

NOINT

suppresses the intercept parameter from the model.

NOLEVELS

specifies that the dynamic panel model be estimated without moment conditions from the level equations. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

NOPRINT

suppresses the normal printed output.

PARKS

specifies that the model be estimated by using the Parks method, which assumes a first-order autoregressive model for the error structure. See the section “[Parks Method \(Autoregressive Model\)](#)” on page 1380 for details.

PHI

prints the Φ matrix of estimated covariances of the observations for the Parks method. The PHI option is relevant only when the PARKS option is used. See the section “[Parks Method \(Autoregressive Model\)](#)” on page 1380 for details.

POOLED

specifies that a pooled (OLS) model be estimated.

POOLTEST

requests poolability tests for one-way fixed effects and pooled models.

PRINTFIXED

prints the fixed effects.

RANONE

specifies that a one-way random-effects model be estimated.

RANTWO

specifies that a two-way random-effects model be estimated.

RHO

prints the estimated autocorrelation coefficients for the Parks method.

ROBUST

specifies that the robust weighting matrix be used in the calculation of the variance-covariance matrix of the single-step dynamic panel estimator. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

SINGULAR=number

specifies a singularity criterion for the inversion of the matrix. The default depends on the precision of the computer system.

TIME

specifies that the model be estimated by using the dynamic panel estimator method, but that PROC PANEL includes time dummy variables to model any time effects present in the data. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details.

TWOSTEP

specifies that the model be estimated by using the dynamic panel estimator method, but that two steps be used in the estimation. An initial first step is used to form an estimator for the weighting matrix used in the second step. See the section “[Dynamic Panel Estimator](#)” on page 1384 for details. The panel unit root test (or stationarity test) will test the existence of unit root for the dependent variables only. The following unit root or stationarity tests are allowed in model statement.

UROOTTEST(*test1*<(test-options), *test2*<(test-options)>... > < *option1* < *option2*... > >)

STATIONARITY(*test1*<(test-options), *test2*<(test-options)>... > < *option1* < *option2*... > >)

specifies tests of stationarity or unit root for panel data and the options for each test. Six tests are available. You can specify all or some of these tests, separated by commas. If you specify one or more *test-options* (separated by spaces) inside the parentheses after a particular test, they apply only to that test. If you specify one or more *options* separated by spaces after you specify the tests, they apply to all the tests. If you specify both *test-options* and *options*, the *test-options* override the *options*.

ALL

requests that all panel unit root and stationarity tests be performed.

BREITUNG<(test-options) >

requests Breitung’s unbiased test, *t* test and GLS *t* test that are robust to cross-sectional dependence. The tests are described in Breitung and Meyer (1994), Breitung (2000), and Breitung and Das (2005). The following *test-options* are available for this test:

DETAIL

requests that intermediate results (lag order) be printed.

LAGS=type | value

specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a *value* for the order of lags. If the specified lag order is too big to run linear regression ($\text{LAGS} > T - k$, where T is the number of observations and k is the number of parameters), then the lag order is set to $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. Alternatively, you can specify one of the following *types*:

GS

selects the order of lags by Hall's (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

SG

selects the order of lags by Hall's (1994) sequential testing method: from no lag term to maximum allowed lags.

AIC

selects the order of lags by AIC.

SBC**SIC****SBIC**

selects the order of lags by Bayesian information criterion (or Schwarz criterion).

HQIC

selects the order of lags by the Hannan-Quinn information criterion.

MAIC

selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is $\text{LAGS}=\text{MAIC}$.

MAXLAGS=value

specifies the maximum lag order that the model allows. The default value is $\lfloor 12(T/100)^{1/4} \rfloor$. If *value* is larger than 0 and larger than $T - k$, then the maximum lag order is set to be the default value of $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. This option is ignored if you specify $\text{LAGS}=\text{value}$.

COMBINATION < (test-options) >**FISHER < (test-options) >**

specifies combination tests proposed by Choi (2001) and Maddala and Wu (1999). Fisher's test, as proposed by Maddala and Wu (1991), is a special case of combination tests. You can specify one or more of the following *test-options*:

TEST=ADF | PP

selects the time series unit root test for combination tests (Fisher's test). ADF specifies the augmented Dickey-Fuller (ADF) test, and ignores the BANDWIDTH and KERNEL options for the combination tests. PP specifies the Phillips and Perron (1988) unit root test. When you specifies $\text{TEST} = \text{PP}$, the LAGS and MAXLAGS options are ignored for the combination tests.

The default is $\text{TEST}=\text{PP}$.

KERNEL=*value*

specifies the type of kernel function. You can specify the following *values*:

BARTLETT	specifies the Bartlett kernel function.
PARZEN	specifies the Parzen kernel function.
QS	specifies the quadratic spectral kernel function.
TH	specifies the Turkey-Hanning kernel function.
TRUNCATED	specifies the truncated kernel function.

The default is KERNEL=QS.

BANDWIDTH=ANDREWS | *number*

specifies the bandwidth for the kernel. If you specify BANDWIDTH=ANDREWS, the bandwidth is selected by the Andrews method. If you specify a nonnegative *number*, the bandwidth is set to that value. The default is BANDWIDTH=ANDREWS.

DETAIL

requests that intermediate results (lag order and long-run variance for each cross section) be printed.

LAGS=*type* | *value*

specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a *value* for the order of lags. If the specified lag order is too big to run linear regression ($\text{LAGS} > T - k$, where T is the number of observations and k is the number of parameters), then the lag order is set to $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. Alternatively, you can specify one of the following *types*:

GS

selects the order of lags by Hall's (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

SG

selects the order of lags by Hall's (1994) sequential testing method: from no lag term to maximum allowed lags.

AIC

selects the order of lags by AIC.

SBC**SIC****SBIC**

selects the order of lags by Bayesian information criterion (or Schwarz criterion).

HQIC

selects the order of lags by the Hannan-Quinn information criterion.

MAIC

selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is LAGS=MAIC.

MAXLAGS=value

specifies the maximum lag order that the model allows. The default value is $\lfloor 12(T/100)^{1/4} \rfloor$. If *value* is larger than 0 and larger than $T - k$, then the maximum lag order is set to be the default value of $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. This option is ignored if you specify LAGS=*value*.

HADRI < (test-options) >

specifies Hadri's (2000) panel stationarity test. You can specify the following *test-options*:

DETAIL

requests that intermediate results (lag order and long-run variance for each cross section) be printed.

KERNEL=value

specifies the type of kernel function. You can specify the following *values*:

BARTLETT	specifies the Bartlett kernel function.
PARZEN	specifies the Parzen kernel function.
QS	specifies the quadratic spectral kernel function.
TH	specifies the Turkey-Hanning kernel function.
TRUNCATED	specifies the truncated kernel function.

The default is KERNEL=QS.

BANDWIDTH=ANDREWS | number

specifies the bandwidth for the kernel. If you specify BANDWIDTH=ANDREWS, the bandwidth is selected with the Andrews method. If you specify a nonnegative *number*, the bandwidth is set to that value. The default is BANDWIDTH=ANDREWS.

HT

specifies Harris and Tzavalis's (1999) panel unit root test. No options are available for this test.

IPS < (test-options) >

specifies the Im, Pesaran, and Shin's (2003) panel unit root test. You can specify the following *test-options*:

DETAIL

requests that intermediate results (lag order) be printed.

LAGS=type | value

specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a *value* for the order of lags. If the specified lag order is too big to run linear regression ($\text{LAGS} > T - k$, where T is the number of observations and k is the number of parameters), then the lag order is set to $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. Alternatively, you can specify one of the following *types*:

GS

selects the order of lags by Hall's (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

SG

selects the order of lags by Hall's (1994) sequential testing method: from no lag term to maximum allowed lags.

AIC

selects the order of lags by AIC.

SBC**SIC****SBIC**

selects the order of lags by Bayesian information criterion (or Schwarz criterion).

HQIC

selects the order of lags by the Hannan-Quinn information criterion.

MAIC

selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is LAGS=MAIC.

MAXLAGS=value

specifies the maximum lag order that the model allows. The default value is $\lfloor 12(T/100)^{1/4} \rfloor$. If *value* is larger than 0 and larger than $T - k$, then the maximum lag order is set to be the default value of $\lfloor 12(T/100)^{1/4} \rfloor$ or $T - k - 1$, whichever is smaller. This option is ignored if you specify LAGS=*value*.

LLC < (test-options) >

specifies the Levin, Lin, and Chu (2002) panel unit root test. You can specify the following *test-options*:

DETAIL

requests that intermediate results (lag order and long-run variance for each cross section) be printed.

KERNEL=value

specifies the type of kernel function. You can specify the following *values*:

BARTLETT	specifies the Bartlett kernel function.
PARZEN	specifies the Parzen kernel function.
QS	specifies the quadratic spectral kernel function.
TH	specifies the Turkey-Hanning kernel function.
TRUNCATED	specifies the truncated kernel function.

The default is KERNEL=QS.

BANDWIDTH=ANDREWS | *number*

specifies the bandwidth for the kernel. If you specify **BANDWIDTH=ANDREWS**, the bandwidth is selected with the Andrews method. If you specify a nonnegative *number*, the bandwidth is set to that value. The default is **BANDWIDTH=LLCBAND**, where the bandwidth is set to be $\bar{k} = \left\lfloor 3.21T^{\frac{1}{3}} \right\rfloor$, according to Levin, Lin, and Chu (2002).

LAGS=type | *value*

specifies the method to choose the lag order for the augmented Dickey-Fuller (ADF) regressions. You can specify a *value* for the order of lags. If the specified lag order is too big to run linear regression ($\text{LAGS} > T - k$, where T is the number of observations and k is the number of parameters), then the lag order is set to $\left\lfloor 12(T/100)^{1/4} \right\rfloor$ or $T - k - 1$, whichever is smaller. Alternatively, you can specify one of the following *types*:

GS

selects the order of lags by Hall's (1994) sequential testing method: from the most general model (maximum lags) to lower order of lag terms.

SG

selects the order of lags by Hall's (1994) sequential testing method: from no lag term to maximum allowed lags.

AIC

selects the order of lags by AIC.

SBC**SIC****SBIC**

selects the order of lags by Bayesian information criterion (or Schwarz criterion).

HQIC

selects the order of lags by the Hannan-Quinn information criterion.

MAIC

selects the order of lags by the modified AIC that is proposed by Ng and Perron (2001).

The default is **LAGS=MAIC**.

MAXLAGS=*value*

specifies the maximum lag order that the model allows. The default value is $\left\lfloor 12(T/100)^{1/4} \right\rfloor$. If *value* is larger than 0 and larger than $T - k$, then the maximum lag order is set to be the default value of $\left\lfloor 12(T/100)^{1/4} \right\rfloor$ or $T - k - 1$, whichever is smaller. This option is ignored if you specify **LAGS=***value*.

Two tests, LLC and BREITUNG's, are specified in the following **UROOTTEST** option specification:

```
uroottest = (llc=(kernel=parzen lags=aic), breitung= (lags=gs ) maxlags=2
kernel=bartlett)
```

For the LLC test, the lag order is selected by AIC with maximum lag order 2, and the kernel is specified as Parzen (overriding Bartlett). For the BREITUNG's test, the lag order is GS with a maximum lag order 2. The **KERNEL** option is ignored by BREITUNG's test because it is not a valid option.

VCOMP=FB | NL | WH | WK

specifies the type of variance component estimate to use. The default is VCOMP=FB for balanced data and VCOMP=WK for unbalanced data. See the section “[One-Way Random-Effects Model](#)” on page 1372 and “[Two-Way Random-Effects Model](#)” on page 1375 for details.

OUTPUT Statement

OUTPUT OUT=SAS-data-set < = options ... > ;

The OUTPUT statement creates an output SAS data set as specified by the following options:

OUT=SAS-data-set

names the output SAS data set to contain the predicted and transformed values. If the OUT= option is not specified, the new data set is named according to the DATA n convention.

PREDICTED=name**P=name**

writes the predicted values to the output data set.

RESIDUAL=name**R=name**

writes the residuals from the predicted values based on both the structural and time series parts of the model to the output data set.

RESTRICT Statement

RESTRICT < "string" > equation < ,equation2... > ;

The RESTRICT statement specifies linear equality restrictions on the parameters in the previous model statement. There can be as many unique restrictions as the number of parameters in the preceding model statement. Multiple RESTRICT statements are understood as joint restrictions on a model's parameters. Restrictions on the intercept are obtained by the use of the keyword INTERCEPT.

Currently, only linear equality restrictions are permitted in PROC PANEL. Tests and restriction expressions can only be composed of algebraic operations that involve the addition symbol (+), subtraction symbol (−), and multiplication symbol (*).

The RESTRICT statement accepts labels that are produced in the printed output. RESTRICT statement can be labeled in two ways. A RESTRICT statement can be preceded by a label followed by a colon. This is illustrated in **rest1** in the example below. Alternatively, the keyword RESTRICT can be followed by a quoted string.

The following statements illustrate the use of the RESTRICT statement:

```
proc panel;
  model y = x1 x2 x3;
  restrict x1 = 0, x2 * .5 + 2 * x3 = 0;
  rest1: restrict x2 = 0, x3 = 0;
```

```

    restrict "rest2" intercept=1;
run;

```

Note that a restrict statement cannot include a division sign in its formulation.

TEST Statement

```

TEST <"string"> equation <,equation2...> </options> ;

```

The TEST statement performs Wald, Lagrange multiplier and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT refers to the coefficient of the intercept.

The following options can be specified on the TEST statement after the slash (/):

ALL

specifies Wald, Lagrange multiplier and likelihood ratio tests.

WALD

specifies the WALD test.

LM

specifies the Lagrange multiplier test.

LR

specifies the likelihood ratio test.

The Wald test is performed by default.

The following statements illustrate the use of the TEST statement:

```

proc panel;
  id csid tsid;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0;
  test_int: test intercept = 0, x3 = 0;
run;

```

The first test investigates the joint hypothesis that

$$\beta_1 = 0$$

and

$$.5\beta_2 + 2\beta_3 = 0$$

Currently, only linear equality restrictions and tests are permitted in PROC PANEL. Tests and restriction expressions can be composed only of algebraic operations that involve the addition symbol (+), subtraction symbol (−), and multiplication symbol (*).

The TEST statement accepts labels that are produced in the printed output. The TEST statement can be labeled in two ways. A TEST statement can be preceded by a label followed by a colon. Alternatively, the keyword TEST can be followed by a quoted string. If both are presented, PROC PANEL uses the quoted string. In the event no label is present, PROC PANEL automatically labels the tests. If both a TEST and a RESTRICT statement are specified, the test is run with restrictions applied.

Note that for the DaSilva method, only the WALD test is available.

Details: PANEL Procedure

Missing Values

Any observation in the input data set with a missing value for one or more of the regressors is ignored by PROC PANEL and is not used in the model fit.

If there are observations in the input data set with missing dependent variable values but with nonmissing regressors, PROC PANEL can compute predicted values and store them in an output data set by using the OUTPUT statement. Note that the presence of such observations with missing dependent variable values does not affect the model fit because these observations are excluded from the calculation.

If either some regressors or the dependent variable values are missing, the model is estimated as unbalanced where the number of time series observations across different cross sections does not have to be equal. The Parks and Da Silva methods cannot be used with unbalanced data.

Computational Resources

The more parameters there are to be estimated, the more memory and time are required to estimate the model. Also affecting these resources are the estimation method chosen and the method to calculate variance components. If the model has p parameters including the intercept, there are at least $p + [p * (p + 1)]/2$ numbers being held in the memory.

If the Arellano and Bond GMM approach is used, the amount of memory grows proportionately to the number of instruments in the INSTRUMENT statement. If the ITGMM (iterated GMM) option is selected, the computation time also depends on the convergence criteria selected and the maximum number of iterations allowed.

Restricted Estimates

A consequence of estimating a linear model with a restriction is that the error degrees of freedom increase by the number of restrictions. PROC PANEL produces the Lagrange multiplier associated with each restriction.

Say that you are interested in linear regression in which there are r restrictions. A linear restriction implies the following set of equations that relate the regression coefficients:

$$\begin{aligned} R_{1,1}\beta_1 + R_{1,2}\beta_2 + \cdots + R_{1,p}\beta_p &= q_1 \\ R_{2,1}\beta_1 + R_{2,2}\beta_2 + \cdots + R_{2,p}\beta_p &= q_2 \\ &\dots\dots\dots \\ R_{r,1}\beta_1 + R_{r,2}\beta_2 + \cdots + R_{r,p}\beta_p &= q_r \end{aligned}$$

To economize on notation, you can represent the restriction structure in the following matrix notation $\mathbf{R}\boldsymbol{\beta} = \mathbf{q}$. The restricted $\boldsymbol{\beta}$ estimator is given by:

$$\boldsymbol{\beta}^* = \boldsymbol{\beta} - (\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1} (\mathbf{R}\boldsymbol{\beta} - \mathbf{q})$$

The Lagrange multipliers are given as:

$$\boldsymbol{\lambda}_* = \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1} (\mathbf{R}\boldsymbol{\beta} - \mathbf{q})$$

The standard errors of the Lagrange Multipliers are calculated from the following relationship:

$$\text{Var}(\boldsymbol{\lambda}_*) = \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1} \mathbf{R} \text{Var}(\boldsymbol{\beta}) \mathbf{R}' \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1}$$

A significant Lagrange multiplier implies that you can reject the null hypothesis that the restrictions are not binding.

Note that in the special case of the fixed-effects models, the NOINT option and RESTRICT INTERCEPT=0 option give different estimates. This is not an error; it reflects two perspectives on the same issue. In the FIXONE case, the intercept is the last cross section's fixed effect (or the last time affecting the case of FIXONETIME). Specifying the NOINT option removes the intercept, but allows the last effect in. The NOINT command simply reclassifies the effects. The dummy variables become true cross section effects. If you specify the NOINT option with the FIXTWO option, the restriction is imposed that the last time effect is zero. A RESTRICT INTERCEPT=0 statement suppresses the estimation of the last effect in the FIXONE and FIXONETIME case. A RESTRICT INTERCEPT=0 has similar effects on the FIXTWO estimator. In general, restricting the intercept to zero is not recommended because OLS loses its unbiased nature.

Notation

The following notation represents the usual panel structure, with the specification of u_{it} dependent on the particular model:

$$y_{it} = \sum_{k=1}^K x_{itk}\beta_k + u_{it} \quad i = 1, \dots, N; t = 1, \dots, T_i$$

The total number of observations $M = \sum_{i=1}^N T_i$. For the balanced data case, $T_i = T$ for all i . The $M \times M$ covariance matrix of u_{it} is denoted by \mathbf{V} . Let \mathbf{X} and \mathbf{y} be the independent and dependent variables arranged by cross section and by time within each cross section. Let \mathbf{X}_s be the \mathbf{X} matrix without the intercept. All other notation is specific to each section.

One-Way Fixed-Effects Model

The specification for the one-way fixed-effects model is

$$u_{it} = \gamma_i + \epsilon_{it}$$

where the γ_i s are nonrandom parameters to be estimated.

Let $\mathbf{Q}_0 = \text{diag}(\mathbf{E}_{T_i})$, with $\bar{\mathbf{J}}_{T_i} = \mathbf{J}_{T_i}/T_i$ and $\mathbf{E}_{T_i} = \mathbf{I}_{T_i} - \bar{\mathbf{J}}_{T_i}$, where \mathbf{J}_{T_i} is a matrix of T_i ones.

The matrix \mathbf{Q}_0 represents the within transformation. In the one-way model, the within transformation is the conversion of the raw data to deviations from a cross section's mean. The vector $\tilde{\mathbf{x}}_{it}$ is a row of the general matrix \mathbf{X}_s , where the subscripted s implies the constant (column of ones) is missing.

Let $\tilde{\mathbf{X}}_s = \mathbf{Q}_0\mathbf{X}_s$ and $\tilde{\mathbf{y}} = \mathbf{Q}_0\mathbf{y}$. The estimator of the slope coefficients is given by

$$\tilde{\beta}_s = (\tilde{\mathbf{X}}_s' \tilde{\mathbf{X}}_s)^{-1} \tilde{\mathbf{X}}_s' \tilde{\mathbf{y}}$$

Once the slope estimates are in hand, the estimation of an intercept or the cross-sectional fixed effects is handled as follows. First, you obtain the cross-sectional effects:

$$\gamma_i = \bar{y}_i - \tilde{\beta}_s \bar{x}_i \quad \text{for } i = 1 \dots N$$

If the NOINT option is specified, then the dummy variables' coefficients are set equal to the fixed effects. If an intercept is desired, then the i th dummy variable is obtained from the following expression:

$$D_i = \gamma_i - \gamma_N \quad \text{for } i = 1 \dots N - 1$$

The intercept is the N th fixed effect γ_N .

The within model sum of squared errors is:

$$\text{SSE} = \sum_{i=1}^N \sum_{t=1}^{T_i} (y_{it} - \gamma_i - \mathbf{X}_s \tilde{\beta}_s)^2$$

The estimated error variance can be written:

$$\hat{\sigma}_\epsilon^2 = \text{SSE}/(M - N - (K - 1))$$

Alternatively, an equivalent way to express the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{Q}_0 \tilde{\mathbf{u}} / (M - N - (K - 1))$$

where the residuals $\tilde{\mathbf{u}}$ are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}_M' / M)(\mathbf{y} - \mathbf{X}_s \tilde{\beta}_s)$ if there is an intercept and by $\tilde{\mathbf{u}} = (\mathbf{y} - \mathbf{X}_s \tilde{\beta}_s)$ if there is not. The drawback is that the formula changes (but the results do not) with the inclusion of a constant.

The variance covariance matrix of $\tilde{\beta}_s$ is given by:

$$\text{Var}[\tilde{\beta}_s] = \hat{\sigma}_\epsilon^2 (\tilde{\mathbf{X}}_s' \tilde{\mathbf{X}}_s)^{-1}$$

The covariance of the dummy variables and the dummy variables with the $\tilde{\beta}_s$ is dependent on whether the intercept is included in the model.

- *no intercept:*

$$\text{Var}[\gamma_i] = \text{Var}[D_i] = \frac{\hat{\sigma}_\epsilon^2}{T_i} + \bar{\mathbf{x}}_i' \text{Var}[\tilde{\beta}_s] \bar{\mathbf{x}}_i.$$

$$\text{Cov}[\gamma_i, \gamma_j] = \text{Cov}[D_i, D_j] = \bar{\mathbf{x}}_i' \text{Var}[\tilde{\beta}_s] \bar{\mathbf{x}}_j.$$

$$\text{Cov}[\gamma_i, \tilde{\beta}_s] = \text{Cov}[D_i, \tilde{\beta}_s] = -\bar{\mathbf{x}}_i' \text{Var}[\tilde{\beta}_s]$$

- *intercept:*

$$\text{Var}[D_i] = \frac{\hat{\sigma}_\epsilon^2}{T_i} + (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})' \text{Var}[\tilde{\beta}_s] (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})$$

$$\text{Cov}[D_i, D_j] = \frac{\hat{\sigma}_\epsilon^2}{T_i} + (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})' \text{Var}[\tilde{\beta}_s] (\bar{\mathbf{x}}_j - \bar{\mathbf{x}}_{N\cdot})$$

$$\text{Var}[\text{Intercept}] = \text{Var}[\gamma_N] = \frac{\hat{\sigma}_\epsilon^2}{T_N} + \bar{\mathbf{x}}_N' \text{Var}[\tilde{\beta}_s] \bar{\mathbf{x}}_N.$$

$$\text{Cov}[D_i, \tilde{\beta}_s] = -(\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})' \text{Var}[\tilde{\beta}_s]$$

$$\text{Cov}[\text{Intercept}, D_i] = -\frac{\hat{\sigma}_\epsilon^2}{T_i} + \bar{\mathbf{x}}_N' \text{Var}[\tilde{\beta}_s] (\bar{\mathbf{x}}_i - \bar{\mathbf{x}}_{N\cdot})$$

$$\text{Cov}[\text{Intercept}, \tilde{\beta}_s] = -\bar{\mathbf{x}}_N' \text{Var}[\tilde{\beta}_s]$$

Alternatively, the model option `FIXONETIME` estimates a one-way model where the heterogeneity comes from time effects. This option is analogous to re-sorting the data by time and then by cross section and running a `FIXONE` model. The advantage of using the `FIXONETIME` option is that sorting is avoided and the model remains labeled correctly.

Two-Way Fixed-Effects Model

The specification for the two-way fixed-effects model is

$$u_{it} = \gamma_i + \alpha_t + \epsilon_{it}$$

where the γ_i s and α_t s are nonrandom parameters to be estimated.

If you do not specify the `NOINT` option, which suppresses the intercept, the estimates for the fixed effects are reported under the restriction that $\gamma_N = 0$ and $\alpha_T = 0$. If you specify the `NOINT` option to suppress the intercept, only the restriction $\alpha_T = 0$ is imposed.

Balanced Panels

Assume that the data are balanced (for example, all cross sections have T observations). Then you can write the following:

$$\tilde{y}_{it} = y_{it} - \bar{y}_{i\cdot} - \bar{y}_{\cdot t} + \bar{\bar{y}}$$

$$\tilde{\mathbf{x}}_{it} = \mathbf{x}_{it} - \bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{\cdot t} + \bar{\bar{\mathbf{x}}}$$

where the symbols:

y_{it} and \mathbf{x}_{it} are the dependent variable (a scalar) and the explanatory variables (a vector whose columns are the explanatory variables not including a constant), respectively

$\bar{y}_{i\cdot}$ and $\bar{\mathbf{x}}_{i\cdot}$ are cross section means

$\bar{y}_{\cdot t}$ and $\bar{\mathbf{x}}_{\cdot t}$ are time means

$\bar{\bar{y}}$ and $\bar{\bar{\mathbf{x}}}$ are the overall means

The two-way fixed-effects model is simply a regression of \tilde{y}_{it} on $\tilde{\mathbf{x}}_{it}$. Therefore, the two-way β is given by:

$$\tilde{\beta}_s = (\tilde{\mathbf{X}}' \tilde{\mathbf{X}})^{-1} \tilde{\mathbf{X}}' \tilde{\mathbf{y}}$$

The calculations of cross section dummy variables, time dummy variables, and intercepts follow in a fashion similar to that used in the one-way model.

First, you obtain the net cross-sectional and time effects. Denote the cross-sectional effects by γ and the time effects by α . These effects are calculated from the following relations:

$$\hat{\gamma}_i = (\bar{y}_{i\cdot} - \bar{\bar{y}}) - \tilde{\beta}_s (\bar{x}_{i\cdot} - \bar{\bar{x}})$$

$$\hat{\alpha}_t = (\bar{y}_{\cdot t} - \bar{\bar{y}}) - \tilde{\beta}_s (\bar{x}_{\cdot t} - \bar{\bar{x}})$$

Denote the cross-sectional dummy variables and time dummy variables with the superscript C and T. Under the NOINT option the following equations give the dummy variables:

$$D_i^C = \hat{\gamma}_i + \hat{\alpha}_T$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

When an intercept is specified, the equations for dummy variables and intercept are:

$$D_i^C = \hat{\gamma}_i - \hat{\gamma}_N$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

$$\text{Intercept} = \hat{\gamma}_N + \hat{\alpha}_T$$

The sum of squared errors is:

$$\text{SSE} = \sum_{i=1}^N \sum_{t=1}^{T_i} (y_{it} - \gamma_i - \alpha_t - \mathbf{X}_s \tilde{\beta}_s)^2$$

The estimated error variance is:

$$\hat{\sigma}_\epsilon^2 = \text{SSE} / (M - N - T - (K - 1))$$

With or without a constant, the variance covariance matrix of $\tilde{\beta}_s$ is given by:

$$\text{Var}[\tilde{\beta}_s] = \hat{\sigma}_\epsilon^2 (\tilde{\mathbf{X}}_s' \tilde{\mathbf{X}}_s)^{-1}$$

Variance Covariance of Dummy Variables with No Intercept

The variances and covariances of the dummy variables are given with the NOINT specification as follows:

$$\begin{aligned}
 \text{Var} \left(D_i^C \right) &= \hat{\sigma}_\epsilon^2 \left(\frac{1}{T} + \frac{1}{N} - \frac{1}{NT} \right) \\
 &\quad + \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right) \\
 \text{Var} \left(D_t^T \right) &= \frac{2\hat{\sigma}_\epsilon^2}{N} + \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right) \\
 \text{Cov} \left(D_i^C, D_j^C \right) &= \hat{\sigma}_\epsilon^2 \left(\frac{1}{N} - \frac{1}{NT} \right) \\
 &\quad + \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{j\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right) \\
 \text{Cov} \left(D_t^T, D_u^T \right) &= \frac{\hat{\sigma}_\epsilon^2}{N} + \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{\cdot u} - \bar{\mathbf{x}}_{\cdot T} \right) \\
 \text{Cov} \left(D_i^C, D_t^T \right) &= -\frac{\hat{\sigma}_\epsilon^2}{N} + \left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right) \\
 \text{Cov} \left(D_i^C, \beta \right) &= -\left(\bar{\mathbf{x}}_{i\cdot} + \bar{\mathbf{x}}_{\cdot t} - \bar{\bar{\mathbf{x}}} \right)' \text{Var} \left[\tilde{\beta}_s \right] \\
 \text{Cov} \left(D_t^T, \beta \right) &= -\left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var} \left[\tilde{\beta}_s \right]
 \end{aligned}$$

Variance Covariance of Dummy Variables with Intercept

The variances and covariances of the dummy variables are given when the intercept is included as follows:

$$\begin{aligned}
 \text{Var} \left(D_i^C \right) &= \frac{2\hat{\sigma}_\epsilon^2}{T} + \left(\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot} \right) \\
 \text{Var} \left(D_t^T \right) &= \frac{2\hat{\sigma}_\epsilon^2}{N} + \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right) \\
 \text{Var} (\text{Intercept}) &= \hat{\sigma}_\epsilon^2 \left(\frac{1}{T} + \frac{1}{N} - \frac{1}{NT} \right) + \left(\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}} \right) \\
 \text{Cov} \left(D_i^C, D_j^C \right) &= \frac{\hat{\sigma}_\epsilon^2}{T} + \left(\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{j\cdot} - \bar{\mathbf{x}}_{N\cdot} \right) \\
 \text{Cov} \left(D_t^T, D_u^T \right) &= \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{\cdot u} - \bar{\mathbf{x}}_{\cdot T} \right) \\
 \text{Cov} \left(D_i^C, \text{Intercept} \right) &= -\left(\frac{\hat{\sigma}_\epsilon^2}{T} \right) + \left(\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}} \right) \\
 \text{Cov} \left(D_t^T, \text{Intercept} \right) &= -\left(\frac{\hat{\sigma}_\epsilon^2}{N} \right) + \left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var} \left[\tilde{\beta}_s \right] \left(\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}} \right) \\
 \text{Cov} \left(D_i^C, \tilde{\beta} \right) &= -\left(\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{N\cdot} \right)' \text{Var} \left[\tilde{\beta}_s \right] \\
 \text{Cov} \left(D_t^T, \tilde{\beta} \right) &= -\left(\bar{\mathbf{x}}_{\cdot t} - \bar{\mathbf{x}}_{\cdot T} \right)' \text{Var} \left[\tilde{\beta}_s \right] \\
 \text{Cov} \left(\text{Intercept}, \tilde{\beta} \right) &= -\left(\bar{\mathbf{x}}_{N\cdot} + \bar{\mathbf{x}}_{\cdot T} - \bar{\bar{\mathbf{x}}} \right)' \text{Var} \left[\tilde{\beta}_s \right]
 \end{aligned}$$

Unbalanced Panels

Let \mathbf{X}_* and \mathbf{y}_* be the independent and dependent variables arranged by time and by cross section within each time period. (Note that the input data set used by the PANEL procedure must be sorted by cross section and then by time within each cross section.) Let M_t be the number of cross sections observed in year t and let $\sum_t M_t = M$. Let \mathbf{D}_t be the $M_t \times N$ matrix obtained from the $N \times N$ identity matrix from which rows that correspond to cross sections not observed at time t have been omitted. Consider

$$\mathbf{Z} = (\mathbf{Z}_1, \mathbf{Z}_2)$$

where $\mathbf{Z}_1 = (\mathbf{D}'_1, \mathbf{D}'_2, \dots, \mathbf{D}'_T)'$ and $\mathbf{Z}_2 = \text{diag}(\mathbf{D}_1 \mathbf{j}_N, \mathbf{D}_2 \mathbf{j}_N, \dots, \mathbf{D}_T \mathbf{j}_N)$. The matrix \mathbf{Z} gives the dummy variable structure for the two-way model.

Let

$$\begin{aligned}\Delta_N &= \mathbf{Z}'_1 \mathbf{Z}_1 \\ \Delta_T &= \mathbf{Z}'_2 \mathbf{Z}_2 \\ \mathbf{A} &= \mathbf{Z}'_2 \mathbf{Z}_1 \\ \bar{\mathbf{Z}} &= \mathbf{Z}_2 - \mathbf{Z}_1 \Delta_N^{-1} \mathbf{A}' \\ \mathbf{Q} &= \Delta_T - \mathbf{A} \Delta_N^{-1} \mathbf{A}' \\ \mathbf{P} &= (\mathbf{I}_M - \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1) - \bar{\mathbf{Z}} \mathbf{Q}^{-1} \bar{\mathbf{Z}}'\end{aligned}$$

The estimate of the regression slope coefficients is given by

$$\tilde{\beta}_s = (\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{P} \mathbf{y}_*$$

where \mathbf{X}_{*s} is the \mathbf{X}_* matrix without the vector of 1s.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / (M - T - N + 1 - (K - 1))$$

where the residuals are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}'_M / M)(\mathbf{y}_* - \mathbf{X}_{*s} \tilde{\beta}_s)$ if there is an intercept in the model and by $\tilde{\mathbf{u}} = \mathbf{y}_* - \mathbf{X}_{*s} \tilde{\beta}_s$ if there is no intercept.

The actual implementation is quite different from the theory. The PANEL procedure transforms all series using the \mathbf{P} matrix.

$$\bar{\mathbf{v}} = \mathbf{P} \mathbf{v}$$

The variable being transformed is v , which could be \mathbf{y} or any column of \mathbf{X} . After the data are properly transformed, OLS is run on the resulting series.

Given $\tilde{\beta}_s$, the next step is estimating the cross-sectional and time effects. Given that $\boldsymbol{\gamma}$ is the column vector of cross-sectional effects and $\boldsymbol{\alpha}$ is the column vector of time effects,

$$\begin{aligned}\tilde{\boldsymbol{\alpha}} &= \mathbf{Q}^{-1} \bar{\mathbf{Z}}' \mathbf{y} - \mathbf{Q}^{-1} \bar{\mathbf{Z}}' \mathbf{X}_s \tilde{\beta}_s \\ \tilde{\boldsymbol{\gamma}} &= (\Theta_1 + \Theta_2 - \Theta_3) \mathbf{y} - (\Theta_1 + \Theta_2 - \Theta_3) \mathbf{X}_s \tilde{\beta}_s\end{aligned}$$

$$\Theta_1 = \Delta_N^{-1} \mathbf{Z}'_1$$

$$\Theta_2 = \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{Z}'_2$$

$$\Theta_3 = \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \mathbf{Z}'_1$$

Given the cross-sectional and time effects, the next step is to derive the associated dummy variables. Using the NOINT option, the following equations give the dummy variables:

$$D_i^C = \hat{\gamma}_i + \hat{\alpha}_T$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

When an intercept is desired, the equations for dummy variables and intercept are:

$$D_i^C = \hat{\gamma}_i - \hat{\gamma}_N$$

$$D_t^T = \hat{\alpha}_t - \hat{\alpha}_T$$

$$\text{Intercept} = \hat{\gamma}_N + \hat{\alpha}_T$$

The calculation of the variance-covariance matrix is as follows:

$$\begin{aligned} \text{Var}[\hat{\boldsymbol{\gamma}}] &= \hat{\sigma}_\epsilon^2 (\Delta_N^{-1} - \Sigma_1 + \Sigma_2) \\ &+ (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}[\tilde{\boldsymbol{\beta}}_s] (\Theta_1 + \Theta_2 - \Theta_3)' \end{aligned}$$

where

$$\Sigma_1 = \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1}$$

$$\Sigma_2 = \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \Delta_T \mathbf{Q}^{-1} \mathbf{A} \Delta_N$$

$$\text{Var}[\hat{\boldsymbol{\alpha}}] = \hat{\sigma}_\epsilon^2 (\mathbf{Q}^{-1} \bar{\mathbf{Z}}' \bar{\mathbf{Z}} \mathbf{Q}^{-1}) + (\mathbf{Q}^{-1} \bar{\mathbf{Z}}' \mathbf{X}_s) \text{Var}[\tilde{\boldsymbol{\beta}}_s] (\mathbf{X}_s' \bar{\mathbf{Z}} \mathbf{Q}^{-1})$$

$$\begin{aligned} \text{Cov}[\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\gamma}}'] &= \hat{\sigma}_\epsilon^2 \Delta_N^{-1} [\mathbf{A}' \mathbf{Q}^{-1} \Delta_T - \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \mathbf{A}'] \mathbf{Q}^{-1} \\ &+ (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}[\tilde{\boldsymbol{\beta}}_s] (\mathbf{X}_s' \bar{\mathbf{Z}} \mathbf{Q}^{-1}) \end{aligned}$$

$$\text{Cov}[\hat{\boldsymbol{\gamma}}, \tilde{\boldsymbol{\beta}}] = (\Theta_1 + \Theta_2 - \Theta_3) \text{Var}[\tilde{\boldsymbol{\beta}}_s]$$

$$\text{Cov}[\hat{\boldsymbol{\alpha}}, \tilde{\boldsymbol{\beta}}] = (\mathbf{Q}^{-1} \bar{\mathbf{Z}}' \mathbf{X}_s) \text{Var}[\tilde{\boldsymbol{\beta}}_s]$$

Now you work out the variance covariance estimates for the dummy variables.

Variance Covariance of Dummy Variables with No Intercept

The variances and covariances of the dummy variables are given under the NOINT selection as follows:

$$\begin{aligned}
 \text{Cov} \left(D_i^C, D_j^C \right) &= \text{Cov} \left(\hat{\gamma}_i, \hat{\gamma}_j \right) + \text{Cov} \left(\hat{\gamma}_i, \hat{\alpha}_T \right) + \text{Cov} \left(\hat{\gamma}_j, \hat{\alpha}_T \right) + \text{Var} \left(\hat{\alpha}_T \right) \\
 \text{Cov} \left(D_t^T, D_u^T \right) &= \text{Cov} \left(\hat{\alpha}_t, \hat{\alpha}_u \right) - \text{Cov} \left(\hat{\alpha}_t, \hat{\alpha}_T \right) - \text{Cov} \left(\hat{\alpha}_u, \hat{\alpha}_T \right) + \text{Var} \left(\hat{\alpha}_T \right) \\
 \text{Cov} \left(D_i^C, D_t^T \right) &= \text{Cov} \left(\hat{\gamma}_i, \hat{\alpha}_t \right) + \text{Cov} \left(\hat{\gamma}_i, \hat{\alpha}_T \right) - \text{Cov} \left(\hat{\gamma}_i, \hat{\alpha}_T \right) - \text{Var} \left(\hat{\alpha}_T \right) \\
 \text{Cov} \left(D_i^C, \tilde{\beta} \right) &= -\text{Cov} \left(\hat{\gamma}_i, \tilde{\beta} \right) - \text{Cov} \left(\hat{\alpha}_T, \tilde{\beta} \right) \\
 \text{Cov} \left(D_t^T, \tilde{\beta} \right) &= -\text{Cov} \left(\hat{\alpha}_t, \tilde{\beta} \right) + \text{Cov} \left(\hat{\alpha}_T, \tilde{\beta} \right)
 \end{aligned}$$

Variance Covariance of Dummy Variables with Intercept

The variances and covariances of the dummy variables are given as follows when the intercept is included:

$$\begin{aligned}
 \text{Cov} \left(D_i^C, D_j^C \right) &= \text{Cov} \left(\hat{\gamma}_i, \hat{\gamma}_j \right) - \text{Cov} \left(\hat{\gamma}_i, \hat{\gamma}_N \right) - \text{Cov} \left(\hat{\gamma}_j, \hat{\gamma}_N \right) + \text{Var} \left(\hat{\gamma}_N \right) \\
 \text{Cov} \left(D_t^T, D_u^T \right) &= \text{Cov} \left(\hat{\alpha}_t, \hat{\alpha}_u \right) - \text{Cov} \left(\hat{\alpha}_t, \hat{\alpha}_T \right) - \text{Cov} \left(\hat{\alpha}_u, \hat{\alpha}_T \right) + \text{Var} \left(\hat{\alpha}_T \right) \\
 \text{Cov} \left(D_i^C, D_t^T \right) &= \text{Cov} \left(\hat{\gamma}_i, \hat{\alpha}_t \right) - \text{Cov} \left(\hat{\gamma}_i, \hat{\alpha}_T \right) - \text{Cov} \left(\hat{\gamma}_N, \hat{\alpha}_t \right) + \text{Cov} \left(\hat{\gamma}_N, \hat{\alpha}_T \right) \\
 \text{Cov} \left(D_i^C, \text{Intercept} \right) &= \text{Cov} \left(\hat{\gamma}_i, \hat{\gamma}_N \right) + \text{Cov} \left(\hat{\gamma}_i, \hat{\alpha}_T \right) - \text{Cov} \left(\hat{\gamma}_j, \hat{\alpha}_T \right) - \text{Var} \left(\hat{\gamma}_N \right) \\
 \text{Cov} \left(D_t^T, \text{Intercept} \right) &= \text{Cov} \left(\hat{\alpha}_t, \hat{\alpha}_T \right) + \text{Cov} \left(\hat{\alpha}_t, \hat{\gamma}_N \right) - \text{Cov} \left(\hat{\alpha}_T, \hat{\alpha}_N \right) - \text{Var} \left(\hat{\alpha}_T \right) \\
 \text{Cov} \left(D_i^C, \tilde{\beta} \right) &= -\text{Cov} \left(\hat{\gamma}_i, \tilde{\beta} \right) - \text{Cov} \left(\hat{\gamma}_N, \tilde{\beta} \right) \\
 \text{Cov} \left(D_t^T, \tilde{\beta} \right) &= -\text{Cov} \left(\hat{\alpha}_t, \tilde{\beta} \right) + \text{Cov} \left(\hat{\alpha}_T, \tilde{\beta} \right) \\
 \text{Cov} \left(\text{Intercept}, \tilde{\beta} \right) &= -\text{Cov} \left(\hat{\alpha}_T, \tilde{\beta} \right) - \text{Cov} \left(\hat{\gamma}_N, \tilde{\beta} \right)
 \end{aligned}$$

Between Estimators

The between groups estimator is the regression of the cross section means of y on the cross section means of \tilde{X}_s . In other words, you fit the following regression:

$$\bar{y}_{i\cdot} = \bar{x}_{i\cdot} \beta^{BG} + \eta_i$$

The between time periods estimator is the regression of the time means of y on the time means of \tilde{X}_s . In other words, you fit the following regression:

$$\bar{y}_{\cdot t} = \bar{x}_{\cdot t} \beta^{BT} + \zeta_t$$

In either case, the error is assumed to be normally distributed with mean zero and a constant variance.

Pooled Estimator

PROC PANEL allows you to pool time series cross-sectional data and run regressions on the data. Pooling is admissible if there are no fixed effects or random effects present in the data. This feature is included to aid in analysis and comparison across model types and to give you access to HCCME standard errors and other panel diagnostics. In general, this model type should not be used with time series cross-sectional data.

One-Way Random-Effects Model

The specification for the one-way random-effects model is

$$u_{it} = v_i + \epsilon_{it}$$

Let $\mathbf{Z}_0 = \text{diag}(\mathbf{J}_{T_i})$, $\mathbf{P}_0 = \text{diag}(\bar{\mathbf{J}}_{T_i})$, and $\mathbf{Q}_0 = \text{diag}(\mathbf{E}_{T_i})$, with $\bar{\mathbf{J}}_{T_i} = \mathbf{J}_{T_i}/T_i$ and $\mathbf{E}_{T_i} = \mathbf{I}_{T_i} - \bar{\mathbf{J}}_{T_i}$. Define $\tilde{\mathbf{X}}_s = \mathbf{Q}_0\mathbf{X}_s$ and $\tilde{\mathbf{y}} = \mathbf{Q}_0\mathbf{y}$ and \mathbf{J} as a vector of ones T_i long.

In the one-way model, estimation proceeds in a two-step fashion. First, you obtain estimates of the variance of the σ_ϵ^2 and σ_v^2 . There are multiple ways to derive these estimates; PROC PANEL provides four options. All four options are valid for balanced or unbalanced panels. Once these estimates are in hand, they are used to form a weighting factor θ , and estimation proceeds via OLS on partial deviations from group means.

PROC PANEL gives the following options for variance component estimators.

Fuller and Battese's Method

The Fuller and Battese method for estimating variance components can be obtained with the option VCOMP = FB and the option RANONE. The variance components are given by the following equations (see Baltagi and Chang (1994) and Fuller and Battese (1974) for the approach in the two-way model). Let

$$R(v) = \mathbf{y}'\mathbf{Z}_0(\mathbf{Z}_0'\mathbf{Z}_0)^{-1}\mathbf{Z}_0'\mathbf{y}$$

$$R(\beta|v) = ((\tilde{\mathbf{X}}_s'\tilde{\mathbf{X}}_s)^{-1}\tilde{\mathbf{X}}_s'\tilde{\mathbf{y}})'(\tilde{\mathbf{X}}_s'\tilde{\mathbf{y}})$$

$$R(\beta) = (\mathbf{X}_s'\mathbf{y})'(\mathbf{X}_s'\mathbf{X}_s)^{-1}\mathbf{X}_s'\mathbf{y}$$

$$R(v|\beta) = R(\beta|v) + R(v) - R(\beta)$$

The estimator of the error variance is given by

$$\hat{\sigma}_\epsilon^2 = (\mathbf{y}'\mathbf{y} - R(\beta|v) - R(v))/(M - N - (K - 1))$$

If the NOINT option is specified, the estimator is

$$\hat{\sigma}_\epsilon^2 = (\mathbf{y}'\mathbf{y} - R(\beta|v) - R(v))/(M - N - K)$$

The estimator of the cross-sectional variance component is given by

$$\hat{\sigma}_v^2 = (R(v|\beta) - (N - 1)\hat{\sigma}_\epsilon^2)/(M - \text{tr}(\mathbf{Z}_0'\mathbf{X}_s(\mathbf{X}_s'\mathbf{X}_s)^{-1}\mathbf{X}_s'\mathbf{Z}_0))$$

Note that the error variance is the variance of the residual of the within estimator.

According to Baltagi and Chang (1994), the Fuller and Battese method is appropriate to apply to both balanced and unbalanced data. The Fuller and Battese method is the default for estimation of one-way random-effects models with balanced panels. However, the Fuller and Battese method does not always obtain nonnegative estimates for the cross section (or group) variance. In the case of a negative estimate, a warning is printed and the estimate is set to zero.

Wansbeek and Kapteyn's Method

The Wansbeek and Kapteyn method for estimating variance components can be obtained by setting VCOMP = WK (together with the option RANONE). The estimation of the one-way unbalanced data model is performed by using a specialization (Baltagi and Chang 1994) of the approach used by Wansbeek and Kapteyn (1989) for unbalanced two-way models. The Wansbeek and Kapteyn method is the default for unbalanced data. If just RANONE is specified, without the VCOMP= option, PROC PANEL estimates the variance component under Wansbeek and Kapteyn's method.

The estimation of the variance components is performed by using a quadratic unbiased estimation (QUE) method. This involves focusing on quadratic forms of the centered residuals, equating their expected values to the realized quadratic forms, and solving for the variance components.

Let

$$q_1 = \tilde{\mathbf{u}}' \mathbf{Q}_0 \tilde{\mathbf{u}}$$

$$q_2 = \tilde{\mathbf{u}}' \mathbf{P}_0 \tilde{\mathbf{u}}$$

where the residuals $\tilde{\mathbf{u}}$ are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}_M' / M)(\mathbf{y} - \mathbf{X}_s(\tilde{\mathbf{X}}_s' \tilde{\mathbf{X}}_s)^{-1} \tilde{\mathbf{X}}_s' \tilde{\mathbf{y}})$ if there is an intercept and by $\tilde{\mathbf{u}} = \mathbf{y} - \mathbf{X}_s(\tilde{\mathbf{X}}_s' \tilde{\mathbf{X}}_s)^{-1} \tilde{\mathbf{X}}_s' \tilde{\mathbf{y}}$ if there is not. A vector of M ones is represented by \mathbf{j} .

Consider the expected values

$$E(q_1) = (M - N - (K - 1))\sigma_\epsilon^2$$

$$E(q_2) = (N - 1 + \text{tr}[(\mathbf{X}_s' \mathbf{Q}_0 \mathbf{X}_s)^{-1} \mathbf{X}_s' \mathbf{P}_0 \mathbf{X}_s] - \text{tr}[(\mathbf{X}_s' \mathbf{Q}_0 \mathbf{X}_s)^{-1} \mathbf{X}_s' \bar{\mathbf{J}}_M \mathbf{X}_s])\sigma_\epsilon^2 \\ [M - (\sum_i T_i^2 / M)]\sigma_v^2$$

where $\hat{\sigma}_\epsilon^2$ and $\hat{\sigma}_v^2$ are obtained by equating the quadratic forms to their expected values.

The estimator of the error variance is the residual variance of the within estimate. The Wansbeek and Kapteyn method can also generate negative variance components estimates.

Wallace and Hussain's Method

The Wallace and Hussain method for estimating variance components can be obtained by setting VCOMP = WH (together with the option RANONE). Wallace-Hussain estimates start from OLS residuals on a data that are assumed to exhibit groupwise heteroscedasticity. As in the Wansbeek and Kapteyn method, you start with

$$q_1 = \tilde{\mathbf{u}}_{OLS}' \mathbf{Q}_0 \tilde{\mathbf{u}}_{OLS}$$

$$q_2 = \tilde{\mathbf{u}}_{OLS}' \mathbf{P}_0 \tilde{\mathbf{u}}_{OLS}$$

However, instead of using the ‘true’ errors, you substitute the OLS residuals. You solve the system

$$E(\hat{q}_1) = E(\hat{u}'_{OLS} \mathbf{Q}_0 \hat{u}_{OLS}) = \delta_{11} \hat{\sigma}_v^2 + \delta_{12} \hat{\sigma}_\epsilon^2$$

$$E(\hat{q}_2) = E(\hat{u}'_{OLS} \mathbf{P}_0 \hat{u}_{OLS}) = \delta_{21} \hat{\sigma}_v^2 + \delta_{22} \hat{\sigma}_\epsilon^2$$

The constants $\delta_{11}, \delta_{12}, \delta_{21}, \delta_{22}$ are given by

$$\delta_{11} = \text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{Z}_0\mathbf{Z}_0'\mathbf{X} \right) - \text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{P}_0\mathbf{X} \left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{Z}_0\mathbf{Z}_0'\mathbf{X} \right)$$

$$\delta_{12} = M - N - K + \text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{P}_0\mathbf{X} \right)$$

$$\delta_{21} = M - 2\text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{Z}_0\mathbf{Z}_0'\mathbf{X} \right) + \text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{P}_0\mathbf{X} \right)$$

$$\delta_{22} = N - \text{tr} \left(\left(\mathbf{X}'\mathbf{X} \right)^{-1} \mathbf{X}'\mathbf{P}_0\mathbf{X} \right)$$

where $\text{tr}()$ is the trace operator on a square matrix.

Solving this system produces the variance components. This method is applicable to balanced and unbalanced panels. However, there is no guarantee of positive variance components. Any negative values are fixed equal to zero.

Nerlove's Method

The Nerlove method for estimating variance components can be obtained by setting $\text{VCOMP} = \text{NL}$. The Nerlove method (see Baltagi 1995, page 17) is assured to give estimates of the variance components that are always positive. Furthermore, it is simple in contrast to the previous estimators.

If γ_i is the i th fixed effect, Nerlove's method uses the variance of the fixed effects as the estimate of $\hat{\sigma}_v^2$. You have $\hat{\sigma}_v^2 = \sum_{i=1}^N \frac{(\gamma_i - \bar{\gamma})^2}{N-1}$, where $\bar{\gamma}$ is the mean fixed effect. The estimate of σ_ϵ^2 is simply the residual sum of squares of the one-way fixed-effects regression divided by the number of observations.

With the variance components in hand, from any method, the next task is to estimate the regression model of interest. For each individual, you form a weight (θ_i) as follows:

$$\theta_i = 1 - \sigma_\epsilon / w_i$$

$$w_i^2 = T_i \sigma_v^2 + \sigma_\epsilon^2$$

where T_i is the i th cross section's time observations.

Taking the θ_i , you form the partial deviations,

$$\tilde{y}_{it} = y_{it} - \theta_i \bar{y}_i.$$

$$\tilde{x}_{it} = x_{it} - \theta_i \bar{x}_i.$$

where \bar{y}_i and \bar{x}_i are cross section means of the dependent variable and independent variables (including the constant if any), respectively.

The random-effects β is then the result of simple OLS on the transformed data.

Two-Way Random-Effects Model

The specification for the two-way random-effects model is

$$u_{it} = v_i + e_t + \epsilon_{it}$$

As in the one-way random-effects model, the PANEL procedure provides four options for variance component estimators. Unlike the one-way random-effects model, unbalanced panels present some special concerns.

Let \mathbf{X}_* and \mathbf{y}_* be the independent and dependent variables arranged by time and by cross section within each time period. (Note that the input data set used by the PANEL procedure must be sorted by cross section and then by time within each cross section.) Let M_t be the number of cross sections observed in time t and $\sum_t M_t = M$. Let \mathbf{D}_t be the $M_t \times N$ matrix obtained from the $N \times N$ identity matrix from which rows that correspond to cross sections not observed at time t have been omitted. Consider

$$\mathbf{Z} = (\mathbf{Z}_1, \mathbf{Z}_2)$$

where $\mathbf{Z}_1 = (\mathbf{D}'_1, \mathbf{D}'_2, \dots, \mathbf{D}'_T)'$ and $\mathbf{Z}_2 = \text{diag}(\mathbf{D}_1\mathbf{j}_N, \mathbf{D}_2\mathbf{j}_N, \dots, \mathbf{D}_T\mathbf{j}_N)$.

The matrix \mathbf{Z} gives the dummy variable structure for the two-way model.

For notational ease, let

$$\Delta_N = \mathbf{Z}'_1\mathbf{Z}_1, \Delta_T = \mathbf{Z}'_2\mathbf{Z}_2, \mathbf{A} = \mathbf{Z}'_2\mathbf{Z}_1$$

$$\bar{\mathbf{Z}} = \mathbf{Z}_2 - \mathbf{Z}_1\Delta_N^{-1}\mathbf{A}'$$

$$\bar{\Delta}_1 = \mathbf{I}_M - \mathbf{Z}_1\Delta_N^{-1}\mathbf{Z}'_1$$

$$\bar{\Delta}_2 = \mathbf{I}_M - \mathbf{Z}_2\Delta_T^{-1}\mathbf{Z}'_2$$

$$\mathbf{Q} = \Delta_T - \mathbf{A}\Delta_N^{-1}\mathbf{A}'$$

$$\mathbf{P} = (\mathbf{I}_M - \mathbf{Z}_1\Delta_N^{-1}\mathbf{Z}'_1) - \bar{\mathbf{Z}}\mathbf{Q}^{-1}\bar{\mathbf{Z}}'$$

Fuller and Battese's Method

The Fuller and Battese method for estimating variance components can be obtained by setting VCOMP = FB (with the option RANTWO). FB is the default method for a RANTWO model with balanced panel. If RANTWO is requested without specifying the VCOMP= option, PROC PANEL proceeds under the Fuller and Battese method.

Following the discussion in Baltagi, et. al. (2002), the Fuller and Battese method forms the estimates as follows.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}'\mathbf{P}\tilde{\mathbf{u}}/(M - T - N + 1 - (K - 1))$$

where \mathbf{P} is the Wansbeek and Kapteyn within estimator for unbalanced (or balanced) panel in a two-way setting.

The estimator of the error variance is the same as that in the Wansbeek and Kapteyn method.

Consider the expected values

$$\begin{aligned}
 E(q_N) &= \sigma_e^2 [M - T - K + 1] \\
 &+ \sigma_v^2 \left[M - T - \text{tr} \left(\mathbf{X}'_s \bar{\Delta}_2 \mathbf{Z}_1 \mathbf{Z}'_1 \bar{\Delta}_2 \mathbf{X}_s (\mathbf{X}'_s \bar{\Delta}_2 \mathbf{X}_s)^{-1} \right) \right] \\
 E(q_T) &= \sigma_e^2 [M - N - K + 1] \\
 &+ \sigma_e^2 \left[M - N - \text{tr} \left(\mathbf{X}'_s \bar{\Delta}_1 \mathbf{Z}_2 \mathbf{Z}'_2 \bar{\Delta}_1 \mathbf{X}_s (\mathbf{X}'_s \bar{\Delta}_1 \mathbf{X}_s)^{-1} \right) \right]
 \end{aligned}$$

Just as in the one-way case, there is always the possibility that the (estimated) variance components will be negative. In such a case, the negative components are fixed to equal zero. After substituting the group sum of the within residuals for (q_N) , the time sums of the within residuals for (q_T) , and $\hat{\sigma}_e^2$, the two equations are solved for $\hat{\sigma}_v^2$ and $\hat{\sigma}_e^2$.

Wansbeek and Kapteyn's Method

The Wansbeek and Kapteyn method for estimating variance components can be obtained by setting VCOMP = WK. The following methodology, outlined in Wansbeek and Kapteyn (1989) is used to handle both balanced and unbalanced data. The Wansbeek and Kapteyn method is the default for a RANTWO model with unbalanced panel. If RANTWO is requested without specifying the VCOMP= option, PROC PANEL proceeds under the Wansbeek and Kapteyn method if the panel is unbalanced.

The estimator of the error variance is

$$\hat{\sigma}_e^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / (M - T - N + 1 - (K - 1))$$

where the $\tilde{\mathbf{u}}$ are given by $\tilde{\mathbf{u}} = (\mathbf{I}_M - \mathbf{j}_M \mathbf{j}'_M / M)(\mathbf{y}_* - \mathbf{X}_{*s}(\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{P} \mathbf{y}_*)$ if there is an intercept and by $\tilde{\mathbf{u}} = (\mathbf{y}_* - \mathbf{X}_{*s}(\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{P} \mathbf{y}_*)$ if there is not.

The estimation of the variance components is performed by using a quadratic unbiased estimation (QUE) method that involves computing on quadratic forms of the residuals $\tilde{\mathbf{u}}$, equating their expected values to the realized quadratic forms, and solving for the variance components.

Let

$$q_N = \tilde{\mathbf{u}}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}'_2 \tilde{\mathbf{u}}$$

$$q_T = \tilde{\mathbf{u}}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1 \tilde{\mathbf{u}}$$

The expected values are

$$\begin{aligned}
 E(q_N) &= (T + k_N - (1 + k_0))\sigma^2 + (T - \frac{\lambda_1}{M})\sigma_v^2 + (M - \frac{\lambda_2}{M})\sigma_e^2 \\
 E(q_T) &= (N + k_T - (1 + k_0))\sigma^2 \\
 &+ (M - \frac{\lambda_1}{M})\sigma_v^2 + (N - \frac{\lambda_2}{M})\sigma_e^2
 \end{aligned}$$

where

$$k_0 = \mathbf{j}'_M \mathbf{X}_{*s} (\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{j}_M / M$$

$$k_N = \text{tr}((\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}'_2 \mathbf{X}_{*s})$$

$$k_T = \text{tr}((\mathbf{X}'_{*s} \mathbf{P} \mathbf{X}_{*s})^{-1} \mathbf{X}'_{*s} \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1 \mathbf{X}_{*s})$$

$$\lambda_1 = \mathbf{j}'_M \mathbf{Z}_1 \mathbf{Z}'_1 \mathbf{j}_M$$

$$\lambda_2 = \mathbf{j}'_M \mathbf{Z}_2 \mathbf{Z}'_2 \mathbf{j}_M$$

The quadratic unbiased estimators for σ_v^2 and σ_e^2 are obtained by equating the expected values to the quadratic forms and solving for the two unknowns.

When the NOINT option is specified, the variance component equations change slightly. In particular, the following is true (Wansbeek and Kapteyn 1989):

$$E(q_N) = (T + k_N)\sigma^2 + T\sigma_v^2 + M\sigma_e^2$$

$$E(q_T) = (N + k_T)\sigma^2 + M\sigma_v^2 + N\sigma_e^2$$

Wallace and Hussain's Method

The Wallace and Hussain method for estimating variance components can be obtained by setting VCOMP = WH. Wallace and Hussain's method is by far the most computationally intensive. It uses the OLS residuals to estimate the variance components. In other words, the Wallace and Hussain method assumes that the following holds:

$$q_\epsilon = \tilde{\mathbf{u}}'_{OLS} \mathbf{P} \tilde{\mathbf{u}}_{OLS}$$

$$q_N = \tilde{\mathbf{u}}'_{OLS} \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}'_2 \tilde{\mathbf{u}}_{OLS}$$

$$q_T = \tilde{\mathbf{u}}'_{OLS} \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1 \tilde{\mathbf{u}}_{OLS}$$

Taking expectations yields

$$E(q_\epsilon) = E(\tilde{\mathbf{u}}'_{OLS} \mathbf{P} \tilde{\mathbf{u}}_{OLS}) = \delta_{11}\sigma_\epsilon^2 + \delta_{12}\sigma_v^2 + \delta_{13}\sigma_e^2$$

$$E(q_N) = E(\tilde{\mathbf{u}}'_{OLS} \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}'_2 \tilde{\mathbf{u}}_{OLS}) = \delta_{21}\sigma_\epsilon^2 + \delta_{22}\sigma_v^2 + \delta_{23}\sigma_e^2$$

$$E(q_T) = E(\tilde{\mathbf{u}}'_{OLS} \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}'_1 \tilde{\mathbf{u}}_{OLS}) = \delta_{31}\sigma_\epsilon^2 + \delta_{32}\sigma_v^2 + \delta_{33}\sigma_e^2$$

where the δ_{js} constants are defined by

$$\delta_{11} = M - N - T + 1 - \text{tr}(\mathbf{X}' \mathbf{P} \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1})$$

$$\delta_{12} = \text{tr}(\mathbf{X}' \mathbf{Z}_1 \mathbf{Z}'_1 \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} (\mathbf{X}' \mathbf{P} \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1}))$$

$$\delta_{13} = \text{tr}(\mathbf{X}' \mathbf{Z}_2 \mathbf{Z}'_2 \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} (\mathbf{X}' \mathbf{P} \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1}))$$

$$\delta_{21} = T - \text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right)$$

$$\begin{aligned} \delta_{22} &= T - 2\text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \mathbf{Z}_1 \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \\ &\quad + \text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \mathbf{X}' \mathbf{Z}_1 \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \end{aligned}$$

$$\begin{aligned} \delta_{23} &= T - 2\text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \\ &\quad + \text{tr} \left(\mathbf{X}' \mathbf{Z}_2 \Delta_T^{-1} \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \mathbf{X}' \mathbf{Z}_2 \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \end{aligned}$$

$$\delta_{31} = N - \text{tr} \left(\mathbf{X}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right)$$

$$\begin{aligned} \delta_{32} &= M - 2\text{tr} \left(\mathbf{X}' \mathbf{Z}_1 \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \\ &\quad + \text{tr} \left(\mathbf{X}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \mathbf{X}' \mathbf{Z}_1 \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \end{aligned}$$

$$\begin{aligned} \delta_{33} &= N - 2\text{tr} \left(\mathbf{X}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \mathbf{Z}_2 \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \\ &\quad + \text{tr} \left(\mathbf{X}' \mathbf{Z}_1 \Delta_N^{-1} \mathbf{Z}_1' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \mathbf{X}' \mathbf{Z}_2 \mathbf{Z}_2' \mathbf{X} (\mathbf{X}' \mathbf{X})^{-1} \right) \end{aligned}$$

The PANEL procedure solves this system for the estimates $\hat{\sigma}_\epsilon$, $\hat{\sigma}_v$, and $\hat{\sigma}_e$. Some of the estimated variance components can be negative. Negative components are set to zero and estimation proceeds.

Nerlove's Method

The Nerlove method for estimating variance components can be obtained with by setting VCOMP = NL.

The estimator of the error variance is

$$\hat{\sigma}_\epsilon^2 = \tilde{\mathbf{u}}' \mathbf{P} \tilde{\mathbf{u}} / M$$

The variance components for cross section and time effects are:

$$\hat{\sigma}_v^2 = \sum_{i=1}^N \frac{(\gamma_i - \bar{\gamma})^2}{N-1} \text{ where } \gamma_i \text{ is the } i\text{th cross section effect}$$

and

$$\hat{\sigma}_e^2 = \sum_{t=1}^T \frac{(\alpha_t - \bar{\alpha})^2}{T-1} \text{ where } \alpha_t \text{ is the } t\text{th time effect}$$

With the estimates of the variance components in hand, you can proceed to the final estimation. If the panel is balanced, partial mean deviations are used:

$$\tilde{y}_{it} = y_{it} - \theta_1 \bar{y}_{i\cdot} - \theta_2 \bar{y}_{\cdot t} + \theta_3 \bar{y}_{\cdot\cdot}$$

$$\tilde{x}_{it} = x_{it} - \theta_1 \bar{x}_{i\cdot} - \theta_2 \bar{x}_{\cdot t} + \theta_3 \bar{x}_{\cdot\cdot}$$

The θ estimates are obtained from

$$\theta_1 = 1 - \frac{\sigma_\epsilon}{\sqrt{T\sigma_v^2 + \sigma_\epsilon^2}}$$

$$\theta_2 = 1 - \frac{\sigma_\epsilon}{\sqrt{N\sigma_e^2 + \sigma_\epsilon^2}}$$

$$\theta_3 = \theta_1 + \theta_2 + \frac{\sigma_\epsilon}{\sqrt{T\sigma_v^2 + N\sigma_e^2 + \sigma_\epsilon^2}} - 1;$$

With these partial deviations, PROC PANEL uses OLS on the transformed series (including an intercept if so desired).

The case of an unbalanced panel is somewhat trickier. You could naively substitute the variance components in the equation below:

$$\Omega = \sigma_\epsilon^2 \mathbf{I}_M + \sigma_v^2 \mathbf{Z}_1 \mathbf{Z}_1' + \sigma_e^2 \mathbf{Z}_2 \mathbf{Z}_2'$$

After inverting the expression for Ω , it is possible to do GLS on the data (even if the panel is unbalanced). However, the inversion of Ω is no small matter because the dimension is at least $\frac{M(M+1)}{2}$.

Wansbeek and Kapteyn show that the inverse of Ω can be written as

$$\sigma_\epsilon^2 \Omega^{-1} = \mathbf{V} - \mathbf{V} \mathbf{Z}_2 \tilde{\mathbf{P}}^{-1} \mathbf{Z}_2' \mathbf{V}$$

with the following:

$$\begin{aligned} \mathbf{V} &= \mathbf{I}_M - \mathbf{Z}_1 \tilde{\Delta}_N^{-1} \mathbf{Z}_1' \\ \tilde{\mathbf{P}} &= \tilde{\Delta}_T - \mathbf{A} \tilde{\Delta}_N^{-1} \mathbf{A}' \\ \tilde{\Delta}_N &= \Delta_N + \left(\frac{\sigma_\epsilon^2}{\sigma_v^2} \right) \mathbf{I}_N \\ \tilde{\Delta}_T &= \Delta_T + \left(\frac{\sigma_\epsilon^2}{\sigma_e^2} \right) \mathbf{I}_T \end{aligned}$$

Computationally, this is a much less intensive approach.

By using the inverse of the variance-covariance matrix of the error, it becomes possible to complete GLS on the unbalanced panel.

Parks Method (Autoregressive Model)

Parks (1967) considered the first-order autoregressive model in which the random errors u_{it} , $i = 1, 2, \dots, N$, and $t = 1, 2, \dots, T$ have the structure

$$\begin{aligned} E(u_{it}^2) &= \sigma_{ii}(\text{heteroscedasticity}) \\ E(u_{it}u_{jt}) &= \sigma_{ij}(\text{contemporaneously correlated}) \\ u_{it} &= \rho_i u_{i,t-1} + \epsilon_{it}(\text{autoregression}) \end{aligned}$$

where

$$\begin{aligned} E(\epsilon_{it}) &= 0 \\ E(u_{i,t-1}\epsilon_{jt}) &= 0 \\ E(\epsilon_{it}\epsilon_{jt}) &= \phi_{ij} \\ E(\epsilon_{it}\epsilon_{js}) &= 0 (s \neq t) \\ E(u_{i0}) &= 0 \\ E(u_{i0}u_{j0}) &= \sigma_{ij} = \phi_{ij}/(1 - \rho_i\rho_j) \end{aligned}$$

The model assumed is first-order autoregressive with contemporaneous correlation between cross sections. In this model, the covariance matrix for the vector of random errors \mathbf{u} can be expressed as

$$E(\mathbf{u}\mathbf{u}') = \mathbf{V} = \begin{bmatrix} \sigma_{11}P_{11} & \sigma_{12}P_{12} & \dots & \sigma_{1N}P_{1N} \\ \sigma_{21}P_{21} & \sigma_{22}P_{22} & \dots & \sigma_{2N}P_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{N1}P_{N1} & \sigma_{N2}P_{N2} & \dots & \sigma_{NN}P_{NN} \end{bmatrix}$$

where

$$P_{ij} = \begin{bmatrix} 1 & \rho_j & \rho_j^2 & \dots & \rho_j^{T-1} \\ \rho_i & 1 & \rho_j & \dots & \rho_j^{T-2} \\ \rho_i^2 & \rho_i & 1 & \dots & \rho_j^{T-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \rho_i^{T-1} & \rho_i^{T-2} & \rho_i^{T-3} & \dots & 1 \end{bmatrix}$$

The matrix \mathbf{V} is estimated by a two-stage procedure, and $\boldsymbol{\beta}$ is then estimated by generalized least squares. The first step in estimating \mathbf{V} involves the use of ordinary least squares to estimate $\boldsymbol{\beta}$ and obtain the fitted residuals, as follows:

$$\hat{\mathbf{u}} = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{OLS}$$

A consistent estimator of the first-order autoregressive parameter is then obtained in the usual manner, as follows:

$$\hat{\rho}_i = \left(\sum_{t=2}^T \hat{u}_{it}\hat{u}_{i,t-1} \right) / \left(\sum_{t=2}^T \hat{u}_{i,t-1}^2 \right) \quad i = 1, 2, \dots, N$$

Finally, the autoregressive characteristic of the data is removed (asymptotically) by the usual transformation of taking weighted differences. That is, for $i = 1, 2, \dots, N$,

$$y_{i1} \sqrt{1 - \hat{\rho}_i^2} = \sum_{k=1}^p X_{i1k} \sqrt{1 - \hat{\rho}_i^2} + u_{i1} \sqrt{1 - \hat{\rho}_i^2}$$

$$y_{it} - \hat{\rho}_i y_{i,t-1} = \sum_{k=1}^p (X_{itk} - \hat{\rho}_i X_{i,t-1,k}) \beta_k + u_{it} - \hat{\rho}_i u_{i,t-1} \quad t = 2, \dots, T$$

which is written

$$y_{it}^* = \sum_{k=1}^p X_{itk}^* \beta_k + u_{it}^* \quad i = 1, 2, \dots, N; \quad t = 1, 2, \dots, T$$

Notice that the transformed model has not lost any observations (Seely and Zyskind 1971).

The second step in estimating the covariance matrix \mathbf{V} is applying ordinary least squares to the preceding transformed model, obtaining

$$\hat{\mathbf{u}}^* = \mathbf{y}^* - \mathbf{X}^* \hat{\boldsymbol{\beta}}_{OLS}^*$$

from which the consistent estimator of σ_{ij} is calculated as follows:

$$s_{ij} = \frac{\hat{\phi}_{ij}}{(1 - \hat{\rho}_i \hat{\rho}_j)}$$

where

$$\hat{\phi}_{ij} = \frac{1}{(T-p)} \sum_{t=1}^T \hat{u}_{it}^* \hat{u}_{jt}^*$$

Estimated generalized least squares (EGLS) then proceeds in the usual manner,

$$\hat{\boldsymbol{\beta}}_P = (\mathbf{X}' \hat{\mathbf{V}}^{-1} \mathbf{X})^{-1} \mathbf{X}' \hat{\mathbf{V}}^{-1} \mathbf{y}$$

where $\hat{\mathbf{V}}$ is the derived consistent estimator of \mathbf{V} . For computational purposes, $\hat{\boldsymbol{\beta}}_P$ is obtained directly from the transformed model,

$$\hat{\boldsymbol{\beta}}_P = (\mathbf{X}^{*'} (\hat{\Phi}^{-1} \otimes I_T) \mathbf{X}^*)^{-1} \mathbf{X}^{*'} (\hat{\Phi}^{-1} \otimes I_T) \mathbf{y}^*$$

where $\hat{\Phi} = [\hat{\phi}_{ij}]_{i,j=1,\dots,N}$.

The preceding procedure is equivalent to Zellner's two-stage methodology applied to the transformed model (Zellner 1962).

Parks demonstrates that this estimator is consistent and asymptotically, normally distributed with

$$\text{Var}(\hat{\boldsymbol{\beta}}_P) = (\mathbf{X}' \mathbf{V}^{-1} \mathbf{X})^{-1}$$

Standard Corrections

For the PARKS option, the first-order autocorrelation coefficient must be estimated for each cross section. Let ρ be the $N \times 1$ vector of true parameters and $R = (r_1, \dots, r_N)'$ be the corresponding vector of estimates. Then, to ensure that only range-preserving estimates are used in PROC PANEL, the following modification for R is made:

$$r_i = \begin{cases} r_i & \text{if } |r_i| < 1 \\ \max(.95, r_{\max}) & \text{if } r_i \geq 1 \\ \min(-.95, r_{\min}) & \text{if } r_i \leq -1 \end{cases}$$

where

$$r_{\max} = \begin{cases} 0 & \text{if } r_i < 0 \text{ or } r_i \geq 1 \quad \forall i \\ \max_j [r_j : 0 \leq r_j < 1] & \text{otherwise} \end{cases}$$

and

$$r_{\min} = \begin{cases} 0 & \text{if } r_i > 0 \text{ or } r_i \leq -1 \quad \forall i \\ \max_j [r_j : -1 < r_j \leq 0] & \text{otherwise} \end{cases}$$

Whenever this correction is made, a warning message is printed.

Da Silva Method (Variance-Component Moving Average Model)

The Da Silva method assumes that the observed value of the dependent variable at the t th time point on the i th cross-sectional unit can be expressed as

$$y_{it} = \mathbf{x}_{it}'\beta + a_i + b_t + e_{it} \quad i = 1, \dots, N; t = 1, \dots, T$$

where

$\mathbf{x}_{it}' = (x_{it1}, \dots, x_{itp})$ is a vector of explanatory variables for the t th time point and i th cross-sectional unit

$\beta = (\beta_1, \dots, \beta_p)'$ is the vector of parameters

a_i is a time-invariant, cross-sectional unit effect

b_t is a cross-sectionally invariant time effect

e_{it} is a residual effect unaccounted for by the explanatory variables and the specific time and cross-sectional unit effects

Since the observations are arranged first by cross sections, then by time periods within cross sections, these equations can be written in matrix notation as

$$\mathbf{y} = \mathbf{X}\beta + \mathbf{u}$$

where

$$\mathbf{u} = (\mathbf{a} \otimes \mathbf{1}_T) + (\mathbf{1}_N \otimes \mathbf{b}) + \mathbf{e}$$

$$\begin{aligned}
 \mathbf{y} &= (y_{11}, \dots, y_{1T}, y_{21}, \dots, y_{NT})' \\
 \mathbf{X} &= (\mathbf{x}_{11}, \dots, \mathbf{x}_{1T}, \mathbf{x}_{21}, \dots, \mathbf{x}_{NT})' \\
 \mathbf{a} &= (a_1 \dots a_N)' \\
 \mathbf{b} &= (b_1 \dots b_T)' \\
 \mathbf{e} &= (e_{11}, \dots, e_{1T}, e_{21}, \dots, e_{NT})'
 \end{aligned}$$

Here $\mathbf{1}_N$ is an $N \times 1$ vector with all elements equal to 1, and \otimes denotes the Kronecker product.

The following conditions are assumed:

1. \mathbf{x}_{it} is a sequence of nonstochastic, known $p \times 1$ vectors in \Re^p whose elements are uniformly bounded in \Re^p . The matrix \mathbf{X} has a full column rank p .
2. $\boldsymbol{\beta}$ is a $p \times 1$ constant vector of unknown parameters.
3. \mathbf{a} is a vector of uncorrelated random variables such that $E(a_i) = 0$ and $\text{var}(a_i) = \sigma_a^2$, $\sigma_a^2 > 0, i = 1, \dots, N$.
4. \mathbf{b} is a vector of uncorrelated random variables such that $E(b_t) = 0$ and $\text{var}(b_t) = \sigma_b^2$ where $\sigma_b^2 > 0$ and $t = 1, \dots, T$.
5. $\mathbf{e}_i = (e_{i1}, \dots, e_{iT})'$ is a sample of a realization of a finite moving-average time series of order $m < T - 1$ for each i ; hence,

$$e_{it} = \alpha_0 \epsilon_{it} + \alpha_1 \epsilon_{it-1} + \dots + \alpha_m \epsilon_{it-m} \quad t = 1, \dots, T; i = 1, \dots, N$$

where $\alpha_0, \alpha_1, \dots, \alpha_m$ are unknown constants such that $\alpha_0 \neq 0$ and $\alpha_m \neq 0$, and $\{\epsilon_{ij}\}_{j=-\infty}^{j=\infty}$ is a white noise process for each i —that is, a sequence of uncorrelated random variables with $E(\epsilon_t) = 0$, $E(\epsilon_t^2) = \sigma_\epsilon^2$, and $\sigma_\epsilon^2 > 0$. $\{\epsilon_{ij}\}_{j=-\infty}^{j=\infty}$ for $i = 1, \dots, N$ are mutually uncorrelated.

6. The sets of random variables $\{a_i\}_{i=1}^N$, $\{b_t\}_{t=1}^T$, and $\{e_{it}\}_{t=1}^T$ for $i = 1, \dots, N$ are mutually uncorrelated.
7. The random terms have normal distributions $a_i \sim N(0, \sigma_a^2)$, $b_t \sim N(0, \sigma_b^2)$, and $\epsilon_{t-k} \sim N(0, \sigma_\epsilon^2)$, for $i = 1, \dots, N$; $t = 1, \dots, T$; and $k = 1, \dots, m$.

If assumptions 1–6 are satisfied, then

$$E(\mathbf{y}) = \mathbf{X}\boldsymbol{\beta}$$

and

$$\text{var}(\mathbf{y}) = \sigma_a^2 (\mathbf{I}_N \otimes \mathbf{J}_T) + \sigma_b^2 (\mathbf{J}_N \otimes \mathbf{I}_T) + (\mathbf{I}_N \otimes \boldsymbol{\Psi}_T)$$

where $\boldsymbol{\Psi}_T$ is a $T \times T$ matrix with elements ψ_{ts} as follows:

$$\text{Cov}(e_{it} e_{is}) = \begin{cases} \psi(|t-s|) & \text{if } |t-s| \leq m \\ 0 & \text{if } |t-s| > m \end{cases}$$

where $\psi(k) = \sigma_\epsilon^2 \sum_{j=0}^{m-k} \alpha_j \alpha_{j+k}$ for $k = |t - s|$. For the definition of I_N , I_T , J_N , and J_T , see the section “Fuller and Battese’s Method” on page 1372.

The covariance matrix, denoted by \mathbf{V} , can be written in the form

$$\mathbf{V} = \sigma_a^2(I_N \otimes J_T) + \sigma_b^2(J_N \otimes I_T) + \sum_{k=0}^m \psi(k)(I_N \otimes \Psi_T^{(k)})$$

where $\Psi_T^{(0)} = I_T$, and, for $k=1, \dots, m$, $\Psi_T^{(k)}$ is a band matrix whose k th off-diagonal elements are 1’s and all other elements are 0’s.

Thus, the covariance matrix of the vector of observations \mathbf{y} has the form

$$\text{Var}(\mathbf{y}) = \sum_{k=1}^{m+3} v_k V_k$$

where

$$\begin{aligned} v_1 &= \sigma_a^2 \\ v_2 &= \sigma_b^2 \\ v_k &= \psi(k-3) \quad k = 3, \dots, m+3 \\ V_1 &= I_N \otimes J_T \\ V_2 &= J_N \otimes I_T \\ V_k &= I_N \otimes \Psi_T^{(k-3)} \quad k = 3, \dots, m+3 \end{aligned}$$

The estimator of β is a two-step GLS-type estimator—that is, GLS with the unknown covariance matrix replaced by a suitable estimator of \mathbf{V} . It is obtained by substituting Seely estimates for the scalar multiples v_k , $k = 1, 2, \dots, m+3$.

Seely (1969) presents a general theory of unbiased estimation when the choice of estimators is restricted to finite dimensional vector spaces, with a special emphasis on quadratic estimation of functions of the form $\sum_{i=1}^n \delta_i v_i$.

The parameters v_i ($i = 1, \dots, n$) are associated with a linear model $E(\mathbf{y}) = \mathbf{X}\beta$ with covariance matrix $\sum_{i=1}^n v_i V_i$ where V_i ($i = 1, \dots, n$) are real symmetric matrices. The method is also discussed by Seely (1970a, 1970b) and Seely and Zyskind (1971). Seely and Soong (1971) consider the MINQUE principle, using an approach along the lines of Seely (1969).

Dynamic Panel Estimator

For an example on dynamic panel estimation using GMM option, see “Example 20.6: The Cigarette Sales Data: Dynamic Panel Estimation with GMM” on page 1435.

Consider the case of the following general model:

$$y_{it} = \sum_{l=1}^{maxlag} \phi_l y_{i(t-l)} + \sum_{k=1}^K \beta_k x_{itk} + \gamma_i + \alpha_t + \epsilon_{it}$$

Note that the maximum size of the \mathbf{H}_i matrix is T-2. The origins of the initial weighting matrix are the expected error covariances. Notice that on the diagonals,

$$E(v_{it}v_{it}) = E(\epsilon_{it}^2 - 2\epsilon_{it}\epsilon_{i(t-1)} + \epsilon_{i(t-1)}^2) = 2\sigma_\epsilon^2$$

and off diagonals,

$$E(v_{it}v_{i(t-1)}) = E(\epsilon_{it}\epsilon_{i(t-1)} - \epsilon_{it}\epsilon_{i(t-2)} - \epsilon_{i(t-1)}\epsilon_{i(t-1)} + \epsilon_{i(t-1)}\epsilon_{i(t-2)}) = -\sigma_\epsilon^2$$

If you let the vector of lagged differences (in the series y_{it}) be denoted as Δy_{i-} and the dependent variable as Δy_i , then the optimal GMM estimator is

$$\phi = \left[\left(\sum_i \Delta y'_{i-} \mathbf{Z}_i \right) A_N \left(\sum_i \mathbf{Z}'_i \Delta y_{i-} \right) \right]^{-1} \left(\sum_i \Delta y'_{i-} \mathbf{Z}_i \right) A_N \left(\sum_i \mathbf{Z}'_i \Delta y_i \right)$$

Using the estimate, $\hat{\phi}$, you can obtain estimates of the errors, $\hat{\epsilon}$, or the differences, \hat{v} . From the errors, the variance is calculated as,

$$\sigma^2 = \frac{\hat{\epsilon}'\hat{\epsilon}}{M-1}$$

where $M = \sum_{i=1}^N T_i$ is the total number of observations.

Furthermore, you can calculate the variance of the parameter as,

$$\sigma^2 \left[\left(\sum_i \Delta y'_{i-} \mathbf{Z}_i \right) A_N \left(\sum_i \mathbf{Z}'_i \Delta y_{i-} \right) \right]^{-1}$$

Alternatively, you can view the initial estimate of the ϕ as a first step. That is, by using $\hat{\phi}$, you can improve the estimate of the weight matrix, A_N .

Instead of imposing the structure of the weighting, you form the \mathbf{H}_i matrix through the following:

$$\mathbf{H}_i = \hat{v}_i \hat{v}'_i$$

You then complete the calculation as previously shown. The PROC PANEL option TWOSTEP specifies this estimation.

The case of multiple right-hand-side variables illustrates more clearly the power of Arellano and Bond (1991) and Arellano and Bover (1995).

Considering the general case you have:

$$y_{it} = \sum_{l=1}^{maxlag} \phi_l y_{i(t-l)} + \mathbf{X}_i + \gamma_i + \alpha_t + \epsilon_{it}$$

It is clear that lags of the dependent variable are both not exogenous and correlated to the fixed effects. However, the independent variables can fall into one of several categories. An independent variable can

be correlated and exogenous, uncorrelated and exogenous, correlated and predetermined, and uncorrelated and predetermined. The category in which an independent variable is found influences when or whether it becomes a suitable instrument. Note, however, that neither PROC PANEL nor Arellano and Bond require that a regressor be an instrument or that an instrument be a regressor.

First, consider the question of exogenous or endogenous. An exogenous variable is not correlated with the error term in the model at all. Therefore, all observations (on the exogenous variable) become valid instruments at all time periods. If the model has only one instrument and it happens to be exogenous, then the optimal instrument matrix looks like,

$$\mathbf{Z}_i = \begin{pmatrix} x_{i1} \cdots x_{iT} & 0 & 0 & 0 & 0 \\ 0 & x_{i1} \cdots x_{iT} & 0 & 0 & 0 \\ 0 & 0 & x_{i1} \cdots x_{iTS} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & x_{i1} \cdots x_{iTS} \end{pmatrix}$$

The situation for the predetermined variables becomes a little more difficult. A predetermined variable is one whose future realizations can be correlated to current shocks in the dependent variable. With such an understanding, it is admissible to allow all current and lagged realizations as instruments. In other words you have,

$$\mathbf{Z}_i = \begin{pmatrix} x_{i1} & 0 & 0 & 0 & 0 \\ 0 & x_{i1} x_{i2} & 0 & 0 & 0 \\ 0 & 0 & x_{i1} \cdots x_{i3} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & x_{i1} \cdots x_{i(TS-2)} \end{pmatrix}$$

When the data contain a mix of endogenous, exogenous, and predetermined variables, the instrument matrix is formed by combining the three. The third observation would have one observation on the dependent variable as an instrument, three observations on the predetermined variables as instruments, and all observations on the exogenous variables.

There is yet another set of moment restrictions that can be employed. An uncorrelated variable means that the variable's level is not affected by the individual specific effect. You write the general model presented above as:

$$y_{it} = \sum_{l=1}^{maxlag} \phi_l y_{i(t-l)} + \sum_{k=1}^K \beta_k x_{itk} + \alpha_t + \mu_{it}$$

where $\mu_{it} = \gamma_i + \epsilon_{it}$.

Since the variables are uncorrelated with γ and uncorrelated with the error, you can perform a system estimation with the difference and level equations. That is, the uncorrelated variables imply moment restrictions on the level equation. If you denote the new instrument matrix with the full complement of instruments available by a $*$ and both x^p and x^e are uncorrelated, then you have:

$$\mathbf{Z}_i^* = \begin{pmatrix} \mathbf{Z}_i & 0 & 0 & 0 & 0 \\ 0 & x_{i1}^p & x_{i1}^e & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & x_{iTS}^p & x_{iTS}^e \end{pmatrix}$$

The formation of the initial weighting matrix becomes somewhat problematic. If you denote the new weighting matrix with a *, then you can write the following:

$$A_N^* = \left(\frac{1}{N} \sum_i^N \mathbf{z}_i^{*'} \mathbf{H}_i^* \mathbf{z}_i^* \right)^{-1}$$

where

$$\mathbf{H}_i^* = \begin{pmatrix} \mathbf{H}_i & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & 1 \end{pmatrix}$$

To finish, you write out the two equations (or two stages) that are estimated.

$$\Delta y_{it} = \boldsymbol{\beta}^* \Delta \mathbf{S}_i + \alpha_t - \alpha_{t-1} + v_{it}$$

$$y_{it} = \boldsymbol{\beta}^* \mathbf{S}_i + \gamma_i + \alpha_t + \epsilon_{it}$$

where \mathbf{S}_i is the matrix of all explanatory variables, lagged endogenous, exogenous, and predetermined.

Let \mathbf{y}_{it}^* be given by

$$\mathbf{y}_{it}^* = \begin{pmatrix} \Delta y_{it} \\ y_{it} \end{pmatrix} \quad \boldsymbol{\beta}^* = \begin{pmatrix} \boldsymbol{\phi} & \boldsymbol{\beta} \end{pmatrix} \quad \mathbf{S}_i^* = \begin{pmatrix} \Delta \mathbf{S}_i \\ \mathbf{S}_i \end{pmatrix}$$

Using the information above,

$$\boldsymbol{\beta}^* = \left[\left(\sum_i \mathbf{S}_i^{*'} \mathbf{z}_i^* \right) A_N^* \left(\sum_i \mathbf{z}_i^{*'} \mathbf{S}_i^* \right) \right]^{-1} \left(\sum_i \mathbf{S}_i^{*'} \mathbf{z}_i^* \right) A_N^* \left(\sum_i \mathbf{z}_i^{*'} \mathbf{y}_i^* \right)$$

If the TWOSTEP or ITGMM option is not requested, estimation terminates here. If it terminates, you can obtain the following information.

Variance of the error term comes from the second stage equation—that is,

$$\sigma^2 = \frac{\hat{\epsilon}' \hat{\epsilon}}{M - p}$$

where p is the number of regressors.

The variance covariance matrix can be obtained from

$$\left[\left(\sum_i \mathbf{S}_i^{*'} \mathbf{z}_i^* \right) A_N^* \left(\sum_i \mathbf{z}_i^{*'} \mathbf{S}_i^* \right) \right]^{-1} \sigma^2$$

Alternatively, a robust estimate of the variance covariance matrix can be obtained by specifying the ROBUST option. Without further reestimation of the model, the \mathbf{H}_i^* matrix is recalculated as follows:

$$\mathbf{H}_{i,2}^* = \begin{pmatrix} \mathbf{v} \mathbf{v}' & 0 \\ 0 & \boldsymbol{\epsilon} \boldsymbol{\epsilon}' \end{pmatrix}$$

And the weighting matrix becomes

$$A_{N,2}^* = \left(\frac{1}{N} \sum_i^N \mathbf{z}_i^{*'} \mathbf{H}_{i,2}^* \mathbf{z}_i^* \right)^{-1}$$

Using the information above, you construct the robust variance covariance matrix from the following:

Let \mathbf{G} denote a temporary matrix.

$$\mathbf{G} = \left[\left(\sum_i \mathbf{s}_i^{*'} \mathbf{z}_i^* \right) A_{N,2}^* \left(\sum_i \mathbf{z}_i^{*'} \mathbf{s}_i^* \right) \right]^{-1} \left(\sum_i \mathbf{s}_i^{*'} \mathbf{z}_i^* \right) A_{N,2}^*$$

The robust variance covariance estimate of $\boldsymbol{\beta}^*$ is:

$$\mathbf{V}^{robust}(\boldsymbol{\beta}^*) = \mathbf{G} A_{N,2}^{*-1} \mathbf{G}'$$

Alternatively, the new weighting matrix can be used to form an updated estimate of the regression parameters. This results when the TWOSTEP option is requested. In short,

$$\boldsymbol{\beta}^* = \left[\left(\sum_i \mathbf{s}_i^{*'} \mathbf{z}_i^* \right) A_{N,2}^* \left(\sum_i \mathbf{z}_i^{*'} \mathbf{s}_i^* \right) \right]^{-1} \left(\sum_i \mathbf{s}_i^{*'} \mathbf{z}_i^* \right) A_{N,2}^* \left(\sum_i \mathbf{z}_i^{*'} \mathbf{s}_i^* \right)$$

The variance covariance estimate of the two step $\boldsymbol{\beta}^*$ becomes

$$\mathbf{V}(\boldsymbol{\beta}^*) = \left[\left(\sum_i \mathbf{s}_i^{*'} \mathbf{z}_i^* \right) A_{N,2}^* \left(\sum_i \mathbf{z}_i^{*'} \mathbf{s}_i^* \right) \right]^{-1}$$

As a final note, it is possible to iterate more than twice by specifying the ITGMM option. Such a multiple iteration should result in a more stable estimate of the variance covariance estimate. PROC PANEL allows two convergence criteria. Convergence can occur in the parameter estimates or in the weighting matrices. Iterate until

$$\max_{i,j \leq \dim(A_{N,k})} \frac{|A_{N,k+1}^*(i,j) - A_{N,k}^*(i,j)|}{|A_{N,k}^*(i,j)|} \leq \text{ATOL}$$

or

$$\max_{i \leq \dim(\boldsymbol{\beta}_k^*)} \frac{|\boldsymbol{\beta}_{k+1}^*(i) - \boldsymbol{\beta}_k^*(i)|}{|\boldsymbol{\beta}_k^*(i)|} \leq \text{BTOL}$$

where ATOL is the tolerance for convergence in the weighting matrix and BTOL is the tolerance for convergence in the parameter estimate matrix. The default convergence criteria is BTOL = 1E-8 for PROC PANEL.

Specification Testing For Dynamic Panel

Specification tests under the GMM in PROC PANEL follow Arellano and Bond (1991) very generally. The first test available is a Sargan/Hansen test of over-identification. The test for a one-step estimation is constructed as

$$\left(\sum_i \eta_i' \mathbf{Z}_i^* \right) A_N^* \left(\sum_i \mathbf{Z}_i^{*'} \eta_i \right) \sigma^2$$

where η_i is the stacked error term (of the differenced equation and level equation).

When the robust weighting matrix is used, the test statistic is computed as

$$\left(\sum_i \eta_i' \mathbf{Z}_i^* \right) A_{N,2}^* \left(\sum_i \mathbf{Z}_i^{*'} \eta_i \right)$$

This definition of the Sargan test is used for all iterated estimations. The Sargan test is distributed as a χ^2 with degrees of freedom equal to the number of moment conditions minus the number of parameters.

In addition to the Sargan test, PROC PANEL tests for autocorrelation in the residuals. These tests are distributed as standard normal. PROC PANEL tests the hypothesis that the autocorrelation of the l th lag is significant.

Define ω_l as the lag of the differenced error, with zero padding for the missing values generated. Symbolically,

$$\omega_l = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ v_1 \\ \vdots \\ v_{TS-2-l} \end{pmatrix}$$

You define the constant k_0 as

$$k_0(l) = \sum_i \omega_{l,i}' v_i$$

You next define the constant k_1 as

$$k_1(l) = \sum_i \omega_{l,i}' \mathbf{H}_i \omega_{l,i}$$

Note that the choice of \mathbf{H}_i is dependent on the stage of estimation. If the estimation is first stage, then you would use the matrix with twos along the main diagonal, and minus ones along the primary subdiagonals. In a robust estimation or multi-step estimation, this matrix would be formed from the outer product of the residuals (from the previous step).

Define the constant k_2 as

$$k_2(l) = -2 \left(\sum_i \omega_{l,i}' \Delta \mathbf{S}_i \right) \mathbf{G} \left(\sum_i \Delta \mathbf{S}_i' \mathbf{Z}_i \right) A_{N,k} \left(\sum_i \mathbf{Z}_i' \mathbf{H}_i \omega_{l,i} \right)$$

The matrix \mathbf{G} is defined as

$$\mathbf{G} = \left[\left(\sum_i \Delta \mathbf{S}_i^* \mathbf{Z}_i^* \right) \mathbf{A}_{\mathbf{N},k}^* \left(\sum_i \mathbf{Z}_i^* \Delta \mathbf{S}_i^* \right) \right]^{-1}$$

The constant k_3 is defined as

$$k_3(l) = \left(\sum_i \omega'_{l,i} \Delta \mathbf{S}_i \right) \mathbf{V}(\boldsymbol{\beta}^*) \left(\sum_i \Delta \mathbf{S}_i' \omega_{l,i} \right)$$

Using the four quantities, the test for autoregressive structure in the differenced residual is

$$m(l) = \frac{k_0(l)}{\sqrt{k_1(l) + k_2(l) + k_3(l)}}$$

The m statistic is distributed as a normal random variable with mean zero and standard deviation of one.

Instrument Choice

Arellano and Bond's technique is a very useful method for dealing with any autoregressive characteristics in the data. However, there is one caveat to consider. Too many instruments bias the estimator to the within estimate. Furthermore, many instruments make this technique not scalable. The weighting matrix becomes very large, so every operation that involves it becomes more computationally intensive. The PANEL procedure enables you to specify a bandwidth for instrument selection. For example, specifying MAXBAND=10 means that at most there will be ten time observations for each variable that enters as an instrument. The default is to follow the Arellano-Bond methodology.

In specifying a maximum bandwidth, you can also specify the selection of the time observations. There are three possibilities: leading, trailing (default), and centered. The exact consequence of choosing any of those possibilities depends on the variable type (correlated, exogenous, or predetermined) and the time period of the current observation.

If the MAXBAND option is specified, then the following is true under any selection criterion (let t be the time subscript for the current observation). The first observation for the endogenous variable (as instrument) is $\max(t - \text{MAXBAND}, 1)$ and the last instrument is $t - 2$. The first observation for a predetermined variable is $\max(t - \text{MAXBAND}, 1)$ and the last is $t - 1$. The first and last observation for an exogenous variable is given in the following list:

- *Trailing:* If $t < \text{MAXBAND}$, then the first instrument is for the first time period and the last observation is MAXBAND. Otherwise, if $t \geq \text{MAXBAND}$, then the first observation is $t - \text{MAXBAND} + 1$ and the last instrument to enter is t .
- *Centered:* If $t \leq \frac{\text{MAXBAND}}{2}$, then the first observation is the first time period and the last observation is MAXBAND. If $t > T - \frac{\text{MAXBAND}}{2}$, then the first instrument included is $T - \text{MAXBAND} + 1$ and the last observation is T . If $\frac{\text{MAXBAND}}{2} < t \leq T - \frac{\text{MAXBAND}}{2}$, then the first included instrument is $t - \frac{\text{MAXBAND}}{2} + 1$ and the last observation is $t + \frac{\text{MAXBAND}}{2}$. If the MAXBAND value is an odd number, the procedure decrements by one.

- *Leading* : If $t > T - \text{MAXBAND}$, then the first instrument corresponds to time period $T - \text{MAXBAND} + 1$ and the last observation is T . Otherwise, if $t \leq T - \text{MAXBAND}$, then the first observation is t and the last observation is $t + \text{MAXBAND} + 1$.

The PANEL procedure enables you to include dummy variables to deal with the presence of time effects that are not captured by including the lagged dependent variable. The dummy variables directly affect the level equations. However, this implies that the difference of the dummy variable for time period t and $t - 1$ enters the difference equation. The first usable observation occurs at $t = 3$. If the level equation is not used in the estimation, then there is no way to identify the dummy variables. Selecting the TIME option gives the same result as that which would be obtained by creating dummy variables in the data set and using those in the regression.

The PANEL procedure gives you several options when it comes to missing values and unbalanced panel. By default, any time period for which there are missing values is skipped. The corresponding rows and columns of \mathbf{H} matrices are zeroed, and the calculation is continued. Alternatively, you can elect to replace missing values and missing observations with zeros (ZERO), the overall mean of the series (OAM), the cross-sectional mean (CSM), or the time series mean (TSM).

Linear Hypothesis Testing

For a linear hypothesis of the form $\mathbf{R}\beta = \mathbf{r}$ where \mathbf{R} is $J \times K$ and \mathbf{r} is $J \times 1$, the F -statistic with $J, M - K$ degrees of freedom is computed as

$$(\mathbf{R}\beta - \mathbf{r})' [\mathbf{R}\hat{\mathbf{V}}\mathbf{R}']^{-1} (\mathbf{R}\beta - \mathbf{r})$$

However, it is also possible to write the F statistic as

$$F = \frac{(\hat{\mathbf{u}}_*' \hat{\mathbf{u}}_* - \hat{\mathbf{u}}' \hat{\mathbf{u}}) / J}{\hat{\mathbf{u}}' \hat{\mathbf{u}} / (M - K)}$$

where

- $\hat{\mathbf{u}}_*$ is the residual vector from the restricted regression
- $\hat{\mathbf{u}}$ is the residual vector from the unrestricted regression
- J is the number of restrictions
- $(M - K)$ are the degrees of freedom, M is the number of observations, and K is the number of parameters in the model

The Wald, likelihood ratio (LR) and Lagrange multiplier (LM) tests are all related to the F test. You use this relationship of the F test to the likelihood ratio and Lagrange multiplier tests. The Wald test is calculated from its definition.

The Wald test statistic is:

$$W = (\mathbf{R}\beta - \mathbf{r})' [\mathbf{R}\hat{\mathbf{V}}\mathbf{R}']^{-1} (\mathbf{R}\beta - \mathbf{r})$$

The advantage of calculating Wald in this manner is that it enables you to substitute a heteroscedasticity-corrected covariance matrix for the matrix \mathbf{V} . PROC PANEL makes such a substitution if you request the HCCME option in the MODEL statement.

The likelihood ratio is:

$$LR = M \ln \left[1 + \frac{1}{M - K} JF \right]$$

The Lagrange multiplier test statistic is:

$$LM = M \left[\frac{JF}{M - K + JF} \right]$$

where JF represents the number of restrictions multiplied by the result of the F test.

Note that only the Wald is changed when the HCCME option is selected. The LR and LM tests are unchanged.

The distribution of these test statistics is the χ^2 with degrees of freedom equal to the number of restrictions imposed (J). The three tests are asymptotically equivalent, but they have differing small sample properties. Greene (2000, p. 392) and Davidson and MacKinnon (1993, pg. 456-458) discuss the small sample properties of these statistics.

Heteroscedasticity-Corrected Covariance Matrices

The HCCME= option in the MODEL statement selects the type of heteroscedasticity-consistent covariance matrix. In the presence of heteroscedasticity, the covariance matrix has a complicated structure that can result in inefficiencies in the OLS estimates and biased estimates of the variance-covariance matrix. The variances for cross-sectional and time dummy variables and the covariances with or between the dummy variables are not corrected for heteroscedasticity in the one-way and two-way models. Whether or not HCCME is specified, they are the same. For the two-way models, the variance and the covariances for the intercept are not corrected.¹

Consider the simple linear model:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$$

This discussion parallels the discussion in Davidson and MacKinnon, 1993, pg. 548–562. The assumptions that make the linear regression best linear unbiased estimator (BLUE) are $E(\boldsymbol{\epsilon}) = 0$ and $E(\boldsymbol{\epsilon}\boldsymbol{\epsilon}') = \Omega$, where Ω has the simple structure $\sigma^2\mathbf{I}$. Heteroscedasticity results in a general covariance structure, so that it is not possible to simplify Ω . The result is the following:

$$\tilde{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'(\mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}) = \boldsymbol{\beta} + (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\boldsymbol{\epsilon}$$

¹The dummy variables are removed by the within transformations, so their variances and covariances cannot be calculated the same way as the other regressors. They are recovered by the formulas listed in the sections “One-Way Fixed-Effects Model” on page 1365 and “Two-Way Fixed-Effects Model” on page 1366. The formulas assume homoscedasticity, so they do not apply when HCCME is specified. Therefore, standard errors, variances, and covariances are reported only when the HCCME option is ignored. HCCME standard errors for dummy variables and intercept can be calculated by the dummy variable approach with the pooled model.

As long as the following is true, then you are assured that the OLS estimate is consistent and unbiased:

$$\text{plim}_{n \rightarrow \infty} \left(\frac{1}{n} \mathbf{X}' \boldsymbol{\epsilon} \right) = 0$$

If the regressors are nonrandom, then it is possible to write the variance of the estimated $\boldsymbol{\beta}$ as the following:

$$\text{Var}(\boldsymbol{\beta} - \tilde{\boldsymbol{\beta}}) = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\boldsymbol{\Omega}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}$$

The effect of structure in the variance-covariance matrix can be ameliorated by using generalized least squares (GLS), provided that $\boldsymbol{\Omega}^{-1}$ can be calculated. Using $\boldsymbol{\Omega}^{-1}$, you premultiply both sides of the regression equation,

$$L^{-1}\mathbf{y} = L^{-1}\mathbf{X}_e + L^{-1}\boldsymbol{\epsilon}$$

where L denotes the Cholesky root of $\boldsymbol{\Omega}$. (that is, $\boldsymbol{\Omega} = LL'$ with L lower triangular).

The resulting GLS $\boldsymbol{\beta}$ is

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1} \mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{y}$$

Using the GLS $\boldsymbol{\beta}$, you can write

$$\begin{aligned} \hat{\boldsymbol{\beta}} &= (\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1} \mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{y} \\ &= (\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1} \mathbf{X}'(\boldsymbol{\Omega}^{-1}\mathbf{X}_e + \boldsymbol{\Omega}^{-1}\boldsymbol{\epsilon}) \\ &= \boldsymbol{\beta} + (\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1} \mathbf{X}'\boldsymbol{\Omega}^{-1}\boldsymbol{\epsilon} \end{aligned}$$

The resulting variance expression for the GLS estimator is

$$\begin{aligned} \text{Var}(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}}) &= (\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1} \mathbf{X}'\boldsymbol{\Omega}^{-1}\boldsymbol{\epsilon}\boldsymbol{\epsilon}'\boldsymbol{\Omega}^{-1}\mathbf{X}(\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1} \\ &= (\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1} \mathbf{X}'\boldsymbol{\Omega}^{-1}\boldsymbol{\Omega}\boldsymbol{\Omega}^{-1}\mathbf{X}(\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1} \\ &= (\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1} \end{aligned}$$

The difference in variance between the OLS estimator and the GLS estimator can be written as

$$(\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\boldsymbol{\Omega}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1} - (\mathbf{X}'\boldsymbol{\Omega}^{-1}\mathbf{X})^{-1}$$

By the Gauss-Markov theorem, the difference matrix must be positive definite under most circumstances (zero if OLS and GLS are the same, when the usual classical regression assumptions are met). Thus, OLS is not efficient under a general error structure. It is crucial to realize that OLS does not produce biased results. It would suffice if you had a method for estimating a consistent covariance matrix and you used the OLS $\boldsymbol{\beta}$. Estimation of the $\boldsymbol{\Omega}$ matrix is certainly not simple. The matrix is square and has M^2 elements; unless some sort of structure is assumed, it becomes an impossible problem to solve. However, the heteroscedasticity can have quite a general structure. White (1980) shows that it is not necessary to have a consistent estimate of $\boldsymbol{\Omega}$. On the contrary, it suffices to calculate an estimate of the middle expression. That is, you need an estimate of:

$$\Lambda = \mathbf{X}'\boldsymbol{\Omega}\mathbf{X}$$

This matrix, Λ , is easier to estimate because its dimension is K . PROC PANEL provides the following classical HCCME estimators for Λ :

The matrix is approximated by:

- HCCME=N0:

$$\sigma^2 \mathbf{X}' \mathbf{X}$$

This is the simple OLS estimator. If you do not specify the HCCME= option, PROC PANEL defaults to this estimator.

- HCCME=0:

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}'$$

where N is the number of cross sections and T_i is the number of observations in i th cross section. The \mathbf{x}_{it}' is from the t th observation in the i th cross section, constituting the $(\sum_{j=1}^{i-1} T_j + t)$ th row of the matrix \mathbf{X} . If the CLUSTER option is specified, one extra term is added to the preceding equation so that the estimator of matrix Λ is

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}' + \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \hat{\epsilon}_{it} \hat{\epsilon}_{is} (\mathbf{x}_{it} \mathbf{x}_{is}' + \mathbf{x}_{is} \mathbf{x}_{it}')$$

- HCCME=1:

$$\frac{M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}'$$

where M is the total number of observations, $\sum_{j=1}^N T_j$, and K is the number of parameters. With the CLUSTER option, the estimator becomes

$$\frac{M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}' + \frac{2M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \hat{\epsilon}_{it} \hat{\epsilon}_{is} \mathbf{x}_{it} \mathbf{x}_{is}'$$

- HCCME=2:

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{1 - \hat{h}_{it}} \mathbf{x}_{it} \mathbf{x}_{it}'$$

The \hat{h}_{it} term is the $(\sum_{j=1}^{i-1} T_j + t)$ th diagonal element of the hat matrix. The expression for \hat{h}_{it} is $\mathbf{x}_{it}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_{it}$. The hat matrix attempts to adjust the estimates for the presence of influence or leverage points. With the CLUSTER option, the estimator becomes

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{1 - \hat{h}_{it}} \mathbf{x}_{it} \mathbf{x}_{it}' + 2 \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \frac{\hat{\epsilon}_{it}}{\sqrt{1 - \hat{h}_{it}}} \frac{\hat{\epsilon}_{is}}{\sqrt{1 - \hat{h}_{is}}} \mathbf{x}_{it} \mathbf{x}_{is}'$$

- HCCME=3:

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{(1 - \hat{h}_{it})^2} \mathbf{x}_{it} \mathbf{x}_{it}'$$

With the CLUSTER option, the estimator becomes

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{(1 - \hat{h}_{it})^2} \mathbf{x}_{it} \mathbf{x}_{it}' + 2 \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \frac{\hat{\epsilon}_{it}}{1 - \hat{h}_{it}} \frac{\hat{\epsilon}_{is}}{1 - \hat{h}_{is}} \mathbf{x}_{it} \mathbf{x}_{is}'$$

- HCCME=4: PROC PANEL includes this option for the calculation of the Arellano (1987) version of the White (1980) HCCME in the panel setting. Arellano's insight is that there are N covariance matrices in a panel, and each matrix corresponds to a cross section. Forming the White HCCME for each panel, you need to take only the average of those N estimators that yield Arellano. The details of the estimation follow. First, you arrange the data such that the first cross section occupies the first T_i observations. You treat the panels as separate regressions with the form:

$$\mathbf{y}_i = \alpha_i \mathbf{i} + \mathbf{X}_{is} \tilde{\boldsymbol{\beta}} + \boldsymbol{\epsilon}_i$$

The parameter estimates $\tilde{\boldsymbol{\beta}}$ and α_i are the result of least squares dummy variables (LSDV) or within estimator regressions, and \mathbf{i} is a vector of ones of length T_i . The estimate of the i th cross section's $\mathbf{X}'_s \Omega \mathbf{X}$ matrix (where the s subscript indicates that no constant column has been suppressed to avoid confusion) is $\mathbf{X}'_i \Omega \mathbf{X}_i$. The estimate for the whole sample is:

$$\mathbf{X}'_s \Omega \mathbf{X}_s = \sum_{i=1}^N \mathbf{X}'_i \Omega \mathbf{X}_i$$

The Arellano standard error is in fact a White-Newey-West estimator with constant and equal weight on each component. In the between estimators, selecting HCCME=4 returns the HCCME=0 result since there is no 'other' variable to group by.

In their discussion, Davidson and MacKinnon (1993, pg. 554) argue that HCCME=1 should always be preferred to HCCME=0. Although HCCME=3 is generally preferred to 2 and 2 is preferred to 1, the calculation of HCCME=1 is as simple as the calculation of HCCME=0. Therefore, it is clear that HCCME=1 is preferred when the calculation of the hat matrix is too tedious.

All HCCME estimators have well-defined asymptotic properties. The small sample properties are not well-known, and care must be exercised when sample sizes are small.

The HCCME estimator of $\text{Var}(\boldsymbol{\beta})$ is used to drive the covariance matrices for the fixed effects and the Lagrange multiplier standard errors. Robust estimates of the variance-covariance matrix for $\boldsymbol{\beta}$ imply robust variance-covariance matrices for all other parameters.

Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrices

The HAC option in the MODEL statement selects the type of heteroscedasticity- and autocorrelation-consistent covariance matrix. As with the HCCME option, an estimator of the middle expression Λ in sandwich form is needed. With the HAC option, it is estimated as

$$\Lambda_{\text{HAC}} = a \sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}'_{it} + a \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} k\left(\frac{s-t}{b}\right) \hat{\epsilon}_{it} \hat{\epsilon}_{is} \left(\mathbf{x}_{it} \mathbf{x}'_{is} + \mathbf{x}_{is} \mathbf{x}'_{it} \right)$$

, where $k(\cdot)$ is the real-valued kernel function², b is the bandwidth parameter, and a is the adjustment factor of small sample degrees of freedom (that is, $a = 1$ if the ADJUSTDF option is not specified and otherwise $a = NT/(NT - k)$, where k is the number of parameters including dummy variables). The types of kernel functions are listed in Table 20.2.

²The HCCME=0 with CLUSTER option sets $k(\cdot) = 1$.

Table 20.2 Kernel Functions

Kernel Name	Equation
Bartlett	$k(x) = \begin{cases} 1 - x & x \leq 1 \\ 0 & \text{otherwise} \end{cases}$
Parzen	$k(x) = \begin{cases} 1 - 6x^2 + 6 x ^3 & 0 \leq x \leq 1/2 \\ 2(1 - x)^3 & 1/2 \leq x \leq 1 \\ 0 & \text{otherwise} \end{cases}$
Quadratic spectral	$k(x) = \frac{25}{12\pi^2 x^2} \left(\frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right)$
Truncated	$k(x) = \begin{cases} 1 & x \leq 1 \\ 0 & \text{otherwise} \end{cases}$
Tukey-Hanning	$k(x) = \begin{cases} (1 + \cos(\pi x))/2 & x \leq 1 \\ 0 & \text{otherwise} \end{cases}$

When the BANDWIDTH=ANDREWS option is specified, the bandwidth parameter is estimated as shown in Table 20.3.

Table 20.3 Bandwidth Parameter Estimation

Kernel Name	Bandwidth Parameter
Bartlett	$b = 1.1447(\alpha(1)T)^{1/3}$
Parzen	$b = 2.6614(\alpha(2)T)^{1/5}$
Quadratic spectral	$b = 1.3221(\alpha(2)T)^{1/5}$
Truncated	$b = 0.6611(\alpha(2)T)^{1/5}$
Tukey-Hanning	$b = 1.7462(\alpha(2)T)^{1/5}$

Let $\{g_{ait}\}$ denote each series in $\{g_{it} = \hat{\epsilon}_{it}\mathbf{x}_{it}\}$, and let (ρ_a, σ_a^2) denote the corresponding estimates of the autoregressive and innovation variance parameters of the AR(1) model on $\{g_{ait}\}$, $a = 1, \dots, k$, where the AR(1) model is parameterized as $g_{ait} = \rho g_{ait-1} + \epsilon_{ait}$ with $Var(\epsilon_{ait}) = \sigma_a^2$. The $\alpha(1)$ and $\alpha(2)$ are estimated with the following formulas:

$$\alpha(1) = \frac{\sum_{a=1}^k \frac{4\rho_a^2 \sigma_a^4}{(1-\rho_a)^6(1+\rho_a)^2}}{\sum_{a=1}^k \frac{\sigma_a^4}{(1-\rho_a)^4}} \quad \alpha(2) = \frac{\sum_{a=1}^k \frac{4\rho_a^2 \sigma_a^4}{(1-\rho_a)^8}}{\sum_{a=1}^k \frac{\sigma_a^4}{(1-\rho_a)^4}}$$

When you specify BANDWIDTH=NEWKEYWEST94, according to Newey and West(1994) the bandwidth parameter is estimated as shown in Table 20.4.

Table 20.4 Bandwidth Parameter Estimation

Kernel Name	Bandwidth Parameter
Bartlett	$b = 1.1447(\{s_1/s_0\}^2 T)^{1/3}$
Parzen	$b = 2.6614(\{s_1/s_0\}^2 T)^{1/5}$
Quadratic spectral	$b = 1.3221(\{s_1/s_0\}^2 T)^{1/5}$
Truncated	$b = 0.6611(\{s_1/s_0\}^2 T)^{1/5}$
Tukey-Hanning	$b = 1.7462(\{s_1/s_0\}^2 T)^{1/5}$

The s_1 and s_0 are estimated with the following formulas:

$$s_1 = 2 \sum_{j=1}^n j \sigma_j \qquad s_0 = \sigma_0 + 2 \sum_{j=1}^n \sigma_j$$

where n is the lag selection parameter and is determined by kernels, as listed in [Table 20.5](#).

Table 20.5 Lag Selection Parameter Estimation

Kernel Name	Lag Selection Parameter
Bartlett	$n = c(T/100)^{2/9}$
Parzen	$n = c(T/100)^{4/25}$
Quadratic Spectral	$n = c(T/100)^{2/25}$
Truncated	$n = c(T/100)^{1/5}$
Tukey-Hanning	$n = c(T/100)^{1/5}$

The c in [Table 20.5](#) is specified by the C= option; by default, C=12.

The σ_j is estimated with the equation

$$\sigma_j = T^{-1} \sum_{t=j+1}^T \left(\sum_{a=i}^k g_{at} \sum_{a=i}^k g_{at-j} \right), j = 0, \dots, n$$

where g_{at} is the same as in the Andrews method and i is 1 if the NOINT option in the MODEL statement is specified, and 2 otherwise.

When you specify BANDWIDTH=SAMPLESIZE, the bandwidth parameter is estimated with the equation

$$b = \begin{cases} \lfloor \gamma T^r + c \rfloor & \text{if BANDWIDTH=SAMPLESIZE(INT) option is specified} \\ \gamma T^r + c & \text{otherwise} \end{cases}$$

where T is the sample size, $\lfloor x \rfloor$ is the largest integer less than or equal to x , and γ , r , and c are values specified by BANDWIDTH=SAMPLESIZE(GAMMA=, RATE=, CONSTANT=) options, respectively.

If the PREWHITENING option is specified in the MODEL statement, g_{it} is prewhitened by the VAR(1) model,

$$g_{it} = A_i g_{i,t-1} + w_{it}$$

Then Λ_{HAC} is calculated by

$$\Lambda_{\text{HAC}} = a \sum_{i=1}^N \left\{ ((I - A_i)^{-1})' \left(\sum_{t=1}^{T_i} w_{it} w'_{it} + \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} k\left(\frac{s-t}{b}\right) (w_{it} w'_{is} + w_{is} w'_{it}) \right) (I - A_i)^{-1} \right\}$$

R Square

The conventional R-square measure is inappropriate for all models that the PANEL procedure estimates by using GLS because a number outside the [0,1] range might be produced. Hence, a generalization of the R square measure is reported. The following goodness-of-fit measure (Buse 1973) is reported:

$$R^2 = 1 - \frac{\hat{\mathbf{u}}' \hat{\mathbf{V}}^{-1} \hat{\mathbf{u}}}{\mathbf{y}' \mathbf{D}' \hat{\mathbf{V}}^{-1} \mathbf{D} \mathbf{y}}$$

where $\hat{\mathbf{u}}$ are the residuals of the transformed model, $\hat{\mathbf{u}} = \mathbf{y} - \mathbf{X}(\mathbf{X}' \hat{\mathbf{V}}^{-1} \mathbf{X})^{-1} \mathbf{X}' \hat{\mathbf{V}}^{-1} \mathbf{y}$,

and $\mathbf{D} = \mathbf{I}_M - \mathbf{j}_M \mathbf{j}_M' \left(\frac{\hat{\mathbf{V}}^{-1}}{\mathbf{j}_M' \hat{\mathbf{V}}^{-1} \mathbf{j}_M} \right)$.

This is a measure of the proportion of the transformed sum of squares of the dependent variable that is attributable to the influence of the independent variables.

If there is no intercept in the model, the corresponding measure (Theil 1961) is

$$R^2 = 1 - \frac{\hat{\mathbf{u}}' \hat{\mathbf{V}}^{-1} \hat{\mathbf{u}}}{\mathbf{y}' \hat{\mathbf{V}}^{-1} \mathbf{y}}$$

However, the fixed-effects models are somewhat different. In the case of a fixed-effects model, the choice of including or excluding an intercept becomes merely a choice of classification. Suppressing the intercept in the FIXONE or FIXONETIME case merely changes the name of the intercept to a fixed effect. It makes no sense to redefine the R-square measure since nothing material changes in the model. Similarly, for the FIXTWO model there is no reason to change the R-square measure. In the case of the FIXONE, FIXONETIME, and FIXTWO models, the R square is defined as the Theil (1961) R square as shown in the preceding equation. This makes intuitive sense since you are regressing a transformed (demeaned) series on transformed regressors, excluding a constant. In other words, you are looking at 1 minus the sum of squared errors divided by the sum of squares of the (transformed) dependent variable.

In the case of OLS estimation, both of the R-square formulas given here reduce to the usual R-square formula.

Specification Tests

The PANEL procedure outputs the results of one specification test for fixed effects and two specification tests for random effects.

For fixed effects, let β_f be the n dimensional vector of fixed-effects parameters. The specification test reported is the conventional F statistic for the hypothesis $\beta_f = \mathbf{0}$. The F statistic with $n, M - K$ degrees of freedom is computed as

$$\hat{\beta}_f \hat{\mathbf{S}}_f^{-1} \hat{\beta}_f / n$$

where $\hat{\mathbf{S}}_f$ is the estimated covariance matrix of the fixed-effects parameters.

Hausman's (1978) specification test or m statistic can be used to test hypotheses in terms of bias or inconsistency of an estimator. This test was also proposed by Wu (1973) and further extended in Hausman and Taylor (1982). Hausman's m statistic is as follows.

Consider two estimators, $\hat{\beta}_a$ and $\hat{\beta}_b$, which under the null hypothesis are both consistent, but only $\hat{\beta}_a$ is asymptotically efficient. Under the alternative hypothesis, only $\hat{\beta}_b$ is consistent. The m statistic is

$$m = (\hat{\beta}_b - \hat{\beta}_a)' (\hat{\mathbf{S}}_b - \hat{\mathbf{S}}_a)^{-1} (\hat{\beta}_b - \hat{\beta}_a)$$

where $\hat{\mathbf{S}}_b$ and $\hat{\mathbf{S}}_a$ are consistent estimates of the asymptotic covariance matrices of $\hat{\beta}_b$ and $\hat{\beta}_a$. Then m is distributed χ^2 with k degrees of freedom, where k is the dimension of $\hat{\beta}_a$ and $\hat{\beta}_b$.

In the random-effects specification, the null hypothesis of no correlation between effects and regressors implies that the OLS estimates of the slope parameters are consistent and inefficient but the GLS estimates of the slope parameters are consistent and efficient. This facilitates a Hausman specification test. The reported χ^2 statistic has degrees of freedom equal to the number of slope parameters. If the null hypothesis holds, the random-effects specification should be used.

Breusch and Pagan (1980) lay out a Lagrange multiplier test for random effects based on the simple OLS (pooled) estimator. If \hat{u}_{it} is the i th residual from the OLS regression, then the Breusch-Pagan (BP) test for one-way random effects is

$$BP = \frac{NT}{2(T-1)} \left[\frac{\sum_{i=1}^N \left[\sum_{t=1}^T \hat{u}_{it} \right]^2}{\sum_{i=1}^N \sum_{t=1}^T \hat{u}_{it}^2} - 1 \right]^2$$

The BP test generalizes to the case of a two-way random-effects model (Greene 2000, page 589). Specifically,

$$\begin{aligned} BP2 &= \frac{NT}{2(T-1)} \left[\frac{\sum_{i=1}^n \left[\sum_{t=1}^T \hat{u}_{it} \right]^2}{\sum_{i=1}^N \sum_{t=1}^T \hat{u}_{it}^2} - 1 \right]^2 \\ &+ \frac{NT}{2(N-1)} \left[\frac{\sum_{t=1}^T \left[\sum_{i=1}^N \hat{u}_{it} \right]^2}{\sum_{i=1}^N \sum_{t=1}^T \hat{u}_{it}^2} - 1 \right]^2 \end{aligned}$$

is distributed as a χ^2 statistic with two degrees of freedom. Since the BP2 test generalizes (nests the BP test) the test for random effects, the absence of random effects (nonrejection of the null of no random effects) in the BP2 is a fairly clear indication that there will probably not be any one-way effects either. In both cases (BP and BP2), the residuals are obtained from a pooled regression. There is very little extra cost in selecting both the BP and BP2 test. Notice that in the case of just groupwise heteroscedasticity, the BP2 test

approaches BP. In the case of time based heteroscedasticity, the BP2 test reduces to a BP test of time effects. In the case of unbalanced panels, neither the BP nor BP2 statistics are valid.

Finally, you should be aware that the BP option generates different results depending on whether the estimation is FIXONE or FIXONETIME. Specifically, under the FIXONE estimation technique, the BP tests for cross-sectional random effects. Under the FIXONETIME estimation, the BP tests for time random effects.

While the Hausman statistic is automatically generated, you request Breusch-Pagan via the BP or BP2 option (see Baltagi 1995 for details).

Panel Data Poolability Test

The null hypothesis of poolability assumes homogeneous slope coefficients. An F test can be applied to test for the poolability across cross sections in panel data models.

F Test

For the unrestricted model, run a regression for each cross section and save the sum of squared residuals as SSE_u . For the restricted model, save the sum of squared residuals as SSE_r . If the test applies to all coefficients (including the constant), then the restricted model is the pooled model (OLS); if the test applies to coefficients other than the constant, then the restricted model is the fixed one-way model with cross-sectional fixed effects. If N and T denote the number of cross sections and time periods, then the number of observations is $n = NT$.³ Let k be the number of regressors except the constant. The degree of freedom for the unrestricted model is $df_u = n - N(k + 1)$. If the constant is restricted to be the same, the degree of freedom for the restricted model is $df_r = n - k - 1$ and the number of restrictions is $q = (N - 1)(k + 1)$. If the restricted model is the fixed one-way model, the degree of freedom is $df_r = n - k - N$ and the number of restrictions is $q = (N - 1)k$. So the F test is

$$F = \frac{(SSE_r - SSE_u) / q}{SSE_u / df_u} \sim F(q, df_u)$$

For large N and T , you can use a chi-square distribution to approximate the limiting distribution, namely, $qF \implies \chi^2(q)$. The error term is assumed to be homogeneous; therefore, $\epsilon \sim \mathcal{N}(0, \sigma^2 I_n)$, and an OLS regression is sufficient. The test is the same as the Chow test (Chow 1960) extended to N linear regressions.

LR Test

Zeller (1962) also proved that the likelihood ratio test for null hypothesis of poolability can be based on the F statistic. The likelihood ratio can be expressed as $LR = -2 \log \left((1 + qF/df_u)^{-NT/2} \right) \implies LR = qF + O(n^{-1})$. Under H_0 , LR is asymptotically distributed as a chi-square with q degrees of freedom.

³For the unbalanced panel, the number of time series T_i might be different. The number of observations needs to be redefined accordingly.

Panel Data Unit Root Tests

Levin, Lin, and Chu (2002)

Levin, Lin, and Chu (2002) propose a panel unit root test for the null hypothesis of unit root against a homogeneous stationary hypothesis. The model is specified as

$$\Delta y_{it} = \delta y_{it-1} + \sum_{L=1}^{p_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mt} + \varepsilon_{it} \quad m = 1, 2, 3$$

Three models are considered: (1) $d_{1t} = \phi$ (the empty set) with no individual effects, (2) $d_{2t} = \{1\}$ in which the series y_{it} has an individual-specific mean but no time trend, and (3) $d_{3t} = \{1, t\}$ in which the series y_{it} has an individual-specific mean and linear and individual-specific time trend. The panel unit root test evaluates the null hypothesis of $H_0 : \delta = 0$, for all i , against the alternative hypothesis $H_1 : \delta < 0$ for all i . The lag order p_i is unknown and is allowed to vary across individuals. It can be selected by the methods that are described in the section “[Lag Order Selection in the ADF Regression](#)” on page 1403. Denote the selected lag orders as \hat{p}_i . The test is implemented in three steps.

Step 1 The ADF regressions are implemented for each individual i , and then the orthogonalized residuals are generated and normalized. That is, the following model is estimated:

$$\Delta y_{it} = \delta_i y_{it-1} + \sum_{L=1}^{\hat{p}_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mt} + \varepsilon_{it} \quad m = 1, 2, 3$$

The two orthogonalized residuals are generated by the following two auxiliary regressions:

$$\begin{aligned} \Delta y_{it} &= \sum_{L=1}^{\hat{p}_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mi} + e_{it} \\ y_{it-1} &= \sum_{L=1}^{\hat{p}_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mi} + v_{it-1} \end{aligned}$$

The residuals are saved at \hat{e}_{it} and \hat{v}_{it-1} , respectively. To remove heteroscedasticity, the residuals \hat{e}_{it} and \hat{v}_{it-1} are normalized by the regression standard error from the [ADF](#) regression. Denote the standard error as $\hat{\sigma}_{\varepsilon i}^2 = \sum_{t=\hat{p}_i+2}^T (\hat{e}_{it} - \hat{\delta}_i \hat{v}_{it-1})^2 / (T - p_i - 1)$, and normalize residuals as

$$\tilde{e}_{it} = \frac{\hat{e}_{it}}{\hat{\sigma}_{\varepsilon i}}, \quad \tilde{v}_{it-1} = \frac{\hat{v}_{it-1}}{\hat{\sigma}_{\varepsilon i}}$$

Step 2 The ratios of long-run to short-run standard deviations of Δy_{it} are estimated. Denote the ratios and the long-run variances as s_i and σ_{yi} , respectively. The long-run variances are estimated by the HAC (heteroscedasticity- and autocorrelation-consistent) estimators, which are described in the section “[Long-Run Variance Estimation](#)” on page 1404. Then the ratios are estimated by $\hat{s}_i = \hat{\sigma}_{yi} / \hat{\sigma}_{\varepsilon i}$. Let the average standard deviation ratio be $S_N = (1/N) \sum_{i=1}^N s_i$, and let its estimator be $\hat{S}_N = (1/N) \sum_{i=1}^N \hat{s}_i$.

Step 3 The panel test statistics are calculated. To calculate the t statistic and the adjusted t statistic, the following equation is estimated:

$$\tilde{e}_{it} = \delta \tilde{v}_{it-1} + \tilde{\varepsilon}_{it}$$

The total number of observations is $N\tilde{T}$, with $\bar{p} = \sum_{i=1}^N \hat{p}_i / N$, $\tilde{T} = T - \bar{p} - 1$. The standard t statistic for testing $\delta = 0$ is $t_\delta = \hat{\delta} / STD(\hat{\delta})$, with OLS estimator $\hat{\delta}$ and standard deviation $STD(\hat{\delta})$. However, the standard t statistic diverges to negative infinity for models (2) and (3). Let $\hat{\sigma}_{\tilde{\varepsilon}}$ be the root mean square error from the [step 3](#) regression, and denote it as

$$\hat{\sigma}_{\tilde{\varepsilon}}^2 = \left[\frac{1}{N\tilde{T}} \sum_{i=1}^N \sum_{t=2+\hat{p}_i}^T (\tilde{e}_{it} - \hat{\delta} \tilde{v}_{it-1})^2 \right]$$

Levin, Lin, and Chu (2002) propose the following adjusted t statistic:

$$t_\delta^* = \frac{t_\delta - N\tilde{T}\hat{S}_N\hat{\sigma}_{\tilde{\varepsilon}}^{-2}STD(\hat{\delta})\mu_{m\tilde{T}}^*}{\sigma_{m\tilde{T}}^*}$$

The mean and standard deviation adjustments $(\mu_{m\tilde{T}}^*, \sigma_{m\tilde{T}}^*)$ depend on the time series dimension \tilde{T} and model specification m , which can be found in Table 2 of Levin, Lin, and Chu (2002). The adjusted t statistic converges to the standard normal distribution. Therefore, the standard normal critical values are used in hypothesis testing.

Lag Order Selection in the ADF Regression

The methods for selecting the individual lag orders in the ADF regressions can be divided into two categories: selection based on information criteria and selection via sequential testing.

Lag Selection Based on Information Criteria In this method, the following information criteria can be applied to lag order selection: AIC, SBC, HQIC (HQC), and MAIC. As with other model selection applications, the lag order is selected from 0 to the maximum p_{max} to minimize the objective function, plus a penalty term, which is a function of the number of parameters in the regression. Let k be the number of parameters and T_o be the number of effective observations. For regression models, the objective function is $T_o \log(SSR/T_o)$, where SSR is the sum of squared residuals. For AIC, the penalty term equals $2k$. For SBC, this term is $k \log T_o$. For HQIC, it is $2ck \log [\log(T_o)]$ with c being a constant greater than 1.⁴ For MAIC, the penalty term equals $2(\tau_T(k) + k)$, where

$$\tau_T(k) = (SSR/T_o)^{-1} \hat{\delta}^2 \sum_{t=p_{max}+2}^T y_{t-1}^2$$

and $\hat{\delta}$ is the estimated coefficient of the lagged dependent variable y_{t-1} in the ADF regression.

Lag Selection via Sequential Testing In this method, the lag order estimation is based on the statistical significance of the estimated AR coefficients. Hall (1994) proposed general-to-specific (GS) and specific-to-general (SG) strategies. Levin, Lin, and Chu (2002) recommend the first strategy, following Campbell and Perron (1991). In the GS modeling strategy, starting with the maximum lag order p_{max} , the t test for

⁴In practice c is set to 1, following the literature (Hannan and Quinn 1979; Hall 1994).

the largest lag order in $\hat{\theta}_i$ is performed to determine whether a smaller lag order is preferred. Specifically, when the null of $\hat{\theta}_{iL} = 0$ is not rejected given the significance level (5%), a smaller lag order is preferred. This procedure continues until a statistically significant lag order is reached. On the other hand, the SG modeling strategy starts with lag order 0 and moves toward the maximum lag order p_{max} .

Long-Run Variance Estimation

The long-run variance of Δy_{it} is estimated by a HAC-type estimator. For model (1), given the lag truncation parameter \bar{K} and kernel weights $w_{\bar{K}L}$, the formula is

$$\hat{\sigma}_{yi}^2 = \frac{1}{T-1} \sum_{t=2}^T \Delta y_{it}^2 + 2 \sum_{L=1}^{\bar{K}} w_{\bar{K}L} \left[\frac{1}{T-1} \sum_{t=2+L}^T \Delta y_{it} \Delta y_{it-L} \right]$$

To achieve consistency, the lag truncation parameter must satisfy $\bar{K}/T \rightarrow 0$ and $\bar{K} \rightarrow \infty$ as $T \rightarrow \infty$. Levin, Lin, and Chu (2002) suggest $\bar{K} = \lfloor 3.21T^{1/3} \rfloor$. The weights $w_{\bar{K}L}$ depend on the kernel function. Andrews (1991) proposes data-driven bandwidth (lag truncation parameter + 1 if integer-valued) selection procedures to minimize the asymptotic mean squared error (MSE) criterion. For details about the kernel functions and Andrews (1991) data-driven bandwidth selection procedure, see the section “Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrices” on page 1396 for details. Because Levin, Lin, and Chu (2002) truncate the bandwidth as an integer, when LLCBAND is specified as the BANDWIDTH option, it corresponds to $\text{BANDWIDTH} = \lfloor 3.21T^{1/3} \rfloor + 1$. Furthermore, kernel weights $w_{\bar{K}L} = k(L/(\bar{K} + 1))$ with kernel function $k(\cdot)$.

For model (2), the series Δy_{it} is demeaned individual by individual first. Therefore, Δy_{it} is replaced by $\Delta y_{it} - \bar{\Delta y}_{it}$, where $\bar{\Delta y}_{it}$ is the mean of Δy_{it} for individual i . For model (3) with individual fixed effects and time trend, both the individual mean and trend should be removed before the long-run variance is estimated. That is, first regress Δy_{it} on $\{1, t\}$ for each individual and save the residual $\bar{\Delta y}_{it}$, and then replace Δy_{it} with the residual.

Cross-Sectional Dependence via Time-Specific Aggregate Effects

The Levin, Lin, and Chu (2002) testing procedure is based on the assumption of cross-sectional independence. It is possible to relax this assumption and allow for a limited degree of dependence via time-specific aggregate effects. Let θ_t denote the time-specific aggregate effects; then the data generating process (DGP) becomes

$$\Delta y_{it} = \delta y_{it-1} + \sum_{L=1}^{p_i} \theta_{iL} \Delta y_{it-L} + \alpha_{mi} d_{mt} + \theta_t + \varepsilon_{it} \quad m = 1, 2, 3$$

By subtracting the cross-sectional averages $\bar{y}_t = \sum_{i=1}^N y_{it}$ from the observed dependent variable y_{it} , or equivalently, by including the time-specific intercepts θ_t in the ADF regression, the cross-sectional dependence is removed. The impact of a single aggregate common factor that has an identical impact on all individuals but changes over time can also be removed in this way. After cross-sectional dependence is removed, the three-step procedure is applied to calculate the Levin, Lin, and Chu (2002) adjusted t statistic.

Deterministic Variables

Three deterministic variables can be included in the model for the first-stage estimation: CS_FixedEffects (cross-sectional fixed effects), TS_FixedEffects (time series fixed effects), and TimeTrend (individual linear time trend). When a linear time trend is included, the individual fixed effects are also included. Otherwise the time trend is not identified.

Im, Pesaran, and Shin (2003)

To test for the unit root in heterogeneous panels, Im, Pesaran, and Shin (2003) propose a standardized t -bar test statistic based on averaging the (augmented) Dickey-Fuller statistics across the groups. The limiting distribution is standard normal. The stochastic process y_{it} is generated by the first-order autoregressive process. If $\Delta y_{it} = y_{it} - y_{i,t-1}$, the data generating process can be expressed as in LLC:

$$\Delta y_{it} = \beta_i y_{it-1} + \sum_{j=1}^{p_i} \rho_{ij} \Delta y_{i,t-j} + \alpha_{mi} d_{mt} + \varepsilon_{it} \quad m = 1, 2, 3$$

Unlike the DGP in LLC, β_i is allowed to differ across groups. The null hypothesis of unit roots is

$$H_0 : \beta_i = 0 \quad \text{for all } i$$

against the heterogeneous alternative,

$$H_1 : \beta_i < 0 \quad \text{for } i = 1, \dots, N_1, \quad \beta_i = 0 \quad \text{for } i = N_1 + 1, \dots, N$$

The Im, Pesaran, and Shin test also allows for some (but not all) of the individual series to have unit roots under the alternative hypothesis. But the fraction of the individual processes that are stationary is positive, $\lim_{N \rightarrow \infty} N_1/N = \delta \in (0, 1]$. The t -bar statistic, denoted by $t\text{-bar}_{NT}$, is formed as a simple average of the individual t statistics for testing the null hypothesis of $\beta_i = 0$. If $t_{iT}(p_i, \rho_i)$ is the standard t statistic, then

$$t\text{-bar}_{NT} = \frac{1}{N} \sum_{i=1}^N t_{iT}(p_i, \rho_i)$$

If $T \rightarrow \infty$, then for each i the t statistic (without time trend) converges to the Dickey-Fuller distribution, η_i , defined by

$$\eta_i = \frac{\frac{1}{2}\{[W_i(1)]^2 - 1\} - W_i(1) \int_0^1 W_i(u) du}{\int_0^1 [W_i(u)]^2 du - [\int_0^1 W_i(u) du]^2}$$

where W_i is the standard Brownian motion. The limiting distribution is different when a time trend is included in the regression (Hamilton 1994, p. 499). The mean and variance of the limiting distributions are reported in Nabeya (1999). The standardized t -bar statistic satisfies

$$Z_{tbar}(p, \rho) = \frac{\sqrt{N}\{t\text{-bar}_{NT} - E(\eta)\}}{\sqrt{Var(\eta)}} \Rightarrow \mathcal{N}(0, 1)$$

where the standard normal is the sequential limit with $T \rightarrow \infty$ followed by $N \rightarrow \infty$. To obtain better finite sample approximations, Im, Pesaran, and Shin (2003) propose standardizing the t -bar statistic by means and variances of $t_{iT}(p_i, 0)$ under the null hypothesis $\beta_i = 0$. The alternative standardized t -bar statistic is

$$W_{tbar}(p, \rho) = \frac{\sqrt{N}\{t\text{-bar}_{NT} - \sum_{i=1}^N E[t_{iT}(p_i, 0)|\beta_i = 0]/N\}}{\sqrt{\sum_{i=1}^N Var[t_{iT}(p_i, 0)|\beta_i = 0]/N}} \Rightarrow \mathcal{N}(0, 1)$$

Im, Pesaran, and Shin (2003) simulate the values of $E[t_{iT}(p_i, 0)|\beta_i = 0]$ and $Var[t_{iT}(p_i, 0)|\beta_i = 0]$ for different values of T and p . The lag order in the ADF regression can be selected by the same method as in Levin, Lin, and Chu (2002). See the section “Lag Order Selection in the ADF Regression” on page 1403 for details.

When T is fixed, Im, Pesaran, and Shin (2003) assume serially uncorrelated errors, $p_i = 0$; t_{iT} is likely to have finite second moment, which is not established in the paper. The t statistic is modified by imposing the null hypothesis of a unit root. Denote $\tilde{\sigma}_{iT}$ as the estimated standard error from the **restricted regression** ($\beta_i = 0$),

$$\tilde{t}\text{-bar}_{NT} = \sum_{i=1}^N \tilde{t}_{iT} / N = \sum_{i=1}^N \left[\hat{\beta}_{iT} (y'_{i,-1} M_{\tau} y_{i,-1})^{1/2} / \tilde{\sigma}_{iT} \right] / N$$

where $\hat{\beta}_{iT}$ is the OLS estimator of β_i (unrestricted model), $\tau_T = (1, 1, \dots, 1)'$, $M_{\tau} = I_T - \tau_T (\tau_T' \tau_T)^{-1} \tau_T'$, and $y_{i,-1} = (y_{i0}, y_{i1}, \dots, y_{i,T-1})'$. Under the null hypothesis, the standardized \tilde{t} -bar statistic converges to a standard normal variate,

$$Z_{\tilde{t}bar} = \frac{\sqrt{N} \{ \tilde{t}\text{-bar}_{NT} - E(\tilde{t}_T) \}}{\sqrt{Var(\tilde{t}_T)}} \implies \mathcal{N}(0, 1)$$

where $E(\tilde{t}_T)$ and $Var(\tilde{t}_T)$ are the mean and variance of \tilde{t}_{iT} , respectively. The limit is taken as $N \rightarrow \infty$ and T is fixed. Their values are simulated for finite samples without a time trend. The $Z_{\tilde{t}bar}$ is also likely to converge to standard normal.

When N and T are both finite, an exact test that assumes no serial correlation can be used. The critical values of $t\text{-bar}_{NT}$ and $\tilde{t}\text{-bar}_{NT}$ are simulated.

Combination Tests

Maddala and Wu (1999) and Choi (2001) propose combining the observed significance levels (p -values) from N independent tests of the unit root null hypothesis. Suppose G_i is the test statistic to test the unit root null hypothesis for individual $i = 1, \dots, N$, and $F(\cdot)$ is the cdf (cumulative distribution function) of the asymptotic distribution as $T \rightarrow \infty$. Then the asymptotic p -value is defined as

$$p_i = F(G_i)$$

There are different ways to combine these p -values. The first one is the inverse chi-square test (Fisher 1932); this test is referred to as P test in Choi (2001) and λ in Maddala and Wu (1999):

$$Chi - Square = -2 \sum_{i=1}^N \ln(p_i)$$

When the test statistics $\{G_i\}_{i=1, \dots, N}$ are continuous, $\{p_i\}_{i=1, \dots, N}$ are independent uniform $(0, 1)$ variables. Therefore, $P \Rightarrow \chi^2(2N)$ as $T \rightarrow \infty$ and N fixed. But as $N \rightarrow \infty$, P diverges to infinity in probability. Therefore, it is not applicable for large N . To derive a nondegenerate limiting distribution, the P test (Fisher test with $N \rightarrow \infty$) should be modified to

$$P_m = FI = \sum_{i=1}^N (-2 \ln(p_i) - 2) / 2\sqrt{N} = - \sum_{i=1}^N (\ln(p_i) + 1) / \sqrt{N}$$

Under the null as $T_i \rightarrow \infty$,⁵ and then $N \rightarrow \infty$, $P_m \Rightarrow \mathcal{N}(0, 1)$.⁶

⁵The time series length T is subindexed by $i = 1, \dots, N$ because the panel can be unbalanced.

⁶Choi (2001) also points out that the joint limit result where N and $\{T_i\}_{i=1, \dots, N}$ go to infinity simultaneously is the same as the sequential limit, but it requires more moment conditions.

The second way of combining individual p -values is the inverse normal test,

$$Z = \sum_{i=1}^N \Phi^{-1}(p_i)$$

where $\Phi(\cdot)$ is the standard normal cdf. When $T_i \rightarrow \infty$, $Z \Rightarrow \mathcal{N}(0, 1)$ as N is fixed. When N and T_i are both large, the sequential limit is also standard normal if $T_i \rightarrow \infty$ first and $N \rightarrow \infty$ next.

The third way of combining p -values is the logit test,

$$L^* = \sqrt{k}L = \sqrt{k} \sum_{i=1}^N \ln \left(\frac{p_i}{1 - p_i} \right)$$

where $k = 3(5N + 4) / (\pi^2 N(5N + 2))$. When $T_i \rightarrow \infty$ and N is fixed, $L^* \Rightarrow t_{5N+4}$. In other words, the limiting distribution is the t distribution with degree of freedom $5N + 4$. The sequential limit is $L^* \Rightarrow \mathcal{N}(0, 1)$ as $T_i \rightarrow \infty$ and then $N \rightarrow \infty$. Simulation results in Choi (2001) suggest that the Z test outperforms other combination tests. For the time series unit root test G_i , Maddala and Wu (1999) apply the augmented Dickey-Fuller test. According to Choi (2006), the Elliott, Rothenberg, and Stock (1996) Dickey-Fuller generalized least squares (DF-GLS) test brings significant size and power advantages in finite samples.

Breitung's Unbiased Tests

To account for the nonzero mean of the t statistic in the OLS detrending case, Levin, Lin, and Chu (2002) and Im, Pesaran, and Shin (2003) propose bias-adjusted t statistics. The bias corrections imply a severe loss of power. Breitung and Meyer (1994), Breitung (2000), and Breitung and Das (2005) take an alternative approach to avoid the bias, by using alternative estimates of the deterministic terms. The DGP is the same as in the Im, Pesaran, and Shin approach. When serial correlation is absent, for model (2) with individual specific means, the constant terms are estimated by the initial values y_{i0} . Therefore, the series y_{it} is adjusted by subtracting the initial value. The equation becomes

$$\Delta y_{it} = \delta^* (y_{i,t-1} - y_{i0}) + v_{it}$$

For model (3) with individual specific means and time trends, the time trend can be estimated by $\hat{\beta}_i = T^{-1}(y_{iT} - y_{i0})$. The levels can be transformed as

$$\tilde{y}_{it} = y_{it} - y_{i0} - \hat{\beta}_i t = y_{it} - y_{i0} - t(y_{iT} - y_{i0})/T$$

The Helmert transformation is applied to the dependent variable to remove the mean of the differenced variable:

$$\Delta y_{it}^* = \frac{T-t}{T-t+1} [\Delta y_{it} - (\Delta y_{i,t+1} + \dots + \Delta y_{iT}) / (T-t)]$$

The transformed model is

$$\Delta y_{it}^* = \delta^* \tilde{y}_{i,t-1} + v_{it}$$

The pooled t statistic has a standard normal distribution. Therefore, no adjustment is needed for the t statistic. To adjust for heteroscedasticity across cross sections, Breitung (2000) proposes a UB (unbiased) statistic based on the transformed data,

$$UB = \frac{\sum_{i=1}^N \sum_{t=1}^T \Delta y_{it}^* \tilde{y}_{i,t-1} / \sigma_i^2}{\sum_{i=1}^N \sum_{t=1}^T \tilde{y}_{i,t-1}^2 / \sigma_i^2}$$

where $\sigma_i^2 = E(\Delta y_{it} - \beta_i)^2$. When σ_i^2 is unknown, it can be estimated as

$$\hat{\sigma}_i^2 = \sum_{i=2}^T \left(\Delta y_{it}^* - \sum_{i=2}^T \Delta y_{it}^* / (T-1) \right)^2 / (T-2)$$

The UB statistic has a standard normal limiting distribution as $T \rightarrow \infty$ followed by $N \rightarrow \infty$ sequentially. To account for the short-run dynamics, Breitung and Das (2005) suggest applying the test to the prewhitened series, \hat{y}_{it} . For model (1) and model (2) (constant-only case), they suggested the same method as in step 1 of Levin, Lin, and Chu (2002).⁷ For model (3) (with a constant and linear time trend), the prewhitened series can be obtained by running the following restricted ADF regression under the null hypothesis of a unit root ($\delta = 0$) and no linear time trend ($\beta_i = 0$):

$$\Delta y_{it} = \sum_{L=1}^{\hat{p}_i} \theta_{iL} \Delta y_{it-L} + \mu_i + \varepsilon_{it}$$

where \hat{p}_i is a consistent estimator of the true lag order p_i and can be estimated by the procedures listed in the section “[Lag Order Selection in the ADF Regression](#)” on page 1403. For LLC and IPS tests, the lag orders are selected by running the ADF regressions. But for Breitung and his coauthors’ tests, the restricted ADF regressions are used to be consistent with the prewhitening method. Let $(\hat{\mu}_i, \hat{\theta}_{iL})$ be the estimated coefficients.⁸ The prewhitened series can be obtained by

$$\Delta \hat{y}_{it} = \Delta y_{it} - \sum_{L=1}^{\hat{p}_i} \hat{\theta}_{iL} \Delta y_{it-L} - \hat{\mu}_i$$

and

$$\hat{y}_{it} = y_{it} - \sum_{L=1}^{\hat{p}_i} \hat{\theta}_{iL} y_{it-L} - \hat{\mu}_i$$

The transformed series are random walks under the null hypothesis,

$$\Delta \hat{y}_{it} = \delta \hat{y}_{i,t-1} + v_{it}$$

where $y_{is} = 0$ for $s < 0$. When the cross-section units are independent, the t statistic converges to standard normal under the null, as $T \rightarrow \infty$ followed by $N \rightarrow \infty$,

$$t_{OLS} = \frac{\sum_{i=1}^N \sum_{t=1}^T y_{i,t-1} \Delta y_{it}}{\hat{\sigma} \sqrt{\sum_{i=1}^N \sum_{t=1}^T y_{i,t-1}^2}} \Rightarrow \mathcal{N}(0, 1)$$

where $\hat{\sigma}^2 = \sum_{i=1}^N \sum_{t=1}^T (\Delta y_{it} - \hat{\delta} y_{i,t-1})^2$ with OLS estimator $\hat{\delta}$.

To take account for cross-sectional dependence, Breitung and Das (2005) propose the robust t statistic and

⁷See the section “[Levin, Lin, and Chu \(2002\)](#)” on page 1402 for details. The only difference is the standard error estimate $\hat{\sigma}_{\varepsilon i}^2$. Breitung suggests using $T - p_i - 2$ instead of $T - p_i - 1$ as in LLC to normalize the standard error.

⁸Breitung (2000) suggests the approach in step 1 of Levin, Lin, and Chu (2002), while Breitung and Das (2005) suggest the prewhitening method as described above. In Breitung’s code, to be consistent with the papers, different approaches are adopted for model (2) and (3). Meanwhile, for the order of variable transformation and prewhitening, in model (2), the initial values are deducted (variable transformation) first, and then the prewhitening was applied. For model (3), the order is reversed. The series is prewhitened and then transformed to remove the mean and linear time trend.

a GLS version of the test statistic. Let $v_t = (v_{1t}, \dots, v_{Nt})'$ be the error vector for cross-section unit i , and let $\Omega = E(v_t v_t')$ be a positive definite matrix with eigenvalues $\lambda_1 \geq \dots \geq \lambda_N$. Let $y_t = (y_{1t}, \dots, y_{Nt})'$ and $\Delta y_t = (\Delta y_{1t}, \dots, \Delta y_{Nt})'$. The model can be written as a SUR-type system of equations,

$$\Delta y_t = \delta y_{t-1} + v_t$$

The unknown covariance matrix Ω can be estimated by its sample counterpart,

$$\hat{\Omega} = \sum_{t=1}^T (\Delta y_t - \delta y_t) (\Delta y_t - \delta y_t)'$$

The sequential limit $T \rightarrow \infty$ followed by $N \rightarrow \infty$ of the standard t statistic t_{OLS} is normal with mean 0 and variance $v_{\Omega} = \lim_{N \rightarrow \infty} \text{tr}(\Omega^2/N) / (\text{tr}\Omega/N)^2$. The variance v_{Ω} can be consistently estimated by $\hat{v}_{\hat{\delta}} = \left(\sum_{t=1}^T y'_{t-1} \hat{\Omega} y_{t-1} \right) / \left(\sum_{t=1}^T y'_{t-1} y_{t-1} \right)^2$. Thus the robust t statistic can be calculated as

$$t_{rob} = \frac{\hat{\delta}}{\hat{v}_{\hat{\delta}}} = \frac{\sum_{t=1}^T y'_{t-1} \Delta y_t}{\sqrt{\sum_{t=1}^T y'_{t-1} \hat{\Omega} y_{t-1}}} \Rightarrow \mathcal{N}(0, 1)$$

as $T \rightarrow \infty$ followed by $N \rightarrow \infty$ under the null hypothesis of random walk. Since the finite sample distribution can be quite different, Breitung and Das (2005) list the 1%, 5%, and 10% critical values for different N 's.

When $T > N$, a (feasible) GLS estimator is applied; it is asymptotically more efficient than the OLS estimator. The data are transformed by multiplying $\hat{\Omega}^{-1/2}$ as defined before, $\hat{z}_t = \hat{\Omega}^{-1/2} y_t$. Thus the model is transformed into

$$\Delta \hat{z}_t = \delta \hat{z}_{t-1} + e_t$$

The feasible GLS (FGLS) estimator of δ and the corresponding t statistic are obtained by estimating the transformed model by OLS and denoted by $\hat{\delta}_{GLS}$ and t_{GLS} , respectively:

$$t_{GLS} = \frac{\sum_{t=1}^T y'_{t-1} \hat{\Omega} \Delta y_t}{\sqrt{\sum_{t=1}^T y'_{t-1} \hat{\Omega} y_{t-1}}} \Rightarrow \mathcal{N}(0, 1)$$

Hadri's (2000) Stationarity Tests

Hadri (2000) adopts a component representation where an individual time series is written as a sum of a deterministic trend, a random walk, and a white-noise disturbance term. Under the null hypothesis of stationary, the variance of the random walk equals 0. Specifically, two models are considered:

- For model (1), the time series y_{it} is stationary around a level r_{i0} ,

$$y_{it} = r_{it} + \epsilon_{it} \quad i = 1, \dots, N, \quad t = 1, \dots, T$$

- For model (2), y_{it} is trend stationary,

$$y_{it} = r_{it} + \beta_i t + \epsilon_{it} \quad i = 1, \dots, N, \quad t = 1, \dots, T$$

where r_{it} is the random walk component,

$$r_{it} = r_{it-1} + u_{it} \quad i = 1, \dots, N, \quad t = 1, \dots, T$$

The initial values of the random walks, $\{r_{i0}\}_{i=1, \dots, N}$, are assumed to be fixed unknowns and can be considered as heterogeneous intercepts. The errors ϵ_{it} and u_{it} satisfy $\epsilon_{it} \sim \text{iid}\mathcal{N}(0, \sigma_\epsilon^2)$, $u_{it} \sim \text{iid}\mathcal{N}(0, \sigma_u^2)$ and are mutually independent.

The null hypothesis of stationarity is $H_0 : \sigma_u^2 = 0$ against the alternative random walk hypothesis $H_1 : \sigma_u^2 > 0$.

In matrix form, the models can be written as

$$y_i = X_i \beta_i + e_i$$

where $y'_i = (y_{i1}, \dots, y_{iT})$, $e'_i = (e_{i1}, \dots, e_{iT})$ with $e_{it} = \sum_{j=1}^t u_{ij} + \epsilon_{it}$, and $X_i = (\iota_T, a_T)$ with ι_T being a $T \times 1$ vector of ones, $a'_T = (1, \dots, T)$, and $\beta'_i = (r_{i0}, \beta_i)$.

Let $\hat{\epsilon}_{it}$ be the residuals from the regression of y_i on X_i ; then the LM statistic is

$$LM = \frac{\frac{1}{N} \sum_{i=1}^N \frac{1}{T^2} \sum_{t=1}^T S_{it}^2}{\hat{\sigma}_\epsilon^2}$$

where $S_{it} = \sum_{j=1}^t \epsilon_{ij}$ is the partial sum of the residuals and $\hat{\sigma}_\epsilon^2$ is a consistent estimator of σ_ϵ^2 under the null hypothesis of stationarity. With some regularity conditions,

$$LM \xrightarrow{p} E \left[\int_0^1 V(r) dr \right]$$

where $V(r)$ is a standard Brownian bridge in model (1) and a second-level Brownian bridge in model (2). Let $W(r)$ be a standard Wiener process (Brownian motion),

$$V(r) = \begin{cases} W(r) - rW(1) & \text{for model (1)} \\ W(r) + (2r - 3r^2) + 6r(r-1) \int_0^1 W(s) ds & \text{for model (2)} \end{cases}$$

The mean and variance of the random variable $\int V^2$ can be calculated by using the characteristic functions,

$$\xi = E \left[\int_0^1 V(r) dr \right] = \begin{cases} \frac{1}{6} & \text{for model (1)} \\ \frac{1}{15} & \text{for model (2)} \end{cases}$$

and

$$\xi^2 = \text{var} \left[\int_0^1 V(r) dr \right] = \begin{cases} \frac{1}{45} & \text{for model (1)} \\ \frac{11}{6300} & \text{for model (2)} \end{cases}$$

The LM statistics can be standardized to obtain the standard normal limiting distribution,

$$Z = \frac{\sqrt{N} (LM - \xi)}{\xi^2} \implies \mathcal{N}(0, 1)$$

Consistent Estimator of σ_ϵ^2

Hadri's (2000) test can be applied to the general case of heteroscedasticity and serially correlated disturbance errors. Under homoscedasticity and serially uncorrelated errors, σ_ϵ^2 can be estimated as

$$\hat{\sigma}_\epsilon^2 = \sum_{i=1}^N \sum_{t=1}^T \hat{\epsilon}_{it}^2 / N(T-k)$$

where k is the number of regressors. Therefore, $k = 1$ for model (1) and $k = 2$ for model (2).

When errors are heteroscedastic across individuals, the standard errors $\sigma_{\epsilon,i}^2$ can be estimated by $\hat{\sigma}_{\epsilon,i}^2 = \sum_{t=1}^T \hat{\epsilon}_{it}^2 / (T-k)$ for each individual i and the LM statistic needs to be modified to

$$LM = \frac{1}{N} \sum_{i=1}^N \left(\frac{\frac{1}{T^2} \sum_{t=1}^T S_{it}^2}{\hat{\sigma}_{\epsilon,i}^2} \right)$$

To allow for temporal dependence over t , σ_ϵ^2 has to be replaced by the long-run variance of ϵ_{it} , which is defined as $\sigma^2 = \sum_{i=1}^N \lim_{T \rightarrow \infty} T^{-1} (S_{iT}^2) / N$. A HAC estimator can be used to consistently estimate the long-run variance σ^2 . For more information, see the section “[Long-Run Variance Estimation](#)” on page 1404.

Harris and Tzavalis (1999) Panel Unit Root Tests

Harris and Tzavalis (1999) derive the panel unit root test under fixed T and large N . Three models are considered as in Levin, Lin, and Chu (2002). Model (1) is the homogeneous panel,

$$y_{it} = \varphi y_{it-1} + v_{it}$$

Under the null hypothesis, $\varphi = 0$. For model (2), each series is a unit root process with a heterogeneous drift,

$$y_{it} = \alpha_i + \varphi y_{it-1} + v_{it}$$

Model (3) includes heterogeneous drifts and linear time trends,

$$y_{it} = \alpha_i + \beta_i t + \varphi y_{it-1} + v_{it}$$

Under the null hypothesis $H_0 : \varphi = 1, \beta_i = 0$, so the series is random walks with drift.

Let $\hat{\varphi}$ be the OLS estimator of φ ; then

$$\hat{\varphi} - 1 = \left[\sum_{i=1}^N y'_{i,-1} Q_T y_{i,-1} \right]^{-1} \cdot \left[\sum_{i=1}^N y'_{i,-1} Q_T v_i \right]$$

where $y_{i,-1} = (y_{i0}, \dots, y_{iT-1})$, $v'_i = (v_{i1}, \dots, v_{iT})$, and Q_T is the projection matrix. For model (1), there are no regressors other than the lagged dependent value, so Q_T is the identity matrix I_T . For model (2), a constant is included, so $Q_T = I_T - e_T e'_T / T$ with e_T a $T \times 1$ column of ones. For model (3), a constant and time trend are included. Thus $Q_T = I_T - Z_T (Z'_T Z_T)^{-1} Z'_T / T$, where $Z_T = (e_T, \tau_T)$ and $\tau_T = (1, \dots, T)$.

When $y_{i0} = 0$ in model (1) under the null hypothesis,

$$\sqrt{NT(T-1)/2} (\hat{\varphi} - 1) \xrightarrow{y_{i0}=0, H_0} \mathcal{N}(0, 1)$$

As $T \rightarrow \infty$, it becomes $T \sqrt{N} (\hat{\phi} - 1) \xrightarrow{H_0} \mathcal{N}(0, 1)$.

When the drift is absent in model (2) under the null hypothesis, $\alpha_i = 0$,

$$\sqrt{\frac{5N(T+1)^3(T-1)}{3(17T^2-20T+17)}} \left(\hat{\phi} - 1 - \frac{3}{(T+1)} \right) \xrightarrow{H_0} \mathcal{N}(0, 1)$$

As T grows large, $(T \sqrt{N} (\hat{\phi} - 1) + 3\sqrt{N}) / \sqrt{51/5} \xrightarrow{H_0} \mathcal{N}(0, 1)$.

When the time trend is absent in model (3) under the null hypothesis, $\beta_i = 0$,

$$\sqrt{\frac{112N(T+2)^3(T-2)}{15(193T^2-728T+1147)}} \left(\hat{\phi} - 1 - \frac{15}{2(T+2)} \right) \xrightarrow{H_0} \mathcal{N}(0, 1)$$

When T is sufficiently large, it implies $(T \sqrt{N} (\hat{\phi} - 1) + 7.5\sqrt{N}) / \sqrt{2895/112} \xrightarrow{H_0} \mathcal{N}(0, 1)$.

Troubleshooting

Some guidelines need to be followed when you use PROC PANEL for analysis. For each cross section, PROC PANEL requires at least two time series observations with nonmissing values for all model variables. There should be at least two cross sections for each time point in the data. If these two conditions are not met, then an error message is printed in the log stating that there is only one cross section or time series observation and further computations will be terminated. You have to give adequate data for an estimation method to produce results, and you should check the log for any data related errors.

If the number of cross sections is greater than the number of time series observations per cross section, PROC PANEL while using PARKS method produces an error message stating that the phi matrix is singular. This is analogous to seemingly unrelated regression with fewer observations than equations in the model. To avoid the problem, reduce the number of cross sections.

Your data set could have multiple observations for each time ID within a particular cross section. However, PROC PANEL is applicable only in cases where you have only a single observation for each time ID within each cross section. In such a case, after you have sorted the data, an error warning specifying that the data has not been sorted in ascending sequence with respect to time series ID appears in the log.

The cause of the error is due to multiple observations for each time ID for a given cross section. PROC PANEL allows only one observation for each time ID within each cross section.

The following data set shown in [Figure 20.2](#) illustrates the preceding instance with the correct representation.

Figure 20.2 Single Observation for Each Time Series

Obs	firm	year	production	cost
1	1	1955	5.36598	1.14867
2	1	1960	6.03787	1.45185
3	1	1965	6.37673	1.52257
4	1	1970	6.93245	1.76627
5	2	1955	6.54535	1.35041
6	2	1960	6.69827	1.71109
7	2	1965	7.40245	2.09519
8	2	1970	7.82644	2.39480

In this case, you can observe that there are no multiple observations with respect to a given time series ID within a cross section. This is the correct representation of a data set where PROC PANEL is applicable.

If for state ID 1 you have two observations for the year=1955, then PROC PANEL produces the following error message:

“The data set is not sorted in ascending sequence with respect to time series ID. The current time period has year=1955 and the previous time period has year=1955 in cross section firm=1.”

A data set similar to the previous example with multiple observations for the YEAR=1955 is shown in [Figure 20.3](#); this data set results in an error message due to multiple observations while using PROC PANEL.

Figure 20.3 Multiple Observations for Each Time Series

Obs	firm	year	production	cost
1	1	1955	5.36598	1.14867
2	1	1955	6.37673	1.52257
3	1	1960	6.03787	1.45185
4	1	1970	6.93245	1.76627
5	2	1955	6.54535	1.35041
6	2	1960	6.69827	1.71109
7	2	1965	7.40245	2.09519
8	2	1970	7.82644	2.39480

In order to use PROC PANEL, you need to aggregate the data so that you have unique time ID values within each cross section. One possible way to do this is to run a PROC MEANS on the input data set and compute the mean of all the variables by FIRM and YEAR, and then use the output data set.

Creating ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the PANEL procedure. The table below lists the graph names, the plot descriptions, and the options used.

Table 20.6 ODS Graphics Produced by PROC PANEL

ODS Graph Name	Plot Description	Plots=Option
DiagnosticsPanel	All applicable plots listed below	
ResidualPlot	Plot of the residuals	RESIDUAL, RESID
FitPlot	Predicted versus actual plot	FITPLOT
QQPlot	Plot of the quantiles of the residuals	QQ
ResidSurfacePlot	Surface plot of the residuals	RESIDSURFACE
PredSurfacePlot	Surface plot of the predicted values	PREDSURFACE
ActSurfacePlot	Surface plot of the actual values	ACTSURFACE
ResidStackPlot	Stack plot of the residuals	RESIDSTACK, RESSTACK
ResidHistogram	Plot of the histogram of residuals	RESIDUALHISTOGRAM, RESIDHISTOGRAM

OUTPUT OUT= Data Set

PROC PANEL writes the initial data of the estimated model, predicted values, and residuals to an output data set when the OUTPUT OUT= statement is specified. The OUT= data set contains the following variables:

<code>_MODEL_</code>	is a character variable that contains the label for the MODEL statement if a label is specified.
<code>_METHOD_</code>	is a character variable that identifies the estimation method.
<code>_MODLNO_</code>	is the number of the model estimated.
<code>_ACTUAL_</code>	contains the value of the dependent variable.
<code>_WEIGHT_</code>	contains the weighing variable.
<code>_CSID_</code>	is the value of the cross section ID.
<code>_TSID_</code>	is the value of the time period in the dynamic model.
regressors	are the values of regressor variables specified in the MODEL statement.
<i>name</i>	if PRED= <i>name1</i> and/or RESIDUAL= <i>name2</i> options are specified, then <i>name1</i> and <i>name2</i> are the columns of predicted values of dependent variable and residuals of the regression, respectively.

OUTEST= Data Set

PROC PANEL writes the parameter estimates to an output data set when the OUTEST= option is specified. The OUTEST= data set contains the following variables:

<code>_MODEL_</code>	is a character variable that contains the label for the MODEL statement if a label is specified.
<code>_METHOD_</code>	is a character variable that identifies the estimation method.
<code>_TYPE_</code>	is a character variable that identifies the type of observation. Values of the <code>_TYPE_</code> variable are CORR, COVB, CSPARMS, STD, and the type of model estimated. The CORR observation contains correlations of the parameter estimates, the COVB observation contains covariances of the parameter estimates, the CSPARMS observation contains cross-sectional parameter estimates, the STD observation indicates the row of standard deviations of the corresponding coefficients, and the type of model estimated observation contains the parameter estimates.
<code>_NAME_</code>	is a character variable that contains the name of a regressor variable for COVB and CORR observations and is left blank for other observations. The <code>_NAME_</code> variable is used in conjunction with the <code>_TYPE_</code> values COVB and CORR to identify rows of the correlation or covariance matrix.
<code>_DEPVAR_</code>	is a character variable that contains the name of the response variable.
<code>_MSE_</code>	is the mean square error of the transformed model.
<code>_CSID_</code>	is the value of the cross section ID for CSPARMS observations. The <code>_CSID_</code> variable is used with the <code>_TYPE_</code> value CSPARMS to identify the cross section for the first-order autoregressive parameter estimate contained in the observation. The <code>_CSID_</code> variable is missing for observations with other <code>_TYPE_</code> values. (Currently, only the <code>_A_1</code> variable contains values for CSPARMS observations.)
<code>_VARCS_</code>	is the variance component estimate due to cross sections. The <code>_VARCS_</code> variable is included in the OUTEST= data set when either the FULLER or DASILVA option is specified.
<code>_VARTS_</code>	is the variance component estimate due to time series. The <code>_VARTS_</code> variable is included in the OUTEST= data set when either the FULLER or DASILVA option is specified.
<code>_VARERR_</code>	is the variance component estimate due to error. The <code>_VARERR_</code> variable is included in the OUTEST= data set when the FULLER option is specified.
<code>_A_1</code>	is the first-order autoregressive parameter estimate. The <code>_A_1</code> variable is included in the OUTEST= data set when the PARKS option is specified. The values of <code>_A_1</code> are cross-sectional parameters, meaning that they are estimated for each cross section separately. The <code>_A_1</code> variable has a value only for <code>_TYPE_=CSPARMS</code> observations. The cross section to which the estimate belongs is indicated by the <code>_CSID_</code> variable.
Intercept	is the intercept parameter estimate. (Intercept is missing for models when the NOINT option is specified.)
regressors	are the regressor variables specified in the MODEL statement. The regressor variables in the OUTEST= data set contain the corresponding parameter estimates for the model identified by <code>_MODEL_</code> for <code>_TYPE_=PARMS</code> observations, and the corresponding covariance or correlation matrix elements for <code>_TYPE_=COVB</code> and <code>_TYPE_=CORR</code> observations. The response variable contains the value -1 for the <code>_TYPE_=PARMS</code> observation for its model.

OUTTRANS= Data Set

PROC PANEL writes the transformed series to an output data set. That is, if the user selects FIXONE, FIXONETIME, or RANONE and supplies the OUTTRANS = option, the transformed dependent variable and independent variables are written out to a SAS data set; other variables in the input data set are copied unchanged.

Say that your data set contains variables *y*, *x1*, *x2*, *x3*, and *z2*. The following statements result in a SAS data set:

```
proc panel data=datain outtrans=dataout;
  id cs ts;
  model y = x1 x2 x3 / fixone;
run;
```

First, *z2* is copied over. Then *_Int*, *x1*, *x2*, *y*, and *x3*, are replaced with their mean deviates (from cross sections). Furthermore, two new variables are created.

MODEL is the model's label (if it exists).

METHOD is the model's transformation type. In the FIXONE case, this is *_FIXONE_* or *_FIXONETIME_*. If the model RANONE model is selected, the *_METHOD_* variable is either *_Ran1FB_*, *_Ran1WK_*, *_Ran1WH_*, or *_Ran1NL_*, depending on the variance component estimators chosen.

Printed Output

For each MODEL statement, the printed output from PROC PANEL includes the following:

- a model description, which gives the estimation method used, the model statement label if specified, the number of cross sections and the number of observations in each cross section, and the order of moving average error process for the DASILVA option. For fixed-effects model analysis, an *F* test for the absence of fixed effects is produced, and for random-effects model analysis, a Hausman test is used for the appropriateness of the random-effects specification.
- the estimates of the underlying error structure parameters
- the regression parameter estimates and analysis. For each regressor, this includes the name of the regressor, the degrees of freedom, the parameter estimate, the standard error of the estimate, a *t* statistic for testing whether the estimate is significantly different from 0, and the significance probability of the *t* statistic.

Optionally, PROC PANEL prints the following:

- the covariance and correlation of the resulting regression parameter estimates for each model and assumed error structure
- the $\hat{\Phi}$ matrix that is the estimated contemporaneous covariance matrix for the PARKS option

ODS Table Names

PROC PANEL assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 20.7.

Table 20.7 ODS Tables Produced in PROC PANEL

ODS Table Name	Description	Option
ODS Tables Created by the MODEL Statement		
ModelDescription	Model description	Default
FitStatistics	Fit statistics	Default
FixedEffectsTest	<i>F</i> test for no fixed effects	FIXONE, FIXTWO, FIXONETIME
ParameterEstimates	Parameter estimates	Default
CovB	Covariance of parameter estimates	COVB
CorrB	Correlations of parameter estimates	CORRB
VarianceComponents	Variance component estimates	RANONE, RANTWO, DASILVA
RandomEffectsTest	Hausman test for random effects	RANONE, RANTWO
AR1Estimates	First-order autoregressive parameter estimates	RHO(PARKS)
BreuschPaganTest	Breusch-Pagan one-way test	BP
BreuschPaganTest2	Breusch-Pagan two-way test	BP2

Example: PANEL Procedure

Example 20.1: Analyzing Demand for Liquid Assets

In this example, the demand equations for liquid assets are estimated. The demand function for the demand deposits is estimated under three error structures while demand equations for time deposits and savings and loan (S&L) association shares are calculated using the Parks method. The data for seven states (CA, DC, FL, IL, NY, TX, and WA) are selected out of 49 states. See Feige (1964) for data description. All variables were transformed via natural logarithm. The data set A is shown below.

```
data a;
  length state $ 2;
  input state $ year d t s y rd rt rs;
  label d = 'Per Capita Demand Deposits'
        t = 'Per Capita Time Deposits'
        s = 'Per Capita S & L Association Shares'
        y = 'Permanent Per Capita Personal Income'
        rd = 'Service Charge on Demand Deposits'
        rt = 'Interest on Time Deposits'
        rs = 'Interest on S & L Association Shares';
datalines;
CA  1949  6.2785  6.1924  4.4998  7.2056 -1.0700  0.1080  1.0664
CA  1950  6.4019  6.2106  4.6821  7.2889 -1.0106  0.1501  1.0767
CA  1951  6.5058  6.2729  4.8598  7.3827 -1.0024  0.4008  1.1291
CA  1952  6.4785  6.2729  5.0039  7.4000 -0.9970  0.4492  1.1227
CA  1953  6.4118  6.2538  5.1761  7.4200 -0.8916  0.4662  1.2110
CA  1954  6.4520  6.2971  5.3613  7.4478 -0.6951  0.4756  1.1924
... more lines ...
```

As shown in the following statements, the SORT procedure is used to sort the data into the required time series cross-sectional format; then PROC PANEL analyzes the data.

```
proc sort data=a;
  by state year;
run;

proc panel data=a;
  model d = y rd rt rs / fuller parks dasilva m=7;
  model t = y rd rt rs / parks;
  model s = y rd rt rs / parks;
  id state year;
run;
```

The income elasticities for liquid assets are greater than 1 except for the demand deposit income elasticity (0.692757) estimated by the Da Silva method. In [Output 20.1.1](#), [Output 20.1.2](#), and [Output 20.1.3](#), the coefficient estimates (−0.29094, −0.43591, and −0.27736) of demand deposits (RD) imply that demand deposits increase significantly as the service charge is reduced. The price elasticities (0.227152 and 0.408066) for time deposits (RT) and S&L association shares (RS) have the expected sign. Thus an increase in the interest rate on time deposits or S&L shares will increase the demand for the corresponding liquid asset. Demand deposits and S&L shares appear to be substitutes (see [Output 20.1.2](#), [Output 20.1.3](#), and [Output 20.1.5](#)). Time deposits are also substitutes for S&L shares in the time deposit demand equation (see [Output 20.1.4](#)), while these liquid assets are independent of each other in [Output 20.1.5](#) (insignificant coefficient estimate of RT, −0.02705). Demand deposits and time deposits appear to be weak complements in [Output 20.1.3](#) and [Output 20.1.4](#), while the cross elasticities between demand deposits and time deposits are not significant in [Output 20.1.2](#) and [Output 20.1.5](#).

Example 20.2: The Airline Cost Data: Fixtwo Model

The Christenson Associates airline data are a frequently cited data set (see Greene 2000). The data measure costs, prices of inputs, and utilization rates for six airlines over the time span 1970–1984. This example analyzes the log transformations of the cost, price and quantity, and the raw (not logged) capacity utilization measure. You speculate the following model:

$$\ln(TC_{it}) = \alpha_N + \gamma_T + (\alpha_i - \alpha_N) + (\gamma_t - \gamma_T) + \beta_1 \ln(Q_{it}) + \beta_2 \ln(PF_{it}) + \beta_3 LF_{it} + \epsilon_{it}$$

where the α are the pure cross-sectional effects and γ are the time effects. The actual model speculated is highly nonlinear in the original variables. It would look like the following:

$$TC_{it} = \exp(\alpha_i + \gamma_t + \beta_3 LF_{it} + \epsilon_{it}) Q_{it}^{\beta_1} PF_{it}^{\beta_2}$$

The data and preliminary SAS statements are:

```
data airline;
  input  Obs I T C Q PF LF;
  label obs = "Observation number";
  label I   = "Firm Number (CSID)";
  label T   = "Time period (TSID)";
  label Q   = "Output in revenue passenger miles (index)";
  label C   = "Total cost, in thousands";
  label PF  = "Fuel price";
  label LF  = "Load Factor (utilization index)";
datalines;
1    1    1    1140640    0.95276    106650    0.53449
... more lines ...
```

```

data airline;
  set airline;
  lC = log(C);
  lQ = log(Q);
  lPF = log(PF);
  label lC = "Log transformation of costs";
  label lQ = "Log transformation of quantity";
  label lPF= "Log transformation of price of fuel";
run;

```

The following statements fit the model.

```

proc panel data=airline printfixed;
  id i t;
  model lC = lQ lPF LF / fixtwo;
run;

```

First, you see the model's description in [Output 20.2.1](#). The model is a two-way fixed-effects model. There are six cross sections and fifteen time observations.

Output 20.2.1 The Airline Cost Data—Model Description

The PANEL Procedure	
Fixed Two Way Estimates	
Dependent Variable: lC Log transformation of costs	
Model Description	
Estimation Method	FixTwo
Number of Cross Sections	6
Time Series Length	15

The R square and degrees of freedom can be seen in [Table 20.2.2](#). On the whole, you see a large R square, so there is a reasonable fit. The degrees of freedom of the estimate are 90 minus 14 time dummy variables minus 5 cross section dummy variables and 4 regressors.

Output 20.2.2 The Airline Cost Data—Fit Statistics

Fit Statistics			
SSE	0.1768	DFE	67
MSE	0.0026	Root MSE	0.0514
R-Square	0.9984		

The F test for fixed effects is shown in [Table 20.2.3](#). Testing the hypothesis that there are no fixed effects, you easily reject the null of poolability. There are group effects, or time effects, or both. The test is highly significant. OLS would not give reasonable results.

Output 20.2.3 The Airline Cost Data—Test for Fixed Effects

F Test for No Fixed Effects			
Num DF	Den DF	F Value	Pr > F
19	67	23.10	<.0001

Looking at the parameters, you see a more complicated pattern. Most of the cross-sectional effects are highly significant (with the exception of CS2). This means that the cross sections are significantly different from the sixth cross section. Many of the time effects show significance, but this is not uniform. It looks like the significance might be driven by a large 16th period effect, since the first six time effects are negative and of similar magnitude. The time dummy variables taper off in size and lose significance from time period 12 onward. There are many causes to which you could attribute this decay of time effects. The time period of the data spans the OPEC oil embargoes and the dissolution of the Civil Aeronautics Board (CAB). These two forces are two possible reasons to observe the decay and parameter instability. As for the regression parameters, you see that quantity affects cost positively, and the price of fuel has a positive effect, but load factors negatively affect the costs of the airlines in this sample. The somewhat disturbing result is that the fuel cost is not significant. If the time effects are proxies for the effect of the oil embargoes, then an insignificant fuel cost parameter would make some sense. If the dummy variables proxy for the dissolution of the CAB, then the effect of load factors is also not being precisely estimated.

Output 20.2.4 The Airline Cost Data—Parameter Estimates

ODS Graphics Plots

ODS graphics plots can be obtained to graphically analyze the results. The following statements show how to generate the plots. If the PLOTS=ALL option is specified, all available plots are produced in two panels. For a complete list of options, see the section “Creating ODS Graphics” on page 1413.

```
proc panel data=airline;
  id i t;
  model lc = lq lpf lf / fixtwo plots = all;
run;
```

The preceding statements result in plots shown in [Output 20.2.5](#) and [Output 20.2.6](#).

Output 20.2.5 Diagnostic Panel 1

Output 20.2.6 Diagnostic Panel 2

The UNPACK and ONLY options produce individual detail images of paneled plots. The graph shown in [Output 20.2.7](#) shows a detail plot of residuals by cross section. The packed version always puts all cross sections on one plot while the unpacked one shows the cross sections in groups of ten to avoid loss of detail.

```
proc panel data=airline;
  id i t;
  model lC = lQ lPF lF / fixtwo plots(unpack only) = residsurface;
run;
```

Output 20.2.7 Surface Plot of the Residual

Example 20.3: The Airline Cost Data: Further Analysis

Using the same data as in [Example 20.2](#), you further investigate the ‘true’ effect of fuel prices. Specifically, you run the FixOne model, ignoring time effects. You specify the following statements in PROC PANEL to run this model:

```
proc panel data=airline;
  id i t;
  model lC = lQ lPF LF / fixone;
run;
```

The preceding statements result in [Output 20.3.1](#). The fit seems to have deteriorated somewhat. The SSE rises from 0.1768 to 0.2926.

Output 20.3.1 The Airline Cost Data—Fit Statistics

The PANEL Procedure			
Fixed One Way Estimates			
Dependent Variable: lC Log transformation of costs			
Fit Statistics			
SSE	0.2926	DFE	81
MSE	0.0036	Root MSE	0.0601
R-Square	0.9974		

You still reject poolability based on the F test in [Output 20.3.2](#) at all accepted levels of significance.

Output 20.3.2 The Airline Cost Data—Test for Fixed Effects

F Test for No Fixed Effects			
Num DF	Den DF	F Value	Pr > F
5	81	57.74	<.0001

The parameters change somewhat dramatically as shown in [Output 20.3.3](#). The effect of fuel costs comes in very strong and significant. The load factor's coefficient increases, although not as dramatically. This suggests that the fixed time effects might be proxies for both the oil shocks and deregulation.

Output 20.3.3 The Airline Cost Data—Parameter Estimates

Parameter Estimates						
Variable	DF	Estimate	Standard Error	t Value	Pr > t	Label
Intercept	1	9.79304	0.2636	37.15	<.0001	Intercept
lQ	1	0.919293	0.0299	30.76	<.0001	Log transformation of quantity
lPF	1	0.417492	0.0152	27.47	<.0001	Log transformation of price of fuel
LF	1	-1.07044	0.2017	-5.31	<.0001	Load Factor (utilization index)

Example 20.4: The Airline Cost Data: Random-Effects Models

This example continues to use the Christenson Associates airline data, which measures costs, prices of inputs, and utilization rates for six airlines over the time span 1970–1984. There are six cross sections and fifteen time observations. Here, you examine the different estimates generated from the one-way random-effects and two-way random-effects models, by using four different methods to estimate the variance components: Fuller and Battese, Wansbeek and Kapteyn, Wallace and Hussain, and Nerlove.

The data for this example is created by the PROC PANEL statements shown in [Example 20.2](#). The PROC PANEL statements necessary to generate the estimates are as follows:

```
proc panel data=airline outest=estimates;
  id I T;
  RANONE:   model lC = lQ lPF lF / ranone vcomp=fb;
  RANONEwk: model lC = lQ lPF lF / ranone vcomp=wk;
  RANONEwh: model lC = lQ lPF lF / ranone vcomp=wh;
  RANONEnl: model lC = lQ lPF lF / ranone vcomp=nl;
  RANTWO:   model lC = lQ lPF lF / rantwo vcomp=fb;
  RANTWOwk: model lC = lQ lPF lF / rantwo vcomp=wk;
  RANTWOwh: model lC = lQ lPF lF / rantwo vcomp=wh;
  RANTWOnl: model lC = lQ lPF lF / rantwo vcomp=nl;
  POOLED:   model lC = lQ lPF lF / pooled;
  BTWNG:    model lC = lQ lPF lF / btwng;
  BTWNT:    model lC = lQ lPF lF / btwnt;
run;

data table;
  set estimates;
  VarCS = round(_VARCS_, .00001);
  VarTS = round(_VARTS_, .00001);
  VarErr = round(_VARERR_, .00001);
  Int = round(Intercept, .0001);
  lQ2 = round(lQ, .0001);
  lPF2 = round(lPF, .0001);
  lF2 = round(lF, .0001);
  if _n_ >= 9 then do;
    VarCS = . ;
    VarTS = . ;
  end;
  keep _MODEL_ _METHOD_ VarCS VarTS VarErr Int lQ2 lPF2 lF2;
run;
```

The parameter estimates and variance components for both models are reported in [Output 20.4.1](#) and [Output 20.4.2](#).

Output 20.4.1 Parameter Estimates

In the random-effects model, individual constant terms are viewed as randomly distributed across cross-sectional units and not as parametric shifts of the regression function, as in the fixed-effects model. This is appropriate when the sampled cross-sectional units are drawn from a large population. Clearly, in this example, the six airlines are a sample of all the airlines in the industry and not an exhaustive, or nearly exhaustive, list.

There are four ways of computing the variance components in the one-way random-effects model. The method by Fuller and Battese (1974) (FB), uses a “fitting of constants” methods to estimate them. The Wansbeek and Kapteyn (1989) (WK) method uses the true disturbances, while the Wallace and Hussain (WH) method uses ordinary least squares residuals.

Looking at the estimates of the variance components for cross section and error in [Output 20.4.2](#), you see that equal variance components for error are computed for both FB and WK, while WH and NL are nearly equal.

All four techniques produce different variance components for cross sections. These estimates are then used to estimate the values of the parameters in [Output 20.4.1](#). All the parameters appear to have similar and equally plausible estimates. Both the index for output in revenue passenger miles (IQ) and fuel price (IPF) have small, positive effects on total costs, which you would expect. The load factor (LF) has a somewhat larger and negative effect on total costs, suggesting that as utilization increases, costs decrease.

As in the one-way random-effects model, the variance components for error produced by the FB and WK methods are equal. However, in this case, the WH and NL methods produce variance estimates that are dissimilar. The estimates of the variance component for cross sections are all different, but in a close range. The same cannot be said for the variance component for time series. As varied as each of the variance estimates may be, they produce parameter estimates that are similar and plausible. As with the one-way effects model, the index for output (IQ) and fuel price (IPF) are small and positive. The load factor (LF) estimates are all negative and, with the exception of the estimate produced by the WH method, somewhat smaller than the estimates produced in the one-way model. During the time the data were collected, the Civil Aeronautics Board dissolved, so it is possible that the dummy variables are proxies for this dissolution. This would lead to the decay of time effects and an imprecise estimation of the effects of the load factors, even though the estimates are statistically significant.

The pooled estimates give you something to compare the random-effects estimates against. You see that signs and magnitudes of output and fuel price are similar but that the magnitude of the load factor coefficient is somewhat larger under pooling. Since the model appears to have both cross-sectional and time series effects, the pooled model should not be used.

Finally, you examine the between groups estimators. For the between groups estimate, you are looking at each airline's data averaged across time. You see in [Output 20.4.1](#) that the between groups parameter estimates are radically different from all other parameter estimates. This could indicate that the time component is not being appropriately handled with this technique. For the between times estimate, you are looking at the average across all airlines in each time period. In this case, the parameter estimates are of the same sign and closer in magnitude to the previously computed estimates. Both the output and load factor effects appear to have more bearing on total costs.

Example 20.5: Using the FLATDATA Statement

Sometimes the data can be found in compressed form, where each line consists of all observations for the dependent and independent variables for the cross section. To illustrate, suppose you have a data set with 20 cross sections where each cross section consists of observations for six time periods. Each time period has values for dependent and independent variables $Y_1 \dots Y_6$ and $X_1 \dots X_6$. The *cs* and *num* variables represent other character and numeric variables that are constant across each cross section.

The observations for first five cross sections along with other variables are shown in [Output 20.5.1](#). In this example, *i* represents the cross section. The time period is identified by the subscript on the *Y* and *X* variables; it ranges from 1 to 6.

Output 20.5.1 Compressed Data Set

Obs	i	cs	num	X_1	X_2	X_3	X_4	X_5	
1	1	CS1	-1.56058	0.40268	0.91951	0.69482	-2.28899	-1.32762

4			-0.92771	2.40304	1.48182	2.70579	3.82672	4.01117	1.97639
5			-0.70566	3.58092	6.08917	3.08249	4.26605	3.65452	0.81826

Since the PANEL procedure cannot work directly with the data in compressed form, the FLATDATA statement can be used to transform the data. The OUT= option can be used to output transformed data to a data set.

```
proc panel data=flattest;
  flatdata indid=i tsname="t" base=(X Y)
    keep=( cs num seed ) / out=flat_out;
  id i t;
  model y = x / fixone noint;
run;
```

First, six observations for the uncompressed data set and results for the one-way fixed-effects model fitted are shown in [Output 20.5.2](#) and [Output 20.5.3](#).

Output 20.5.2 Uncompressed Data Set

Obs	I	t	X	Y	CS	NUM

Example 20.6: The Cigarette Sales Data: Dynamic Panel Estimation with GMM

In this example, a dynamic panel demand model for cigarette sales is estimated. It illustrates the application of the method described in the section “[Dynamic Panel Estimator](#)” on page 1384. The data are a panel from 46 American states over the period 1963–92. See Baltagi and Levin (1992) and Baltagi (1995) for data description. All variables were transformed by taking the natural logarithm. The data set CIGAR is shown in the following statements.

```
data cigar;
  input state year price pop pop_16 cpi ndi sales pimin;
  label
    state = 'State abbreviation'
    year = 'YEAR'
    price = 'Price per pack of cigarettes'
    pop = 'Population'
    pop_16 = 'Population above the age of 16'
    cpi = 'Consumer price index with (1983=100)'
    ndi = 'Per capita disposable income'
    sales = 'Cigarette sales in packs per capita'
    pimin = 'Minimum price in adjoining states per pack of cigarettes';
datalines;
1 63 28.6 3383 2236.5 30.6 1558.3045298 93.9 26.1

1 72 42.3 3511 2484.7 41.8 3034.8082969 101.1 37.4

... more lines ...
```

The following statements sort the data by STATE and YEAR variables.

```
proc sort data=cigar;
  by state year;
run;
```

Next, logarithms of the variables required for regression estimation are calculated, as shown in the following statements:

```
data cigar;
  set cigar;
  lsales = log(sales);
  lprice = log(price);
  lndi = log(ndi);
  lpimin = log(pimin);
  label lprice = 'Log price per pack of cigarettes';
  label lndi = 'Log per capita disposable income';
  label lsales = 'Log cigarette sales in packs per capita';
  label lpimin = 'Log minimum price in adjoining states
                  per pack of cigarettes';
run;
```

The following statements create the CIGAR_LAG data set with lagged variable for each cross section.

```
proc panel data=cigar;
  id state year;
  clag lsales(1) / out=cigar_lag;
run;

data cigar_lag;
  set cigar_lag;
  label lsales_1 = 'Lagged log cigarette sales in packs per capita';
run;
```

Finally, the model is estimated by a two step GMM method. Five lags (MAXBAND=5) of the dependent variable are used as instruments. NOLEVELS options is specified to avoid use of level equations, as shown in the following statements:

```
proc panel data=cigar_lag;
  inst depvar;
  model lsales = lsales_1 lprice lndi lpimin
    / gmm nolevels twostep maxband=5 noint;
  id state year;
run;
```

Output 20.6.1 Estimation with GMM

The PANEL Procedure

Overview: PDLREG Procedure

The PDLREG procedure estimates regression models for time series data in which the effects of some of the regressor variables are distributed across time. The distributed lag model assumes that the effect of an input variable X on an output Y is distributed over time. If you change the value of X at time t , Y will experience some immediate effect at time t , and it will also experience a delayed effect at times $t + 1$, $t + 2$, and so on up to time $t + p$ for some limit p .

The regression model supported by PROC PDLREG can include any number of regressors with distribution lags and any number of covariates. (Simple regressors without lag distributions are called covariates.) For example, the two-regressor model with a distributed lag effect for one regressor is written

$$y_t = \alpha + \sum_{i=0}^p \beta_i x_{t-i} + \gamma z_t + u_t$$

Here, x_t is the regressor with a distributed lag effect, z_t is a simple covariate, and u_t is an error term.

The distribution of the lagged effects is modeled by Almon lag polynomials. The coefficients b_i of the lagged values of the regressor are assumed to lie on a polynomial curve. That is,

$$b_i = \alpha_0^* + \sum_{j=1}^d \alpha_j^* i^j$$

where $d(\leq p)$ is the degree of the polynomial. For the numerically efficient estimation, the PDLREG procedure uses *orthogonal polynomials*. The preceding equation can be transformed into orthogonal polynomials:

$$b_i = \alpha_0 + \sum_{j=1}^d \alpha_j f_j(i)$$

where $f_j(i)$ is a polynomial of degree j in the lag length i , and α_j is a coefficient estimated from the data.

The PDLREG procedure supports endpoint restrictions for the polynomial. That is, you can constrain the estimated polynomial lag distribution curve so that $b_{-1} = 0$ or $b_{p+1} = 0$, or both. You can also impose linear restrictions on the parameter estimates for the covariates.

You can specify a minimum degree and a maximum degree for the lag distribution polynomial, and the procedure fits polynomials for all degrees in the specified range. (However, if distributed lags are specified for more than one regressor, you can specify a range of degrees for only one of them.)

The PDLREG procedure can also test for autocorrelated residuals and perform autocorrelated error correction by using the autoregressive error model. You can specify any order autoregressive error model and can specify several different estimation methods for the autoregressive model, including exact maximum likelihood.

The PDLREG procedure computes generalized Durbin-Watson statistics to test for autocorrelated residuals. For models with lagged dependent variables, the procedure can produce Durbin h and Durbin t statistics. You can request significance level p -values for the Durbin-Watson, Durbin h , and Durbin t statistics. See Chapter 8, “[The AUTOREG Procedure](#),” for details about these statistics.

The PDLREG procedure assumes that the input observations form a time series. Thus, the PDLREG procedure should be used only for ordered and equally spaced time series data.

Getting Started: PDLREG Procedure

Use the MODEL statement to specify the regression model. The PDLREG procedure’s MODEL statement is written like MODEL statements in other SAS regression procedures, except that a regressor can be followed by a lag distribution specification enclosed in parentheses.

For example, the following MODEL statement regresses Y on X and Z and specifies a distributed lag for X:

```
model y = x(4,2) z;
```

The notation X(4,2) specifies that the model includes X and 4 lags of X, with the coefficients of X and its lags constrained to follow a second-degree (quadratic) polynomial. Thus, the regression model specified by this MODEL statement is

$$y_t = a + b_0x_t + b_1x_{t-1} + b_2x_{t-2} + b_3x_{t-3} + b_4x_{t-4} + cz_t + u_t$$

$$b_i = \alpha_0 + \alpha_1 f_1(i) + \alpha_2 f_2(i)$$

where $f_1(i)$ is a polynomial of degree 1 in i and $f_2(i)$ is a polynomial of degree 2 in i .

Lag distribution specifications are enclosed in parentheses and follow the name of the regressor variable. The general form of the lag distribution specification is

regressor-name (length, degree, minimum-degree, end-constraint)

where

<i>length</i>	is the length of the lag distribution—that is, the number of lags of the regressor to use.
<i>degree</i>	is the degree of the distribution polynomial.
<i>minimum-degree</i>	is an optional minimum degree for the distribution polynomial.
<i>end-constraint</i>	is an optional endpoint restriction specification, which can have the value FIRST, LAST, or BOTH.

If the *minimum-degree* option is specified, the PDLREG procedure estimates models for all degrees between *minimum-degree* and *degree*.

Introductory Example

The following statements generate simulated data for variables Y and X. Y depends on the first three lags of X, with coefficients .25, .5, and .25. Thus, the effect of changes of X on Y takes effect 25% after one period, 75% after two periods, and 100% after three periods.

```
data test;
  x11 = 0; x12 = 0; x13 = 0;
  do t = -3 to 100;
    x = ranuni(1234);
    y = 10 + .25 * x11 + .5 * x12 + .25 * x13
        + .1 * rannor(1234);
    if t > 0 then output;
    x13 = x12; x12 = x11; x11 = x;
  end;
run;
```

The following statements use the PDLREG procedure to regress Y on a distributed lag of X. The length of the lag distribution is 4, and the degree of the distribution polynomial is specified as 3.

```
proc pdlreg data=test;
  model y = x( 4, 3 );
run;
```

The PDLREG procedure first prints a table of statistics for the residuals of the model, as shown in Figure 21.1. See Chapter 8, “The AUTOREG Procedure,” for an explanation of these statistics.

Figure 21.1 Residual Statistics

The PDLREG Procedure			
Dependent Variable		y	
Ordinary Least Squares Estimates			
SSE	0.86604442	DFE	91
MSE	0.00952	Root MSE	0.09755
SBC	-156.72612	AIC	-169.54786
MAE	0.07761107	AICC	-168.88119
MAPE	0.73971576	HQC	-164.3651
Durbin-Watson	1.9920	Regress R-Square	0.7711
		Total R-Square	0.7711

The PDLREG procedure next prints a table of parameter estimates, standard errors, and t tests, as shown in Figure 21.2.

Figure 21.2 Parameter Estimates

Parameter Estimates					
Variable	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	10.0030	0.0431	231.87	<.0001
x**0	1	0.4406	0.0378	11.66	<.0001
x**1	1	0.0113	0.0336	0.34	0.7377
x**2	1	-0.4108	0.0322	-12.75	<.0001
x**3	1	0.0331	0.0392	0.84	0.4007

The table in Figure 21.2 shows the model intercept and the estimated parameters of the lag distribution polynomial. The parameter labeled X**0 is the constant term, α_0 , of the distribution polynomial. X**1 is the linear coefficient, α_1 ; X**2 is the quadratic coefficient, α_2 ; and X**3 is the cubic coefficient, α_3 .

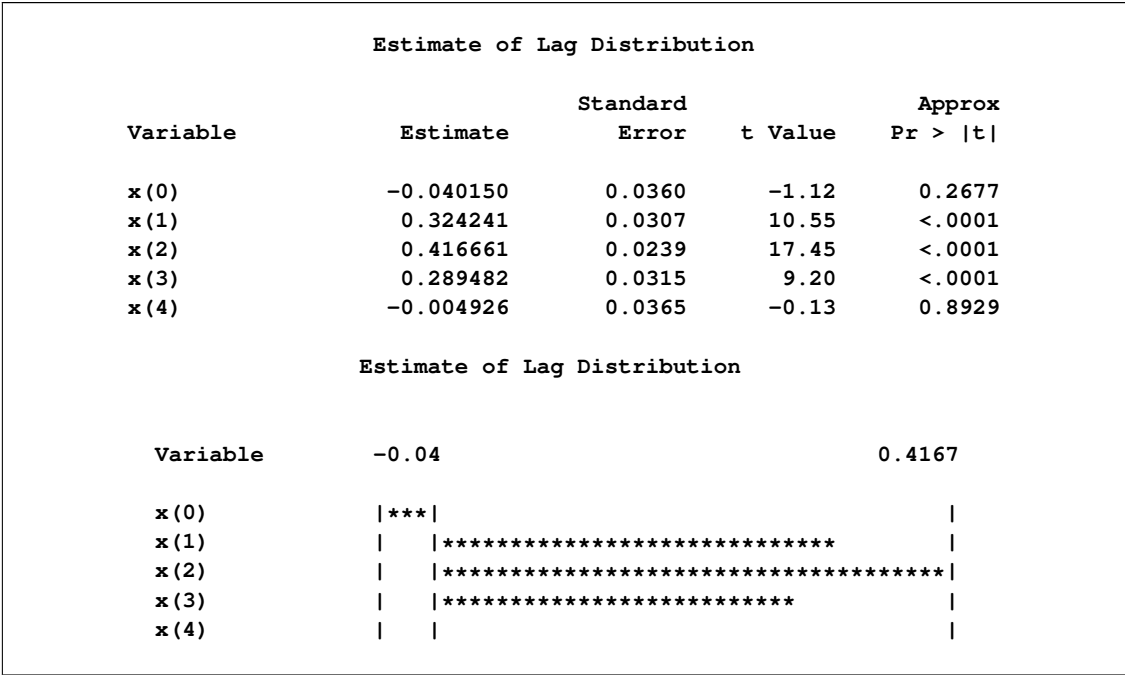

The parameter estimates for the distribution polynomial are not of interest in themselves. Since the PDLREG procedure does not print the orthogonal polynomial basis that it constructs to represent the distribution polynomial, these coefficient values cannot be interpreted.

However, because these estimates are for an orthogonal basis, you can use these results to test the degree of the polynomial. For example, this table shows that the X**3 estimate is not significant; the p -value

for its *t* ratio is 0.4007, while the X**2 estimate is highly significant (*p* < .0001). This indicates that a second-degree polynomial might be more appropriate for this data set.

The PDLREG procedure next prints the lag distribution coefficients and a graphical display of these coefficients, as shown in Figure 21.3.

Figure 21.3 Coefficients and Graph of Estimated Lag Distribution

The lag distribution coefficients are the coefficients of the lagged values of X in the regression model. These coefficients lie on the polynomial curve defined by the parameters shown in Figure 21.2. Note that the estimated values for X(1), X(2), and X(3) are highly significant, while X(0) and X(4) are not significantly different from 0. These estimates are reasonably close to the true values used to generate the simulated data.

The graphical display of the lag distribution coefficients plots the estimated lag distribution polynomial reported in Figure 21.2. The roughly quadratic shape of this plot is another indication that a third-degree distribution curve is not needed for this data set.

Syntax: PDLREG Procedure

The following statements can be used with the PDLREG procedure:

```
PROC PDLREG option ;
  BY variables ;
  MODEL dependents = effects / options ;
  OUTPUT OUT= SAS-data-set keyword = variables ;
  RESTRICT restrictions ;
```

Functional Summary

The statements and options used with the PDLREG procedure are summarized in the following table.

Table 21.1 PDLREG Functional Summary

Description	Statement	Option

output upper confidence limit for the structural predicted values	OUTPUT	UCLM=

PROC PDLREG Statement

PROC PDLREG *option* ;

The PROC PDLREG statement has the following option:

DATA= *SAS-data-set*

specifies the name of the SAS data set containing the input data. If you do not specify the DATA= option, the most recently created SAS data set is used.

In addition, you can place any of the following MODEL statement options in the PROC PDLREG statement, which is equivalent to specifying the option for every MODEL statement: ALL, COEF, CONVERGE=, CORRB, COVB, DW=, DWPROB, GINV, ITPRINT, MAXITER=, METHOD=, NOINT, NOPRINT, and PARTIAL.

BY Statement

BY *variables* ;

A BY statement can be used with PROC PDLREG to obtain separate analyses on observations in groups defined by the BY variables.

MODEL Statement

MODEL *dependent = effects / options* ;

The MODEL statement specifies the regression model. The keyword MODEL is followed by the dependent variable name, an equal sign, and a list of independent effects. Only one MODEL statement is allowed.

Every variable in the model must be a numeric variable in the input data set. Specify an independent effect with a variable name optionally followed by a polynomial lag distribution specification.

Specifying Independent Effects

The general form of an effect is

variable (*length*, *degree*, *minimum-degree*, *constraint*)

The term in parentheses following the variable name specifies a polynomial distributed lag (PDL) for the variable. The PDL specification is as follows:

<i>length</i>	specifies the number of lags of the variable to include in the lag distribution.
<i>degree</i>	specifies the maximum degree of the distribution polynomial. If not specified, the degree defaults to the lag length.
<i>minimum-degree</i>	specifies the minimum degree of the polynomial. By default <i>minimum-degree</i> is the same as <i>degree</i> .
<i>constraint</i>	specifies endpoint restrictions on the polynomial. The value of <i>constraint</i> can be FIRST, LAST, or BOTH. If a value is not specified, there are no endpoint restrictions.

If you do not specify the *degree* or *minimum-degree* parameter, but you do specify endpoint restrictions, you must use commas to show which parameter, *degree* or *minimum-degree*, is left out.

MODEL Statement Options

The following options can appear in the MODEL statement after a slash (/).

ALL

prints all the matrices computed during the analysis of the model.

COEF

prints the transformation coefficients for the first p observations. These coefficients are formed from a scalar multiplied by the inverse of the Cholesky root of the Toeplitz matrix of autocovariances.

CORRB

prints the matrix of estimated correlations between the parameter estimates.

COVB

prints the matrix of estimated covariances between the parameter estimates.

DW= j

prints the generalized Durbin-Watson statistics up to the order of j . The default is DW=1. When you specify the LAGDEP or LAGDEP=*name* option, the Durbin-Watson statistic is not printed unless you specify the DW= option.

DWPROB

prints the marginal probability of the Durbin-Watson statistic.

CONVERGE= *value*

sets the convergence criterion. If the maximum absolute value of the change in the autoregressive parameter estimates between iterations is less than this amount, then convergence is assumed. The default is CONVERGE=.001.

GINV

prints the inverse of the Toeplitz matrix of autocovariances for the Yule-Walker solution.

I

prints $(X'X)^{-1}$, the inverse of the crossproducts matrix for the model; or, if restrictions are specified, it prints $(X'X)^{-1}$ adjusted for the restrictions.

ITPRINT

prints information on each iteration.

LAGDEP**LAGDV**

prints the t statistic for testing residual autocorrelation when regressors contain lagged dependent variables.

LAGDEP= *name*

LAGDV= *name*

prints the Durbin h statistic for testing the presence of first-order autocorrelation when regressors contain the lagged dependent variable whose name is specified as **LAGDEP=***name*. When the h statistic cannot be computed, the asymptotically equivalent t statistic is given.

MAXITER= *number*

sets the maximum number of iterations allowed. The default is **MAXITER=50**.

METHOD= *value*

specifies the type of estimates for the autoregressive component. The values of the **METHOD=** option are as follows:

METHOD=ML	specifies the maximum likelihood method.
METHOD=ULS	specifies unconditional least squares.
METHOD=YW	specifies the Yule-Walker method.
METHOD=ITYW	specifies iterative Yule-Walker estimates.

The default is **METHOD=ML** if you specified the **LAGDEP** or **LAGDEP=** option; otherwise, **METHOD=YW** is the default.

NLAG= *m*

NLAG= (*number-list*)

specifies the order of the autoregressive process or the subset of autoregressive lags to be fit. If you do not specify the **NLAG=** option, PROC PDLREG does not fit an autoregressive model.

NOINT

suppresses the intercept parameter from the model.

NOPRINT

suppresses the printed output.

PARTIAL

prints partial autocorrelations if the NLAG= option is specified.

STB

prints standardized parameter estimates. Sometimes known as a standard partial regression coefficient, a *standardized parameter estimate* is a parameter estimate multiplied by the standard deviation of the associated regressor and divided by the standard deviation of the regressed variable.

XPX

prints the crossproducts matrix, $\mathbf{X}'\mathbf{X}$, used for the model. \mathbf{X} refers to the transformed matrix of regressors for the regression.

OUTPUT Statement

OUTPUT *OUT= SAS-data-set keyword= option ... ;*

The OUTPUT statement creates an output SAS data set with variables as specified by the following keyword options. See the section “Predicted Values” in Chapter 8, “[The AUTOREG Procedure](#),” for a description of the associated computations for these options.

ALPHACLI= *number*

sets the confidence limit size for the estimates of future values of the current realization of the response time series to *number*, where *number* is less than one and greater than zero. The resulting confidence interval has $1-\textit{number}$ confidence. The default value for *number* is 0.05, corresponding to a 95% confidence interval.

ALPHACLM= *number*

sets the confidence limit size for the estimates of the structural or regression part of the model to *number*, where *number* is less than one and greater than zero. The resulting confidence interval has $1-\textit{number}$ confidence. The default value for *number* is 0.05, corresponding to a 95% confidence interval.

OUT= *SAS-data-set*

names the output data.

The following specifications are of the form *KEYWORD=names*, where *KEYWORD=* specifies the statistic to include in the output data set and *names* gives names to the variables that contain the statistics.

CONSTANT= *variable*

writes the transformed intercept to the output data set.

LCL= *name*

requests that the lower confidence limit for the predicted value (specified in the PREDICTED= option) be added to the output data set under the name given.

LCLM= *name*

requests that the lower confidence limit for the structural predicted value (specified in the PREDICTEDM= option) be added to the output data set under the name given.

PREDICTED= *name*

P= *name*

stores the predicted values in the output data set under the name given.

PREDICTEDM= *name*

PM= *name*

stores the structural predicted values in the output data set under the name given. These values are formed from only the structural part of the model.

RESIDUAL= *name*

R= *name*

stores the residuals from the predicted values based on both the structural and time series parts of the model in the output data set under the name given.

RESIDUALM= *name*

RM= *name*

requests that the residuals from the structural prediction be given.

TRANSFORM= *variables*

requests that the specified variables from the input data set be transformed by the autoregressive model and put in the output data set. If you need to reproduce the data suitable for reestimation, you must also transform an intercept variable. To do this, transform a variable that only takes the value 1 or use the **CONSTANT=** option.

UCL= *name*

stores the upper confidence limit for the predicted value (specified in the **PREDICTED=** option) in the output data set under the name given.

UCLM= *name*

stores the upper confidence limit for the structural predicted value (specified in the **PREDICTEDM=** option) in the output data set under the name given.

For example, the SAS statements

```
proc pdlreg data=a;
  model y=x1 x2;
  output out=b p=yhat r=resid;
run;
```

create an output data set named B. In addition to the input data set variables, the data set B contains the variable YHAT, whose values are predicted values of the dependent variable Y, and RESID, whose values are the residual values of Y.

RESTRICT Statement

RESTRICT *equation* , . . . , *equation* ;

The **RESTRICT** statement places restrictions on the parameter estimates for covariates in the preceding **MODEL** statement. A parameter produced by a distributed lag cannot be restricted with the **RESTRICT** statement.

Each restriction is written as a linear equation. If you specify more than one restriction in a RESTRICT statement, the restrictions are separated by commas.

You can refer to parameters by the name of the corresponding regressor variable. Each name used in the equation must be a regressor in the preceding MODEL statement. Use the keyword INTERCEPT to refer to the intercept parameter in the model.

RESTRICT statements can be given labels. You can use labels to distinguish results for different restrictions in the printed output. Labels are specified as follows:

label : **RESTRICT** ...

The following is an example of the use of the RESTRICT statement, in which the coefficients of the regressors X1 and X2 are required to sum to 1:

```
proc pdlreg data=a;
  model y = x1 x2;
  restrict x1 + x2 = 1;
run;
```

Parameter names can be multiplied by constants. When no equal sign appears, the linear combination is set equal to 0. Note that the parameters associated with the variables are restricted, not the variables themselves. Here are some examples of valid RESTRICT statements:

```
restrict x1 + x2 = 1;
restrict x1 + x2 - 1;
restrict 2 * x1 = x2 + x3 , intercept + x4 = 0;
restrict x1 = x2 = x3 = 1;
restrict 2 * x1 - x2;
```

Restricted parameter estimates are computed by introducing a Lagrangian parameter λ for each restriction (Pringle and Rayner 1971). The estimates of these Lagrangian parameters are printed in the parameter estimates table. If a restriction cannot be applied, its parameter value and degrees of freedom are listed as 0.

The Lagrangian parameter, λ , measures the sensitivity of the SSE to the restriction. If the restriction is changed by a small amount ϵ , the SSE is changed by $2\lambda\epsilon$.

The t ratio tests the significance of the restrictions. If λ is zero, the restricted estimates are the same as the unrestricted ones.

You can specify any number of restrictions in a RESTRICT statement, and you can use any number of RESTRICT statements. The estimates are computed subject to all restrictions specified. However, restrictions should be consistent and not redundant.

Details: PDLREG Procedure

Missing Values

The PDLREG procedure skips any observations at the beginning of the data set that have missing values. The procedure uses all observations with nonmissing values for all the independent and dependent variables such that the lag distribution has sufficient nonmissing lagged independent variables.

Polynomial Distributed Lag Estimation

The simple finite distributed lag model is expressed in the form

$$y_t = \alpha + \sum_{i=0}^p \beta_i x_{t-i} + \epsilon_t$$

When the lag length (p) is long, severe multicollinearity can occur. Use the Almon or *polynomial distributed lag* model to avoid this problem, since the relatively low-degree d ($\leq p$) polynomials can capture the true lag distribution. The lag coefficient can be written in the Almon polynomial lag

$$\beta_i = \alpha_0^* + \sum_{j=1}^d \alpha_j^* i^j$$

Emerson (1968) proposed an efficient method of constructing orthogonal polynomials from the preceding polynomial equation as

$$\beta_i = \alpha_0 + \sum_{j=1}^d \alpha_j f_j(i)$$

where $f_j(i)$ is a polynomial of degree j in the lag length i . The polynomials $f_j(i)$ are chosen so that they are orthogonal:

$$\sum_{i=1}^n w_i f_j(i) f_k(i) = \begin{cases} 1 & \text{if } j = k \\ 0 & \text{if } j \neq k \end{cases}$$

where w_i is the weighting factor, and $n = p + 1$. PROC PDLREG uses the equal weights ($w_i = 1$) for all i . To construct the orthogonal polynomials, the following recursive relation is used:

$$f_j(i) = (A_j i + B_j) f_{j-1}(i) - C_j f_{j-2}(i) \quad j = 1, \dots, d$$

The constants A_j , B_j , and C_j are determined as follows:

$$\begin{aligned} A_j &= \left\{ \sum_{i=1}^n w_i i^2 f_{j-1}^2(i) - \left(\sum_{i=1}^n w_i i f_{j-1}(i) \right)^2 \right. \\ &\quad \left. - \left(\sum_{i=1}^n w_i i f_{j-1}(i) f_{j-2}(i) \right)^2 \right\}^{-1/2} \\ B_j &= -A_j \sum_{i=1}^n w_i i f_{j-1}^2(i) \\ C_j &= A_j \sum_{i=1}^n w_i i f_{j-1}(i) f_{j-2}(i) \end{aligned}$$

where $f_{-1}(i) = 0$ and $f_0(i) = 1/\sqrt{\sum_{i=1}^n w_i}$.

PROC PDLREG estimates the orthogonal polynomial coefficients, $\alpha_0, \dots, \alpha_d$, to compute the coefficient estimate of each independent variable (X) with distributed lags. For example, if an independent variable is specified as X(9,3), a third-degree polynomial is used to specify the distributed lag coefficients. The third-degree polynomial is fit as a constant term, a linear term, a quadratic term, and a cubic term. The four terms are constructed to be orthogonal. In the output produced by the PDLREG procedure for this case, parameter estimates with names X**0, X**1, X**2, and X**3 correspond to $\hat{\alpha}_0, \hat{\alpha}_1, \hat{\alpha}_2$, and $\hat{\alpha}_3$, respectively. A test using the t statistic and the approximate p -value (“Approx Pr > | t |”) associated with X**3 can determine whether a second-degree polynomial rather than a third-degree polynomial is appropriate. The estimates of the 10 lag coefficients associated with the specification X(9,3) are labeled X(0), X(1), X(2), X(3), X(4), X(5), X(6), X(7), X(8), and X(9).

Autoregressive Error Model Estimation

The PDLREG procedure uses the same autoregressive error model estimation methods as the AUTOREG procedure. These two procedures share the same computational resources for computing estimates. See Chapter 8, “[The AUTOREG Procedure](#),” for details about estimation methods for autoregressive error models.

OUT= Data Set

The OUT= data set produced by the PDLREG procedure’s OUTPUT statement is similar in form to the OUT= data set produced by the AUTOREG procedure. See Chapter 8, “[The AUTOREG Procedure](#),” for details on the OUT= data set.

Printed Output

The PDLREG procedure prints the following items:

1. the name of the dependent variable
2. the ordinary least squares (OLS) estimates
3. the estimates of autocorrelations and of the autocovariance, and if line size permits, a graph of the autocorrelation at each lag. The autocorrelation for lag 0 is 1. These items are printed if you specify the NLAG= option.
4. the partial autocorrelations if the PARTIAL and NLAG= options are specified. The first partial autocorrelation is the autocorrelation for lag 1.
5. the preliminary mean square error, which results from solving the Yule-Walker equations if you specify the NLAG= option
6. the estimates of the autoregressive parameters, their standard errors, and the ratios of estimates to standard errors (t) if you specify the NLAG= option

7. the statistics of fit for the final model if you specify the NLAG= option. These include the error sum of squares (SSE), the degrees of freedom for error (DFE), the mean square error (MSE), the root mean square error (Root MSE), the mean absolute error (MAE), the mean absolute percentage error (MAPE), the Schwarz information criterion (SBC), the Akaike's information criterion (AIC), Akaike's information criterion corrected (AICC), the regression R^2 (Regress R-Square), the total R^2 (Total R-Square), and the Durbin-Watson statistic (Durbin-Watson). See Chapter 8, “[The AUTOREG Procedure](#),” for details of the regression R^2 and the total R^2 .
8. the parameter estimates for the structural model (B), a standard error estimate, the ratio of estimate to standard error (t), and an approximation to the significance probability for the parameter being 0 (“Approx Pr > | t |”)
9. a plot of the lag distribution (estimate of lag distribution)
10. the covariance matrix of the parameter estimates if the COVB option is specified

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User's Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

PROC PDLREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 21.2 ODS Tables Produced in PROC PDLREG

ODS Table Name	Description	Option
ODS Tables Created by the MODEL Statement		
ARParameterEstimates	Estimates of autoregressive parameters	NLAG=
CholeskyFactor	Cholesky root of gamma	NLAG= and ALL
Coefficients	Coefficients for first NLAG observations	NLAG= and (COEF or ALL)
ConvergenceStatus	Convergence status table	default
CorrB	Correlation of parameter estimates	CORRB
CorrGraph	Estimates of autocorrelations	NLAG=
CovB	Covariance of parameter estimates	COVB
DependenceEquations	Linear dependence equation	
Dependent	Dependent variable	default
DWTest	Durbin-Watson statistics	DW=

Table 21.2 *continued*

ODS Table Name	Description	Option
DWTestProb	Durbin-Watson statistics and p -values	DW=
ExpAutocorr	Expected autocorrelations	DWPROB {NLAG= and (COEF or ALL)} or {NLAG=($l_1 \dots l_m$) where $l_m > m$ }
FitSummary	Summary of regression	default
GammaInverse	Gamma inverse	NLAG= and (GINV or ALL)
IterHistory	Iteration history	ITPRINT
LagDist	Lag distribution	default
ParameterEstimates	Parameter estimates	default
ParameterEstimatesGivenAR	Parameter estimates assuming AR parameters are given	NLAG=
PartialAutoCorr	Partial autocorrelation	PARTIAL
PreMSE	Preliminary MSE	NLAG=

Restrict	Restriction table	default

Examples: PDLREG Procedure

Example 21.1: Industrial Conference Board Data

In this example, a second-degree Almon polynomial lag model is fit to a model with a five-period lag, and dummy variables are used for quarter effects. The PDL model is estimated using capital appropriations data series for the period 1952 to 1967. The estimation model is written

$$CE_t = a_0 + b_1 Q1_t + b_2 Q2_t + b_3 Q3_t + c_0 CA_t + c_1 CA_{t-1} + \dots + c_5 CA_{t-5}$$

where CE represents capital expenditures and CA represents capital appropriations.

Example 21.2: Money Demand Model

This example estimates the demand for money by using the following dynamic specification:

$$m_t = a_0 + b_0 m_{t-1} + \sum_{i=0}^5 c_i y_{t-i} + \sum_{i=0}^2 d_i r_{t-i} + \sum_{i=0}^3 f_i p_{t-i} + u_t$$

where

m_t = log of real money stock (M1)

y_t = log of real GNP

r_t = interest rate (commercial paper rate)

p_t = inflation rate

c_i, d_i , and f_i ($i > 0$) are coefficients for the lagged variables

The following DATA step reads the data and transforms the real money and real GNP variables using the natural logarithm. Refer to Balke and Gordon (1986) for a description of the data.

```
data a;
  input m1 gnp gdf r @@;
  m    = log( 100 * m1 / gdf );
  lagm = lag( m );
  y    = log( gnp );
  p    = log( gdf / lag( gdf ) );
  date = intnx( 'qtr', '1jan1968'd, _n_-1 );
  format date yyqc6.;
  label m      = 'Real Money Stock (M1)'
        lagm   = 'Lagged Real Money Stock'
        y      = 'Real GNP'
        r      = 'Commercial Paper Rate'
        p      = 'Inflation Rate';
datalines;
187.15 1036.22    81.18    5.58

Overview: QLIM Procedure

The QLIM (qualitative and limited dependent variable model) procedure analyzes univariate and multivariate limited dependent variable models in which dependent variables take discrete values or in which dependent variables are observed only in a limited range of values. These models include logit, probit, tobit, selection, and multivariate models. The multivariate model can contain discrete choice and limited endogenous variables in addition to continuous endogenous variables.

The QLIM procedure supports the following models:

- linear regression model with heteroscedasticity
- Box-Cox regression with heteroscedasticity
- probit with heteroscedasticity
- logit with heteroscedasticity
- tobit (censored and truncated) with heteroscedasticity
- bivariate probit
- bivariate tobit
- sample selection and switching regression models
- multivariate limited dependent variables
- stochastic frontier production and cost models

In the linear regression models with heteroscedasticity, the assumption that error variance is constant across observations is relaxed. The QLIM procedure allows for a number of different linear and nonlinear variance specifications. Another way to make the linear model more appropriate to fit the data and reduce skewness is to apply Box-Cox transformation. If the nature of the data is such that the dependent variable is discrete

and it takes only two possible values, ordinary least squares (OLS) estimates are inconsistent. The QLIM procedure offers probit and logit models to overcome these estimation problems. Assumptions about the error variance can also be relaxed in order to estimate probit or logit with heteroscedasticity.

The QLIM procedure also offers a class of models in which the dependent variable is censored or truncated from below or above or both. When a continuous dependent variable is observed only within a certain range and values outside this range are not available, the QLIM procedure offers a class of models that adjust for truncation. In some cases, the dependent variable is continuous only in a certain range and all values outside this range are reported as being on its boundary. For example, if it is not possible to observe negative values, the value of the dependent variable is reported as equal to 0. Because the data are censored, OLS results are inconsistent, and it cannot be guaranteed that the predicted values from the model fall in the appropriate region.

Most of the models in the QLIM procedure can be extended to accommodate bivariate and multivariate scenarios. The assumption that one variable is observed only if another variable takes on certain values lead to the introduction of sample selection models. If the dependent variables are mutually exclusive and observed only for certain ranges of the selection variable, the sample selection can be extended to include cases of switching regression. Stochastic frontier production and cost models allow for random shocks of the production or cost. They include a systematic positive component in the error term that adjusts for technological or cost inefficiency.

The QLIM procedure can use the maximum likelihood method for both univariate and multivariate models or the Bayesian method for univariate models. Initial starting values for the nonlinear optimizations are typically calculated by OLS.

Getting Started: QLIM Procedure

The QLIM procedure is similar in use to the other regression or simultaneous equations model procedures in the SAS System. For example, the following statements are used to estimate a binary choice model by using the probit probability function:

```
proc qlim data=a;
  model y = x1;
  endogenous y ~ discrete;
run;
```

The response variable, *y*, is numeric and has discrete values. PROC QLIM enables the user to specify the type of endogenous variables in the ENDOGENOUS statement. The binary probit model can be also specified as follows:

```
model y = x1 / discrete;
```

When multiple endogenous variables are specified in the QLIM procedure, these equations are estimated as a system. Multiple endogenous variables can be specified with one MODEL statement in the QLIM procedure when these models have the same exogenous variables:

```
model y1 y2 = x1 x2 / discrete;
```

The preceding specification is equivalent to the following statements:

```
proc qlim data=a;
  model y1 = x1 x2;
  model y2 = x1 x2;
  endogenous y1 y2 ~ discrete;
run;
```

Some equations in multivariate models can be continuous while other equations can be discrete. A bivariate model with a discrete and a continuous equation is specified as follows:

```
proc qlim data=a;
  model y1 = x1 x2;
  model y2 = x3 x4;
  endogenous y1 ~ discrete;
run;
```

The standard tobit model is estimated by specifying the endogenous variable to be truncated or censored. The limits of the dependent variable can be specified with the CENSORED or TRUNCATED option in the ENDOGENOUS or MODEL statement when the data are limited by specific values or variables. For example, the two-limit censored model requires two variables that contain the lower (bottom) and upper (top) bound:

```
proc qlim data=a;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=bottom ub=top);
run;
```

The bounds can be numbers if they are fixed for all observations in the data set. For example, the standard tobit model can be specified as follows:

```
proc qlim data=a;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=0);
run;
```

Introductory Example: Binary Probit and Logit Models

The following example illustrates the use of PROC QLIM. The data were originally published by Mroz (1987) and downloaded from Wooldridge (2002). This data set is based on a sample of 753 married white women. The dependent variable is a discrete variable of labor force participation (`inlf`). Explanatory variables are the number of children ages 5 or younger (`kidslt6`), the number of children ages 6 to 18 (`kidsge6`), the woman's age (`age`), the woman's years of schooling (`educ`), wife's labor experience (`exper`), square of experience (`expersq`), and the family income excluding the wife's wage (`nwifeinc`). The program (with data values omitted) is as follows:

```

/*-- Binary Probit --*/
proc qlim data=mroz plots=predicted;
  model inlf = nwifeinc educ exper expersq
            age kidslt6 kidsge6 / discrete;
run;

```

Results of this analysis are shown in the following four figures. In the first table, shown in [Figure 22.1](#), PROC QLIM provides frequency information about each choice. In this example, 428 women participate in the labor force ($\text{inlf} = 1$).

Figure 22.1 Choice Frequency Summary

Binary Data		
The QLIM Procedure		
Discrete Response Profile of inlf		
Index	Value	Total Frequency
1	0	325
2	1	428

The second table is the estimation summary table shown in [Figure 22.2](#). Included are the number of dependent variables, names of dependent variables, the number of observations, the log-likelihood function value, the maximum absolute gradient, the number of iterations, AIC, and Schwarz criterion.

Figure 22.2 Fit Summary Table of Binary Probit

Model Fit Summary	
Number of Endogenous Variables	1
Endogenous Variable	inlf
Number of Observations	753
Log Likelihood	-401.30219
Maximum Absolute Gradient	0.0000669
Number of Iterations	15
Optimization Method	Quasi-Newton
AIC	818.60439
Schwarz Criterion	855.59691

Goodness-of-fit measures are displayed in [Figure 22.3](#). All measures except McKelvey-Zavoina's definition are based on the log-likelihood function value. The likelihood ratio test statistic has chi-square distribution conditional on the null hypothesis that all slope coefficients are zero. In this example, the likelihood ratio statistic is used to test the hypothesis that $\text{kidslt6} = \text{kidge6} = \text{age} = \text{educ} = \text{exper} = \text{expersq} = \text{nwifeinc} = 0$.

Figure 22.3 Goodness of Fit

Goodness-of-Fit Measures		
Measure	Value	Formula
Likelihood Ratio (R)	227.14	$2 * (\text{LogL} - \text{LogL0})$
Upper Bound of R (U)	1029.7	$- 2 * \text{LogL0}$
Aldrich-Nelson	0.2317	$R / (R+N)$
Cragg-Uhler 1	0.2604	$1 - \exp(-R/N)$
Cragg-Uhler 2	0.3494	$(1 - \exp(-R/N)) / (1 - \exp(-U/N))$
Estrella	0.2888	$1 - (1 - R/U)^{(U/N)}$
Adjusted Estrella	0.2693	$1 - ((\text{LogL} - K) / \text{LogL0})^{(-2/N * \text{LogL0})}$
McFadden's LRI	0.2206	R / U
Veall-Zimmermann	0.4012	$(R * (U+N)) / (U * (R+N))$
McKelvey-Zavoina	0.4025	

N = # of observations, K = # of regressors

The parameter estimates and standard errors are shown in [Figure 22.4](#).

Figure 22.4 Parameter Estimates of Binary Probit

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.270077	0.508590	0.53	0.5954
nwifeinc	1	-0.012024	0.004840	-2.48	0.0130
educ	1	0.130905	0.025255	5.18	<.0001
exper	1	0.123348	0.018720	6.59	<.0001
expersq	1	-0.001887	0.000600	-3.14	0.0017
age	1	-0.052853	0.008477	-6.24	<.0001
kidslt6	1	-0.868329	0.118519	-7.33	<.0001
kidsge6	1	0.036005	0.043477	0.83	0.4076

Finally, the QLIM procedure profiles the predicted outcome with respect to the regressors. For example, [Output 22.5](#) shows the predicted values profiled with respect to nwifeinc, educ, exper, expersq, age, and kidslt6.

Figure 22.5 Predictions by Regressors: nwifeinc, educ, exper, expersq, age, and kidslt6

When the error term has a logistic distribution, the binary logit model is estimated. To specify a logistic distribution, add `D=LOGIT` option as follows:

```
/*-- Binary Logit --*/
proc qlim data=mroz;
  model inlf = nwifeinc educ exper expersq
              age kidslt6 kidsge6 / discrete(d=logit);
run;
```

The estimated parameters are shown in [Figure 22.6](#).

Figure 22.6 Parameter Estimates of Binary Logit

Binary Data					
The QLIM Procedure					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.425452	0.860365	0.49	0.6210
nwifeinc	1	-0.021345	0.008421	-2.53	0.0113
educ	1	0.221170	0.043441	5.09	<.0001
exper	1	0.205870	0.032070	6.42	<.0001
expersq	1	-0.003154	0.001017	-3.10	0.0019
age	1	-0.088024	0.014572	-6.04	<.0001
kidslt6	1	-1.443354	0.203575	-7.09	<.0001
kidsge6	1	0.060112	0.074791	0.80	0.4215

The heteroscedastic logit model can be estimated using the HETERO statement. If the variance of the logit model is a function of the family income level excluding wife's income (nwifeinc), the variance can be specified as

$$\text{Var}(\epsilon_i) = \sigma^2 \exp(\gamma * \text{nwifeinc}_i)$$

where σ^2 is normalized to 1 because the dependent variable is discrete. The following SAS statements estimate the heteroscedastic logit model:

```

/*-- Binary Logit with Heteroscedasticity --*/
proc qlim data=mroz;
  model inlf = nwifeinc educ exper expersq
              age kidslt6 kidsge6 / discrete(d=logit);
  hetero inlf ~ nwifeinc / noconst;
run;

```

The parameter estimate, γ , of the heteroscedasticity variable is listed as _H.nwifeinc; see [Figure 22.7](#).

Figure 22.7 Parameter Estimates of Binary Logit with Heteroscedasticity

Binary Data

_H.nwifeinc	1	0.013280	0.013606	0.98	0.3291

Syntax: QLIM Procedure

The QLIM procedure is controlled by the following statements:

```

PROC QLIM options ;
BOUNDS bound1 < , bound2 ... > ;
BY variables ;
CLASS variables ;
FREQ variable ;
ENDOGENOUS variables ~ options ;
HETERO dependent variables ~ exogenous variables / options ;
INIT initvalue1 < , initvalue2 ... > ;
MODEL dependent variables = regressors / options ;
NLOPTIONS options ;
OUTPUT options ;
RESTRICT restriction1 < , restriction2 ... > ;
TEST options ;
WEIGHT variable ;
BAYES <options> ;
PRIOR variables ~ distributions ;

```

At least one MODEL statement is required. If more than one MODEL statement is used, the QLIM procedure estimates a system of models. If a FREQ or WEIGHT statement is specified more than once, the variable specified in the first instance is used. Main effects and higher-order terms can be specified in the MODEL statement, as in the GLM procedure and PROBIT procedure in SAS/STAT. If a CLASS statement is used, it must precede the MODEL statement.

Functional Summary

Table 22.1 summarizes the statements and options used with the QLIM procedure.

Table 22.1 PROC QLIM Functional Summary

Description	Statement	Option
Data Set Options		
Specifies the input data set	QLIM	DATA=
Writes parameter estimates to an output data set	QLIM	OUTEST=
Writes predictions to an output data set	OUTPUT	OUT=
Declaring the Role of Variables		
Specifies BY-group processing	BY	
Specifies classification variables	CLASS	
Specifies a frequency variable	FREQ	
Specifies a weight variable	WEIGHT	NONNORMALIZE
Printing Control Options		
Requests all printing options	QLIM	PRINTALL
Prints correlation matrix of the estimates	QLIM	CORRB
Prints covariance matrix of the estimates	QLIM	COVB
Prints a summary iteration listing	QLIM	ITPRINT
Suppresses the normal printed output	QLIM	NOPRINT
Plotting Options		
Displays plots	QLIM	PLOTS=
Options to Control the Optimization Process		
Specifies the optimization method	QLIM	METHOD=
Specifies the optimization options	NLOPTIONS	see Chapter 6, “Nonlinear Optimization Methods,”
Sets initial values for parameters	INIT	
Specifies upper and lower bounds for the parameter estimates	BOUNDS	
Specifies linear restrictions on the parameter estimates	RESTRICT	
Model Estimation Options		
Specifies options specific to Box-Cox transformation	MODEL	BOXCOX()
Suppresses the intercept parameter	MODEL	NOINT
Specifies variable selection	MODEL	SELECTVAR=()
Specifies a seed for pseudo-random number generation	QLIM	SEED=
Specifies the number of draws for Monte Carlo integration	QLIM	NDRAW=

Table 22.1 *continued*

Description	Statement	Option
Specifies the method to calculate parameter covariance	QLIM	COVEST=
Requests estimation by Heckman's two-step method	QLIM	HECKIT
Bayesian MCMC Options		
Specifies the initial values of the MCMC	INIT	
Specifies the maximum number of tuning phases	BAYES	MAXTUNE=
Specifies the minimum number of tuning phases	BAYES	MINTUNE=
Specifies the number of burn-in iterations	BAYES	NBI=
Specifies the number of iterations during the sampling phase	BAYES	NMC=
Specifies the number of threads to use during the sampling phase	BAYES	NTRDS=
Specifies the number of iterations during the tuning phase	BAYES	NTU=
Controls options for constructing the initial proposal covariance matrix	BAYES	PROPCOV
Specifies the sampling scheme	BAYES	SAMPLING=
Specifies the random number generator seed	BAYES	SEED=
Prints the time required for the MCMC sampling	BAYES	SIMTIME
Controls the thinning of the Markov chain	BAYES	THIN=
Bayesian Summary Statistics and Convergence Diagnostics		
Displays convergence diagnostics	BAYES	DIAGNOSTICS=
Displays summary statistics of the posterior samples	BAYES	STATISTICS=
Bayesian Prior and Posterior Samples		
Specifies a SAS data set for the posterior samples	BAYES	OUTPOST=
Specifies a SAS data set for the prior samples	BAYES	OUTPRIOR=
Bayesian Analysis		
Specifies normal prior distribution	PRIOR	NORMAL(MEAN=, VAR=)
Specifies gamma prior distribution	PRIOR	GAMMA(SHAPE=, SCALE=)
Specifies inverse gamma prior distribution	PRIOR	IGAMMA(SHAPE=, SCALE=)
Specifies uniform prior distribution	PRIOR	UNIFORM(MIN=, MAX=)
Specifies beta prior distribution	PRIOR	BETA(SHAPE1=, SHAPE2=, MIN=, MAX=)
Specifies <i>t</i> prior distribution	PRIOR	T(LOCATION=, DF=)
Endogenous Variable Options		
Specifies discrete variable	ENDOGENOUS	DISCRETE()
Specifies censored variable	ENDOGENOUS	CENSORED()
Specifies truncated variable	ENDOGENOUS	TRUNCATED()

Table 22.1 *continued*

Description	Statement	Option
Specifies variable selection condition	ENDOGENOUS	SELECT()
Specifies stochastic frontier variable	ENDOGENOUS	FRONTIER()
Heteroscedasticity Model Options		
Specifies the function for heteroscedasticity models	HETERO	LINK=
Squares the function for heteroscedasticity models	HETERO	SQUARE
Specifies no constant for heteroscedasticity models	HETERO	NOCONST
Output Control Options		
Outputs predicted values	OUTPUT	PREDICTED
Outputs structured part	OUTPUT	XBETA
Outputs residuals	OUTPUT	RESIDUAL
Outputs error standard deviation	OUTPUT	ERRSTD
Outputs marginal effects	OUTPUT	MARGINAL
Outputs probability for the current response	OUTPUT	PROB
Outputs probability for all responses	OUTPUT	PROBALL
Outputs expected value	OUTPUT	EXPECTED
Outputs conditional expected value	OUTPUT	CONDITIONAL
Outputs inverse Mills ratio	OUTPUT	MILLS
Outputs technical efficiency measures	OUTPUT	TE1
	OUTPUT	TE2
Includes covariances in the OUTEST= data set	QLIM	COVOUT
Includes correlations in the OUTEST= data set	QLIM	CORROUT
Test Request Options		
Requests Wald, Lagrange multiplier, and likelihood ratio tests	TEST	ALL
Requests the WALD test	TEST	WALD
Requests the Lagrange multiplier test	TEST	LM
Requests the likelihood ratio test	TEST	LR

PROC QLIM Statement

PROC QLIM *options* ;

The following options can be used in the PROC QLIM statement.

Data Set Options

DATA=*SAS-data-set*

specifies the input SAS data set. If the DATA= option is not specified, PROC QLIM uses the most recently created SAS data set.

Output Data Set Options

OUTEST=*SAS-data-set*

writes the parameter estimates to an output data set.

COVOUT

writes the covariance matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

CORROUT

writes the correlation matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

Printing Options

NOPRINT

suppresses the normal printed output but does not suppress error listings. If NOPRINT option is set, then any other print option is turned off.

PRINTALL

turns on all the printing-control options. The options set by PRINTALL are COVB and CORRB.

CORRB

prints the correlation matrix of the parameter estimates.

COVB

prints the covariance matrix of the parameter estimates.

ITPRINT

prints the initial parameter estimates, convergence criteria, and all constraints of the optimization. At each iteration, objective function value, step size, maximum gradient, and slope of search direction are printed as well.

Model Estimation Options

COVEST=*covariance-option*

specifies the method to calculate the covariance matrix of parameter estimates. The supported covariance types are as follows:

OP	specifies the covariance from the outer product matrix.
HESSIAN	specifies the covariance from the inverse Hessian matrix.
QML	specifies the covariance from the outer product and Hessian matrices (the quasi-maximum likelihood estimates).

The default is COVEST=HESSIAN.

NDRAW=*value*

specifies the number of draws for Monte Carlo integration.

SEED=*value*

specifies a seed for pseudo-random number generation in Monte Carlo integration.

HECKIT <(UNCORRECTED)> (Experimental)

requests that the selection model be estimated by Heckman's two-step estimation method. You must specify exactly two MODEL statements when you use the HECKIT option. One of the models must be a binary probit model; therefore, you must specify the DISCRETE option in the MODEL or in the ENDOGENOUS statement. You base the selection on the binary probit model for the second model; therefore, you must specify the SELECT option for this model. The selection model is assumed to be linear with a continuous dependent variable. You cannot specify the DISCRETE, CENSORED, TRUNCATED, or FRONTIER option for the selection model. By default, Heckman's two-step estimation model uses corrected standard errors. You can specify the UNCORRECTED suboption to request the conventional OLS standard errors.

Optimization Process Control Options

PROC QLIM uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. You can use any of the NLO options in the NLOPTIONS statement. For details, see Chapter 6, "Nonlinear Optimization Methods."

METHOD=*value*

specifies the optimization method. If this option is specified, it overwrites the TECH= option in NLOPTIONS statement. Valid values are as follows:

CONGRA	performs a conjugate-gradient optimization
DBLDOG	performs a version of double-dogleg optimization
NMSIMP	performs a Nelder-Mead simplex optimization
NEWRAP	performs a Newton-Raphson optimization combining a line-search algorithm with ridging
NRRIDG	performs a Newton-Raphson optimization with ridging
QUANew	performs a quasi-Newton optimization
TRUREG	performs a trust region optimization

The default method is METHOD=QUANew.

Plotting Options

PLOTS<(global-plot-options)> = *plot-request* | (*plot-requests*) (Experimental)

controls the display of plots. By default, the plots are displayed in panels unless the UNPACK *global-plot-option* is specified. When you specify only one *plot-request*, you can omit the parentheses around the *plot-request*.

Global Plot Options

You can specify the following *global-plot-options*:

ONLY

displays only the requested plot.

PRIOR

displays the prior predictive graph that is associated with the requested posterior predictive plot BAYESPRED. This option is available only for Bayesian analysis.

UNPACKPANEL**UNPACK**

specifies that all paneled plots be unpacked, meaning that each plot in a panel is displayed separately.

Plot Requests

You can specify the following *plot-requests*:

ALL

specifies all types of available plots.

AUTOCORR<(LAGS=*n*)>

displays the autocorrelation function plots for the parameters. This *plot-request* is available only for Bayesian analysis. The optional LAGS= suboption the number (up to lag *n*) of autocorrelations to be plotted in the AUTOCORR plot. If this suboption is not specified, autocorrelations are plotted up to lag 50.

BAYESDIAG

displays the TRACE, AUTOCORR, and DENSITY plots. This *plot-request* is available only for Bayesian analysis.

BAYESPRED

displays the predictive analysis. The predictive analysis takes into account the variability of the error term, whereas the PREDICTED *plot-request* does not. The BAYESPRED *plot-request* is available only for Bayesian analysis.

BAYESSUM

displays the posterior distribution, the prior distribution, and the maximum likelihood estimates. This *plot-request* is available only for Bayesian analysis.

CONDITIONAL

displays the conditional expected values for continuous endogenous variables. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

DENSITY<(FRINGE)>

displays the kernel density plots for the parameters. This *plot-request* is available only for Bayesian analysis. If you specify the FRINGE suboption, a fringe plot is created on the X axis of the kernel density plot. This *plot-request* is available only for Bayesian analysis.

ERRSTD

displays the error standard deviation versus observed regressors when you also specify a HETERO statement. This *plot-request* is not available for Bayesian analysis.

EXPECTED

displays the expected values for continuous endogenous variables. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

MARGINAL

displays the marginal effects. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

MILLS

displays the inverse Mills ratio. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

NONE

suppresses all diagnostic plots.

PREDICTED

displays the model predicted values. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

PROB

displays the predicted response probability. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

PROBALL

displays the predicted probabilities for each level of the response. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

PROFLIK

displays the profiled log likelihood. Each profiled graph is obtained by setting all the parameters to their maximum likelihood estimate except for the profiling parameter. The profiling parameter takes values on a predefined grid that is determined by the maximum likelihood estimate of the corresponding standard deviation.

RESIDUAL

displays the residuals versus observed regressors. This *plot-request* is not available for Bayesian analysis.

TE1

displays the technical efficiency for the stochastic frontier model as suggested by Battese and Coelli (1988). Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

TE2

displays the technical efficiency for the stochastic frontier model as suggested by Jondrow et al. (1982). Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This *plot-request* is not available for Bayesian analysis.

TRACE<(SMOOTH)>

displays the trace plots for the parameters. This *plot-request* is available only for Bayesian analysis. The SMOOTH suboption displays a fitted penalized B-spline curve for each TRACE plot.

XBETA

displays the structural part on the right-hand side of the model. Each contributing regressor is set equal to its mean, except for the parameter that is reported on the X axis. This is not available for Bayesian analysis.

BAYES Statement (*Experimental*)

BAYES < *options* > ;

The BAYES statement controls the Metropolis sampling scheme that is used to obtain samples from the posterior distribution of the underlying model and data.

DIAGNOSTICS=ALL | NONE | (*keyword-list*)

DIAG=ALL | NONE | (*keyword-list*)

controls which diagnostics are produced. All the following diagnostics are produced with DIAGNOSTICS=ALL. If you do not want any of these diagnostics, specify DIAGNOSTICS=NONE. If you want some but not all of the diagnostics, or if you want to change certain settings of these diagnostics, specify a subset of the following keywords. The default is DIAGNOSTICS=NONE.

AUTOCORR < (**LAGS=** *numeric-list*) >

computes the autocorrelations at lags that are specified in the *numeric-list*. Elements in the *numeric-list* are truncated to integers, and repeated values are removed. If the LAGS= option is not specified, autocorrelations of lags 1, 5, 10, and are computed.

ESS

computes Carlin's estimate of the effective sample size, the correlation time, and the efficiency of the chain for each parameter.

GEWEKE < (*geweke-options*) >

computes the Geweke spectral density diagnostics, which are essentially a two-sample *t* test between the first f_1 portion and the last f_2 portion of the chain. The default is $f_1 = 0.1$ and $f_2 = 0.5$, but you can choose other fractions by using the following *geweke-options*:

FRAC1=*value*

specifies the fraction f_1 for the first window.

FRAC2=*value*

specifies the fraction f_2 for the second window.

HEIDELBERGER < (*heidel-options*) >

computes the Heidelberg and Welch diagnostic for each variable, which consists of a stationarity test of the null hypothesis that the sample values form a stationary process. If the stationarity test is not rejected, a halfwidth test is then carried out. Optionally, you can specify one or more of the following *heidel-options*:

SALPHA=value

specifies the α level ($0 < \alpha < 1$) for the stationarity test.

HALPHA=value

specifies the α level ($0 < \alpha < 1$) for the halfwidth test.

EPS=value

specifies a positive number ϵ such that if the halfwidth is less than ϵ times the sample mean of the retained iterates, the halfwidth test is passed.

MCSE**MCERROR**

computes the Monte Carlo standard error for each parameter. The Monte Carlo standard error, which measures the simulation accuracy, is the standard error of the posterior mean estimate and is calculated as the posterior standard deviation divided by the square root of the effective sample size.

RAFTERY<(raftery-options)>

computes the Raftery and Lewis diagnostics, which evaluate the accuracy of the estimated quantile ($\hat{\theta}_Q$ for a given $Q \in (0, 1)$) of a chain. $\hat{\theta}_Q$ can achieve any degree of accuracy when the chain is allowed to run for a long time. The computation is stopped when the estimated probability $\hat{P}_Q = \Pr(\theta \leq \hat{\theta}_Q)$ reaches within $\pm R$ of the value Q with probability S ; that is, $\Pr(Q - R \leq \hat{P}_Q \leq Q + R) = S$. The following *raftery-options* enable you to specify Q , R , S , and a precision level ϵ for the test:

QUANTILE | Q=value

specifies the order (a value between 0 and 1) of the quantile of interest. The default is 0.025.

ACCURACY | R=value

specifies a small positive number as the margin of error for measuring the accuracy of estimation of the quantile. The default is 0.005.

PROBABILITY | S=value

specifies the probability of attaining the accuracy of the estimation of the quantile. The default is 0.95.

EPSILON | EPS=value

specifies the tolerance level (a small positive number) for the stationary test. The default is 0.001.

MINTUNE=number

specifies the minimum number of tuning phases. The default is 2.

MAXTUNE=number

specifies the maximum number of tuning phases. The default is 24.

NBI=number

specifies the number of burn-in iterations before the chains are saved. The default is 1,000.

NMC=number

specifies the number of iterations after the burn-in. The default is 1,000.

NTRDS=number**THREADS=number**

specifies the number of threads to be used. The number of threads cannot exceed the number of computer cores available. Each core samples the number of iterations that is specified by the NMC option. The default is 1.

NTU=number

specifies the number of samples for each tuning phase. The default is 500.

OUTPOST=SAS-data-set

names the SAS data set to contain the posterior samples. Alternatively, you can create the output data set by specifying an ODS OUTPUT statement as follows:

ODS OUTPUT POSTERIORSAMPLE = < SAS-data-set > ;

OUTPRIOR=SAS-data-set

names the SAS data set to contain the prior samples used to generate the prior predictive analysis when you request the prior predictive plots. Alternatively, you can create the output data set by specifying an ODS OUTPUT statement as follows:

ODS OUTPUT PRIORSAMPLE = < SAS-data-set > ;

PROPCOV=value

specifies the method used in constructing the initial covariance matrix for the Metropolis-Hastings algorithm. The QUANEW and NMSIMP methods find numerically approximated covariance matrices at the optimum of the posterior density function with respect to all continuous parameters. The tuning phase starts at the optimized values; in some problems, this can greatly increase convergence performance. If the approximated covariance matrix is not positive definite, then an identity matrix is used instead. You can specify the following values:

CONGRA

performs a conjugate-gradient optimization.

DBLDOG

performs a version of double-dogleg optimization.

NEWRAP

performs a Newton-Raphson optimization that combines a line-search algorithm with ridging.

NMSIMP

performs a Nelder-Mead simplex optimization.

NRRIDG

performs a Newton-Raphson optimization with ridging.

QUANEW

performs a quasi-Newton optimization.

TRUREG

performs a trust-region optimization.

SAMPLING=MULTIMETROPOLIS | UNIMETROPOLIS

specifies how to sample from the posterior distribution. **SAMPLING=MULTIMETROPOLIS** implements a Metropolis sampling scheme on a single block that contains all the parameters of the model. **SAMPLING=UNIMETROPOLIS** implements a Metropolis sampling scheme on multiple blocks, one for each parameter of the model. The default is **SAMPLING=MULTIMETROPOLIS**.

SEED=number

specifies an integer seed in the range 1 to $2^{31} - 1$ for the random number generator in the simulation. Specifying a seed enables you to reproduce identical Markov chains for the same specification. If you do not specify the **SEED=** option, or if you specify a nonpositive seed, a random seed is derived from the time of day.

SIMTIME

prints the time required for the MCMC sampling.

STATISTICS <(global-options)> = ALL | NONE | keyword | (keyword-list)**STATS <(global-options)> = ALL | NONE | keyword | (keyword-list)**

controls the number of posterior statistics produced. Specifying **STATISTICS=ALL** is equivalent to specifying **STATISTICS=(SUMMARY INTERVAL COV CORR)**. If you do not want any posterior statistics, specify **STATISTICS=NONE**. The default is **STATISTICS=(SUMMARY INTERVAL)**. You can specify the following *global-options*:

ALPHA=numeric-list

controls the probabilities of the credible intervals. The **ALPHA=** values must be between 0 and 1. Each **ALPHA=** value produces a pair of $100(1-\text{ALPHA})\%$ equal-tail and HPD intervals for each parameter. The default is **ALPHA=0.05**, which yields the 95% credible intervals for each parameter.

PERCENT=numeric-list

requests the percentile points of the posterior samples. The **PERCENT=** values must be between 0 and 100. The default is **PERCENT=25, 50, 75**, which yields the 25th, 50th, and 75th percentile points, respectively, for each parameter.

You can specify the following *keywords*:

CORR

produces the posterior correlation matrix.

COV

produces the posterior covariance matrix.

INTERVAL

produces equal-tail credible intervals and HPD intervals. The default is to produce the 95% equal-tail credible intervals and 95% HPD intervals, but you can use the **ALPHA=** *global-option* to request intervals of any probabilities.

NONE

suppresses printing of all summary statistics.

SUMMARY

produces the means, standard deviations, and percentile points for the posterior samples. To obtain the default percentiles (25th, 50th, and 75th), you must also specify the `INTERVAL` *global-option*. You can use the global `PERCENT=` *global-option* to request specific percentile points.

THIN=*number*

THINNING=*number*

controls the thinning of the Markov chain. Only one in every k samples is used when $\text{THIN}=k$, and if $\text{NBI}=n_0$ and $\text{NMC}=n$, the number of samples that are kept is

$$\left[\frac{n_0 + n}{k} \right] - \left[\frac{n_0}{k} \right]$$

where $[a]$ represents the integer part of the number a . The default is $\text{THIN}=1$.

BOUNDS Statement

BOUNDS *bound1* < , *bound2* ... > ;

The **BOUNDS** statement imposes simple boundary constraints on the parameter estimates. **BOUNDS** statement constraints refer to the parameters estimated by the QLIM procedure. Any number of **BOUNDS** statements can be specified.

Each *bound* is composed of parameters and constants and inequality operators. Parameters associated with regressor variables are referred to by the names of the corresponding regressor variables:

item operator item < *operator item* < *operator item* ... > >

Each *item* is a constant, the name of a parameter, or a list of parameter names. See the section “[Naming of Parameters](#)” on page 1524 for more details on how parameters are named in the QLIM procedure. Each *operator* is '<', '>', '<=', or '>='.

Both the **BOUNDS** statement and the **RESTRICT** statement can be used to impose boundary constraints; however, the **BOUNDS** statement provides a simpler syntax for specifying these kinds of constraints. See the “[RESTRICT Statement](#)” on page 1494 for more information.

The following **BOUNDS** statement constrains the estimates of the parameters associated with the variable `ttime` and the variables `x1` through `x10` to be between 0 and 1. This example illustrates the use of parameter lists to specify boundary constraints.

```
bounds 0 < ttime x1-x10 < 1;
```

The following **BOUNDS** statement constrains the estimates of the correlation (`_RHO`) and sigma (`_SIGMA`) in the bivariate model:

```
bounds _rho >= 0, _sigma.y1 > 1, _sigma.y2 < 5;
```

The BOUNDS statement is not supported if a BAYES statement is also specified. In Bayesian analysis, the restrictions on parameters are usually introduced through the prior distribution.

BY Statement

BY *variables* ;

A BY statement can be used with PROC QLIM to obtain separate analyses on observations in groups defined by the BY variables.

CLASS Statement

CLASS *variables* ;

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

Class levels are determined from the formatted values of the CLASS variables. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in *SAS Language Reference: Dictionary* for details.

ENDOGENOUS Statement

ENDOGENOUS *variables ~ options* ;

The ENDOGENOUS statement specifies the type of dependent variables that appear on the left-hand side of the equation. Endogenous variables listed refer to the dependent variables that appear on the left-hand side of the equation. Currently, no right-hand side endogeneity is handled in PROC QLIM. All variables appearing on the right-hand side of the equation are treated as exogenous.

Discrete Variable Options

DISCRETE <(*discrete-options*)>

specifies that the endogenous variables in this statement are discrete. Valid *discrete-options* are as follows:

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of the discrete variables specified in the ENDOGENOUS statement. This ordering determines which parameters in the model correspond to each level in the data. The following table shows how PROC QLIM interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	Formatted value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=FORMATTED. For the values FORMATTED and INTERNAL, the sort order is machine dependent. For more information about sorting order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide*.

DISTRIBUTION=NORMAL | LOGISTIC

DIST=NORMAL | LOGISTIC

D=NORMAL | LOGISTIC

specifies the cumulative distribution function used to model the response probabilities. DISTRIBUTION=NORMAL specifies the normal distribution for the probit model. DISTRIBUTION=LOGISTIC specifies the logistic distribution for the logit model.

By default, DISTRIBUTION=NORMAL.

If a multivariate model is specified, logistic distribution is not allowed. Only normal distribution is supported.

Censored Variable Options

CENSORED <(censored-options)>

specifies that the endogenous variables in this statement be censored. Valid *censored-options* are as follows:

LB=value or variable

LOWERBOUND=value or variable

specifies the lower bound of the censored variables. If *value* is missing or the value in *variable* is missing, no lower bound is set. By default, no lower bound is set.

UB=value or variable

UPPERBOUND=value or variable

specifies the upper bound of the censored variables. If *value* is missing or the value in *variable* is missing, no upper bound is set. By default, no upper bound is set.

Truncated Variable Options

TRUNCATED <(truncated-options)>

specifies that the endogenous variables in this statement be truncated. Valid *truncated-options* are as follows:

LB=*value or variable*

LOWERBOUND=*value or variable*

specifies the lower bound of the truncated variables. If *value* is missing or the value in *variable* is missing, no lower bound is set. By default, no lower bound is set.

UB=*value or variable*

UPPERBOUND=*value or variable*

specifies the upper bound of the truncated variables. If *value* is missing or the value in *variable* is missing, no upper bound is set. By default, no upper bound is set.

Stochastic Frontier Variable Options

FRONTIER <(frontier-options) >

specifies that the endogenous variable in this statement follow a production or cost frontier. Valid *frontier-options* are as follows:

TYPE=HALF | EXPONENTIAL | TRUNCATED

specifies the model type:

HALF specifies a half-normal model.

EXPONENTIAL specifies an exponential model.

TRUNCATED specifies a truncated normal model.

PRODUCTION

specifies that the model estimated be a production function.

COST

specifies that the model estimated be a cost function.

If neither PRODUCTION nor COST option is specified, production function is estimated by default.

Selection Options

SELECT (*select-option*)

specifies selection criteria for sample selection model. The BAYES statement does not support the SELECT option. The *select-option* specifies the condition for the endogenous variable to be selected. It is written as a variable name, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a number:

variable operator number

The *variable* is the endogenous variable that the selection is based on. The *operator* can be =, <, >, <=, or >=. Multiple *select-options* can be combined with the logic operators: AND, OR. The following example illustrates the use of the SELECT option:

```
endogenous y1 ~ select (z=0);
endogenous y2 ~ select (z=1 or z=2);
```

The SELECT option can be used together with the DISCRETE, CENSORED, or TRUNCATED option. For example:

```
endogenous y1 ~ select (z=0) discrete;
endogenous y2 ~ select (z=1) censored (lb=0);
endogenous y3 ~ select (z=1 or z=2) truncated (ub=10);
```

For more details about selection models with censoring or truncation, see the section “[Selection Models](#)” on page 1508.

FREQ Statement

FREQ *variable* ;

The FREQ statement identifies a variable that contains the frequency of occurrence of each observation. PROC QLIM treats each observation as if it appears n times, where n is the value of the FREQ variable for the observation. If it is not an integer, the frequency value is truncated to an integer. If the frequency value is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1. If you specify more than one FREQ statement, then the first FREQ statement is used.

HETERO Statement

HETERO *dependent variables* ~ *exogenous variables* </ options > ;

The HETERO statement specifies variables that are related to the heteroscedasticity of the residuals and the way these variables are used to model the error variance. The heteroscedastic regression model supported by PROC QLIM is

$$y_i = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$\epsilon_i \sim N(0, \sigma_i^2)$$

See the section “[Heteroscedasticity](#)” on page 1506 for more details on the specification of functional forms.

LINK=value

The functional form can be specified using the LINK= option. The following option values are allowed:

EXP specifies the exponential link function

$$\sigma_i^2 = \sigma^2(1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma}))$$

LINEAR specifies the linear link function

$$\sigma_i^2 = \sigma^2(1 + \mathbf{z}_i' \boldsymbol{\gamma})$$

When the LINK= option is not specified, the exponential link function is specified by default.

NOCONST

specifies that there be no constant in the linear or exponential heteroscedasticity model.

$$\begin{aligned}\sigma_i^2 &= \sigma^2(\mathbf{z}_i' \boldsymbol{\gamma}) \\ \sigma_i^2 &= \sigma^2 \exp(\mathbf{z}_i' \boldsymbol{\gamma})\end{aligned}$$

SQUARE

estimates the model by using the square of linear heteroscedasticity function. For example, you can specify the following heteroscedasticity function:

$$\sigma_i^2 = \sigma^2(1 + (\mathbf{z}_i' \boldsymbol{\gamma})^2)$$

```
model y = x1 x2 / discrete;
hetero y ~ z1 / link=linear square;
```

The option SQUARE does not apply to exponential heteroscedasticity function because the square of an exponential function of $\mathbf{z}_i' \boldsymbol{\gamma}$ is the same as the exponential of $2\mathbf{z}_i' \boldsymbol{\gamma}$. Hence the only difference is that all $\boldsymbol{\gamma}$ estimates are divided by two.

You can use the HETERO statement within a Bayesian framework, but you should do this carefully because convergence can be slower than in the homoscedastic case. For more information see “[Priors for Heteroscedastic Models](#)” on page 1516.

INIT Statement

```
INIT initvalue1 < , initvalue2 ... > ;
```

The INIT statement sets initial values for parameters in the optimization. You can specify any number of INIT statements.

Each *initvalue* is written as a parameter or parameter list, followed by an optional equality operator (=), followed by a number:

```
parameter <=> number
```

If you also specify the BAYES statement, the INIT statement also initializes the Markov chain Monte Carlo (MCMC) algorithm. In particular, the INIT statement does one of the following:

- It initializes the tuning phase (this also includes the PROPCOV option).
- It initializes the sampling phase, if there is no tuning phase.

MODEL Statement

```
MODEL dependent = regressors < / options > ;
```

The MODEL statement specifies the dependent variable and independent regressor variables for the regression model.

You can specify the following *options* after a slash (/).

LIMIT1=ZERO | VARYING

specifies the restriction of the threshold value of the first category when the ordinal probit or logit model is estimated. LIMIT1=ZERO is the default option. When LIMIT1=VARYING is specified, the threshold value is estimated.

NOINT

suppresses the intercept parameter.

Endogenous Variable Options

The endogenous variable options are the same as the options you can specify in the ENDOGENOUS statement. If you specify an ENDOGENOUS statement, all endogenous options of the MODEL statement are ignored.

BOXCOX Estimation Options

BOXCOX (*option-list*)

specifies options that are used for Box-Cox regression or regressor transformation. For example, the Box-Cox regression is specified as

```
model y = x1 x2 / boxcox(y=lambda,x1 x2)
```

PROC QLIM estimates the following Box-Cox regression model:

$$y_i^{(\lambda)} = \beta_0 + \beta_1 x_{1i}^{(\lambda_1)} + \beta_2 x_{2i}^{(\lambda_2)} + \epsilon_i$$

The *option-list* takes the form *variable-list* <= *varname* > separated by commas. The *variable-list* specifies that the list of variables have the same Box-Cox transformation; *varname* specifies the name of this Box-Cox coefficient. If *varname* is not specified, the coefficient is called *_Lambdai*, where *i* increments sequentially.

Variable Selection Options

SELECTVAR <=(*selectvar-option*)>

enables variable selection. The *selectvar-option* specifies a variable selection method based on an information criterion. For more information, see the section “[Variable Selection](#)” on page 1511. You can specify the following *selectvar-options*:

DIRECTION=FORWARD | BACKWARD

specifies the searching algorithm to use in the variable selection method. The default is FORWARD.

CRITER=AIC | SBC

specifies the information criterion to use for the variable selection. The default is AIC.

MAXSTEPS=value

specifies the maximum number of steps that are allowed in the search algorithm. The default is infinite; that is, the algorithm does not stop until the stopping criterion is satisfied.

LSTOP=*value*

specifies the stopping criterion. The *value* represents the percentage of decrease or increase in the AIC or SBC that is required for the algorithm to proceed; it must be a positive number less than 1. The default is 0.

RETAIN(*regressors*)

specifies a list of regressors that are to be retained in any model that the variable selection process considers.

The following rules apply to how regressors are handled when you specify more than one MODEL statement and use the SELECTVAR option:

- If you do not specify the SELECTVAR option in a particular MODEL statement, then all regressors in the original model are included in any model that the variable selection algorithm considers. In other words, omitting the SELECTVAR option is equivalent to providing the option: SELECTVAR=(RETAIN(*all-regressors*)).
- If you specify the SELECTVAR option without any =(option) clause in a MODEL statement, then all regressors in that model (other than the intercept, if present) are eligible for potential exclusion as the variable selection process is executed.

The following example specifies 10 possible regressor candidates, out of which five are selected using the AIC criteria:

```
proc qlim data=one;
  model y = x1-x10 /selectvar=(direction=forward criter=AIC maxsteps=5);
run;
```

NLOPTIONS Statement

NLOPTIONS < *options* > ;

PROC QLIM uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. For a list of all the options of the NLOPTIONS statement, see Chapter 6, “[Nonlinear Optimization Methods](#).”

OUTPUT Statement

OUTPUT < **OUT**=*SAS-data-set* > < *output-options* > ;

The OUTPUT statement creates a new SAS data set containing all variables in the input data set and, optionally, the estimates of $\mathbf{x}'\boldsymbol{\beta}$, predicted value, residual, marginal effects, probability, standard deviation of the error, expected value, conditional expected value, technical efficiency measures, and inverse Mills ratio. When the response values are missing for the observation, all output estimates except residual are still computed as long as none of the explanatory variables is missing. This enables you to compute these statistics for prediction. You can specify only one OUTPUT statement.

Details on the specifications in the OUTPUT statement are as follows:

CONDITIONAL

outputs estimates of conditional expected values of continuous endogenous variables.

ERRSTD

outputs estimates of σ_j , the standard deviation of the error term.

EXPECTED

outputs estimates of expected values of continuous endogenous variables.

MARGINAL

outputs marginal effects.

MILLS

outputs estimates of inverse Mills ratios of censored or truncated continuous, binary discrete, and selection endogenous variables.

OUT=SAS-data-set

names the output data set.

PREDICTED

outputs estimates of predicted endogenous variables.

PROB

outputs estimates of probability of discrete endogenous variables taking the current observed responses.

PROBALL

outputs estimates of probability of discrete endogenous variables for all possible responses.

RESIDUAL

outputs estimates of residuals of continuous endogenous variables.

XBETA

outputs estimates of $\mathbf{x}'\boldsymbol{\beta}$.

TE1

outputs estimates of technical efficiency for each producer in the stochastic frontier model suggested by Battese and Coelli (1988).

TE2

outputs estimates of technical efficiency for each producer in the stochastic frontier model suggested by Jondrow et al. (1982).

PRIOR Statement

PRIOR _REGRESSORS | *parameter-list* ~ *distribution* ;

The PRIOR statement specifies the prior distribution of the model parameters. You must specify a single parameter or a list of parameter, a tilde ~, and then a distribution with its parameters. Multiple PRIOR statements are allowed.

You can specify the following *distributions*:

NORMAL(MEAN= μ , VAR= σ^2)

specifies a normal distribution with parameters MEAN and VAR.

GAMMA(SHAPE= a , SCALE= b)

specifies a gamma distribution with parameters SHAPE and SCALE.

IGAMMA(SHAPE= a , SCALE= b)

specifies an inverse gamma distribution with parameters SHAPE and SCALE.

UNIFORM(MIN= m , MAX= M)

specifies a uniform distribution that is defined between MIN and MAX.

BETA(SHAPE1= a , SHAPE2= b , MIN= m , MAX= M)

specifies a beta distribution with parameters SHAPE1 and SHAPE2 and defined between MIN and MAX.

T(LOCATION= μ , DF= ν)

specifies a noncentral t distribution with DF degrees of freedom and location parameter equal to LOCATION.

See the section “[Standard Distributions](#)” on page 1517 for details about how to specify *distributions*.

You can specify the special keyword REGRESSORS to select all the parameters used in the linear regression component of the model.

RESTRICT Statement

RESTRICT *restriction1* <, *restriction2* ... > ;

The RESTRICT statement is used to impose linear restrictions on the parameter estimates. Any number of RESTRICT statements can be specified, but the number of restrictions imposed is limited by the number of regressors.

Each *restriction* is written as an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

expression operator expression

The *operator* can be =, <, >, <=, or >=. The operator and second expression are optional.

Restriction expressions can be composed of parameter names, multiplication (*), addition (+) and subtraction (−) operators, and constants. Parameters named in restriction expressions must be among the parameters estimated by the model. Parameters associated with a regressor variable are referred to by the name of the corresponding regressor variable. The restriction expressions must be a linear function of the parameters.

The following is an example of the use of the RESTRICT statement:

```
proc qlim data=one;
  model y = x1-x10 / discrete;
  restrict x1*2 <= x2 + x3;
run;
```

The RESTRICT statement can also be used to impose cross-equation restrictions in multivariate models. The following RESTRICT statement imposes an equality restriction on coefficients of x_1 in equation y_1 and x_1 in equation y_2 :

```
proc qlim data=one;
  model y1 = x1-x10;
  model y2 = x1-x4;
  endogenous y1 y2 ~ discrete;
  restrict y1.x1=y2.x1;
run;
```

The RESTRICT statement is not supported if a BAYES statement is also specified. In Bayesian analysis, the restrictions on parameters are usually introduced through the prior distribution.

TEST Statement

<'label'> **TEST** *<'string'> equation [,equation...]/ options ;*

The TEST statement performs Wald, Lagrange multiplier, and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT refers to the coefficient of the intercept.

The following options can be specified in the TEST statement after the slash (/):

ALL

requests Wald, Lagrange multiplier, and likelihood ratio tests.

WALD

requests the Wald test.

LM

requests the Lagrange multiplier test.

LR

requests the likelihood ratio test.

The following illustrates the use of the TEST statement:

```
proc qlim;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0;
  test _int: test intercept = 0, x3 = 0;
run;
```

The first test investigates the joint hypothesis that

$$\beta_1 = 0$$

and

$$0.5\beta_2 + 2\beta_3 = 0$$

In case there is more than one MODEL statement in one QLIM procedure, then TEST statement is capable of testing cross-equation restrictions. Each parameter reference should be preceded by the name of the dependent variable of the particular model and the dot sign. For example,

```
proc qlim;
  model y1 = x1 x2 x3;
  model y2 = x3 x5 x6;
  test y1.x1 + y2.x6 = 1;
run;
```

This cross-equation test investigates the null hypothesis that

$$\beta_{1,1} + \beta_{2,3} = 1$$

in the system of equations

$$\begin{aligned} y_{1,i} &= \alpha_1 + \beta_{1,1}x_{1,i} + \beta_{1,2}x_{2,i} + \beta_{1,3}x_{3,i} \\ y_{2,i} &= \alpha_2 + \beta_{2,1}x_{3,i} + \beta_{2,2}x_{5,i} + \beta_{2,3}x_{6,i} \end{aligned}$$

Only linear equality restrictions and tests are permitted in PROC QLIM. Tests expressions can be composed only of algebraic operations involving the addition symbol (+), subtraction symbol (-), and multiplication symbol (*).

The TEST statement accepts labels that are reproduced in the printed output. TEST statement can be labeled in two ways. A TEST statement can be preceded by a label followed by a colon. Alternatively, the keyword TEST can be followed by a quoted string. If both are present, PROC QLIM uses the label preceding the colon. In the event no label is present, PROC QLIM automatically labels the tests.

You cannot specify both the TEST statement and the BAYES statement.

WEIGHT Statement

WEIGHT *variable* </option> ;

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters. The log likelihood for each observation is multiplied by the corresponding weight variable value.

If the weight of an observation is nonpositive, that observation is not used in the estimation.

The following option can be added to the WEIGHT statement after a slash (/).

NONNORMALIZE

specifies that the weights are required to be used as is. When this option is not specified, the weights are normalized so that they add up to the actual sample size. Weights w_i are normalized by multiplying them by $\frac{n}{\sum_{i=1}^n w_i}$, where n is the sample size.

Details: QLIM Procedure

Ordinal Discrete Choice Modeling

Binary Probit and Logit Model

The binary choice model is

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

where value of the latent dependent variable, y_i^* , is observed only as follows:

$$\begin{aligned} y_i &= 1 \quad \text{if } y_i^* > 0 \\ &= 0 \quad \text{otherwise} \end{aligned}$$

The disturbance, ϵ_i , of the probit model has standard normal distribution with the distribution function (CDF)

$$\Phi(x) = \int_{-\infty}^x \frac{1}{\sqrt{2\pi}} \exp(-t^2/2) dt$$

The disturbance of the logit model has standard logistic distribution with the CDF

$$\Lambda(x) = \frac{\exp(x)}{1 + \exp(x)} = \frac{1}{1 + \exp(-x)}$$

The binary discrete choice model has the following probability that the event $\{y_i = 1\}$ occurs:

$$P(y_i = 1) = F(\mathbf{x}_i' \boldsymbol{\beta}) = \begin{cases} \Phi(\mathbf{x}_i' \boldsymbol{\beta}) & \text{(probit)} \\ \Lambda(\mathbf{x}_i' \boldsymbol{\beta}) & \text{(logit)} \end{cases}$$

The log-likelihood function is

$$\ell = \sum_{i=1}^N \{y_i \log[F(\mathbf{x}_i' \boldsymbol{\beta})] + (1 - y_i) \log[1 - F(\mathbf{x}_i' \boldsymbol{\beta})]\}$$

where the CDF $F(x)$ is defined as $\Phi(x)$ for the probit model while $F(x) = \Lambda(x)$ for logit. The first order derivatives of the logit model are

$$\frac{\partial \ell}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N (y_i - \Lambda(\mathbf{x}_i' \boldsymbol{\beta})) \mathbf{x}_i$$

The probit model has more complicated derivatives

$$\frac{\partial \ell}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N \left[\frac{(2y_i - 1)\phi(\mathbf{x}_i' \boldsymbol{\beta})}{\Phi(\mathbf{x}_i' \boldsymbol{\beta})} \right] \mathbf{x}_i = \sum_{i=1}^N r_i \mathbf{x}_i$$

where

$$r_i = \frac{(2y_i - 1)\phi(\mathbf{x}_i' \boldsymbol{\beta})}{\Phi(\mathbf{x}_i' \boldsymbol{\beta})}$$

Note that the logit maximum likelihood estimates are $\frac{\pi}{\sqrt{3}}$ times greater than probit maximum likelihood estimates, since the probit parameter estimates, $\boldsymbol{\beta}$, are standardized, and the error term with logistic distribution has a variance of $\frac{\pi^2}{3}$.

Ordinal Probit/Logit

When the dependent variable is observed in sequence with M categories, binary discrete choice modeling is not appropriate for data analysis. McKelvey and Zavoina (1975) proposed the ordinal (or ordered) probit model.

Consider the following regression equation:

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

where error disturbances, ϵ_i , have the distribution function F . The unobserved continuous random variable, y_i^* , is identified as M categories. Suppose there are $M + 1$ real numbers, μ_0, \dots, μ_M , where $\mu_0 = -\infty$, $\mu_1 = 0$, $\mu_M = \infty$, and $\mu_0 \leq \mu_1 \leq \dots \leq \mu_M$. Define

$$R_{i,j} = \mu_j - \mathbf{x}_i' \boldsymbol{\beta}$$

The probability that the unobserved dependent variable is contained in the j th category can be written as

$$P[\mu_{j-1} < y_i^* \leq \mu_j] = F(R_{i,j}) - F(R_{i,j-1})$$

The log-likelihood function is

$$\ell = \sum_{i=1}^N \sum_{j=1}^M d_{ij} \log [F(R_{i,j}) - F(R_{i,j-1})]$$

where

$$d_{ij} = \begin{cases} 1 & \text{if } \mu_{j-1} < y_i \leq \mu_j \\ 0 & \text{otherwise} \end{cases}$$

The first derivatives are written as

$$\begin{aligned} \frac{\partial \ell}{\partial \boldsymbol{\beta}} &= \sum_{i=1}^N \sum_{j=1}^M d_{ij} \left[\frac{f(R_{i,j-1}) - f(R_{i,j})}{F(R_{i,j}) - F(R_{i,j-1})} \mathbf{x}_i \right] \\ \frac{\partial \ell}{\partial \mu_k} &= \sum_{i=1}^N \sum_{j=1}^M d_{ij} \left[\frac{\delta_{j,k} f(R_{i,j}) - \delta_{j-1,k} f(R_{i,j-1})}{F(R_{i,j}) - F(R_{i,j-1})} \right] \end{aligned}$$

where $f(x) = \frac{dF(x)}{dx}$ and $\delta_{j,k} = 1$ if $j = k$, and $\delta_{j,k} = 0$ otherwise. When the ordinal probit is estimated, it is assumed that $F(R_{i,j}) = \Phi(R_{i,j})$. The ordinal logit model is estimated if $F(R_{i,j}) = \Lambda(R_{i,j})$. The

first threshold parameter, μ_1 , is estimated when the LIMIT1=VARYING option is specified. By default (LIMIT1=ZERO), so that $M - 2$ threshold parameters (μ_2, \dots, μ_{M-1}) are estimated.

The ordered probit models are analyzed by Aitchison and Silvey (1957), and Cox (1970) discussed ordered response data by using the logit model. They defined the probability that y_i^* belongs to j th category as

$$P[\mu_{j-1} < y_i \leq \mu_j] = F(\mu_j + \mathbf{x}_i' \boldsymbol{\theta}) - F(\mu_{j-1} + \mathbf{x}_i' \boldsymbol{\theta})$$

where $\mu_0 = -\infty$ and $\mu_M = \infty$. Therefore, the ordered response model analyzed by Aitchison and Silvey can be estimated if the LIMIT1=VARYING option is specified. Note that $\boldsymbol{\theta} = -\boldsymbol{\beta}$.

Goodness-of-Fit Measures

The goodness-of-fit measures discussed in this section apply only to discrete dependent variable models.

McFadden (1974) suggested a likelihood ratio index that is analogous to the R^2 in the linear regression model:

$$R_M^2 = 1 - \frac{\ln L}{\ln L_0}$$

where L is the value of the maximum likelihood function and L_0 is the value of a likelihood function when regression coefficients except an intercept term are zero. It can be shown that L_0 can be written as

$$L_0 = \sum_{j=1}^M N_j \ln\left(\frac{N_j}{N}\right)$$

where N_j is the number of responses in category j .

Estrella (1998) proposes the following requirements for a goodness-of-fit measure to be desirable in discrete choice modeling:

- The measure must take values in $[0, 1]$, where 0 represents no fit and 1 corresponds to perfect fit.
- The measure should be directly related to the valid test statistic for significance of all slope coefficients.
- The derivative of the measure with respect to the test statistic should comply with corresponding derivatives in a linear regression.

Estrella's (1998) measure is written

$$R_{E1}^2 = 1 - \left(\frac{\ln L}{\ln L_0} \right)^{-\frac{2}{N} \ln L_0}$$

An alternative measure suggested by Estrella (1998) is

$$R_{E2}^2 = 1 - [(\ln L - K) / \ln L_0]^{-\frac{2}{N} \ln L_0}$$

where $\ln L_0$ is computed with null slope parameter values, N is the number observations used, and K represents the number of estimated parameters.

Other goodness-of-fit measures are summarized as follows:

$$R_{CU1}^2 = 1 - \left(\frac{L_0}{L} \right)^{\frac{2}{N}} \quad (\text{Cragg} - \text{Uhler1})$$

$$R_{CU2}^2 = \frac{1 - (L_0/L)^{\frac{2}{N}}}{1 - L_0^{\frac{2}{N}}} \quad (\text{Cragg} - \text{Uhler2})$$

$$R_A^2 = \frac{2(\ln L - \ln L_0)}{2(\ln L - \ln L_0) + N} \quad (\text{Aldrich} - \text{Nelson})$$

$$R_{VZ}^2 = R_A^2 \frac{2 \ln L_0 - N}{2 \ln L_0} \quad (\text{Veall} - \text{Zimmermann})$$

$$R_{MZ}^2 = \frac{\sum_{i=1}^N (\hat{y}_i - \bar{\hat{y}})^2}{N + \sum_{i=1}^N (\hat{y}_i - \bar{\hat{y}})^2} \quad (\text{McKelvey} - \text{Zavoina})$$

where $\hat{y}_i = \mathbf{x}_i' \hat{\boldsymbol{\beta}}$ and $\bar{\hat{y}} = \sum_{i=1}^N \hat{y}_i / N$.

Limited Dependent Variable Models

Censored Regression Models

When the dependent variable is censored, values in a certain range are all transformed to a single value. For example, the standard tobit model can be defined as

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$y_i = \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases}$$

where $\epsilon_i \sim iid N(0, \sigma^2)$. The log-likelihood function of the standard censored regression model is

$$\ell = \sum_{i \in \{y_i=0\}} \ln[1 - \Phi(\mathbf{x}_i' \boldsymbol{\beta} / \sigma)] + \sum_{i \in \{y_i>0\}} \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) / \sigma \right]$$

where $\Phi(\cdot)$ is the cumulative density function of the standard normal distribution and $\phi(\cdot)$ is the probability density function of the standard normal distribution.

The tobit model can be generalized to handle observation-by-observation censoring. The censored model on both of the lower and upper limits can be defined as

$$y_i = \begin{cases} R_i & \text{if } y_i^* \geq R_i \\ y_i^* & \text{if } L_i < y_i^* < R_i \\ L_i & \text{if } y_i^* \leq L_i \end{cases}$$

The log-likelihood function can be written as

$$\ell = \sum_{i \in \{L_i < y_i < R_i\}} \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) / \sigma \right] + \sum_{i \in \{y_i=R_i\}} \ln \left[\Phi\left(-\frac{R_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) \right] + \sum_{i \in \{y_i=L_i\}} \ln \left[\Phi\left(\frac{L_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) \right]$$

Log-likelihood functions of the lower- or upper-limit censored model are easily derived from the two-limit censored model. The log-likelihood function of the lower-limit censored model is

$$\ell = \sum_{i \in \{y_i > L_i\}} \ln \left[\phi \left(\frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) / \sigma \right] + \sum_{i \in \{y_i = L_i\}} \ln \left[\Phi \left(\frac{L_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) \right]$$

The log-likelihood function of the upper-limit censored model is

$$\ell = \sum_{i \in \{y_i < R_i\}} \ln \left[\phi \left(\frac{y_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) / \sigma \right] + \sum_{i \in \{y_i = R_i\}} \ln \left[1 - \Phi \left(\frac{R_i - \mathbf{x}'_i \boldsymbol{\beta}}{\sigma} \right) \right]$$

Types of Tobit Models

Amemiya (1984) classified Tobit models into five types based on characteristics of the likelihood function. For notational convenience, let P denote a distribution or density function, y_{ji}^* is assumed to be normally distributed with mean $\mathbf{x}'_{ji} \boldsymbol{\beta}_j$ and variance σ_j^2 .

Type 1 Tobit

The Type 1 Tobit model was already discussed in the preceding section.

$$\begin{aligned} y_{1i}^* &= \mathbf{x}'_{1i} \boldsymbol{\beta}_1 + u_{1i} \\ y_{1i} &= y_{1i}^* \quad \text{if } y_{1i}^* > 0 \\ &= 0 \quad \text{if } y_{1i}^* \leq 0 \end{aligned}$$

The likelihood function is characterized as $P(y_1 < 0)P(y_1)$.

Type 2 Tobit

The Type 2 Tobit model is defined as

$$\begin{aligned} y_{1i}^* &= \mathbf{x}'_{1i} \boldsymbol{\beta}_1 + u_{1i} \\ y_{2i}^* &= \mathbf{x}'_{2i} \boldsymbol{\beta}_2 + u_{2i} \\ y_{1i} &= 1 \quad \text{if } y_{1i}^* > 0 \\ &= 0 \quad \text{if } y_{1i}^* \leq 0 \\ y_{2i} &= y_{2i}^* \quad \text{if } y_{1i}^* > 0 \\ &= 0 \quad \text{if } y_{1i}^* \leq 0 \end{aligned}$$

where $(u_{1i}, u_{2i}) \sim N(0, \Sigma)$. The likelihood function is described as $P(y_1 < 0)P(y_1 > 0, y_2)$.

Type 3 Tobit

The Type 3 Tobit model is different from the Type 2 Tobit in that y_{1i}^* of the Type 3 Tobit is observed when $y_{1i}^* > 0$.

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{1i} &= y_{1i}^* \text{ if } y_{1i}^* > 0 \\
 &= 0 \text{ if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \text{ if } y_{1i}^* > 0 \\
 &= 0 \text{ if } y_{1i}^* \leq 0
 \end{aligned}$$

where $(u_{1i}, u_{2i})' \sim iidN(0, \Sigma)$.

The likelihood function is characterized as $P(y_1 < 0)P(y_1, y_2)$.

Type 4 Tobit

The Type 4 Tobit model consists of three equations:

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{3i}^* &= \mathbf{x}_{3i}'\boldsymbol{\beta}_3 + u_{3i} \\
 y_{1i} &= y_{1i}^* \text{ if } y_{1i}^* > 0 \\
 &= 0 \text{ if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \text{ if } y_{1i}^* > 0 \\
 &= 0 \text{ if } y_{1i}^* \leq 0 \\
 y_{3i} &= y_{3i}^* \text{ if } y_{1i}^* \leq 0 \\
 &= 0 \text{ if } y_{1i}^* > 0
 \end{aligned}$$

where $(u_{1i}, u_{2i}, u_{3i})' \sim iidN(0, \Sigma)$. The likelihood function of the Type 4 Tobit model is characterized as $P(y_1 < 0, y_3)P(y_1, y_2)$.

Type 5 Tobit

The Type 5 Tobit model is defined as follows:

$$\begin{aligned}
 y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + u_{1i} \\
 y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + u_{2i} \\
 y_{3i}^* &= \mathbf{x}_{3i}'\boldsymbol{\beta}_3 + u_{3i} \\
 y_{1i} &= 1 \text{ if } y_{1i}^* > 0 \\
 &= 0 \text{ if } y_{1i}^* \leq 0 \\
 y_{2i} &= y_{2i}^* \text{ if } y_{1i}^* > 0 \\
 &= 0 \text{ if } y_{1i}^* \leq 0 \\
 y_{3i} &= y_{3i}^* \text{ if } y_{1i}^* \leq 0 \\
 &= 0 \text{ if } y_{1i}^* > 0
 \end{aligned}$$

where $(u_{1i}, u_{2i}, u_{3i})'$ are from *iid* trivariate normal distribution. The likelihood function of the Type 5 Tobit model is characterized as $P(y_1 < 0, y_3)P(y_1 > 0, y_2)$.

Code examples for these models can be found in “[Example 22.6: Types of Tobit Models](#)” on page 1538.

Truncated Regression Models

In a truncated model, the observed sample is a subset of the population where the dependent variable falls in a certain range. For example, when neither a dependent variable nor exogenous variables are observed for $y_i^* \leq 0$, the truncated regression model can be specified.

$$\ell = \sum_{i \in \{y_i > 0\}} \left\{ -\ln \Phi(\mathbf{x}_i' \boldsymbol{\beta} / \sigma) + \ln \left[\frac{\phi((y_i - \mathbf{x}_i' \boldsymbol{\beta}) / \sigma)}{\sigma} \right] \right\}$$

Two-limit truncation model is defined as

$$y_i = y_i^* \text{ if } L_i < y_i^* < R_i$$

The log-likelihood function of the two-limit truncated regression model is

$$\ell = \sum_{i=1}^N \left\{ \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) / \sigma \right] - \ln \left[\Phi\left(\frac{R_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) - \Phi\left(\frac{L_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) \right] \right\}$$

The log-likelihood functions of the lower- and upper-limit truncation model are

$$\begin{aligned} \ell &= \sum_{i=1}^N \left\{ \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) / \sigma \right] - \ln \left[1 - \Phi\left(\frac{L_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) \right] \right\} \quad (\text{lower}) \\ \ell &= \sum_{i=1}^N \left\{ \ln \left[\phi\left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) / \sigma \right] - \ln \left[\Phi\left(\frac{R_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) \right] \right\} \quad (\text{upper}) \end{aligned}$$

Stochastic Frontier Production and Cost Models

Stochastic frontier production models were first developed by Aigner, Lovell, and Schmidt (1977) and Meeusen and van den Broeck (1977). Specification of these models allow for random shocks of the production or cost but also include a term for technological or cost inefficiency. Assuming that the production function takes a log-linear Cobb-Douglas form, the stochastic frontier production model can be written as

$$\ln(y_i) = \beta_0 + \sum_n \beta_n \ln(x_{ni}) + \epsilon_i$$

where $\epsilon_i = v_i - u_i$. The v_i term represents the stochastic error component and u_i is the nonnegative, technology inefficiency error component. The v_i error component is assumed to be distributed *iid* normal and independently from u_i . If $u_i > 0$, the error term, ϵ_i , is negatively skewed and represents technology inefficiency. If $u_i < 0$, the error term ϵ_i is positively skewed and represents cost inefficiency. PROC QLIM models the u_i error component as a half normal, exponential, or truncated normal distribution.

The Normal-Half Normal Model

In case of the normal-half normal model, v_i is iid $N(0, \sigma_v^2)$, u_i is iid $N^+(0, \sigma_u^2)$ with v_i and u_i independent of each other. Given the independence of error terms, the joint density of v and u can be written as

$$f(u, v) = \frac{2}{2\pi\sigma_u\sigma_v} \exp \left\{ -\frac{u^2}{2\sigma_u^2} - \frac{v^2}{2\sigma_v^2} \right\}$$

Substituting $v = \epsilon + u$ into the preceding equation gives

$$f(u, \epsilon) = \frac{2}{2\pi\sigma_u\sigma_v} \exp \left\{ -\frac{u^2}{2\sigma_u^2} - \frac{(\epsilon + u)^2}{2\sigma_v^2} \right\}$$

Integrating u out to obtain the marginal density function of ϵ results in the following form:

$$\begin{aligned} f(\epsilon) &= \int_0^\infty f(u, \epsilon) du \\ &= \frac{2}{\sqrt{2\pi}\sigma} \left[1 - \Phi \left(\frac{\epsilon\lambda}{\sigma} \right) \right] \exp \left\{ -\frac{\epsilon^2}{2\sigma^2} \right\} \\ &= \frac{2}{\sigma} \phi \left(\frac{\epsilon}{\sigma} \right) \Phi \left(-\frac{\epsilon\lambda}{\sigma} \right) \end{aligned}$$

where $\lambda = \sigma_u/\sigma_v$ and $\sigma = \sqrt{\sigma_u^2 + \sigma_v^2}$.

In the case of a stochastic frontier cost model, $v = \epsilon - u$ and

$$f(\epsilon) = \frac{2}{\sigma} \phi \left(\frac{\epsilon}{\sigma} \right) \Phi \left(\frac{\epsilon\lambda}{\sigma} \right)$$

The log-likelihood function for the production model with N producers is written as

$$\ln L = \text{constant} - N \ln \sigma + \sum_i \ln \Phi \left(-\frac{\epsilon_i \lambda}{\sigma} \right) - \frac{1}{2\sigma^2} \sum_i \epsilon_i^2$$

The Normal-Exponential Model

Under the normal-exponential model, v_i is iid $N(0, \sigma_v^2)$ and u_i is iid exponential with scale parameter σ_u . Given the independence of error term components u_i and v_i , the joint density of v and u can be written as

$$f(u, v) = \frac{1}{\sqrt{2\pi}\sigma_u\sigma_v} \exp \left\{ -\frac{u}{\sigma_u} - \frac{v^2}{2\sigma_v^2} \right\}$$

The marginal density function of ϵ for the production function is

$$\begin{aligned} f(\epsilon) &= \int_0^\infty f(u, \epsilon) du \\ &= \left(\frac{1}{\sigma_u} \right) \Phi \left(-\frac{\epsilon}{\sigma_v} - \frac{\sigma_v}{\sigma_u} \right) \exp \left\{ \frac{\epsilon}{\sigma_u} + \frac{\sigma_v^2}{2\sigma_u^2} \right\} \end{aligned}$$

and the marginal density function for the cost function is equal to

$$f(\epsilon) = \left(\frac{1}{\sigma_u}\right) \Phi\left(\frac{\epsilon}{\sigma_v} - \frac{\sigma_v}{\sigma_u}\right) \exp\left\{-\frac{\epsilon}{\sigma_u} + \frac{\sigma_v^2}{2\sigma_u^2}\right\}$$

The log-likelihood function for the normal-exponential production model with N producers is

$$\ln L = \text{constant} - N \ln \sigma_u + N \left(\frac{\sigma_v^2}{2\sigma_u^2}\right) + \sum_i \frac{\epsilon_i}{\sigma_u} + \sum_i \ln \Phi\left(\frac{\epsilon_i}{\sigma_v} - \frac{\sigma_v}{\sigma_u}\right)$$

The Normal-Truncated Normal Model

The normal-truncated normal model is a generalization of the normal-half normal model by allowing the mean of u_i to differ from zero. Under the normal-truncated normal model, the error term component v_i is iid $N(0, \sigma_v^2)$ and u_i is iid $N^+(\mu, \sigma_u^2)$. The joint density of v_i and u_i can be written as

$$f(u, v) = \frac{1}{2\pi\sigma_u\sigma_v\Phi(\mu/\sigma_u)} \exp\left\{-\frac{(u-\mu)^2}{2\sigma_u^2} - \frac{v^2}{2\sigma_v^2}\right\}$$

The marginal density function of ϵ for the production function is

$$\begin{aligned} f(\epsilon) &= \int_0^\infty f(u, \epsilon) du \\ &= \frac{1}{\sqrt{2\pi}\sigma\Phi(\mu/\sigma_u)} \Phi\left(\frac{\mu}{\sigma\lambda} - \frac{\epsilon\lambda}{\sigma}\right) \exp\left\{-\frac{(\epsilon+\mu)^2}{2\sigma^2}\right\} \\ &= \frac{1}{\sigma} \phi\left(\frac{\epsilon+\mu}{\sigma}\right) \Phi\left(\frac{\mu}{\sigma\lambda} - \frac{\epsilon\lambda}{\sigma}\right) \left[\Phi\left(\frac{\mu}{\sigma_u}\right)\right]^{-1} \end{aligned}$$

and the marginal density function for the cost function is

$$f(\epsilon) = \frac{1}{\sigma} \phi\left(\frac{\epsilon-\mu}{\sigma}\right) \Phi\left(\frac{\mu}{\sigma\lambda} + \frac{\epsilon\lambda}{\sigma}\right) \left[\Phi\left(\frac{\mu}{\sigma_u}\right)\right]^{-1}$$

The log-likelihood function for the normal-truncated normal production model with N producers is

$$\begin{aligned} \ln L &= \text{constant} - N \ln \sigma - N \ln \Phi\left(\frac{\mu}{\sigma_u}\right) + \sum_i \ln \Phi\left(\frac{\mu}{\sigma\lambda} - \frac{\epsilon_i\lambda}{\sigma}\right) \\ &\quad - \frac{1}{2} \sum_i \left(\frac{\epsilon_i + \mu}{\sigma}\right)^2 \end{aligned}$$

For more detail on normal-half normal, normal-exponential, and normal-truncated models, see Kumbhakar and Knox Lovell (2000) and Coelli, Prasada Rao, and Battese (1998).

Heteroscedasticity and Box-Cox Transformation

Heteroscedasticity

If the variance of regression disturbance, (ϵ_i) , is heteroscedastic, the variance can be specified as a function of variables

$$E(\epsilon_i^2) = \sigma_i^2 = f(\mathbf{z}_i' \boldsymbol{\gamma})$$

The following table shows various functional forms of heteroscedasticity and the corresponding options to request each model.

No.	Model	Options
1	$f(\mathbf{z}_i' \boldsymbol{\gamma}) = \sigma^2(1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma}))$	LINK=EXP (default)
2	$f(\mathbf{z}_i' \boldsymbol{\gamma}) = \sigma^2 \exp(\mathbf{z}_i' \boldsymbol{\gamma})$	LINK=EXP NOCONST
3	$f(\mathbf{z}_i' \boldsymbol{\gamma}) = \sigma^2(1 + \sum_{l=1}^L \gamma_l z_{li})$	LINK=LINEAR
4	$f(\mathbf{z}_i' \boldsymbol{\gamma}) = \sigma^2(1 + (\sum_{l=1}^L \gamma_l z_{li})^2)$	LINK=LINEAR SQUARE
5	$f(\mathbf{z}_i' \boldsymbol{\gamma}) = \sigma^2(\sum_{l=1}^L \gamma_l z_{li})$	LINK=LINEAR NOCONST
6	$f(\mathbf{z}_i' \boldsymbol{\gamma}) = \sigma^2((\sum_{l=1}^L \gamma_l z_{li})^2)$	LINK=LINEAR SQUARE NOCONST

For discrete choice models, σ^2 is normalized ($\sigma^2 = 1$) since this parameter is not identified. Note that in models 3 and 5, it may be possible that variances of some observations are negative. Although the QLIM procedure assigns a large penalty to move the optimization away from such region, it is possible that the optimization cannot improve the objective function value and gets locked in the region. Signs of such outcome include extremely small likelihood values or missing standard errors in the estimates. In models 2 and 6, variances are guaranteed to be greater or equal to zero, but it may be possible that variances of some observations are very close to zero. In these scenarios, standard errors may be missing. Models 1 and 4 do not have such problems. Variances in these models are always positive and never close to zero.

The heteroscedastic regression model is estimated using the following log-likelihood function:

$$\ell = -\frac{N}{2} \ln(2\pi) - \sum_{i=1}^N \frac{1}{2} \ln(\sigma_i^2) - \frac{1}{2} \sum_{i=1}^N \left(\frac{e_i}{\sigma_i}\right)^2$$

where $e_i = y_i - \mathbf{x}_i' \boldsymbol{\beta}$.

Box-Cox Modeling

The Box-Cox transformation on x is defined as

$$x^{(\lambda)} = \begin{cases} \frac{x^\lambda - 1}{\lambda} & \text{if } \lambda \neq 0 \\ \ln(x) & \text{if } \lambda = 0 \end{cases}$$

The Box-Cox regression model with heteroscedasticity is written as

$$\begin{aligned} y_i^{(\lambda_0)} &= \beta_0 + \sum_{k=1}^K \beta_k x_{ki}^{(\lambda_k)} + \epsilon_i \\ &= \mu_i + \epsilon_i \end{aligned}$$

where $\epsilon_i \sim N(0, \sigma_i^2)$ and transformed variables must be positive. In practice, too many transformation parameters cause numerical problems in model fitting. It is common to have the same Box-Cox transformation performed on all the variables — that is, $\lambda_0 = \lambda_1 = \dots = \lambda_K$. It is required for the magnitude of transformed variables to be in the tolerable range if the corresponding transformation parameters are $|\lambda| > 1$.

The log-likelihood function of the Box-Cox regression model is written as

$$\ell = -\frac{N}{2} \ln(2\pi) - \sum_{i=1}^N \ln(\sigma_i) - \frac{1}{2\sigma_i^2} \sum_{i=1}^N e_i^2 + (\lambda_0 - 1) \sum_{i=1}^N \ln(y_i)$$

where $e_i = y_i^{(\lambda_0)} - \mu_i$.

When the dependent variable is discrete, censored, or truncated, the Box-Cox transformation can be applied only to explanatory variables.

Bivariate Limited Dependent Variable Modeling

The generic form of a bivariate limited dependent variable model is

$$\begin{aligned} y_{1i}^* &= \mathbf{x}_{1i}' \boldsymbol{\beta}_1 + \epsilon_{1i} \\ y_{2i}^* &= \mathbf{x}_{2i}' \boldsymbol{\beta}_2 + \epsilon_{2i} \end{aligned}$$

where the disturbances, ϵ_{1i} and ϵ_{2i} , have joint normal distribution with zero mean, standard deviations σ_1 and σ_2 , and correlation of ρ . y_1^* and y_2^* are latent variables. The dependent variables y_1 and y_2 are observed if the latent variables y_1^* and y_2^* fall in certain ranges:

$$\begin{aligned} y_1 &= y_{1i} \text{ if } y_{1i}^* \in D_1(y_{1i}) \\ y_2 &= y_{2i} \text{ if } y_{2i}^* \in D_2(y_{2i}) \end{aligned}$$

D is a transformation from (y_{1i}^*, y_{2i}^*) to (y_{1i}, y_{2i}) . For example, if y_1 and y_2 are censored variables with lower bound 0, then

$$\begin{aligned} y_1 &= y_{1i} \text{ if } y_{1i}^* > 0, \quad y_1 = 0 \text{ if } y_{1i}^* \leq 0 \\ y_2 &= y_{2i} \text{ if } y_{2i}^* > 0, \quad y_2 = 0 \text{ if } y_{2i}^* \leq 0 \end{aligned}$$

There are three cases for the log likelihood of (y_{1i}, y_{2i}) . The first case is that $y_{1i} = y_{1i}^*$ and $y_{2i} = y_{2i}^*$. That is, this observation is mapped to one point in the space of latent variables. The log likelihood is computed from a bivariate normal density,

$$\ell_i = \ln \left[\phi_2 \left(\frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}, \frac{y_2 - \mathbf{x}_2' \boldsymbol{\beta}_2}{\sigma_2}, \rho \right) \right] - \ln \sigma_1 - \ln \sigma_2$$

where $\phi_2(u, v, \rho)$ is the density function for standardized bivariate normal distribution with correlation ρ ,

$$\phi_2(u, v, \rho) = \frac{e^{-(1/2)(u^2 + v^2 - 2\rho uv)/(1-\rho^2)}}{2\pi(1-\rho^2)^{1/2}}$$

The second case is that one observed dependent variable is mapped to a point of its latent variable and the other dependent variable is mapped to a segment in the space of its latent variable. For example, in the bivariate censored model specified, if observed $y_1 > 0$ and $y_2 = 0$, then $y_1^* = y_1$ and $y_2^* \in (-\infty, 0]$. In general, the log likelihood for one observation can be written as follows (the subscript i is dropped for simplicity): If one set is a single point and the other set is a range, without loss of generality, let $D_1(y_1) = \{y_1\}$ and $D_2(y_2) = [L_2, R_2]$,

$$\begin{aligned} \ell_i = & \ln \left[\phi \left(\frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1} \right) \right] - \ln \sigma_1 \\ & + \ln \left[\Phi \left(\frac{R_2 - \mathbf{x}_2' \boldsymbol{\beta}_2 - \rho \frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}}{\sigma_2} \right) - \Phi \left(\frac{L_2 - \mathbf{x}_2' \boldsymbol{\beta}_2 - \rho \frac{y_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}}{\sigma_2} \right) \right] \end{aligned}$$

where ϕ and Φ are the density function and the cumulative probability function for standardized univariate normal distribution.

The third case is that both dependent variables are mapped to segments in the space of latent variables. For example, in the bivariate censored model specified, if observed $y_1 = 0$ and $y_2 = 0$, then $y_1^* \in (-\infty, 0]$ and $y_2^* \in (-\infty, 0]$. In general, if $D_1(y_1) = [L_1, R_1]$ and $D_2(y_2) = [L_2, R_2]$, the log likelihood is

$$\ell_i = \ln \int_{\frac{L_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}}^{\frac{R_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}} \int_{\frac{L_2 - \mathbf{x}_2' \boldsymbol{\beta}_2}{\sigma_2}}^{\frac{R_2 - \mathbf{x}_2' \boldsymbol{\beta}_2}{\sigma_2}} \phi_2(u, v, \rho) du dv$$

Selection Models

In sample selection models, one or several dependent variables are observed when another variable takes certain values. For example, the standard Heckman selection model can be defined as

$$\begin{aligned} z_i^* &= \mathbf{w}_i' \boldsymbol{\gamma} + u_i \\ z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\ y_i &= \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i \quad \text{if } z_i = 1 \end{aligned}$$

where u_i and ϵ_i are jointly normal with 0 mean, standard deviations of 1 and σ , respectively, and correlation of ρ . Selection is based on the variable z , and y is observed when z has a value of 1. Least squares regression that uses the observed data of y produces inconsistent estimates of $\boldsymbol{\beta}$. The maximum likelihood method is used to estimate selection models. It is also possible to estimate these models by using Heckman's method, which is more computationally efficient. But it can be shown that the resulting estimates, although consistent, are not asymptotically efficient under a normality assumption. Moreover, this method often violates the constraint on the correlation coefficient $|\rho| \leq 1$.

The log-likelihood function of the Heckman selection model is written as

$$\begin{aligned} \ell = & \sum_{i \in \{z_i=0\}} \ln[1 - \Phi(\mathbf{w}_i' \boldsymbol{\gamma})] \\ & + \sum_{i \in \{z_i=1\}} \left\{ \ln \phi \left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma} \right) - \ln \sigma + \ln \Phi \left(\frac{\mathbf{w}_i' \boldsymbol{\gamma} + \rho \frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right\} \end{aligned}$$

The selection can be based on only one variable, but the selection can lead to several variables. For example, selection is based on the variable z in the following switching regression model:

$$\begin{aligned} z_i^* &= \mathbf{w}_i' \boldsymbol{\gamma} + u_i \\ z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\ y_{1i} &= \mathbf{x}_{1i}' \boldsymbol{\beta}_1 + \epsilon_{1i} \quad \text{if } z_i = 0 \\ y_{2i} &= \mathbf{x}_{2i}' \boldsymbol{\beta}_2 + \epsilon_{2i} \quad \text{if } z_i = 1 \end{aligned}$$

If $z = 0$, then y_1 is observed. If $z = 1$, then y_2 is observed. Because y_1 and y_2 are never observed at the same time, the correlation between y_1 and y_2 cannot be estimated. Only the correlation between z and y_1 and the correlation between z and y_2 can be estimated. This estimation uses the maximum likelihood method.

A brief example of the SAS statements for this model can be found in “[Example 22.4: Sample Selection Model](#)” on page 1534.

The Heckman selection model can include censoring or truncation. For a brief example of the SAS statements for these models see “[Example 22.5: Sample Selection Model with Truncation and Censoring](#)” on page 1535. The following example shows a variable y_i that is censored from below at zero:

$$\begin{aligned} z_i^* &= \mathbf{w}_i' \boldsymbol{\gamma} + u_i \\ z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\ y_i^* &= \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i \quad \text{if } z_i = 1 \\ y_i &= \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases} \end{aligned}$$

In this case, the log-likelihood function of the Heckman selection model needs to be modified as follows to include the censored region:

$$\begin{aligned} \ell &= \sum_{\{i|z_i=0\}} \ln[1 - \Phi(\mathbf{w}_i' \boldsymbol{\gamma})] \\ &+ \sum_{\{i|z_i=1, y_i=y_i^*\}} \left\{ \ln \left[\phi \left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma} \right) \right] - \ln \sigma + \ln \left[\Phi \left(\frac{\mathbf{w}_i' \boldsymbol{\gamma} + \rho \frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right] \right\} \\ &+ \sum_{\{i|z_i=1, y_i=0\}} \ln \int_{-\infty}^{\frac{-\mathbf{x}_i' \boldsymbol{\beta}}{\sigma}} \int_{-\mathbf{w}_i' \boldsymbol{\gamma}}^{\infty} \phi_2(u, v, \rho) du dv \end{aligned}$$

In case y_i is truncated from below at 0 instead of censored, the likelihood function can be written as

$$\begin{aligned} \ell &= \sum_{\{i|z_i=0\}} \ln[1 - \Phi(\mathbf{w}_i' \boldsymbol{\gamma})] \\ &+ \sum_{\{i|z_i=1\}} \left\{ \ln \left[\phi \left(\frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma} \right) \right] - \ln \sigma + \ln \left[\Phi \left(\frac{\mathbf{w}_i' \boldsymbol{\gamma} + \rho \frac{y_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma}}{\sqrt{1 - \rho^2}} \right) \right] - \ln [\Phi(\mathbf{x}_i' \boldsymbol{\beta} / \sigma)] \right\} \end{aligned}$$

Heckman's Two-Step Selection Method

Sample selection bias arises from nonrandom selection of the sample from the population. A classic example is using a sample of market wages for working women to estimate female labor supply function. This sample is nonrandom because it includes only the wages of women whose market wage exceeds their home wage at zero hours of work.

A simple selection model can be written as the latent model

$$\begin{aligned} z_i^* &= \mathbf{w}_i' \boldsymbol{\gamma} + u_i \\ z_i &= \begin{cases} 1 & \text{if } z_i^* > 0 \\ 0 & \text{if } z_i^* \leq 0 \end{cases} \\ y_i &= \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i \quad \text{if } z_i = 1 \end{aligned}$$

where u_i and ϵ_i are jointly normal with 0 mean, standard deviations of 1 and σ , respectively, and correlation of ρ . The dependent variable y_i (wage) is observed if the latent variable z_i^* (the difference between market wage and reservation wage) is positive or if the indicator variable z_i (labor force participation) is 1.

The model of interest that applies to the observations in the selected sample can be written as

$$E(y_i | \mathbf{x}_i, z_i = 1) = \mathbf{x}_i' \boldsymbol{\beta} + \rho\sigma\lambda(\mathbf{w}_i' \boldsymbol{\gamma})$$

where $\lambda(\mathbf{w}_i' \boldsymbol{\gamma}) = \phi(\mathbf{w}_i' \boldsymbol{\gamma}) / \Phi(\mathbf{w}_i' \boldsymbol{\gamma})$. Hence, the following regression equation is valid for the observations for which $z_i = 1$:

$$y_i = \mathbf{x}_i' \boldsymbol{\beta} + \rho\sigma\lambda(\mathbf{w}_i' \boldsymbol{\gamma}) + v_i$$

Therefore, estimates of $\boldsymbol{\beta}$ that are obtained from the OLS regression of y on \mathbf{x} by using the selected sample (that is, the sample for which $z_i = 1$) suffer from omitted variable bias if selection bias is really the case. Although maximum likelihood estimation of $\boldsymbol{\beta}$ is consistent and efficient, Heckman's two-step method is more frequently used. Heckman's two-step method can be requested by specifying the HECKIT option of the QLIM statement.

Heckman's two-step method is as follows:

1. Obtain $\hat{\boldsymbol{\gamma}}$, the estimate of the parameters of the probability that $z_i^* > 0$, by using regressors \mathbf{w}_i and the binary dependent variable z_i by probit analysis for the full sample. Compute $\hat{\lambda}_i = \lambda(\mathbf{w}_i' \hat{\boldsymbol{\gamma}})$.
2. Obtain $\hat{\boldsymbol{\beta}}$ and $\hat{\beta}_\lambda$, the estimates of $\boldsymbol{\beta}$ and $\rho\sigma$, by least squares regression of y_i on \mathbf{x}_i and $\hat{\lambda}_i$ by using observations on the selected subsample.

The standard least squares estimators of the population variance σ^2 and the variances of the estimated coefficients are incorrect. To test hypotheses, the correct ones need to be calculated. An estimator of σ^2 is

$$\hat{\sigma}^2 = \frac{1}{N_1} \sum_{i=1}^{N_1} e_i^2 + \hat{\beta}_\lambda^2 \frac{1}{N_1} \sum_{i=1}^{N_1} \hat{\delta}_i$$

where N_1 is the selected subsample size, e_i is the residual for the i th observation obtained from step 2, and $\hat{\delta}_i = \hat{\lambda}_i^2 + \hat{\lambda}_i \mathbf{w}_i' \hat{\boldsymbol{\gamma}}$. Let \mathbf{X}_* be an $N_1 \times (K + 1)$ matrix with i th row $[\mathbf{x}_i' \quad \lambda_i]$, and define \mathbf{W} similarly with i th row \mathbf{w}_i' . Then the estimator of the asymptotic covariance of $[\hat{\boldsymbol{\beta}}, \hat{\beta}_\lambda]$ is

$$\text{EstAsyVar}[\hat{\boldsymbol{\beta}}, \hat{\beta}_\lambda] = \hat{\sigma}^2 [\mathbf{X}_*' \mathbf{X}_*]^{-1} [\mathbf{X}_*' (\mathbf{I} - \hat{\rho}^2 \hat{\boldsymbol{\Delta}}) \mathbf{X}_* + \mathbf{Q}] [\mathbf{X}_*' \mathbf{X}_*]^{-1}$$

where $\hat{\rho}^2 = \hat{\beta}_\lambda^2 / \hat{\sigma}^2$, $\hat{\mathbf{A}} = \text{diag}(\hat{\delta}_i)$, and

$$\mathbf{Q} = \hat{\sigma}^2 (\mathbf{X}'_* \hat{\mathbf{A}} \mathbf{W}) \text{Est.Asy.Var}(\hat{\boldsymbol{\gamma}}) (\mathbf{W}' \hat{\mathbf{A}} \mathbf{X}_*)$$

where $\text{EstAsyVar}(\hat{\boldsymbol{\gamma}})$ is the estimator of the asymptotic covariance of the probit coefficients that are obtained in step 1. With the HECKIT option, a numerical estimated asymptotic variance is used.

In the selected regression model, when the coefficient of $\lambda(\mathbf{w}'_i \boldsymbol{\gamma})$ is zero, there is no need for Heckman's two-step estimation method; a simple regression of y on \mathbf{x} produces consistent estimates for $\boldsymbol{\beta}$, and the OLS standard errors are correct. Thus, a standard t test on $\hat{\beta}_\lambda$ (using the estimate from step 2 and the uncorrected standard errors) is a valid test of the null hypothesis of no selection bias.

Multivariate Limited Dependent Models

The multivariate model is similar to bivariate models. The generic form of the multivariate limited dependent variable model is

$$\begin{aligned} y_{1i}^* &= \mathbf{x}'_{1i} \boldsymbol{\beta}_1 + \epsilon_{1i} \\ y_{2i}^* &= \mathbf{x}'_{2i} \boldsymbol{\beta}_2 + \epsilon_{2i} \\ &\dots \\ y_{mi}^* &= \mathbf{x}'_{mi} \boldsymbol{\beta}_m + \epsilon_{mi} \end{aligned}$$

where m is the number of models to be estimated. The vector ϵ has multivariate normal distribution with mean 0 and variance-covariance matrix Σ . Similar to bivariate models, the likelihood may involve computing multivariate normal integrations. This is done using Monte Carlo integration. (See Genz (1992) and Hajivassiliou and McFadden (1998).)

When the number of equations, N , increases in a system, the number of parameters increases at the rate of N^2 because of the correlation matrix. When the number of parameters is large, sometimes the optimization converges but some of the standard deviations are missing. This usually means that the model is over-parameterized. The default method for computing the covariance is to use the inverse Hessian matrix. The Hessian is computed by finite differences, and in over-parameterized cases, the inverse cannot be computed. It is recommended that you reduce the number of parameters in such cases. Sometimes using the outer product covariance matrix (COVEST=OP option) may also help.

Variable Selection

Variable Selection

Variable selection uses either Akaike's information criterion (AIC) or the Schwartz Bayesian criterion (SBC) and either a forward selection method or a backward elimination method.

Forward selection starts from a small subset of variables. In each step, the variable that gives the largest decrease in the value of the information criterion specified in the CRITER= option (AIC or SBC) is added. The process stops when the next candidate to be added does not reduce the value of the information criterion by more than the amount specified in the LSTOP= option in the MODEL statement.

Backward elimination starts from a larger subset of variables. In each step, one variable is dropped based on the information criterion that is chosen.

Tests on Parameters

Tests on Parameters

In general, the hypothesis tested can be written as

$$H_0 : \mathbf{h}(\theta) = 0$$

where $\mathbf{h}(\theta)$ is an r by 1 vector valued function of the parameters θ given by the r expressions specified in the TEST statement.

Let \hat{V} be the estimate of the covariance matrix of $\hat{\theta}$. Let $\hat{\theta}$ be the unconstrained estimate of θ and $\tilde{\theta}$ be the constrained estimate of θ such that $\mathbf{h}(\tilde{\theta}) = 0$. Let

$$A(\theta) = \partial \mathbf{h}(\theta) / \partial \theta \big|_{\hat{\theta}}$$

Using this notation, the test statistics for the three kinds of tests are computed as follows.

The Wald test statistic is defined as

$$W = \mathbf{h}'(\hat{\theta}) \left(A(\hat{\theta}) \hat{V} A'(\hat{\theta}) \right)^{-1} \mathbf{h}(\hat{\theta})$$

The Wald test is not invariant to reparameterization of the model (Gregory 1985; Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

The Lagrange multiplier test statistic is

$$LM = \lambda' A(\tilde{\theta}) \tilde{V} A'(\tilde{\theta}) \lambda$$

where λ is the vector of Lagrange multipliers from the computation of the restricted estimate $\tilde{\theta}$.

The likelihood ratio test statistic is

$$LR = 2 \left(L(\hat{\theta}) - L(\tilde{\theta}) \right)$$

where $\tilde{\theta}$ represents the constrained estimate of θ and L is the concentrated log-likelihood value.

For each kind of test, under the null hypothesis the test statistic is asymptotically distributed as a χ^2 random variable with r degrees of freedom, where r is the number of expressions in the TEST statement. The p -values reported for the tests are computed from the $\chi^2(r)$ distribution and are only asymptotically valid.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation to its small sample distribution than that of the other two tests. However, the Wald test has the lowest computational cost, since it does not require computation of the constrained estimate $\tilde{\theta}$.

The following is an example of using the TEST statement to perform a likelihood ratio test:

```
proc qlim;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0 /lr;
run;
```

Bayesian Analysis

To perform Bayesian analysis, you must specify a BAYES statement. Unless otherwise stated, all options in this section are options in the BAYES statement.

By default, PROC QLIM uses the random walk Metropolis algorithm to obtain posterior samples. For the implementation details of the Metropolis algorithm in PROC QLIM, such as the blocking of the parameters and tuning of the covariance matrices, see the sections “[Blocking of Parameters](#)” on page 1513 and “[Tuning the Proposal Distribution](#)” on page 1513.

The Bayes theorem states that

$$p(\theta|\mathbf{y}) \propto \pi(\theta)L(\mathbf{y}|\theta)$$

where θ is a parameter or a vector of parameters and $\pi(\theta)$ is the product of the prior densities that are specified in the [PRIOR](#) statement. The term $L(\mathbf{y}|\theta)$ is the likelihood associated with the [MODEL](#) statement.

Blocking of Parameters

In a multivariate parameter model, all the parameters are updated in one single block (by default or when you specify the `SAMPLING=MULTIMETROPOLIS` option). This could be inefficient, especially when parameters have vastly different scales. As an alternative, you could update the parameters one at the time (by specifying `SAMPLING=UNIMETROPOLIS`).

Tuning the Proposal Distribution

One key factor in achieving high efficiency of a Metropolis-based Markov chain is finding a good proposal distribution for each block of parameters. This process is called tuning. The tuning phase consists of a number of loops controlled by the options `MINTUNE` and `MAXTUNE`. The `MINTUNE=` option controls the minimum number of tuning loops and has a default value of 2. The `MAXTUNE=` option controls the maximum number of tuning loops and has a default value of 24. Each loop is iterated the number of times specified by the `NTU=` option, which has a default of 500. At the end of every loop, PROC QLIM examines the acceptance probability for each block. The acceptance probability is the percentage of NTU proposed values that have been accepted. If this probability does not fall within the acceptance tolerance range (see the following section), the proposal distribution is modified before the next tuning loop.

A good proposal distribution should resemble the actual posterior distribution of the parameters. Large sample theory states that the posterior distribution of the parameters approaches a multivariate normal distribution (see Gelman et al. 2004, Appendix B; Schervish 1995, Section 7.4). That is why a normal proposal distribution often works well in practice. The default proposal distribution in PROC QLIM is the normal distribution.

Scale Tuning

The acceptance rate is closely related to the sampling efficiency of a Metropolis chain. For a random walk Metropolis, a high acceptance rate means that most new samples occur right around the current data point. Their frequent acceptance means that the Markov chain is moving rather slowly and not exploring the parameter space fully. A low acceptance rate means that the proposed samples are often rejected; hence the chain is not moving much. An efficient Metropolis sampler has an acceptance rate that is neither too high nor too low. The scale c in the proposal distribution $q(\cdot|\cdot)$ effectively controls this acceptance probability.

Roberts, Gelman, and Gilks (1997) show that if both the target and proposal densities are normal, the optimal acceptance probability for the Markov chain should be around 0.45 in a one-dimension problem and should asymptotically approach 0.234 in higher-dimension problems. The corresponding optimal scale is 2.38, which is the initial scale that is set for each block.

Because of the nature of stochastic simulations, it is impossible to fine-tune a set of variables so that the Metropolis chain has exactly the desired acceptance rate that you want. In addition, Roberts and Rosenthal (2001) empirically demonstrate that an acceptance rate between 0.15 and 0.5 is at least 80% efficient, so there is really no need to fine-tune the algorithms to reach an acceptance probability that is within a small tolerance of the optimal values. PROC QLIM works with a probability range, determined by $\text{TargetAcceptance} \pm 0.075$. If the observed acceptance rate in a given tuning loop is less than the lower bound of the range, the scale is reduced; if the observed acceptance rate is greater than the upper bound of the range, the scale is increased. During the tuning phase, a scale parameter in the normal distribution is adjusted as a function of the observed acceptance rate and the target acceptance rate. PROC QLIM uses the following updating scheme:¹

$$c_{\text{new}} = \frac{c_{\text{cur}} \cdot \Phi^{-1}(p_{\text{opt}}/2)}{\Phi^{-1}(p_{\text{cur}}/2)}$$

where c_{cur} is the current scale, p_{cur} is the current acceptance rate, and p_{opt} is the optimal acceptance probability.

Covariance Tuning

To tune a covariance matrix, PROC QLIM takes a weighted average of the old proposal covariance matrix and the recent observed covariance matrix, based on the number samples (as specified by the NTU= option) NTU samples in the current loop. The formula to update the covariance matrix is:

$$\text{COV}_{\text{new}} = 0.75 \text{COV}_{\text{cur}} + 0.25 \text{COV}_{\text{old}}$$

There are two ways to initialize the covariance matrix:

- The default is an identity matrix that is multiplied by the initial scale of 2.38 and divided by the square root of the number of estimated parameters in the model. A number of tuning phases might be required before the proposal distribution is tuned to its optimal stage, because the Markov chain needs to spend time to learn about the posterior covariance structure. If the posterior variances of your parameters vary by more than a few orders of magnitude, if the variances of your parameters are much different from 1, or if the posterior correlations are high, then the proposal tuning algorithm might have difficulty forming an acceptable proposal distribution.
- Alternatively, you can use a numerical optimization routine, such as the quasi-Newton method, to find a starting covariance matrix. The optimization is performed on the joint posterior distribution, and the covariance matrix is a quadratic approximation at the posterior mode. In some cases this is a better and more efficient way of initializing the covariance matrix. However, there are cases, such as when the number of parameters is large, where the optimization could fail to find a matrix that is positive definite. In those cases, the tuning covariance matrix is reset to the identity matrix.

¹ Roberts, Gelman, and Gilks (1997) and Roberts and Rosenthal (2001) demonstrate that the relationship between acceptance probability and scale in a random walk Metropolis scheme is $p = 2\Phi\left(-\sqrt{I}c/2\right)$, where c is the scale, p is the acceptance rate, Φ is the CDF of a standard normal, and $I \equiv E_f[(f'(x)/f(x))^2]$, $f(x)$ is the density function of samples. This relationship determines the updating scheme, with I replaced by the identity matrix to simplify calculation.

A by-product of the optimization routine is that it also finds the maximum a posteriori (MAP) estimates with respect to the posterior distribution. The MAP estimates are used as the initial values of the Markov chain.

For more information, see the section “[INIT Statement](#)” on page 1490.

Initial Values of the Markov Chains

You can assign initial values to any parameters. See the [INIT](#) statement for more details. If you use the optimization [PROPCOV=](#) option, PROC QLIM starts the tuning at the optimized values. This option overwrites the provided initial values.

Prior Distributions

The PRIOR statement is used to specify the prior distribution of the model parameters. You must specify a list of parameters, a tilde (~), and then a distribution with its parameters. You can specify multiple [PRIOR](#) statements to define independent priors. Parameters that are associated with a regressor variable are referred to by the name of the corresponding regressor variable.

You can specify the special keyword `_REGRESSORS` to consider all the regressors of a model. If multiple prior statements affect the same parameter, the prior that is specified is used. For example, in a regression with three regressors (X1, X2, X3) the following statements imply that the prior on X1 is `NORMAL(MEAN=0, VAR=1)`, the prior on X2 is `GAMMA(SHAPE=3, SCALE=4)`, and the prior on X3 is `UNIFORM(MIN=0, MAX=1)`:

```
...
prior _Regressors ~ uniform(min=0, max=1);
prior X1 X2 ~ gamma(shape=3, scale=4);
prior X1 ~ normal(mean=0, var=1);
...
```

If a parameter is not associated with a [PRIOR](#) statement or if some of the prior hyperparameters are missing, then the following default choices are considered:

Table 22.2 Default values for prior distributions.

PRIOR <i>distribution</i>	Hyperparameter ₁	Hyperparameter ₂	Min	Max	Parameters Default Choice
NORMAL	MEAN=0	VAR=1E6	$-\infty$	∞	Regression-Location-Threshold Scale
IGAMMA	SHAPE=2.000001	SCALE=1	> 0	∞	
GAMMA	SHAPE=1	SCALE=1	0	∞	
UNIFORM			$-\infty$	∞	
BETA	SHAPE1=1	SHAPE2=1	$-\infty$	∞	
T	LOCATION=0	DF=3	$-\infty$	∞	

See the section “[Standard Distributions](#)” on page 1517 for density specification.

Priors for Heteroscedastic Models

The choice of the prior distribution for a heteroscedastic model is particularly interesting. Based on the notation provided in section “**HETERO Statement**” on page 1489, you need to provide a prior for $\boldsymbol{\gamma}$. This prior is enough to induce different σ_i^2 into the analysis. The resulting inference is a compromise between two cases: the inference based on the entire sample and the inference based on a single unit \mathbf{z}_i . The degree of compromise is determined by $\pi(\boldsymbol{\gamma})$.

This type of modeling is similar to a method called “hierarchical Bayes,” in which the prior is characterized by two levels: one for each individual $\pi(\sigma_i^2|\boldsymbol{\gamma})$ and one for the entire population $\pi(\boldsymbol{\gamma})$. In this scenario the degree of compromise between the information provided by a unit and the information provided by the entire sample is determined by the data.

The choice of the prior might not be straightforward, and it can heavily affect sampling performance. Depending on how the heteroscedastic effects are modeled, the default priors are

$$\begin{aligned} \text{if } [1 + \exp(\mathbf{z}'_i \boldsymbol{\gamma})], \quad \pi(\gamma_j) &= \text{normal} \left\{ \text{mean} = \frac{1}{\bar{z}_j J} \left[\log \left(\frac{\varepsilon^4}{1 + \varepsilon^2} \right) \right], \text{var} = \frac{1}{\bar{z}_j^2 J} \left[\log \left(\frac{1 + \varepsilon^2}{\varepsilon^2} \right) \right] \right\} \\ \text{if } [\exp(\mathbf{z}'_i \boldsymbol{\gamma})], \quad \pi(\gamma_j) &= \text{normal} \left\{ \text{mean} = \frac{1}{\bar{z}_j J} \left[\log \left(\frac{1}{2} \right) \right], \text{var} = \frac{1}{\bar{z}_j^2 J} [\log(2)] \right\} \\ \text{if } (1 + \mathbf{z}'_i \boldsymbol{\gamma}), \quad \pi(\gamma_j) &= \text{normal} \left\{ \text{mean} = 0, \text{var} = \frac{1}{\bar{z}_j^2 J} \right\} \\ \text{if } (\mathbf{z}'_i \boldsymbol{\gamma}), \quad \pi(\gamma_j) &= \text{normal} \left\{ \text{mean} = \frac{1}{\bar{z}_j J}, \text{var} = \frac{1}{\bar{z}_j^2 J} \right\} \\ \text{if } [1 + (\mathbf{z}'_i \boldsymbol{\gamma})^2], \quad \pi(\gamma_j) &= \text{normal} \left\{ \text{mean} = \frac{(\varepsilon^2 - 1/2)^{1/4}}{\bar{z}_j J}, \text{var} = \frac{\varepsilon - (\varepsilon^2 - 1/2)^{1/2}}{\bar{z}_j^2 J} \right\} \\ \text{if } [(\mathbf{z}'_i \boldsymbol{\gamma})^2], \quad \pi(\gamma_j) &= \text{normal} \left\{ \text{mean} = \frac{(1/2)^{1/4}}{\bar{z}_j J}, \text{var} = \frac{1 - (1/2)^{1/2}}{\bar{z}_j^2 J} \right\} \end{aligned}$$

where $\bar{z}_j = \frac{1}{n} \sum_{i=1}^n z_{ij}$, $\forall j$, and ε is a small number (by default, $\varepsilon = 0.1$ for the EXPONENTIAL link function and $\varepsilon = 0.71$ for the QUADRATIC link function).

The priors for the EXPONENTIAL and QUADRATIC link functions are not straightforward. To understand the choices, do the following:

1. Assume that

$$\mathbf{z}'_i \boldsymbol{\gamma} = z_{i1}\gamma_1 + \dots + z_{iJ}\gamma_J \approx \bar{z}_1\gamma_1 + \dots + \bar{z}_J\gamma_J, \quad \forall i$$

2. Set the priors according to the link function type:

- For the EXPONENTIAL link function, set

$$\begin{aligned} \text{E}[\exp(\mathbf{z}'_i \boldsymbol{\gamma})] &\approx \text{E}[\exp(\bar{z}_1\gamma_1)] \times \dots \times \text{E}[\exp(\bar{z}_J\gamma_J)] = \varepsilon \\ \text{V}[\exp(\mathbf{z}'_i \boldsymbol{\gamma})] &\approx \text{E}[\exp(2\bar{z}_1\gamma_1)] \times \dots \times \text{E}[\exp(2\bar{z}_J\gamma_J)] - \varepsilon^2 = 1 \end{aligned}$$

Assume a normal prior for $\pi(\gamma_j)$, and set

$$\begin{aligned} E[\exp(\bar{z}_j \gamma_j)] &= \varepsilon^{\frac{1}{J}}, \forall j \\ E[\exp(2\bar{z}_j \gamma_j)] &= (1 + \varepsilon^2)^{\frac{1}{J}}, \forall j \end{aligned}$$

Based on the properties of the lognormal distribution, the prior hyperparameters for γ_j can be derived. Notice that J is the number of regressors that are used in the heterogeneous regression. If the intercept is excluded, then $\varepsilon = 1$.

- For the QUADRATIC link function, set

$$\begin{aligned} E[(\mathbf{z}'_i \boldsymbol{\gamma})^2] &\approx [E(\bar{z}_1 \gamma_1 + \dots + \bar{z}_J \gamma_J)]^2 + V[\bar{z}_1 \gamma_1 + \dots + \bar{z}_J \gamma_J] = \varepsilon \\ V[\exp(\mathbf{z}'_i \boldsymbol{\gamma})] &\approx E[(\bar{z}_1 \gamma_1 + \dots + \bar{z}_J \gamma_J)^4] - \varepsilon^2 = 1 \end{aligned}$$

Assume a normal prior for $\pi(\gamma_j)$. Based on the properties of the normal distribution, the preceding expressions return

$$\begin{aligned} E[\bar{z}_1 \gamma_1 + \dots + \bar{z}_J \gamma_J] &= (\varepsilon^2 - 1/2)^{1/4} \\ V[\bar{z}_1 \gamma_1 + \dots + \bar{z}_J \gamma_J] &= \varepsilon - (\varepsilon^2 - 1/2)^{1/2} \\ \varepsilon &> (1/2)^{1/2} \end{aligned}$$

The prior hyperparameters for γ_j can be derived by setting

$$\begin{aligned} E[\bar{z}_j \gamma_j] &= \frac{(\varepsilon^2 - 1/2)^{1/4}}{J}, \forall j \\ V[\bar{z}_j \gamma_j] &= \frac{\varepsilon - (\varepsilon^2 - 1/2)^{1/2}}{J}, \forall j \end{aligned}$$

Notice that J is the number of regressors that are used in the heterogeneous regression. If the intercept is excluded, then $\varepsilon = 1$. It is important to emphasize that the restriction $\varepsilon > (1/2)^{1/2}$ is likely to introduce some distortion because ε cannot be any “small” number.

Standard Distributions

Table 22.3 through Table 22.8 show all the distribution density functions that PROC QLIM recognizes. You specify these distribution densities in the **PRIOR** statement.

Table 22.3 Beta Distribution

PRIOR statement	BETA(SHAPE1= a , SHAPE2= b , MIN= m , MAX= M)
	Note: Commonly $m = 0$ and $M = 1$.
Density	$\frac{(\theta - m)^{a-1} (M - \theta)^{b-1}}{B(a, b) (M - m)^{a+b-1}}$
Parameter restriction	$a > 0, \quad b > 0, \quad -\infty < m < M < \infty$
Range	$\begin{cases} [m, M] & \text{when } a = 1, b = 1 \\ [m, M) & \text{when } a = 1, b \neq 1 \\ (m, M] & \text{when } a \neq 1, b = 1 \\ (m, M) & \text{otherwise} \end{cases}$
Mean	$\frac{a}{a+b} \times (M - m) + m$

Variance	$\frac{ab}{(a+b)^2(a+b+1)} \times (M - m)^2$
Mode	$\begin{cases} \frac{a-1}{a+b-2} \times M + \frac{b-1}{a+b-2} \times m & a > 1, b > 1 \\ m \text{ and } M & a < 1, b < 1 \\ m & \begin{cases} a < 1, b \geq 1 \\ a = 1, b > 1 \end{cases} \\ M & \begin{cases} a \geq 1, b < 1 \\ a > 1, b = 1 \end{cases} \\ \text{not unique} & a = b = 1 \end{cases}$
Defaults	SHAPE1=SHAPE2=1, MIN $\rightarrow -\infty$, MAX $\rightarrow \infty$

Table 22.4 Gamma Distribution

PRIOR statement	GAMMA(SHAPE= a , SCALE= b)
Density	$\frac{1}{b^a \Gamma(a)} \theta^{a-1} e^{-\theta/b}$
Parameter restriction	$a > 0, b > 0$
Range	$[0, \infty)$
Mean	ab
Variance	ab^2
Mode	$(a - 1)b$
Defaults	SHAPE=SCALE=1

Table 22.5 Inverse-Gamma Distribution

PRIOR statement	IGAMMA(SHAPE= a , SCALE= b)
Density	$\frac{b^a}{\Gamma(a)} \theta^{-(a+1)} e^{-b/\theta}$
Parameter restriction	$a > 0, b > 0$
Range	$0 < \theta < \infty$
Mean	$\frac{b}{a-1}, \quad a > 1$
Variance	$\frac{b^2}{(a-1)^2(a-2)}, \quad a > 2$
Mode	$\frac{b}{a+1}$
Defaults	SHAPE=2.000001, SCALE=1

Table 22.6 Normal Distribution

PRIOR statement	NORMAL(MEAN= μ , VAR= σ^2)
Density	$\frac{1}{\sigma \sqrt{2\pi}} \exp\left(-\frac{(\theta-\mu)^2}{2\sigma^2}\right)$
Parameter restriction	$\sigma^2 > 0$

Range	$-\infty < \theta < \infty$
Mean	μ
Variance	σ^2
Mode	μ
Defaults	MEAN=0, VAR=1000000

Table 22.7 *t* Distribution

PRIOR statement	T(LOCATION= μ , DF= ν)
Density	$\frac{\Gamma(\frac{\nu+1}{2})}{\Gamma(\frac{\nu}{2})\sqrt{\pi\nu}} \left[1 + \frac{(\theta-\mu)^2}{\nu} \right]^{-\frac{\nu+1}{2}}$
Parameter restriction	$\nu > 0$
Range	$-\infty < \theta < \infty$
Mean	μ , for $\nu > 1$
Variance	$\frac{\nu}{\nu-2}$, for $\nu > 2$
Mode	μ
Defaults	LOCATION=0, DF=3

Table 22.8 Uniform Distribution

PRIOR statement	UNIFORM(MIN= m , MAX= M)
Density	$\frac{1}{M-m}$
Parameter restriction	$-\infty < m < M < \infty$
Range	$\theta \in [m, M]$
Mean	$\frac{m+M}{2}$
Variance	$\frac{(M-m)^2}{12}$
Mode	Not unique
Defaults	MIN $\rightarrow -\infty$, MAX $\rightarrow \infty$

Output to SAS Data Set

XBeta, Predicted, Residual

Xbeta is the structural part on the right-hand side of the model. Predicted value is the predicted dependent variable value. For censored variables, if the predicted value is outside the boundaries, it is reported as the closest boundary. For discrete variables, it is the level whose boundaries Xbeta falls between. Residual is defined only for continuous variables and is defined as

$$\text{Residual} = \text{Observed} - \text{Predicted}$$

Error Standard Deviation

Error standard deviation is σ_i in the model. It varies only when the HETERO statement is used.

Marginal Effects

Marginal effect is defined as a contribution of one control variable to the response variable. For the binary choice model with two response categories, $\mu_0 = -\infty$, $\mu_1 = 0$, $\mu_0 = -\infty$; and ordinal response model with M response categories, μ_0, \dots, μ_M , define

$$R_{i,j} = \mu_j - \mathbf{x}_i' \boldsymbol{\beta}$$

The probability that the unobserved dependent variable is contained in the j th category can be written as

$$P[\mu_{j-1} < y_i^* \leq \mu_j] = F(R_{i,j}) - F(R_{i,j-1})$$

The marginal effect of changes in the regressors on the probability of $y_i = j$ is then

$$\frac{\partial \text{Prob}[y_i = j]}{\partial \mathbf{x}} = [f(\mu_{j-1} - \mathbf{x}_i' \boldsymbol{\beta}) - f(\mu_j - \mathbf{x}_i' \boldsymbol{\beta})] \boldsymbol{\beta}$$

where $f(x) = \frac{dF(x)}{dx}$. In particular,

$$f(x) = \frac{dF(x)}{dx} = \begin{cases} \frac{1}{\sqrt{2\pi}} e^{-x^2/2} & (\text{probit}) \\ \frac{e^{-x}}{[1+e^{(-x)}]^2} & (\text{logit}) \end{cases}$$

The marginal effects in the Box-Cox regression model are

$$\frac{\partial E[y_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \frac{x^{\lambda_k - 1}}{y^{\lambda_0 - 1}}$$

The marginal effects in the truncated regression model are

$$\frac{\partial E[y_i | L_i < y_i^* < R_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \left[1 - \frac{(\phi(a_i) - \phi(b_i))^2}{(\Phi(b_i) - \Phi(a_i))^2} + \frac{a_i \phi(a_i) - b_i \phi(b_i)}{\Phi(b_i) - \Phi(a_i)} \right]$$

where $a_i = \frac{L_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$ and $b_i = \frac{R_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$.

The marginal effects in the censored regression model are

$$\frac{\partial E[y | \mathbf{x}_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \times \text{Prob}[L_i < y_i^* < R_i]$$

Inverse Mills Ratio, Expected and Conditionally Expected Values

Expected and conditionally expected values are computed only for continuous variables. The inverse Mills ratio is computed for censored or truncated continuous, binary discrete, and selection endogenous variables.

Let L_i and R_i be the lower boundary and upper boundary, respectively, for the y_i . Define $a_i = \frac{L_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$ and $b_i = \frac{R_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$. Then the inverse Mills ratio is defined as

$$\lambda = \frac{(\phi(a_i) - \phi(b_i))}{(\Phi(b_i) - \Phi(a_i))}$$

for a continuous variable and defined as

$$\lambda = \frac{\phi(\mathbf{x}_i' \boldsymbol{\beta})}{\Phi(\mathbf{x}_i' \boldsymbol{\beta})}$$

for a binary discrete variable.

The expected value is the unconditional expectation of the dependent variable. For a censored variable, it is

$$E[y_i] = \Phi(a_i)L_i + (\mathbf{x}_i' \boldsymbol{\beta} + \lambda \sigma_i)(\Phi(b_i) - \Phi(a_i)) + (1 - \Phi(b_i))R_i$$

For a left-censored variable ($R_i = \infty$), this formula is

$$E[y_i] = \Phi(a_i)L_i + (\mathbf{x}_i' \boldsymbol{\beta} + \lambda \sigma_i)(1 - \Phi(a_i))$$

where $\lambda = \frac{\phi(a_i)}{1 - \Phi(a_i)}$.

For a right-censored variable ($L_i = -\infty$), this formula is

$$E[y_i] = (\mathbf{x}_i' \boldsymbol{\beta} + \lambda \sigma_i)\Phi(b_i) + (1 - \Phi(b_i))R_i$$

where $\lambda = -\frac{\phi(b_i)}{\Phi(b_i)}$.

For a noncensored variable, this formula is

$$E[y_i] = \mathbf{x}_i' \boldsymbol{\beta}$$

The conditional expected value is the expectation given that the variable is inside the boundaries:

$$E[y_i | L_i < y_i < R_i] = \mathbf{x}_i' \boldsymbol{\beta} + \lambda \sigma_i$$

Probability

Probability applies only to discrete responses. It is the marginal probability that the discrete response is taking the value of the observation. If the PROBALL option is specified, then the probability for all of the possible responses of the discrete variables is computed.

Technical Efficiency

Technical efficiency for each producer is computed only for stochastic frontier models.

In general, the stochastic production frontier can be written as

$$y_i = f(x_i; \boldsymbol{\beta}) \exp\{v_i\} TE_i$$

where y_i denotes producer i 's actual output, $f(\cdot)$ is the deterministic part of production frontier, $\exp\{v_i\}$ is a producer-specific error term, and TE_i is the technical efficiency coefficient, which can be written as

$$TE_i = \frac{y_i}{f(x_i; \boldsymbol{\beta}) \exp\{v_i\}}.$$

In the case of a Cobb-Douglas production function, $TE_i = \exp\{-u_i\}$. See the section “[Stochastic Frontier Production and Cost Models](#)” on page 1503.

Cost frontier can be written in general as

$$E_i = c(y_i, w_i; \beta) \exp\{v_i\} / CE_i$$

where w_i denotes producer i 's input prices, $c(\cdot)$ is the deterministic part of cost frontier, $\exp\{v_i\}$ is a producer-specific error term, and CE_i is the cost efficiency coefficient, which can be written as

$$CE_i = \frac{c(x_i, w_i; \beta) \exp\{v_i\}}{E_i}$$

In the case of a Cobb-Douglas cost function, $CE_i = \exp\{-u_i\}$. See the section “[Stochastic Frontier Production and Cost Models](#)” on page 1503. Hence, both technical and cost efficiency coefficients are the same. The estimates of technical efficiency are provided in the following subsections.

Normal-Half Normal Model

Define $\mu_* = -\epsilon\sigma_u^2/\sigma^2$ and $\sigma_*^2 = \sigma_u^2\sigma_v^2/\sigma^2$. Then, as it is shown by Jondrow et al. (1982), conditional density is as follows:

$$f(u|\epsilon) = \frac{f(u, \epsilon)}{f(\epsilon)} = \frac{1}{\sqrt{2\pi}\sigma_*} \exp\left\{-\frac{(u - \mu_*)^2}{2\sigma_*^2}\right\} \Bigg/ \left[1 - \Phi\left(-\frac{\mu_*}{\sigma_*}\right)\right]$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\mu_*, \sigma_*^2)$.

Using this result, it follows that the estimate of technical efficiency (Battese and Coelli, 1988) is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \left[\frac{1 - \Phi(\sigma_* - \mu_{*i}/\sigma_*)}{1 - \Phi(-\mu_{*i}/\sigma_*)}\right] \exp\left\{-\mu_{*i} + \frac{1}{2}\sigma_*^2\right\}$$

The second version of the estimate (Jondrow et al., 1982) is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \mu_{*i} + \sigma_* \left[\frac{\phi(-\mu_{*i}/\sigma_*)}{1 - \Phi(-\mu_{*i}/\sigma_*)} \right] = \sigma_* \left[\frac{\phi(\epsilon_i\lambda/\sigma)}{1 - \Phi(\epsilon_i\lambda/\sigma)} - \left(\frac{\epsilon_i\lambda}{\sigma}\right) \right]$$

Normal-Exponential Model

Define $A = -\tilde{\mu}/\sigma_v$ and $\tilde{\mu} = -\epsilon - \sigma_v^2/\sigma_u$. Then, as it is shown by Kumbhakar and Lovell (2000), conditional density is as follows:

$$f(u|\epsilon) = \frac{1}{\sqrt{2\pi}\sigma_v\Phi(-\tilde{\mu}/\sigma_v)} \exp\left\{-\frac{(u - \tilde{\mu})^2}{2\sigma^2}\right\}$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\tilde{\mu}, \sigma_v^2)$.

Using this result, it follows that the estimate of technical efficiency is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \left[\frac{1 - \Phi(\sigma_v - \tilde{\mu}_i/\sigma_v)}{1 - \Phi(-\tilde{\mu}_i/\sigma_v)}\right] \exp\left\{-\tilde{\mu}_i + \frac{1}{2}\sigma_v^2\right\}$$

The second version of the estimate is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \tilde{\mu}_i + \sigma_v \left[\frac{\phi(-\tilde{\mu}_i/\sigma_v)}{1 - \Phi(-\tilde{\mu}_i/\sigma_v)} \right] = \sigma_v \left[\frac{\phi(A)}{\Phi(-A)} - A \right]$$

Normal-Truncated Normal Model

Define $\tilde{\mu} = (-\sigma_u^2\epsilon_i + \mu\sigma_v^2)/\sigma^2$ and $\sigma_*^2 = \sigma_u^2\sigma_v^2/\sigma^2$. Then, as it is shown by Kumbhakar and Lovell (2000), conditional density is as follows:

$$f(u|\epsilon) = \frac{1}{\sqrt{2\pi}\sigma_*[1 - \Phi(-\tilde{\mu}/\sigma_*)]} \exp \left\{ -\frac{(u - \tilde{\mu})^2}{2\sigma_*^2} \right\}$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\tilde{\mu}, \sigma_*^2)$.

Using this result, it follows that the estimate of technical efficiency is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \frac{1 - \Phi(\sigma_* - \tilde{\mu}_i/\sigma_*)}{1 - \Phi(-\tilde{\mu}_i/\sigma_*)} \exp \left\{ -\tilde{\mu}_i + \frac{1}{2}\sigma_*^2 \right\}$$

The second version of the estimate is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \tilde{\mu}_i + \sigma_* \left[\frac{\phi(\tilde{\mu}_i/\sigma_*)}{1 - \Phi(-\tilde{\mu}_i/\sigma_*)} \right]$$

OUTEST= Data Set

The OUTEST= data set contains all the parameters estimated in a MODEL statement. The OUTEST= option can be used when the PROC QLIM call contains one MODEL statement:

```
proc qlim data=a outest=e;
  model y = x1 x2 x3;
  endogenous y ~ censored(lb=0);
run;
```

Each parameter contains the estimate for the corresponding parameter in the corresponding model. In addition, the OUTEST= data set contains the following variables:

<code>_NAME_</code>	the name of the independent variable
<code>_TYPE_</code>	type of observation. PARM indicates the row of coefficients; STD indicates the row of standard deviations of the corresponding coefficients.
<code>_STATUS_</code>	convergence status for optimization

The rest of the columns correspond to the explanatory variables.

The OUTEST= data set contains one observation for the MODEL statement, giving the parameter estimates for that model. If the COVOUT option is specified, the OUTEST= data set includes additional observations for the MODEL statement, giving the rows of the covariance matrix of parameter estimates. For covariance observations, the value of the _TYPE_ variable is COV, and the _NAME_ variable identifies the parameter associated with that row of the covariance matrix. If the CORROUT option is specified, the OUTEST= data set includes additional observations for the MODEL statement, giving the rows of the correlation matrix of parameter estimates. For correlation observations, the value of the _TYPE_ variable is CORR, and the _NAME_ variable identifies the parameter associated with that row of the correlation matrix.

Naming

Naming of Parameters

When there is only one equation in the estimation, parameters are named in the same way as in other SAS procedures such as REG, PROBIT, and so on. The constant in the regression equation is called Intercept. The coefficients on independent variables are named by the independent variables. The standard deviation of the errors is called _Sigma. If there are Box-Cox transformations, the coefficients are named _Lambdai, where i increments from 1, or as specified by the user. The limits for the discrete dependent variable are named _Limiti. If the LIMIT=varying option is specified, then _Limiti starts from 1. If the LIMIT=varying option is not specified, then _Limit1 is set to 0 and the limit parameters start from $i = 2$. If the HETERO statement is included, the coefficients of the independent variables in the hetero equation are called _H.x, where x is the name of the independent variable. If the parameter name includes interaction terms, it needs to be enclosed in quotation marks followed by N . The following example restricts the parameter that includes the interaction term to be greater than zero:

```
proc qlim data=a;
  model y = x1|x2;
  endogenous y ~ discrete;
  restrict "x1*x2"N>0;
run;
```

When there are multiple equations in the estimation, the parameters in the main equation are named in the format of $y.x$, where y is the name of the dependent variable and x is the name of the independent variable. The standard deviation of the errors is called _Sigma.y. The correlation of the errors is called _Rho for bivariate model. For the model with three variables it is _Rho.y1.y2, _Rho.y1.y3, _Rho.y2.y3. The construction of correlation names for multivariate models is analogous. Box-Cox parameters are called _Lambdai.y and limit variables are called _Limiti.y. Parameters in the HETERO statement are named as _H.y.x. In the OUTEST= data set, all variables are changed from '.' to '_'.

Naming of Output Variables

The following table shows the option in the OUTPUT statement, with the corresponding variable names and their explanation.

Option	Name	Explanation
PREDICTED	P_y	Predicted value of y
RESIDUAL	RESID_y	Residual of y , (y -Predicted Y)
XBETA	XBETA_y	Structure part ($\mathbf{x}'\boldsymbol{\beta}$) of y equation
ERRSTD	ERRSTD_y	Standard deviation of error term
PROB	PROB_y	Probability that y is taking the observed value in this observation (discrete y only)
PROBALL	PROB i _y	Probability that y is taking the i th value (discrete y only)
MILLS	MILLS_y	Inverse Mills ratio for y
EXPECTED	EXPCT_y	Unconditional expected value of y
CONDITIONAL	CEXPCT_y	Conditional expected value of y , condition on the truncation.
MARGINAL	MEFF_x	Marginal effect of x on y ($\frac{\partial y}{\partial x}$) with single equation
	MEFF_y_x	Marginal effect of x on y ($\frac{\partial y}{\partial x}$) with multiple equations
	MEFF_Pi_x	Marginal effect of x on y ($\frac{\partial Prob(y=i)}{\partial x}$) with single equation and discrete y
	MEFF_Pi_y_x	Marginal effect of x on y ($\frac{\partial Prob(y=i)}{\partial x}$) with multiple equations and discrete y
TE1	TE1	Technical efficiency estimate for each producer proposed by Battese and Coelli (1988)
TE2	TE2	Technical efficiency estimate for each producer proposed by Jondrow et al. (1982)

If you prefer to name the output variables differently, you can use the RENAME option in the data set. For example, the following statements rename the residual of y as *Resid*:

```
proc qlim data=one;
  model y = x1-x10 / censored;
  output out=outds(rename=(resid_y=resid)) residual;
run;
```

ODS Table Names

PROC QLIM assigns a name to each table it creates. You can use these names to denote the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the [Table 22.9](#).

Examples: QLIM Procedure

Example 22.1: Ordered Data Modeling

Cameron and Trivedi (1986) studied Australian Health Survey data. Variable definitions are given in Cameron and Trivedi (1998, p. 68).

```

data docvisit;
  input sex age agesq income levyplus freepoor freerepa
        illness actdays hscore chcond1 chcond2 dvisits;
  y = (dvisits > 0);
  if ( dvisits > 8 ) then dvisits = 8;
datalines;
1 0.19 0.0361 0.55 1 0 0 1 4 1 0 0 1
1 0.19 0.0361 0.45 1 0 0 1 2 1 0 0 1
... more lines ...

1 0.37 0.1369 0.25 0 0 1 1 0 1 0 0 0
1 0.52 0.2704 0.65 0 0 0 0 0 0 0 0 0
0 0.72 0.5184 0.25 0 0 1 0 0 0 0 0 0
;

```

The dependent variable, `dvisits`, has nine ordered values. The following SAS statements estimate the ordinal probit model:

```
/*-- Ordered Discrete Responses --*/
proc qlim data=docvisit;
  model dvisits = sex age agesq income levyplus
               freepoor freerepa illness actdays hscore

By default, ordinal probit/logit models are estimated assuming that the first threshold or limit parameter (μ_1) is 0. However, this parameter can also be estimated when the LIMIT1=VARYING option is specified. The probability that y_i^* belongs to the j th category is defined as

$$P[\mu_{j-1} < y_i^* < \mu_j] = F(\mu_j - x_i' \beta) - F(\mu_{j-1} - x_i' \beta)$$

where $F(\cdot)$ is the logistic or standard normal CDF, $\mu_0 = -\infty$ and $\mu_9 = \infty$. Output 22.1.2 lists ordinal probit estimates computed in the following program. Note that the intercept term is suppressed for model identification when μ_1 is estimated.

```

/*-- Ordered Probit --*/
proc qlim data=docvisit;
    model dvisits = sex age agesq income levyplus
              freepoor freerepa illness actdays hscore
              chcond1 chcond2 / discrete(d=normal) limit1=varying;
run;

```

Example 22.2: Tobit Analysis

The following statements show a subset of the Mroz (1987) data set. In these data, Hours is the number of hours the wife worked outside the household in a given year, Yrs_Ed is the years of education, and Yrs_Exp is the years of work experience. A Tobit model will be fit to the hours worked with years of education and experience as covariates.

By the nature of the data it is clear that there are a number of women who committed some positive number of hours to outside work ($y_i > 0$ is observed). There are also a number of women who did not work at all ($y_i = 0$ is observed). This gives us the following model:

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$y_i = \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases}$$

where $\epsilon_i \sim iidN(0, \sigma^2)$. The set of explanatory variables is denoted by x_i .

```

In the “Parameter Estimates” table there are four rows. The first three of these rows correspond to the vector estimate of the regression coefficients β . The last one is called `_Sigma`, which corresponds to the estimate of the error variance σ .

Example 22.3: Bivariate Probit Analysis

This example shows how to estimate a bivariate probit model. Note the `INIT` statement in the following program, which sets the initial values for some parameters in the optimization:

```
data a;
  keep y1 y2 x1 x2;
  do i = 1 to 500;
    x1 = rannor( 19283 );
    x2 = rannor( 19283 );
    u1 = rannor( 19283 );
    u2 = rannor( 19283 );
    y1l = 1 + 2 * x1 + 3 * x2 + u1;
    y2l = 3 + 4 * x1 - 2 * x2 + u1*.2 + u2;
    if ( y1l > 0 ) then y1 = 1;
    else y1 = 0;
    if ( y2l > 0 ) then y2 = 1;
    else y2 = 0;
    output;
  end;
run;

/*-- Bivariate Probit --*/
proc qlim data=a method=qn;
  init y1.x1 2.8, y1.x2 2.1, _rho .1;
  model y1 = x1 x2;
  model y2 = x1 x2;
  endogenous y1 y2 ~ discrete;
run;
```

The output of the QLIM procedure is shown in [Output 22.3.1](#).

Example 22.4: Sample Selection Model

This example illustrates the use of PROC QLIM for sample selection models. The data set is the same one from Mroz (1987). The goal is to estimate a wage offer function for married women, accounting for potential selection bias. Of the 753 women, the wage is observed for 428 working women. The labor force participation equation estimated in the introductory example is used for selection. The wage equation uses log wage (`lwage`) as the dependent variable. The explanatory variables in the wage equation are the woman's years of schooling (`educ`), wife's labor experience (`exper`), and square of experience (`expersq`). The program is as follows:

```

/*-- Sample Selection --*/
proc qlim data=mroz;
  model inlf = nwifeinc educ exper expersq
              age kidslt6 kidsge6 /discrete;
  model lwage = educ exper expersq / select(inlf=1);
run;

```

The output of the QLIM procedure is shown in [Output 22.4.1](#).

Output 22.4.1 Sample Selection

Binary Data					
The QLIM Procedure					
Model Fit Summary					
Number of Endogenous Variables				2	
Endogenous Variable				inlf lwage	
Number of Observations				753	
Log Likelihood				-832.88509	
Maximum Absolute Gradient				0.00502	
Number of Iterations				78	
Optimization Method				Quasi-Newton	
AIC				1694	
Schwarz Criterion				1759	
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
lwage.Intercept	1	-0.552716	0.260371	-2.12	0.0338
lwage.educ	1	0.108351	0.014861	7.29	<.0001
lwage.exper	1	0.042837	0.014878	2.88	0.0040
lwage.expersq	1	-0.000837	0.000417	-2.01	0.0449
_Sigma.lwage	1	0.663397	0.022706	29.22	<.0001
inlf.Intercept	1	0.266459	0.508954	0.52	0.6006
inlf.nwifeinc	1	-0.012132	0.004877	-2.49	0.0129
inlf.educ	1	0.131341	0.025383	5.17	<.0001
inlf.exper	1	0.123282	0.018728	6.58	<.0001
inlf.expersq	1	-0.001886	0.000601	-3.14	0.0017
inlf.age	1	-0.052829	0.008479	-6.23	<.0001
inlf.kidslt6	1	-0.867398	0.118647	-7.31	<.0001
inlf.kidsge6	1	0.035872	0.043476	0.83	0.4093
_Rho	1	0.026617	0.147073	0.18	0.8564

Note the correlation estimate is insignificant. This indicates that selection bias is not a big problem in the estimation of wage equation.

Example 22.5: Sample Selection Model with Truncation and Censoring

In this example the data are generated such that the selection variable is discrete and the variable Y is truncated from below by zero. The program follows, with the results shown in [Output 22.5.1](#):

```

data trunc;
  keep z y x1 x2;
  do i = 1 to 500;
    x1 = rannor( 19283 );
    x2 = rannor( 19283 );
    u1 = rannor( 19283 );
    u2 = rannor( 19283 );
    z1 = 1 + 2 * x1 + 3 * x2 + u1;
    y = 3 + 4 * x1 - 2 * x2 + u1*.2 + u2;
    if ( z1 > 0 ) then z = 1;
    else z = 0;
    if y>=0 then output;
  end;
run;

/*-- Sample Selection with Truncation ---*/
proc qlim data=trunc method=qn;
  model z = x1 x2 / discrete;
  model y = x1 x2 / select(z=1) truncated(lb=0);
run;

```

Output 22.5.1 Sample Selection with Truncation

Example 22.7: Stochastic Frontier Models

This example illustrates the estimation of stochastic frontier production and cost models.

First, a production function model is estimated. The data for this example were collected by Christensen Associates; they represent a sample of 125 observations on inputs and output for 10 airlines between 1970 and 1984. The explanatory variables (inputs) are fuel (LF), materials (LM), equipment (LE), labor (LL), and property (LP), and (LQ) is an index that represents passengers, charter, mail, and freight transported.

The following statements create the dataset:

```

title1 'Stochastic Frontier Production Model';
data airlines;
  input TS FIRM NI LQ LF LM LE LL LP;
datalines;
1 1 15 -0.0484 0.2473 0.2335 0.2294 0.2246 0.2124
1 1 15 -0.0133 0.2603 0.2492 0.241 0.2216 0.1069
2 1 15 0.088 0.2666 0.3273 0.3365 0.2039 0.0865
3 1 15 0.1619 0.3019 0.4573 0.3532 0.2346 0.0242

... more lines ...

```

The following statements estimate a stochastic frontier exponential production model that uses Christensen Associates data:

```

/*-- Stochastic Frontier Production Model --*/
proc qlim data=airlines;
  model LQ=LF LM LE LL LP;
  endogenous LQ ~ frontier (type=exponential production);
run;

```

Figure 22.7.1 shows the results from this production model.

Output 22.7.1 Stochastic Frontier Production Model

Stochastic Frontier Production Model					
The QLIM Procedure

_Sigma_u	1	0.060611	0.017603	3.44	0.0006

Similarly, the stochastic frontier production function can be estimated with (type=half) or (type=truncated) options that represent half-normal and truncated normal production models.

In the next step, stochastic frontier cost function is estimated. The data for the cost model are provided by Christensen and Greene (1976). The data describe costs and production inputs of 145 U.S. electricity producers in 1955. The model being estimated follows the nonhomogenous version of the Cobb-Douglas cost function:

$$\log\left(\frac{\text{Cost}}{\text{FPrice}}\right) = \beta_0 + \beta_1 \log\left(\frac{\text{KPrice}}{\text{FPrice}}\right) + \beta_2 \log\left(\frac{\text{LPrice}}{\text{FPrice}}\right) + \beta_3 \log(\text{Output}) + \beta_4 \frac{1}{2} \log(\text{Output})^2 + \epsilon$$

All dollar values are normalized by fuel price. The quadratic log of the output is added to capture nonlinearities due to scale effects in cost functions. New variables, log_C_PF, log_PK_PF, log_PL_PF, log_y, and log_y_sq, are created to reflect transformations. The following statements create the data set and transformed variables:

```

data electricity;
    input Firm Year Cost Output LPrice LShare KPrice KShare FPrice FShare;
datalines;
1 1955 .0820 2.0 2.090 .3164 183.000 .4521 17.9000 .2315
2 1955 .6610 3.0 2.050 .2073 174.000 .6676 35.1000 .1251
3 1955 .9900 4.0 2.050 .2349 171.000 .5799 35.1000 .1852
4 1955 .3150 4.0 1.830 .1152 166.000 .7857 32.2000 .0990
5 1955 .1970 5.0 2.120 .2300 233.000 .3841 28.6000 .3859

... more lines ...

/* Data transformations */
data electricity;
    set electricity;
    label Firm="firm index"
           Year="1955 for all observations"
           Cost="Total cost"
           Output="Total output"
           LPrice="Wage rate"
           LShare="Cost share for labor"
           KPrice="Capital price index"
           KShare="Cost share for capital"
           FPrice="Fuel price"
           FShare="Cost share for fuel";
    log_C_PF=log(Cost/FPrice);
    log_PK_PF=log(KPrice/FPrice);
    log_PL_PF=log(LPrice/FPrice);
    log_y=log(Output);
    log_y_sq=log_y**2/2;
run;

```

The following statements estimate a stochastic frontier exponential cost model that uses Christensen and Greene (1976) data:

```

/*-- Stochastic Frontier Cost Model --*/
proc qlim data=electricity;
    model log_C_PF = log_PK_PF log_PL_PF log_y log_y_sq;
    endogenous log_C_PF ~ frontier (type=exponential cost);
run;

```

Output 22.7.2 shows the results.

Output 22.7.2 Exponential Distribution

_Mu	1	0.477097	0.116295	4.10	<.0001

If no (Production) or (Cost) option is specified, the stochastic frontier production model is estimated by default.

Example 22.8: Bayesian Modeling

This example illustrates how to use the QLIM procedure to perform Bayesian analysis. The generated data mimic a hypothetical scenario in which you study the number of tickets sold for a sports event given the probability of the hosting team winning and the price of the tickets. The following statements create the dataset:

```

title1 'Bayesian Analysis';

ods graphics on;

data test;
  do i=1 to 200;
    e1 = rannor(8726)*2000;
    WinChance = ranuni(8772);
    Price = 10+ranexp(8773)*4;
    y = 48000 + 5000*WinChance - 100 * price + e1;
    if y>50000 then TicketSales = 50000;
    if y<=50000 then TicketSales = y;
    output;
  end;
  keep WinChance price y TicketSales;
run;

```

The following statements perform Bayesian analysis of a Tobit model:

```

proc qlim data=test plots(prior)=all;
  model TicketSales = WinChance price;
  endogenous TicketSales ~ censored(lb=0 ub= 50000);
  prior intercept~normal(mean=48000);
  prior WinChance~normal(mean=5000);
  prior Price~normal(mean=-100);
  bayes NBI=10000 NMC=30000 THIN=1 ntrds=1 DIAG=ALL STATS=ALL seed=2;
run;

```

Output 22.8.1 shows the results from the maximum likelihood estimation and the Bayesian analysis with diffuse prior of this Tobit model.

Output 22.8.1 Bayesian Tobit Model

Overview: SEVERITY Procedure

The SEVERITY procedure estimates parameters of any arbitrary continuous probability distribution that is used to model the magnitude (severity) of a continuous-valued event of interest. Some examples of such events are loss amounts paid by an insurance company and demand of a product as depicted by its sales. PROC SEVERITY is especially useful when the severity of an event does not follow typical distributions such as the normal distribution that are often assumed by standard statistical methods.

PROC SEVERITY provides a default set of probability distribution models that includes the Burr, exponential, gamma, generalized Pareto, inverse Gaussian (Wald), lognormal, Pareto, Tweedie, and Weibull distributions. In the simplest form, you can estimate the parameters of any of these distributions by using a list of severity values that are recorded in a SAS data set. The values can optionally be grouped by a set of BY variables. PROC SEVERITY computes the estimates of the model parameters, their standard errors, and their covariance structure by using the maximum likelihood method for each of the BY groups.

PROC SEVERITY can fit multiple distributions at the same time and choose the best distribution according to a specified selection criterion. Seven different statistics of fit can be used as selection criteria. They are log likelihood, Akaike’s information criterion (AIC), corrected Akaike’s information criterion (AICC), Schwarz Bayesian information criterion (BIC), Kolmogorov-Smirnov statistic (KS), Anderson-Darling statistic (AD), and Cramér-von Mises statistic (CvM).

You can request the procedure to output the status of the estimation process, the parameter estimates and their standard errors, the estimated covariance structure of the parameters, the statistics of fit, estimated cumulative distribution function (CDF) for each of the specified distributions, and the empirical distribution function (EDF) estimate (which is used to compute the KS, AD, and CvM statistics of fit).

A high-performance version of PROC SEVERITY is available as the HPSEVERITY procedure in the SAS High-Performance Analytics product. The following key features make PROC SEVERITY and PROC HPSEVERITY unique among SAS procedures that can estimate continuous probability distributions:

- Both procedures enable you to fit a distribution model when the severity values are truncated or censored or both. You can specify any combination of the following types of censoring and truncation effects: left-censoring, right-censoring, left-truncation, or right-truncation. This is especially useful in applications with an insurance-type model where a severity (loss) is reported and recorded only if it is greater than the deductible amount (left-truncation) and where a severity value greater than or equal to the policy limit is recorded at the limit (right-censoring). Another useful application is that of interval-censored data, where you know both the lower limit (right-censoring) and upper limit (left-censoring) on the severity, but you do not know the exact value.

PROC SEVERITY also enables you to specify a *probability of observability* for the left-truncated data, which is a probability of observing values greater than the left-truncation threshold. This additional information can be useful in certain applications to more correctly model the distribution of the severity of events.

When truncation or censoring is specified, the procedure can compute the empirical distribution function (EDF) estimate by using either Kaplan-Meier's product-limit estimator or Turnbull's estimator. The former is used by default when only one form of censoring effect (right-censoring or left-censoring) is specified, whereas the latter is used by default when both left-censoring and right-censoring effects are specified. PROC SEVERITY also computes the standard errors for the EDF estimates.

- Both procedures enable you to define any arbitrary continuous parametric distribution model and to estimate its parameters. You just need to define the key components of the distribution, such as its probability density function (PDF) and cumulative distribution function (CDF), as a set of functions and subroutines written with the FCMP procedure, which is part of Base SAS software. As long as the functions and subroutines follow certain rules, the SEVERITY and HPSEVERITY procedures can fit the distribution model defined by them.
- Both procedures can model the effect of exogenous or regressor variables on a probability distribution, as long as the distribution has a scale parameter. A linear combination of the regressor variables is assumed to affect the scale parameter via an exponential link function.

If a distribution does not have a scale parameter, then either it needs to have another parameter that can be derived from a scale parameter by using a supported transformation or it needs to be reparameterized to have a scale parameter. If neither of these is possible, then regression effects cannot be modeled.

- PROC SEVERITY enables you to specify your own objective function to be optimized for estimating the parameters of a model. You can write SAS programming statements to specify the contribution of each observation to the objective function. You can use keyword functions such as `_PDF_` and `_CDF_` to generalize the objective function to any distribution. If you do not specify your own objective function, then PROC SEVERITY estimates the parameters of a model by maximizing the likelihood function of the data.
- Both procedures use multithreading to significantly reduce the time it takes to fit a distribution model.

Getting Started: SEVERITY Procedure

This section outlines the use of the SEVERITY procedure to fit continuous probability distribution models. Three examples illustrate different features of the procedure.

A Simple Example of Fitting Predefined Distributions

The simplest way to use PROC SEVERITY is to fit all the predefined distributions to a set of values and let the procedure identify the best fitting distribution.

Consider a lognormal distribution, whose probability density function (PDF) f and cumulative distribution function (CDF) F are as follows, respectively, where Φ denotes the CDF of the standard normal distribution:

$$f(x; \mu, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2} \quad \text{and} \quad F(x; \mu, \sigma) = \Phi\left(\frac{\log(x)-\mu}{\sigma}\right)$$

The following DATA step statements simulate a sample from a lognormal distribution with population parameters $\mu = 1.5$ and $\sigma = 0.25$, and store the sample in the variable Y of a data set Work.Test_sev1:

```
/*----- Simple Lognormal Example -----*/
data test_sev1(keep=y label='Simple Lognormal Sample');
  call streaminit(45678);
  label y='Response Variable';
  Mu = 1.5;
  Sigma = 0.25;
  do n = 1 to 100;
    y = exp(Mu) * rand('LOGNORMAL')**Sigma;
    output;
  end;
run;
```

The following statements fit all the predefined distribution models to the values of Y and identify the best distribution according to the corrected Akaike's information criterion (AICC):

```
proc severity data=test_sev1 crit=aicc;
  loss y;
  dist _predefined_;
run;
```

The PROC SEVERITY statement specifies the input data set along with the model selection criterion, the LOSS statement specifies the variable to be modeled, and the DIST statement with the _PREDEFINED_ keyword specifies that all the predefined distribution models be fitted.

Some of the default output displayed by this step is shown in [Figure 23.1](#) through [Figure 23.5](#). First, information about the input data set is displayed followed by the “Model Selection Table”, as shown in [Figure 23.1](#). The model selection table displays the convergence status, the value of the selection criterion, and the selection status for each of the candidate models. The Converged column indicates whether the estimation process for a given distribution model has converged, might have converged, or failed. The Selected column indicates whether a given distribution has the best fit for the data according to the selection criterion. For this example, the lognormal distribution model is selected, because it has the lowest value for the selection criterion.

Figure 23.1 Data Set Information and Model Selection Table

The SEVERITY Procedure			
Input Data Set			
Name	WORK.TEST_SEV1		
Label	Simple Lognormal Sample		
Model Selection Table			
Distribution	Converged	Corrected Akaike's Information Criterion	Selected
Burr	Yes	322.50845	No
Exp	Yes	508.12287	No
Gamma	Yes	320.50264	No
Igauss	Yes	319.61652	No
Logn	Yes	319.56579	Yes
Pareto	Yes	510.28172	No
Gpd	Yes	510.20576	No
Weibull	Yes	334.82373	No

Next, two comparative plots are prepared. These plots enable you to visually verify how the models differ from each other and from the nonparametric estimates. The plot in [Figure 23.2](#) displays the cumulative distribution function (CDF) estimates of all the models and the estimates of the empirical distribution function (EDF). The CDF plot indicates that the Exp (exponential), Pareto, and Gpd (generalized Pareto) distributions are a poor fit as compared to the EDF estimate. The Weibull distribution is also a poor fit, although not as poor as exponential, Pareto, and Gpd. The other four distributions seem to be quite close to each other and to the EDF estimate.

Figure 23.2 Comparison of EDF and CDF Estimates of the Fitted Models

The plot in [Figure 23.3](#) displays the probability density function (PDF) estimates of all the models and the nonparametric kernel and histogram estimates. The PDF plot enables better visual comparison between the Burr, Gamma, Igauss (inverse Gaussian), and Logn (lognormal) models. The Burr and Gamma differ significantly from the Igauss and Logn distributions in the central portion of the range of Y values, while the latter two fit the data almost identically. This provides a visual confirmation of the information in the “Model Selection Table” of [Figure 23.1](#), which indicates that the AICC values of Igauss and Logn distributions are very close.

Figure 23.3 Comparison of PDF Estimates of the Fitted Models

The comparative plots are followed by the estimation information for each of the candidate models. The information for the lognormal model, which is the best fitting model, is shown in Figure 23.4. The first table displays a summary of the distribution. The second table displays the convergence status. This is followed by a summary of the optimization process which indicates the technique used, the number of iterations, the number of times the objective function was evaluated, and the log likelihood attained at the end of the optimization. Since the model with lognormal distribution has converged, PROC SEVERITY displays its statistics of fit and parameter estimates. The estimates of $\mu=1.49605$ and $\sigma=0.26243$ are quite close to the population parameters of $\mu=1.5$ and $\sigma=0.25$ from which the sample was generated. The p -value for each estimate indicates the rejection of the null hypothesis that the estimate is 0, implying that both the estimates are significantly different from 0.

Mu	1.49605	0.02651	56.43	<.0001
Sigma	0.26243	0.01874	14.00	<.0001

The parameter estimates of the Burr distribution are shown in [Figure 23.5](#). These estimates are used in the next example.

Figure 23.5 Parameter Estimates for the Burr Model

Parameter Estimates for Burr Distribution				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Theta	4.62348	0.46181	10.01	<.0001
Alpha	1.15706	0.47493	2.44	0.0167
Gamma	6.41227	0.99039	6.47	<.0001

An Example with Left-Truncation and Right-Censoring

PROC SEVERITY enables you to specify that the response variable values are left-truncated or right-censored. The following DATA step expands the data set of the previous example to simulate a scenario that is typically encountered by an automobile insurance company. The values of the variable Y represent the loss values on claims that are reported to an auto insurance company. The variable THRESHOLD records the deductible on the insurance policy. If the actual value of Y is less than or equal to the deductible, then it is unobservable and does not get recorded. In other words, THRESHOLD specifies the left-truncation of Y. LIMIT records the policy limit. If the value of Y is equal to or greater than the recorded value, then the observation is right-censored.

```

/*----- Lognormal Model with left-truncation and censoring -----*/
data test_sev2(keep=y threshold limit
    label='A Lognormal Sample With Censoring and Truncation');
    set test_sev1;
    label y='Censored & Truncated Response';
    if _n_ = 1 then call streaminit(45679);

    /* make about 20% of the observations left-truncated */
    if (rand('UNIFORM') < 0.2) then
        threshold = y * (1 - rand('UNIFORM'));
    else
        threshold = .;
    /* make about 15% of the observations right-censored */
    iscens = (rand('UNIFORM') < 0.15);
    if (iscens) then
        limit = y;
    else
        limit = .;
run;

```

The following statements use the AICC criterion to analyze which of the four predefined distributions (lognormal, Burr, gamma, and Weibull) has the best fit for the data:

```

proc severity data=test_sev2 crit=aicc
    print=all plots=(cdfperdist pp qq);
    loss y / lt=threshold rc=limit;

    dist logn burr gamma weibull;
run;

```

The LOSS statement specifies the left-truncation and right-censoring variables. Each candidate distribution needs to be specified by using a separate DIST statement. The PRINT= option in the PROC SEVERITY statement requests that all the displayed output be prepared. The PLOTS= option in the PROC SEVERITY statement requests that the CDF plot, P-P plot, and Q-Q plot be prepared for each candidate distribution in addition to the default plots.

Some of the key results prepared by PROC SEVERITY are shown in Figure 23.6 through Figure 23.13. In addition to the estimates of the range, mean, and standard deviation of Y, the “Descriptive Statistics for Y” table shown in Figure 23.6 also indicates the number of observations that are left-truncated or right-censored. The “Model Selection Table” in Figure 23.6 shows that models with all the candidate distributions have converged and that the Logn (lognormal) model has the best fit for the data according to the AICC criterion.

Figure 23.6 Summary Results for the Truncated and Censored Data

The SEVERITY Procedure			
Input Data Set			
Name	WORK.TEST_SEV2		
Label	A Lognormal Sample With Censoring and Truncation		
Descriptive Statistics for Variable y			
Number of Observations			100
Number of Observations Used for Estimation			100
Minimum			2.30264
Maximum			8.34116
Mean			4.62007
Standard Deviation			1.23627
Number of Left Truncated Observations			23
Number of Right Censored Observations			14
Model Selection Table			
		Corrected Akaike's Information Criterion	
Distribution	Converged		Selected
Logn	Yes	298.92672	Yes
Burr	Yes	302.66229	No
Gamma	Yes	299.45293	No
Weibull	Yes	309.26779	No

PROC SEVERITY also prepares a table that shows all the fit statistics for all the candidate models. It is useful to see which model would be the best fit according to each of the criteria. The “All Fit Statistics Table” prepared for this example is shown in Figure 23.7. It indicates that the lognormal model is chosen by all the criteria.

Figure 23.7 Comparing All Statistics of Fit for the Truncated and Censored Data

All Fit Statistics Table					
Distribution	-2 Log Likelihood	AIC	AICC	BIC	KS
Logn	294.80301*	298.80301*	298.92672*	304.01335*	0.51824*
Burr	296.41229	302.41229	302.66229	310.22780	0.66984
Gamma	295.32921	299.32921	299.45293	304.53955	0.62511
Weibull	305.14408	309.14408	309.26779	314.35442	0.93307

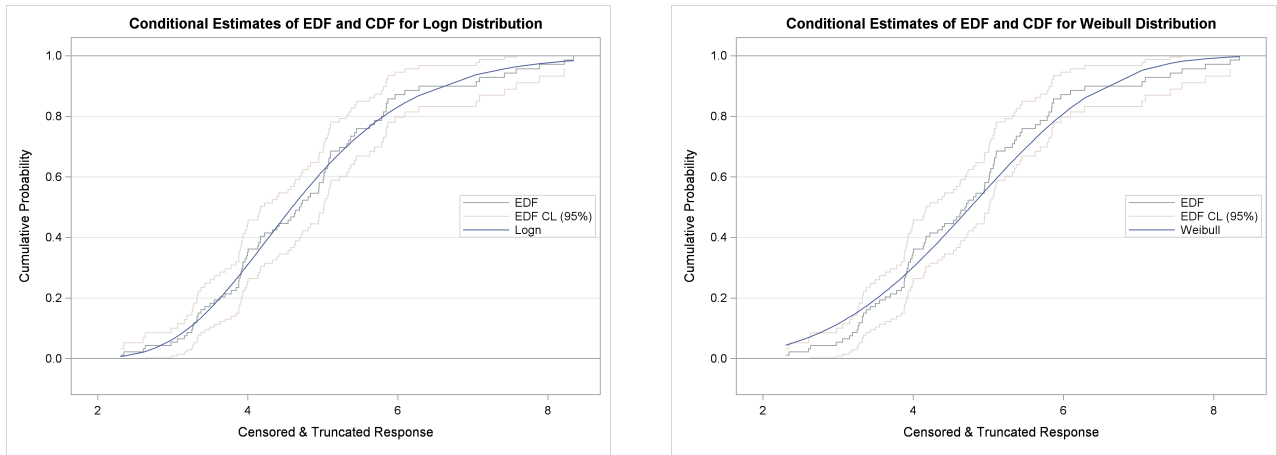

All Fit Statistics Table		
Distribution	AD	CvM
Logn	0.34736*	0.05159*
Burr	0.36712	0.05726
Gamma	0.42921	0.05526
Weibull	1.40699	0.17465

The plot that compares EDF and CDF estimates is shown in Figure 23.8. When left-truncation is specified, both the EDF and CDF estimates are conditional on the response variable being greater than the smallest left-truncation threshold in the sample.

Figure 23.8 EDF and CDF Estimates for the Truncated and Censored Data

When you specify the `PLOTS=CDFPERDIST` option, PROC SEVERITY prepares a plot that compares the nonparametric EDF estimates with the parametric CDF estimates for each distribution. These plots for lognormal and Weibull distributions are shown in Figure 23.9. These plots also contain the lower and upper confidence limits of EDF for the specified confidence level. Because no confidence level was specified in the `EDFALPHA=` option in the PROC SEVERITY statement, a default confidence level of 95% is used, which is equivalent to specifying `EDFALPHA=0.05`. If the CDF estimates lie entirely within the EDF confidence interval, then you can be 95% confident that the parametric and nonparametric estimates are in agreement.

Figure 23.9 Comparing EDF and CDF Estimates for Lognormal and Weibull Models Fitted to Truncated and Censored Data

There are two additional ways to compare nonparametric (empirical) and parametric estimates for each model that has not failed to converge:

- A P-P plot is a scatter plot of the EDF and the CDF estimates. The model for which the points are scattered closer to the unit-slope reference line is a better fit. The P-P plot for the lognormal distribution is shown in Figure 23.10. It indicates that the EDF and the CDF match very closely. In contrast, the P-P plot for the Weibull distribution, also shown in Figure 23.10, indicates a poor fit.

Figure 23.10 P-P Plots for Lognormal and Weibull Models Fitted to Truncated and Censored Data

- A Q-Q plot is a scatter plot of empirical quantiles and the quantiles of a parametric distribution. Like the P-P plot, points scattered closer to the unit-slope reference line indicate a better fit. The Q-Q plots of lognormal and Weibull distributions are shown in Figure 23.11, which confirm the conclusions arrived at by comparing the P-P plots.

Figure 23.11 Q-Q Plots for Lognormal and Weibull Models Fitted to Truncated and Censored Data

Specifying Initial Values for Parameters

All the predefined distributions have parameter initialization functions built into them. For the current example, Figure 23.12 shows the initial values that are obtained by the predefined method for the Burr distribution. It also shows the summary of the optimization process and the final parameter estimates.

Figure 23.12 Burr Model Summary for the Truncated and Censored Data

Initial Parameter Values and Bounds for Burr Distribution			
Parameter	Initial Value	Lower Bound	Upper Bound
Theta	4.78102	1.05367E-8	Infty
Alpha	2.00000	1.05367E-8	Infty
Gamma	2.00000	1.05367E-8	Infty
Optimization Summary for Burr Distribution			
Optimization Technique	Trust Region		
Number of Iterations	8		
Number of Function Evaluations	23		
Log Likelihood	-148.20614		

Figure 23.12 *continued*

Parameter Estimates for Burr Distribution				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Theta	4.76980	0.62492	7.63	<.0001
Alpha	1.16363	0.58859	1.98	0.0509
Gamma	5.94081	1.05004	5.66	<.0001

You can specify a different set of initial values if estimates are available from fitting the distribution to similar data. For this example, the parameters of the Burr distribution can be initialized with the final parameter estimates of the Burr distribution that were obtained in the first example (shown in [Figure 23.5](#)). One of the ways in which you can specify the initial values is as follows:

```
/*----- Specifying initial values using INIT= option -----*/
proc severity data=test_sev2 crit=aicc print=all plots=none;
  loss y / lt=threshold rc=limit;

  dist burr(init=(theta=4.62348 alpha=1.15706 gamma=6.41227));
run;
```

The names of the parameters specified in the INIT option must match the names used in the definition of the distribution. The results obtained with these initial values are shown in [Figure 23.13](#). These results indicate that new set of initial values causes the optimizer to reach the same solution with fewer iterations and function evaluations as compared to the default initialization.

An Example of Modeling Regression Effects

Consider a scenario in which the magnitude of the response variable might be affected by some regressor (exogenous or independent) variables. The SEVERITY procedure enables you to model the effect of such variables on the distribution of the response variable via an exponential link function. In particular, if you have k random regressor variables denoted by x_j ($j = 1, \dots, k$), then the distribution of the response variable Y is assumed to have the form

$$Y \sim \exp\left(\sum_{j=1}^k \beta_j x_j\right) \cdot \mathcal{F}(\Theta)$$

where \mathcal{F} denotes the distribution of Y with parameters Θ and β_j ($j = 1, \dots, k$) denote the regression parameters (coefficients). For the effective distribution of Y to be a valid distribution from the same parametric family as \mathcal{F} , it is necessary for \mathcal{F} to have a scale parameter. The effective distribution of Y can be written as

$$Y \sim \mathcal{F}(\theta, \Omega)$$

where θ denotes the scale parameter and Ω denotes the set of nonscale parameters. The scale θ is affected by the regressors as

$$\theta = \theta_0 \cdot \exp\left(\sum_{j=1}^k \beta_j x_j\right)$$

where θ_0 denotes a *base* value of the scale parameter.

Given this form of the model, PROC SEVERITY allows a distribution to be a candidate for modeling regression effects only if it has an untransformed or a log-transformed scale parameter.

All the predefined distributions, except the lognormal distribution, have a direct scale parameter (that is, a parameter that is a scale parameter without any transformation). For the lognormal distribution, the parameter μ is a log-transformed scale parameter. This can be verified by replacing μ with a parameter $\theta = e^\mu$, which results in the following expressions for the PDF f and the CDF F in terms of θ and σ , respectively, where Φ denotes the CDF of the standard normal distribution:

$$f(x; \theta, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x) - \log(\theta)}{\sigma}\right)^2} \quad \text{and} \quad F(x; \theta, \sigma) = \Phi\left(\frac{\log(x) - \log(\theta)}{\sigma}\right)$$

With this parameterization, the PDF satisfies the $f(x; \theta, \sigma) = \frac{1}{\theta} f\left(\frac{x}{\theta}; 1, \sigma\right)$ condition and the CDF satisfies the $F(x; \theta, \sigma) = F\left(\frac{x}{\theta}; 1, \sigma\right)$ condition. This makes θ a scale parameter. Hence, $\mu = \log(\theta)$ is a log-transformed scale parameter and the lognormal distribution is eligible for modeling regression effects.

The following DATA step simulates a lognormal sample whose scale is decided by the values of the three regressors X1, X2, and X3 as follows:

$$\mu = \log(\theta) = 1 + 0.75 X1 - X2 + 0.25 X3$$

```

/*----- Lognormal Model with Regressors -----*/
data test_sev3(keep=y x1-x3
              label='A Lognormal Sample Affected by Regressors');
  array x{*} x1-x3;
  array b{4} _TEMPORARY_ (1 0.75 -1 0.25);
  call streaminit(45678);
  label y='Response Influenced by Regressors';
  Sigma = 0.25;
  do n = 1 to 100;
    Mu = b(1); /* log of base value of scale */
    do i = 1 to dim(x);
      x(i) = rand('UNIFORM');
      Mu = Mu + b(i+1) * x(i);
    end;
    y = exp(Mu) * rand('LOGNORMAL')**Sigma;
    output;
  end;
run;

```

The following PROC SEVERITY step fits the lognormal, Burr, and gamma distribution models to this data. The regressors are specified in the SCALEMODEL statement. The DFMIXTURE= option in the SCALEMODEL statement specifies the method of computing the CDF estimates that are used to compute the EDF-based statistics of fit.

```

proc severity data=test_sev3 crit=aicc print=all;
  loss y;
  scalemodel x1-x3 / dfmixture=full;

  dist logn burr gamma;
run;

```

Some of the key results prepared by PROC SEVERITY are shown in Figure 23.14 through Figure 23.18. The descriptive statistics of all the variables are shown in Figure 23.14.

Figure 23.14 Summary Results for the Regression Example

The SEVERITY Procedure	
Input Data Set

The distribution information and the convergence results of the lognormal model are shown in Figure 23.16. The iteration history gives you a summary of how the optimizer is traversing the surface of the log-likelihood function in its attempt to reach the optimum. Both the change in the log likelihood and the maximum gradient of the objective function with respect to any of the parameters typically approach 0 if the optimizer converges.

The final parameter estimates of the lognormal model are shown in Figure 23.17. All the estimates are significantly different from 0. The estimate that is reported for the parameter *Mu* is the base value for the log-transformed scale parameter μ . Let x_i ($1 \leq i \leq 3$) denote the observed value for regressor X_i . If the lognormal distribution is chosen to model Y , then the effective value of the parameter μ varies with the observed values of regressors as

$$\mu = 1.04047 + 0.65221 x_1 - 0.91116 x_2 + 0.16243 x_3$$

These estimated coefficients are reasonably close to the population parameters (that is, within one or two standard errors).

Figure 23.17 Parameter Estimates for the Lognormal Model with Regressors

Parameter Estimates for Logn Distribution				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Mu	1.04047	0.07614	13.66	<.0001
Sigma	0.22177	0.01609	13.78	<.0001

x3	0.16243	0.07782	2.09	0.0395

The estimates of the gamma distribution model, which is the best model according to a majority of the EDF-based statistics, are shown in Figure 23.18. The estimate that is reported for the parameter *Theta* is

the base value for the scale parameter θ . If the gamma distribution is chosen to model Y , then the effective value of the scale parameter is $\theta = 0.14293 \exp(0.64562 x_1 - 0.89831 x_2 + 0.14901 x_3)$.

PROC SEVERITY Statement

PROC SEVERITY *options* ;

The PROC SEVERITY statement invokes the procedure. You can specify two types of *options* in the PROC SEVERITY statement. One set of *options* controls input and output. The other set of *options* controls the model estimation and selection process.

The following *options* control the input data sets used by PROC SEVERITY and various forms of output generated by PROC SEVERITY. The *options* are listed in alphabetical order:

COVOUT

specifies that the OUTEST= data set contain the estimate of the covariance structure of the parameters. This option has no effect if the OUTEST= option is not specified. For more information about how the covariance is reported in the OUTEST= data set, see the section “OUTEST= Data Set” on page 1648.

DATA=SAS-data-set

names the input data set. If the DATA= option is not specified, then the most recently created SAS data set is used.

INEST=SAS-data-set

names the input data set that contains the initial values of the parameter estimates to start the optimization process. The initial values specified in the INIT= option in the DIST statement take precedence over any initial values specified in this data set. For more information about the variables in this data set, see the section “[INEST= Data Set](#)” on page 1646.

NOPRINT

turns off all displayed and graphical output. If specified, any value specified for the PRINT= and PLOTS= options is ignored.

OUTCDF=SAS-data-set

names the output data set to contain estimates of the cumulative distribution function (CDF) value at each of the observations. The information is output for each specified model whose parameter estimation process converges. The data set also contains the estimates of the empirical distribution function (EDF). For more information about the variables in this data set, see the section “[OUTCDF= Data Set](#)” on page 1647.

OUTEST=SAS-data-set

names the output data set to contain estimates of the parameter values and their standard errors for each model whose parameter estimation process converges. For more information about the variables in this data set, see the section “[OUTEST= Data Set](#)” on page 1648.

OUTMODELINFO=SAS-data-set

names the output data set to contain the status of each fitted model. The status information includes the convergence status of the optimization process that is used to estimate the parameters, the status of estimating the covariance matrix, and whether a model is the best according to the specified selection criterion. For more information about the variables in this data set, see the section “[OUTMODELINFO= Data Set](#)” on page 1649.

OUTSTAT=SAS-data-set

names the output data set to contain the values of statistics of fit for each model whose parameter estimation process converges. For more information about the variables in this data set, see the section “[OUTSTAT= Data Set](#)” on page 1649.

PLOTS <(global-plot-options)> <=(plot-request-option)>**PLOTS <(global-plot-options)> <=(plot-request-option . . . plot-request-option)>**

specifies the desired graphical output. If you specify more than one *global-plot-option*, then separate them with spaces and enclose them in parentheses. If you specify more than one *plot-request-option*, then separate them with spaces and enclose them in parentheses.

The following *global-plot-options* are available:

HISTOGRAM

plots the histogram of the response variable on the PDF plots.

KERNEL

plots the kernel estimate of the probability density of the response variable on the PDF plots.

ONLY

turns off the default graphical output and prepares only the requested plots.

The following *plot-request-options* are available:

ALL

displays all the graphical output.

CDF

prepares a plot that compares the cumulative distribution function (CDF) estimates of all the candidate distribution models and the empirical distribution function (EDF) estimate. The plot does not contain CDF estimates for models whose parameter estimation process does not converge.

CDFPERDIST

prepares a plot of the CDF estimates of each candidate distribution model. A plot is not prepared for models whose parameter estimation process does not converge.

NONE

displays none of the graphical output. If specified, this option overrides all the other plot request options. The default graphical output is also suppressed.

PDF

prepares a plot that compares the probability density function (PDF) estimates of all the candidate distribution models. The plot does not contain PDF estimates for models whose parameter estimation process does not converge.

PDFPERDIST

prepares a plot of the PDF estimates of each candidate distribution model. A plot is not prepared for models whose parameter estimation process does not converge.

PP

prepares the probability-probability plot (known as the P-P plot), which compares the CDF estimate of each candidate distribution model against the empirical distribution function (EDF). The data shown in this plot are used for computing the EDF-based statistics of fit.

QQ

prepares the quantile-quantile plot (known as the Q-Q plot), which compares the empirical quantiles against the quantiles of each candidate distribution model.

If the PLOTS= option is not specified or the ONLY *global-plot-option* is not specified, then the default graphical output is equivalent to specifying PLOTS=(CDF PDF).

PRINT <(global-display-option)> <=display-option>

PRINT <(global-display-option)> <=(display-option ... display-option)>

specifies the desired displayed output. If you specify more than one *display-option*, then separate them with spaces and enclose them in parentheses.

The following *global-display-option* is available:

ONLY

turns off the default displayed output and displays only the requested output.

The following *display-options* are available:

ALL

displays all the output.

ALLFITSTATS

displays the comparison of all the statistics of fit for all the models in one table. The table does not include the models whose parameter estimation process does not converge.

CONVSTATUS

displays the convergence status of the parameter estimation process.

DESCSTATS

displays the descriptive statistics for the response variable and the regressor variables, if they are specified.

DISTINFO

displays the information about each specified distribution. For each distribution, the information includes the name, description, validity status, and number of distribution parameters.

ESTIMATES | PARMEST

displays the final estimates of parameters. The estimates are not displayed for models whose parameter estimation process does not converge.

INITIALVALUES

displays the initial values and bounds used for estimating each model.

NLOHISTORY

displays the iteration history of the nonlinear optimization process used for estimating the parameters.

NLOSUMMARY

displays the summary of the nonlinear optimization process used for estimating the parameters.

NONE

displays none of the output. If specified, this option overrides all the other display options. The default displayed output is also suppressed.

SELECTION | SELECT

displays the model selection table.

STATISTICS | FITSTATS

displays the statistics of fit for each model. The statistics of fit are not displayed for models whose parameter estimation process does not converge.

If the PRINT= option is not specified or the ONLY *global-display-option* is not specified, then the default displayed output is equivalent to specifying PRINT=(SELECTION CONVSTATUS NLOSUMMARY STATISTICS ESTIMATES).

VARDEF=option

specifies the denominator to use for computing the covariance estimates. You can specify one of the following values for *option*:

DF

specifies that the number of nonmissing observations minus the model degrees of freedom (number of parameters) be used.

N

specifies that the number of nonmissing observations be used.

For more information about the covariance estimation, see the section “[Estimating Covariance and Standard Errors](#)” on page 1608.

VERBOSE=verbosity-level

specifies the amount of messages printed to the SAS log by PROC SEVERITY. A higher number prints messages with the same or more detail.

The following options control the model estimation and selection process:

CRITERION | CRITERIA | CRIT=criterion-option

specifies the model selection criterion.

If two or more models are specified for estimation, then the one with the best value for the selection criterion is chosen as the best model. If the OUTMODELINFO= data set is specified, then the best model’s observation has a value of 1 for the `_SELECTED_` variable. You can specify one of the following *criterion-options*:

AD

specifies the Anderson-Darling (AD) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

AIC

specifies the Akaike’s information criterion (AIC) as the selection criterion. A lower value is deemed better.

AICC

specifies the finite-sample corrected Akaike’s information criterion (AICC) as the selection criterion. A lower value is deemed better.

BIC

specifies Schwarz Bayesian information criterion (BIC) as the selection criterion. A lower value is deemed better.

CUSTOM

specifies the custom objective function as the selection criterion. You can specify this only if you also specify the [OBJECTIVE=](#) option. A lower value is deemed better.

CVM

specifies the Cramér-von Mises (CvM) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

KS

specifies the Kolmogorov-Smirnov (KS) statistic value, which is computed by using the empirical distribution function (EDF) estimate, as the selection criterion. A lower value is deemed better.

LOGLIKELIHOOD | LL

specifies $-2 * \log(L)$ as the selection criterion, where L is the likelihood of the data. A lower value is deemed better. This is the default.

For more information about these *criterion-options*, see the section “[Statistics of Fit](#)” on page 1619.

EMPIRICALCDF | EDF=method

specifies the method to use for computing the nonparametric or empirical estimate of the cumulative distribution function of the data. You can specify one of the following values for *method*:

AUTOMATIC | AUTO

specifies that the method be chosen automatically based on the data specification. This option is the default. If no censoring or truncation is specified, then the standard empirical estimation method (STANDARD) is chosen. If right-censoring or left-censoring are both specified, then Turnbull’s estimation method (TURNBULL) is chosen. For all other combinations of censoring and truncation, the Kaplan-Meier method (KAPLANMEIER) is chosen.

KAPLANMEIER | KM

specifies that the product limit estimator proposed by Kaplan and Meier (1958) be used. You cannot specify this method when both right-censoring and left-censoring are specified.

MODIFIEDKM | MKM <(options)>

specifies that the modified product limit estimator be used. This method allows Kaplan-Meier’s product limit estimates to be more robust by ignoring the contributions to the estimate due to small risk-set sizes. The risk set is the set of observations at the risk of failing, where an observation is said to fail if it has not been processed yet and might experience censoring or truncation. The minimum risk-set size that makes it eligible to be included in the estimation can be specified either as an absolute lower bound on the size (RSLB= option) or a relative lower bound determined by the formula cn^α proposed by Lai and Ying (1991). Values of c and α can be specified by using the C= and ALPHA= options, respectively. By default, the relative lower bound is used with values of $c = 1$ and $\alpha = 0.5$. However, you can modify the default by using the following *options*:

ALPHA | A=number

specifies the value to use for α when the lower bound on the risk set size is defined as cn^α . This value must satisfy $0 < \alpha < 1$.

C=number

specifies the value to use for c when the lower bound on the risk set size is defined as cn^α . This value must satisfy $c > 0$.

RSLB=number

specifies the absolute lower bound on the risk set size to be included in the estimate.

You cannot specify this method when both right-censoring and left-censoring are specified.

STANDARD | STD

specifies that the standard empirical estimation method be used. This ignores any censoring or truncation information even if specified, and can thus result in estimates that are more biased than those obtained with other methods more suitable for such data. You cannot specify this method when both right-censoring and left-censoring are specified.

TURNBULL | EM <(options)> (Experimental)

specifies that the Turnbull's method be used. This method is used when both right-censoring and left-censoring are specified. An iterative expectation-maximization (EM) algorithm proposed by Turnbull (1976) is used to compute the empirical estimates. If truncation is also specified, then the modification suggested by Frydman (1994) is used. You can modify the default behavior of the EM algorithm by using the following *options*:

ENSUREMLE

specifies that the final EDF estimates be maximum likelihood estimates. The Kuhn-Tucker conditions are computed for the likelihood maximization problem and checked to ensure that EM algorithm converges to maximum likelihood estimates. The method generalizes the method proposed by Gentleman and Geyer (1994) by taking into account the truncation information, if specified.

EPS=number

specifies the maximum relative error to be allowed between estimates of two consecutive iterations. This criterion is used to check the convergence of the algorithm. If you do not specify this option, then PROC SEVERITY uses a default value of 1.0E–8.

MAXITER=number

specifies the maximum number of iterations to attempt to find the empirical estimates. If you do not specify this option, then PROC SEVERITY uses a default value of 500.

ZEROPROB=number

specifies the threshold below which an empirical estimate of the probability is considered zero. This option is used to decide if the final estimate is a maximum likelihood estimate. This option does not have an effect if you do not specify the ENSUREMLE option. If you specify the ENSUREMLE option, but do not specify this option, then PROC SEVERITY uses a default value of 1.0E–8.

For more information about each of the methods, see the section “[Empirical Distribution Function Estimation Methods](#)” on page 1613.

EDFALPHA=confidence-level

specifies the confidence level in the (0,1) range that is used for computing the confidence intervals for the EDF estimates. The lower and upper confidence limits that correspond to this level are reported in the OUTCDF= data set, if specified, and displayed in the plot that is prepared when you specify the PLOTS=CDFPERDIST option.

If you do not specify this option, then PROC SEVERITY uses a default value of 0.05.

OBJECTIVE=symbol-name (Experimental)

names the symbol that represents the objective function in the specified SAS programming statements. For each model to be estimated, PROC SEVERITY executes the programming statements to compute the value of this symbol for each observation. The values are added across all observations to obtain

the value of the objective function. The optimization algorithm estimates the model parameters such that the objective function value is *minimized*. A separate optimization problem is solved for each candidate distribution. If a BY statement is specified, then a separate optimization problem is solved for each candidate distribution within each BY group.

For more information about writing SAS programming statements to define your own objective function, see the section “[Custom Objective Functions \(Experimental\)](#)” on page 1641.

BY Statement

A BY statement can be used in the SEVERITY procedure to process the input data set in groups of observations defined by the BY variables.

When a BY statement appears, the procedure expects the input data set to be sorted in the order of the BY variables.

LOSS Statement

LOSS < *response-variable-name* > < / *censoring-truncation-options* > ;

The LOSS statement specifies the name of the response or loss variable whose distribution needs to be modeled. You can also specify additional options to indicate any truncation or censoring of the response. The specification of response variable is optional if at least one type of censoring is specified. You must specify a response variable if no censoring is specified. If you specify more than one LOSS statement, then the first statement is used.

All the analysis variables specified in this statement must be present in the input data set that is specified by using the DATA= option in the PROC SEVERITY statement. The response variable is expected to have nonmissing values. If the variable has a missing value in an observation, then a warning is written to the SAS log and that observation is ignored.

The following *censoring-truncation-options* can be used in the LOSS statement:

LEFTCENSORED | **LC=***variable-name*

LEFTCENSORED | **LC=***number*

specifies the left-censoring variable or a global left-censoring limit.

You can use the *variable-name* argument to specify a data set variable that contains the left-censoring limit. If the value of this variable is missing, then PROC SEVERITY assumes that such observations are not left-censored.

Alternatively, you can use the *number* argument to specify a left-censoring limit value that applies to all the observations in the data set. This limit must be a nonzero positive number.

By definition of left-censoring, an exact value of the response is not known when it is less than or equal to the left-censoring limit. If the response variable is specified and the value of that variable is less than or equal to the value of the left-censoring limit for some observations, then PROC SEVERITY treats such observations as left-censored and the value of the response variable is ignored. If the response variable is specified and the value of that variable is greater than the value of the left-censoring limit

for some observations, then PROC SEVERITY assumes that such observations are not left-censored and the value of the left-censoring limit is ignored.

If both right-censoring and left-censoring limits are specified, then the left-censoring limit must be greater than or equal to the right-censoring limit. If both limits are identical, then the observation is assumed to be uncensored.

For more information about left-censoring, see the section “[Censoring and Truncation](#)” on page 1604.

LEFTTRUNCATED | **LT=***variable-name* < (*left-truncation-option*) >

LEFTTRUNCATED | **LT=***number* < (*left-truncation-option*) >

specifies the left-truncation variable or a global left-truncation threshold.

You can use the *variable-name* argument to specify a data set variable that contains the left-truncation threshold. If the value of this variable is missing or 0 for some observations, then PROC SEVERITY assumes that such observations are not left-truncated.

Alternatively, you can use the *number* argument to specify a left-truncation threshold that applies to all the observations in the data set. This threshold must be a nonzero positive number.

It is assumed that the response variable contains the observed values. By definition of left-truncation, you can observe only a value that is greater than the left-truncation threshold. If a response variable value is less than or equal to the left-truncation threshold, a warning is printed to the SAS log, and the observation is ignored. For more information about left-truncation, see the section “[Censoring and Truncation](#)” on page 1604.

The following left-truncation option can be specified for an alternative interpretation of the left-truncation threshold:

PROBOBSERVED | **POBS=***number*

specifies the probability of observability, which is defined as the probability that the underlying severity event is observed (and recorded) for the specified left-threshold value.

The specified *number* must lie in the (0.0, 1.0] interval. A value of 1.0 is equivalent to specifying that there is no left-truncation, because it means that no severity events can occur with a value less than or equal to the threshold. If you specify value of 1.0, PROC SEVERITY prints a warning to the SAS log and proceeds by assuming that **LEFTTRUNCATED=** option is not specified.

For more information, see the section “[Probability of Observability](#)” on page 1605.

RIGHTCENSORED | **RC=***variable-name*

RIGHTCENSORED | **RC=***number*

specifies the right-censoring variable or a global right-censoring limit.

You can use the *variable-name* argument to specify a data set variable that contains the right-censoring limit. If the value of this variable is missing, then PROC SEVERITY assumes that such observations are not right-censored.

Alternatively, you can use the *number* argument to specify a right-censoring limit value that applies to all the observations in the data set. This limit must be a nonzero positive number.

By definition of right-censoring, an exact value of the response is not known when it is greater than or equal to the right-censoring limit. If the response variable is specified and the value of that variable is greater than or equal to the value of the right-censoring limit for some observations, then PROC SEVERITY treats such observations as right-censored and the value of the response variable is ignored. If the response variable is specified and the value of that variable is less than the value of the right-censoring limit for some observations, then PROC SEVERITY assumes that such observations are not right-censored and the value of the right-censoring limit is ignored.

If both right-censoring and left-censoring limits are specified, then the left-censoring limit must be greater than or equal to the right-censoring limit. If both limits are identical, then the observation is assumed to be uncensored.

For more information about right-censoring, see the section “[Censoring and Truncation](#)” on page 1604.

RIGHTTRUNCATED | *RT=variable-name*

RIGHTTRUNCATED | *RT=number*

specifies the right-truncation variable or a global right-truncation threshold.

You can use the *variable-name* argument to specify a data set variable that contains the right-truncation threshold. If the value of this variable is missing for some observations, then PROC SEVERITY assumes that such observations are not right-truncated.

Alternatively, you can use the *number* argument to specify a right-truncation threshold that applies to all the observations in the data set. This threshold must be a nonzero positive number.

It is assumed that the response variable contains the observed values. By definition of right-truncation, you can observe only a value that is less than or equal to the right-truncation threshold. If a response variable value is greater than the right-truncation threshold, a warning is printed to the SAS log, and the observation is ignored. For more information about right-truncation, see the section “[Censoring and Truncation](#)” on page 1604.

WEIGHT Statement

WEIGHT *variable-name* ;

The WEIGHT statement specifies the name of a variable whose values represent the weight of each observation. PROC SEVERITY associates a weight of w to each observation, where w is the value of the WEIGHT variable for the observation. If the weight value is missing or less than or equal to 0, then the observation is ignored and a warning is written to the SAS log. When the WEIGHT statement is not specified, each observation is assigned a weight of 1. If you specify more than one WEIGHT statement, then the last statement is used.

The weights are normalized so that they add up to the actual sample size. In particular, weight of each observation is multiplied by $\frac{N}{\sum_{i=1}^N w_i}$, where N is the sample size.

SCALEMODEL Statement

SCALEMODEL *regressor-variable-list* < / *scalemodel-option* > ;

The SCALEMODEL statement specifies regression variables. All the variables specified in this statement must be present in the input data set that is specified by the DATA= option in the PROC SEVERITY statement. The scale parameter of each candidate distribution is linked to a linear combination of these regression variables along with an intercept. If a distribution does not have a scale parameter, then a model based on that distribution is not estimated. If you specify more than one SCALEMODEL statement, then the first statement is used.

The regressor variables are expected to have nonmissing values. If any of the variables has a missing value in an observation, then a warning is written to the SAS log and that observation is ignored.

For more information about modeling regression effects, see the section “[Estimating Regression Effects](#)” on page 1609.

You can specify the following *scalemodel-option* in the SCALEMODEL statement:

DFMIXTURE=*method-name* < (*method-options*) >

specifies the method for computing representative estimates of the cumulative distribution function (CDF) and the probability density function (PDF).

When regression variables are specified, the scale of the distribution depends on the values of the regressors. For a given distribution family, each observation in the input data set implies a different scaled version of the distribution. To compute estimates of CDF and PDF that are comparable across different distribution families, PROC SEVERITY needs to construct a single representative distribution from all such distributions. You can specify one of the following *method-name* values to specify the method that is used to construct the representative distribution. For more information about each of the methods, see the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1611.

FULL

specifies that the representative distribution be the mixture of N distributions such that each distribution has a scale value that is implied by each of the N observations that are used for estimation. This method is the slowest.

MEAN

specifies that the representative distribution be the one-point mixture of the distribution whose scale value is the mean of the N scale values that are implied by the N observations that are used for estimation. If you do not specify the DFMIXTURE= option, then this method is used by default. This is also the fastest method.

QUANTILE < (K=q) >

specifies that the representative distribution be the mixture of a fixed number of distributions whose scale values are the quantiles from the sample of N scale values that are implied by the N observations in the current BY group (or in the entire DATA= data set if the BY statement is not specified).

You can use the K= option to specify the number of distributions in the mixture. If you specify K=q, then the mixture contains $(q - 1)$ distributions such that each distribution has as its scale one of the $(q - 1)$ -quantiles.

If you do not specify the `K=` option, then PROC SEVERITY uses the default of 2, which implies the use of a one-point mixture with a distribution whose scale value is the median of all scale values.

RANDOM <(random-method-options)>

specifies that the representative distribution be the mixture of a fixed number of distributions whose scale values are the scale values that are implied by a randomly chosen subset of the set of all observations in the current BY group (or in the entire DATA= data set if the BY statement is not specified). The same subset of observations is used for each distribution family.

You can specify the following *random-method-options* to specify how the subset is chosen:

K=r

specifies the number of distributions to include in the mixture. If you do not specify this option, then PROC SEVERITY uses the default of 15.

SEED=number

specifies the seed that is used to generate the uniform random sample of observation indices. If you do not specify this option, then PROC SEVERITY generates a seed internally that is based on the current value of the system clock.

DIST Statement

DIST *distribution-name-or-keyword* <(distribution-option)> <distribution-name-or-keyword> <(distribution-option)> > ... ></ preprocess-options> ;

The DIST statement specifies candidate distributions to be estimated by the SEVERITY procedure. You can specify multiple DIST statements, and each statement can contain one or more distribution specifications.

For your convenience, PROC SEVERITY provides the following 10 different predefined distributions (the name in the parentheses is the name to use in the DIST statement): Burr (BURR), exponential (EXP), gamma (GAMMA), generalized Pareto (GPD), inverse Gaussian or Wald (IGAUSS), lognormal (LOGN), Pareto (PARETO), Tweedie (TWEEDIE), scaled Tweedie (STWEEDIE), and Weibull (WEIBULL). These are described in detail in the section “[Predefined Distributions](#)” on page 1594.

You can specify any of the predefined distributions or any distribution that you have defined. If the specified distribution is not a predefined distribution, then you must submit the CMPLIB= system option with appropriate libraries before you submit the PROC SEVERITY step to enable the procedure to find the functions associated with your distribution. The predefined distributions are defined in the Sashelp.Svrtldist library. However, you are not required to specify this library in the CMPLIB= system option.

As a convenience, you can also use a shortcut keyword to indicate a list of distributions. You can specify one or more of the following keywords:

ALL

specifies all the predefined distributions and the distributions that you have defined in the libraries that are specified in the CMPLIB= system option. In addition to the eight predefined distributions included by the _PREDEFINED_ keyword, this list also includes the Tweedie and scaled Tweedie distributions that are defined in the Sashelp.Svrtldist library.

PREDEFINED

specifies the list of eight predefined distributions: BURR, EXP, GAMMA, GPD, IGAUSS, LOGN, PARETO, and WEIBULL. Although the TWEEDIE and STWEEDIE distributions are available in the Sashelp.Svrtldist library along with these eight distributions, they are not included by this keyword. If you want to fit the TWEEDIE and STWEEDIE distributions, then you must specify them explicitly or use the `_ALL_` keyword.

USER

specifies the list of all the distributions that you have defined in the libraries that are specified in the `CMPLIB=` system option. This list does not include the distributions defined in the Sashelp.Svrtldist library, even if you have specified Sashelp.Svrtldist in the `CMPLIB=` option.

The use of these keywords, especially `_ALL_`, can result in a large list of distributions, which might take a longer time to estimate. A warning is printed to the SAS log if the number of total distribution models to estimate exceeds 10.

If you specify the `OUTCDF=` option or request a CDF plot and you do not specify any `DIST` statement, then PROC SEVERITY does not fit any distributions and produces the empirical estimates of the cumulative distribution function.

The following *distribution-option* values can be used in the `DIST` statement for a distribution name that is not a shortcut keyword:

INIT=(name=value ... name=value)

specifies the initial values to be used for the distribution parameters to start the parameter estimation process. The values must be specified by parameter names. The parameter names must match the names used in the model definition. For example, let a model M's definition contain a `M_PDF` function with following signature:

```
function M_PDF(x, alpha, beta);
```

For this model, the names **alpha** and **beta** must be used for the `INIT` option. The names are case-insensitive. If you do not specify initial values for some parameters in the `INIT` statement, then a default value of 0.001 is assumed for those parameters. If you specify an incorrect parameter, PROC SEVERITY prints a warning to the SAS log and does not fit the model. All specified values must be nonmissing.

If you are modeling regression effects, then the initial value of the first distribution parameter (**alpha** in the preceding example) should be the initial *base* value of the scale parameter or log-transformed scale parameter. For more information, see the section “[Estimating Regression Effects](#)” on page 1609.

The use of `INIT=` option is one of the three methods available for initializing the parameters. For more information, see the section “[Parameter Initialization](#)” on page 1608. If none of the initialization methods is used, then PROC SEVERITY initializes all parameters to 0.001.

You can specify the following *preprocess-options* in the DIST statement:

LISTONLY

specifies that the list of all candidate distributions be printed to the SAS log without doing any further processing on them. This option is especially useful when you use a shortcut keyword to include a list of distributions. It enables you to find out which distributions are included by the keyword.

VALIDATEONLY

specifies that all candidate distributions be checked for validity without doing any further processing on them. If a distribution is invalid, the reason for invalidity is written to the SAS log. If all distributions are valid, then the distribution information is written to the SAS log. The information includes name, description, validity status (valid or invalid), and number of distribution parameters. The information is not written to the SAS log if you have specified an OUTMODELINFO= data set or the PRINT=DISTINFO or PRINT=ALL option in the PROC SEVERITY statement. This option is especially useful when you specify your own distributions or when you specify the `_USER_` or `_ALL_` keywords in the DIST statement. It enables you to check whether your custom distribution definitions satisfy PROC SEVERITY's requirements for the specified modeling task. It is recommended that you specify the SCALEMODEL statement if you intend to fit a model with regression effects, because the SCALEMODEL statement instructs PROC SEVERITY to perform additional checks to validate whether regression effects can be modeled on each candidate distribution.

NLOPTIONS Statement

NLOPTIONS *options* ;

The SEVERITY procedure uses the nonlinear optimization (NLO) subsystem to perform the nonlinear optimization of the likelihood function to obtain the estimates of distribution and regression parameters. You can use the NLOPTIONS statement to control different aspects of this optimization process. For most problems, the default settings of the optimization process are adequate. However, in some cases it might be useful to change the optimization technique or to change the maximum number of iterations. The following statement uses the MAXITER= option to set the maximum number of iterations to 200 and uses the TECH= option to change the optimization technique to the double-dogleg optimization (DBLDOG) rather than the default technique, the trust region optimization (TRUEG), used in the SEVERITY procedure:

```
nloptions tech=dbldog maxiter=200;
```

A discussion of the full range of *options* that can be used with the NLOPTIONS statement is given in Chapter 6, “Nonlinear Optimization Methods.” The SEVERITY procedure supports all of those options except the options that are related to displaying the optimization information. You can use the PRINT= option in the PROC SEVERITY statement to request the optimization summary and iteration history. If you specify more than one NLOPTIONS statement, then the first statement is used.

Programming Statements (Experimental)

You can use a series of programming statements that use variables in the input data set specified by `DATA=` option in the `PROC SEVERITY` statement to assign a value to an objective function symbol. The objective function symbol must be specified using the `OBJECTIVE=` option in the `PROC SEVERITY` statement. If you do not specify the `OBJECTIVE=` option in the `PROC SEVERITY` statement, then the programming statements are ignored and models are estimated using the maximum likelihood method.

You can use most `DATA` step statements and functions in your program. Any additional functions, restrictions, and differences are listed in the section “[Custom Objective Functions \(Experimental\)](#)” on page 1641.

Details: SEVERITY Procedure

Predefined Distributions

`PROC SEVERITY` assumes the following model for the response variable Y

$$Y \sim \mathcal{F}(\Theta)$$

where \mathcal{F} is a continuous probability distribution with parameters Θ . The model hypothesizes that the observed response is generated from a stochastic process that is governed by the distribution \mathcal{F} . This model is typically referred to as the error model. Given a representative input sample of response variable values, `PROC SEVERITY` estimates the model parameters for any distribution \mathcal{F} and computes the statistics of fit for each model. This enables you to find the distribution that is most likely to generate the observed sample.

A set of predefined distributions is provided with the `SEVERITY` procedure. A summary of the distributions is provided in [Table 23.2](#). For each distribution, the table lists the name of the distribution that should be used in the `DIST` statement, the parameters of the distribution along with their bounds, and the mathematical expressions for the probability density function (PDF) and cumulative distribution function (CDF) of the distribution.

All the predefined distributions, except `LOGN` and `TWEEDIE`, are parameterized such that their first parameter is the scale parameter. For `LOGN`, the first parameter μ is a log-transformed scale parameter. `TWEEDIE` does not have a scale parameter. The presence of scale parameter or a log-transformed scale parameter enables you to use all of the predefined distributions, except `TWEEDIE`, as a candidate for estimating regression effects.

A distribution model is associated with each predefined distribution. You can also define your own distribution model, which is a set of functions and subroutines that you define by using the `FCMP` procedure. See the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1623 for more information.

Table 23.2 Predefined SEVERITY Distributions

Name	Distribution	Parameters	PDF (f) and CDF (F)
BURR	Burr	$\theta > 0, \alpha > 0,$ $\gamma > 0$	$f(x) = \frac{\alpha \gamma z^\gamma}{x(1+z^\gamma)^{(\alpha+1)}}$ $F(x) = 1 - \left(\frac{1}{1+z^\gamma}\right)^\alpha$
EXP	Exponential	$\theta > 0$	$f(x) = \frac{1}{\theta} e^{-z}$ $F(x) = 1 - e^{-z}$
GAMMA	Gamma	$\theta > 0, \alpha > 0$	$f(x) = \frac{z^\alpha e^{-z}}{x \Gamma(\alpha)}$ $F(x) = \frac{\gamma(\alpha, z)}{\Gamma(\alpha)}$
GPD	Generalized Pareto	$\theta > 0, \xi > 0$	$f(x) = \frac{1}{\theta} (1 + \xi z)^{-1-1/\xi}$ $F(x) = 1 - (1 + \xi z)^{-1/\xi}$
IGAUSS	Inverse Gaussian (Wald)	$\theta > 0, \alpha > 0$	$f(x) = \frac{1}{\theta} \sqrt{\frac{\alpha}{2\pi z^3}} e^{-\frac{\alpha(z-1)^2}{2z}}$ $F(x) = \Phi\left((z-1)\sqrt{\frac{\alpha}{z}}\right) + \Phi\left(-(z+1)\sqrt{\frac{\alpha}{z}}\right) e^{2\alpha}$
LOGN	Lognormal	μ (no bounds), $\sigma > 0$	$f(x) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2}$ $F(x) = \Phi\left(\frac{\log(x)-\mu}{\sigma}\right)$
PARETO	Pareto	$\theta > 0, \alpha > 0$	$f(x) = \frac{\alpha \theta^\alpha}{(x+\theta)^{\alpha+1}}$ $F(x) = 1 - \left(\frac{\theta}{x+\theta}\right)^\alpha$
TWEEDIE	Tweedie ⁶	$\mu > 0, \phi > 0,$ $p > 1$	$f(x) = a(x, \phi) \exp\left[\frac{1}{\phi} \left(\frac{x\mu^{1-p}}{1-p} - \kappa(\mu, p)\right)\right]$ $F(x) = \int_0^x f(t) dt$
STWEEDIE	Scaled Tweedie ⁶	$\theta > 0, \lambda > 0,$ $1 < p < 2$	$f(x) = a(x, \theta, \lambda, p) \exp\left(-\frac{x}{\theta} - \lambda\right)$ $F(x) = \int_0^x f(t) dt$
WEIBULL	Weibull	$\theta > 0, \tau > 0$	$f(x) = \frac{1}{x} \tau z^\tau e^{-z^\tau}$ $F(x) = 1 - e^{-z^\tau}$

Notes:

1. $z = x/\theta$, wherever z is used.
2. θ denotes the scale parameter for all the distributions. For LOGN, $\log(\theta) = \mu$.
3. Parameters are listed in the order in which they are defined in the distribution model.
4. $\gamma(a, b) = \int_0^b t^{a-1} e^{-t} dt$ is the lower incomplete gamma function.
5. $\Phi(y) = \frac{1}{2} \left(1 + \operatorname{erf}\left(\frac{y}{\sqrt{2}}\right)\right)$ is the standard normal CDF.
6. See the section “[Tweedie Distributions](#)” on page 1596 for more information.

Tweedie Distributions

Tweedie distributions are a special case of the exponential dispersion family (Jørgensen, 1987) with a property that the variance of the distribution is equal to $\phi\mu^p$, where μ is the mean of the distribution, ϕ is a dispersion parameter, and p is an index parameter as discovered by Tweedie (1984). The distribution is defined for all values of p except for values of p in the open interval $(0, 1)$. Many important known distributions are a special case of Tweedie distributions including normal ($p=0$), Poisson ($p=1$), gamma ($p=2$), and the inverse Gaussian ($p=3$). Apart from these special cases, the probability density function (PDF) of the Tweedie distribution does not have an analytic expression. For $p > 1$, it has the form (Dunn and Smyth 2005),

$$f(x; \mu, \phi, p) = a(x, \phi) \exp \left[\frac{1}{\phi} \left(\frac{x\mu^{1-p}}{1-p} - \kappa(\mu, p) \right) \right]$$

where $\kappa(\mu, p) = \mu^{2-p}/(2-p)$ for $p \neq 2$ and $\kappa(\mu, p) = \log(\mu)$ for $p = 2$. The function $a(x, \phi)$ does not have an analytical expression. It is typically evaluated using series expansion methods described in Dunn and Smyth (2005).

For $1 < p < 2$, the Tweedie distribution is a compound Poisson-gamma mixture distribution, which is the distribution of S defined as

$$S = \sum_{i=1}^N X_i$$

where $N \sim \text{Poisson}(\lambda)$ and $X_i \sim \text{gamma}(\alpha, \theta)$ are iid gamma random variables with shape parameter α and scale parameter θ . At $X = 0$, the density is a probability mass that is governed by the Poisson distribution, and for values of $X > 0$, it is a mixture of gamma variates with Poisson mixing probability. The parameters λ , α and θ are related to the natural parameters μ , ϕ , and p of the Tweedie distribution as

$$\begin{aligned} \lambda &= \frac{\mu^{2-p}}{\phi(2-p)} \\ \alpha &= \frac{2-p}{p-1} \\ \theta &= \phi(p-1)\mu^{p-1} \end{aligned}$$

The mean of a Tweedie distribution is positive for $p > 1$.

Two predefined versions of the Tweedie distribution are provided with the SEVERITY procedure. The first version, named **TWEEDIE** and defined for $p > 1$, has the natural parameterization with parameters μ , ϕ , and p . The second version, named **STWEEDIE** and defined for $1 < p < 2$, is the version with a scale parameter. It corresponds to the compound Poisson-gamma distribution with gamma scale parameter θ , Poisson mean parameter λ , and the index parameter p . The index parameter decides the shape parameter α of the gamma distribution as

$$\alpha = \frac{2-p}{p-1}$$

The parameters θ and λ of the **STWEEDIE** distribution are related to the parameters μ and ϕ of the **TWEEDIE** distribution as

$$\begin{aligned} \mu &= \lambda\theta\alpha \\ \phi &= \frac{(\lambda\theta\alpha)^{2-p}}{\lambda(2-p)} = \frac{\theta}{(p-1)(\lambda\theta\alpha)^{p-1}} \end{aligned}$$

You can fit either version when there are no regression variables. Each version has its own merits. If you fit the TWEEDIE version, you have the direct estimate of the overall mean of the distribution. If you are interested in the most practical range of the index parameter $1 < p < 2$, then you can fit the STWEEDIE version, which provides you direct estimates of the Poisson and gamma components that comprise the distribution (an estimate of the gamma shape parameter α is easily obtained from the estimate of p).

If you want to estimate the effect of exogenous (regression) variables on the distribution, then you must use the STWEEDIE version, because PROC SEVERITY requires a distribution to have a scale parameter in order to estimate regression effects. See the section “[Estimating Regression Effects](#)” on page 1609 for more information. The gamma scale parameter θ is the scale parameter of the STWEEDIE distribution. If you are interested in determining the effect of regression variables on the mean of the distribution, you can do so by first fitting the STWEEDIE distribution to determine the effect of the regression variables on the scale parameter θ . Then, you can easily estimate how the mean of the distribution μ is affected by the regression variables using the relationship $\mu = c\theta$, where $c = \lambda\alpha = \lambda(2-p)/(p-1)$. The estimates of the regression parameters remain the same, whereas the estimate of the intercept parameter is adjusted by the estimates of the λ and p parameters.

Parameter Initialization for Predefined Distributions

The parameters are initialized by using the method of moments for all the distributions, except for the gamma and the Weibull distributions. For the gamma distribution, approximate maximum likelihood estimates are used. For the Weibull distribution, the method of percentile matching is used.

Given n observations of the severity value y_i ($1 \leq i \leq n$), the estimate of k th raw moment is denoted by m_k and computed as

$$m_k = \frac{1}{n} \sum_{i=1}^n y_i^k$$

The 100 p th percentile is denoted by π_p ($0 \leq p \leq 1$). By definition, π_p satisfies

$$F(\pi_p-) \leq p \leq F(\pi_p)$$

where $F(\pi_p-) = \lim_{h \downarrow 0} F(\pi_p - h)$. PROC SEVERITY uses the following practical method of computing π_p . Let $\hat{F}_n(y)$ denote the empirical distribution function (EDF) estimate at a severity value y . Let y_p^- and y_p^+ denote two consecutive values in the ascending sequence of y values such that $\hat{F}_n(y_p^-) < p$ and $\hat{F}_n(y_p^+) \geq p$. Then, the estimate $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = y_p^- + \frac{p - \hat{F}_n(y_p^-)}{\hat{F}_n(y_p^+) - \hat{F}_n(y_p^-)}(y_p^+ - y_p^-)$$

Let ϵ denote the smallest double-precision floating-point number such that $1 + \epsilon > 1$. This machine precision constant can be obtained by using the CONSTANT function in Base SAS software.

The details of how parameters are initialized for each predefined distribution are as follows:

BURR The parameters are initialized by using the method of moments. The k th raw moment of the Burr distribution is:

$$E[X^k] = \frac{\theta^k \Gamma(1 + k/\gamma) \Gamma(\alpha - k/\gamma)}{\Gamma(\alpha)}, \quad -\gamma < k < \alpha\gamma$$

Three moment equations $E[X^k] = m_k$ ($k = 1, 2, 3$) need to be solved for initializing the three parameters of the distribution. In order to get an approximate closed form solution, the second shape parameter $\hat{\gamma}$ is initialized to a value of 2. If $2m_3 - 3m_1m_2 > 0$, then simplifying and solving the moment equations yields the following feasible set of initial values:

$$\hat{\theta} = \sqrt{\frac{m_2m_3}{2m_3 - 3m_1m_2}}, \quad \hat{\alpha} = 1 + \frac{m_3}{2m_3 - 3m_1m_2}, \quad \hat{\gamma} = 2$$

If $2m_3 - 3m_1m_2 < \epsilon$, then the parameters are initialized as follows:

$$\hat{\theta} = \sqrt{m_2}, \quad \hat{\alpha} = 2, \quad \hat{\gamma} = 2$$

EXP The parameters are initialized by using the method of moments. The k th raw moment of the exponential distribution is:

$$E[X^k] = \theta^k \Gamma(k + 1), \quad k > -1$$

Solving $E[X] = m_1$ yields the initial value of $\hat{\theta} = m_1$.

GAMMA The parameter α is initialized by using its *approximate* maximum likelihood (ML) estimate. For a set of n iid observations y_i ($1 \leq i \leq n$), drawn from a gamma distribution, the log likelihood, l , is defined as follows:

$$\begin{aligned} l &= \sum_{i=1}^n \log \left(y_i^{\alpha-1} \frac{e^{-y_i/\theta}}{\theta^\alpha \Gamma(\alpha)} \right) \\ &= (\alpha - 1) \sum_{i=1}^n \log(y_i) - \frac{1}{\theta} \sum_{i=1}^n y_i - n\alpha \log(\theta) - n \log(\Gamma(\alpha)) \end{aligned}$$

Using a shorter notation of \sum to denote $\sum_{i=1}^n$ and solving the equation $\partial l / \partial \theta = 0$ yields the following ML estimate of θ :

$$\hat{\theta} = \frac{\sum y_i}{n\alpha} = \frac{m_1}{\alpha}$$

Substituting this estimate in the expression of l and simplifying gives

$$l = (\alpha - 1) \sum \log(y_i) - n\alpha - n\alpha \log(m_1) + n\alpha \log(\alpha) - n \log(\Gamma(\alpha))$$

Let d be defined as follows:

$$d = \log(m_1) - \frac{1}{n} \sum \log(y_i)$$

Solving the equation $\partial l / \partial \alpha = 0$ yields the following expression in terms of the digamma function, $\psi(\alpha)$:

$$\log(\alpha) - \psi(\alpha) = d$$

The digamma function can be approximated as follows:

$$\hat{\psi}(\alpha) \approx \log(\alpha) - \frac{1}{\alpha} \left(0.5 + \frac{1}{12\alpha + 2} \right)$$

This approximation is within 1.4% of the true value for all the values of $\alpha > 0$ except when α is arbitrarily close to the positive root of the digamma function (which is approximately 1.461632). Even for the values of α that are close to the positive root, the absolute error between true and approximate values is still acceptable ($|\hat{\psi}(\alpha) - \psi(\alpha)| < 0.005$ for $\alpha > 1.07$). Solving the equation that arises from this approximation yields the following estimate of α :

$$\hat{\alpha} = \frac{3 - d + \sqrt{(d - 3)^2 + 24d}}{12d}$$

If this approximate ML estimate is infeasible, then the method of moments is used. The k th raw moment of the gamma distribution is:

$$E[X^k] = \theta^k \frac{\Gamma(\alpha + k)}{\Gamma(\alpha)}, \quad k > -\alpha$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial value for α :

$$\hat{\alpha} = \frac{m_1^2}{m_2 - m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance), then α is initialized as follows:

$$\hat{\alpha} = 1$$

After computing the estimate of α , the estimate of θ is computed as follows:

$$\hat{\theta} = \frac{m_1}{\hat{\alpha}}$$

Both the maximum likelihood method and the method of moments arrive at the same relationship between $\hat{\alpha}$ and $\hat{\theta}$.

GPD

The parameters are initialized by using the method of moments. Notice that for $\xi > 0$, the CDF of the generalized Pareto distribution (GPD) is:

$$\begin{aligned} F(x) &= 1 - \left(1 + \frac{\xi x}{\theta}\right)^{-1/\xi} \\ &= 1 - \left(\frac{\theta/\xi}{x + \theta/\xi}\right)^{1/\xi} \end{aligned}$$

This is equivalent to a Pareto distribution with scale parameter $\theta_1 = \theta/\xi$ and shape parameter $\alpha = 1/\xi$. Using this relationship, the parameter initialization method used for the PARETO distribution is used to get the following initial values for the parameters of the GPD distribution:

$$\hat{\theta} = \frac{m_1 m_2}{2(m_2 - m_1^2)}, \quad \hat{\xi} = \frac{m_2 - 2m_1^2}{2(m_2 - m_1^2)}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance) or $m_2 - 2m_1^2 < \epsilon$, then the parameters are initialized as follows:

$$\hat{\theta} = \frac{m_1}{2}, \quad \hat{\xi} = \frac{1}{2}$$

IGAUSS The parameters are initialized by using the method of moments. Note that the standard parameterization of the inverse Gaussian distribution (also known as the Wald distribution), in terms of the location parameter μ and shape parameter λ , is as follows (Klugman, Panjer, and Willmot 1998, p. 583):

$$f(x) = \sqrt{\frac{\lambda}{2\pi x^3}} \exp\left(\frac{-\lambda(x - \mu)^2}{2\mu^2 x}\right)$$

$$F(x) = \Phi\left(\left(\frac{x}{\mu} - 1\right) \sqrt{\frac{\lambda}{x}}\right) + \Phi\left(-\left(\frac{x}{\mu} + 1\right) \sqrt{\frac{\lambda}{x}}\right) \exp\left(\frac{2\lambda}{\mu}\right)$$

For this parameterization, it is known that the mean is $E[X] = \mu$ and the variance is $Var[X] = \mu^3/\lambda$, which yields the second raw moment as $E[X^2] = \mu^2(1 + \mu/\lambda)$ (computed by using $E[X^2] = Var[X] + (E[X])^2$).

The predefined IGAUSS distribution in PROC SEVERITY uses the following alternate parameterization to allow the distribution to have a scale parameter, θ :

$$f(x) = \sqrt{\frac{\alpha\theta}{2\pi x^3}} \exp\left(\frac{-\alpha(x - \theta)^2}{2x\theta}\right)$$

$$F(x) = \Phi\left(\left(\frac{x}{\theta} - 1\right) \sqrt{\frac{\alpha\theta}{x}}\right) + \Phi\left(-\left(\frac{x}{\theta} + 1\right) \sqrt{\frac{\alpha\theta}{x}}\right) \exp(2\alpha)$$

The parameters θ (scale) and α (shape) of this alternate form are related to the parameters μ and λ of the preceding form such that $\theta = \mu$ and $\alpha = \lambda/\mu$. Using this relationship, the first and second raw moments of the IGAUSS distribution are:

$$E[X] = \theta$$

$$E[X^2] = \theta^2 \left(1 + \frac{1}{\alpha}\right)$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\theta} = m_1, \quad \hat{\alpha} = \frac{m_1^2}{m_2 - m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance), then the parameters are initialized as follows:

$$\hat{\theta} = m_1, \quad \hat{\alpha} = 1$$

LOGN The parameters are initialized by using the method of moments. The k th raw moment of the lognormal distribution is:

$$E[X^k] = \exp\left(k\mu + \frac{k^2\sigma^2}{2}\right)$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\mu} = 2 \log(m_1) - \frac{\log(m_2)}{2}, \quad \hat{\sigma} = \sqrt{\log(m_2) - 2 \log(m_1)}$$

PARETO The parameters are initialized by using the method of moments. The k th raw moment of the Pareto distribution is:

$$E[X^k] = \frac{\theta^k \Gamma(k+1) \Gamma(\alpha-k)}{\Gamma(\alpha)}, \quad -1 < k < \alpha$$

Solving $E[X] = m_1$ and $E[X^2] = m_2$ yields the following initial values:

$$\hat{\theta} = \frac{m_1 m_2}{m_2 - 2m_1^2}, \quad \hat{\alpha} = \frac{2(m_2 - m_1^2)}{m_2 - 2m_1^2}$$

If $m_2 - m_1^2 < \epsilon$ (almost zero sample variance) or $m_2 - 2m_1^2 < \epsilon$, then the parameters are initialized as follows:

$$\hat{\theta} = m_1, \quad \hat{\alpha} = 2$$

TWEEDIE The parameter p is initialized by assuming that the sample is generated from a gamma distribution with shape parameter α and by computing $\hat{p} = \frac{\hat{\alpha}+2}{\hat{\alpha}+1}$. The initial value $\hat{\alpha}$ is obtained from using the method previously described for the GAMMA distribution. The parameter μ is the mean of the distribution. Hence, it is initialized to the sample mean as

$$\hat{\mu} = m_1$$

Variance of a Tweedie distribution is equal to $\phi\mu^p$. Thus, the sample variance is used to initialize the value of ϕ as

$$\hat{\phi} = \frac{m_2 - m_1^2}{\hat{\mu} \hat{p}}$$

STWEEDIE STWEEDIE is a compound Poisson-gamma mixture distribution with mean $\mu = \lambda\theta\alpha$, where α is the shape parameter of the gamma random variables in the mixture and the parameter p is determined solely by α . First, the parameter p is initialized by assuming that the sample is generated from a gamma distribution with shape parameter α and by computing $\hat{p} = \frac{\hat{\alpha}+2}{\hat{\alpha}+1}$. The initial value $\hat{\alpha}$ is obtained from using the method previously described for the GAMMA distribution. As done for initializing the parameters of the TWEEDIE distribution, the sample mean and variance are used to compute the values $\hat{\mu}$ and $\hat{\phi}$ as

$$\hat{\mu} = m_1$$

$$\hat{\phi} = \frac{m_2 - m_1^2}{\hat{\mu}\hat{p}}$$

Based on the relationship between the parameters of TWEEDIE and STWEEDIE distributions described in the section “[Tweedie Distributions](#)” on page 1596, values of θ and λ are initialized as

$$\hat{\theta} = \hat{\phi}(\hat{p} - 1)\hat{\mu}^{p-1}$$

$$\hat{\lambda} = \frac{\hat{\mu}}{\hat{\theta}\hat{\alpha}}$$

WEIBULL The parameters are initialized by using the percentile matching method. Let $q1$ and $q3$ denote the estimates of the 25th and 75th percentiles, respectively. Using the formula for the CDF of Weibull distribution, they can be written as

$$1 - \exp(-(q1/\theta)^\tau) = 0.25$$

$$1 - \exp(-(q3/\theta)^\tau) = 0.75$$

Simplifying and solving these two equations yields the following initial values:

$$\hat{\theta} = \exp\left(\frac{r \log(q1) - \log(q3)}{r - 1}\right), \quad \hat{\tau} = \frac{\log(\log(4))}{\log(q3) - \log(\hat{\theta})}$$

where $r = \log(\log(4))/\log(\log(4/3))$. These initial values agree with those suggested in Klugman, Panjer, and Willmot (1998).

A summary of the initial values of all the parameters for all the predefined distributions is given in [Table 23.3](#). The table also provides the names of the parameters to use in the **INIT=** option in the DIST statement if you want to provide a different initial value.

Table 23.3 Parameter Initialization for Predefined Distributions

Distribution	Parameter	Name for INIT option	Default Initial Value
BURR	θ	theta	$\sqrt{\frac{m_2 m_3}{2m_3 - 3m_1 m_2}}$
	α	alpha	$1 + \frac{m_3}{2m_3 - 3m_1 m_2}$
	γ	gamma	2
EXP	θ	theta	m_1
GAMMA	θ	theta	m_1/α
	α	alpha	$\frac{3-d+\sqrt{(d-3)^2+24d}}{12d}$
GPD	θ	theta	$m_1 m_2 / (2(m_2 - m_1^2))$
	ξ	xi	$(m_2 - 2m_1^2) / (2(m_2 - m_1^2))$
IGAUSS	θ	theta	m_1
	α	alpha	$m_1^2 / (m_2 - m_1^2)$
LOGN	μ	mu	$2 \log(m_1) - \log(m_2)/2$
	σ	sigma	$\sqrt{\log(m_2) - 2 \log(m_1)}$
PARETO	θ	theta	$m_1 m_2 / (m_2 - 2m_1^2)$
	α	alpha	$2(m_2 - m_1^2) / (m_2 - 2m_1^2)$
TWEEDIE	μ	mu	m_1
	ϕ	phi	$(m_2 - m_1^2) / m_1^p$
	p	p	$(\alpha + 2) / (\alpha + 1)$ where $\alpha = \frac{3-d+\sqrt{(d-3)^2+24d}}{12d}$
STWEEDIE	θ	theta	$(m_2 - m_1^2)(p - 1) / m_1$
	λ	lambda	$m_1^2 / (\alpha(m_2 - m_1^2)(p - 1))$
	p	p	$(\alpha + 2) / (\alpha + 1)$ where $\alpha = \frac{3-d+\sqrt{(d-3)^2+24d}}{12d}$
WEIBULL	θ	theta	$\exp\left(\frac{r \log(q1) - \log(q3)}{r-1}\right)$
	τ	tau	$\log(\log(4)) / (\log(q3) - \log(\hat{\theta}))$

Notes:

- m_k denotes the k th raw moment
- $d = \log(m_1) - (\sum \log(y_i)) / n$
- $q1$ and $q3$ denote the 25th and 75th percentiles, respectively
- $r = \log(\log(4)) / \log(\log(4/3))$

Censoring and Truncation

One of the key features of PROC SEVERITY is that it enables you to specify whether the severity event's magnitude is observable and if it is observable, then whether the exact value of the magnitude is known. If an event is unobservable when the magnitude is in certain intervals, then it is referred to as a truncation effect. If the exact magnitude of the event is not known, but it is known to have a value in a certain interval, then it is referred to as a censoring effect.

PROC SEVERITY allows a severity event to be subject to any combination of the following four censoring and truncation effects:

- **Left-truncation:** An event is said to be left-truncated if it is observed only when $Y > T^l$, where Y denotes the random variable for the magnitude and T^l denotes a random variable for the truncation threshold. You can specify left-truncation using the `LEFTTRUNCATED=` option in the LOSS statement.
- **Right-truncation:** An event is said to be right-truncated if it is observed only when $Y \leq T^r$, where Y denotes the random variable for the magnitude and T^r denotes a random variable for the truncation threshold. You can specify right-truncation using the `RIGHTTRUNCATED=` option in the LOSS statement.
- **Left-censoring:** An event is said to be left-censored if it is known that the magnitude is $Y \leq C^l$, but the exact value of Y is not known. C^l is a random variable for the censoring limit. You can specify left-censoring using the `LEFTCENSORED=` option in the LOSS statement.
- **Right-censoring:** An event is said to be right-censored if it is known that the magnitude is $Y > C^r$, but the exact value of Y is not known. C^r is a random variable for the censoring limit. You can specify right-censoring using the `RIGHTCENSORED=` option in the LOSS statement.

For each effect, you can specify a different threshold or limit for each observation or specify a single threshold or limit that applies to all the observations.

If all the four types of effects are present on an event, then the following relationship holds: $T^l < C^r \leq C^l \leq T^r$. PROC SEVERITY checks these relationships and write a warning to the SAS log if any is violated.

If the response variable is specified in the LOSS statement, then PROC SEVERITY also checks whether each observation satisfies the definitions of the specified censoring and truncation effects. If left-truncation is specified, then PROC SEVERITY ignores observations where $Y \leq T^l$, because such observations are not observable by definition. Similarly, if right-truncation is specified, then PROC SEVERITY ignores observations where $Y > T^r$. If left-censoring is specified, then PROC SEVERITY treats an observation with $Y > C^l$ as uncensored and ignores the value of C^l . The observations with $Y \leq C^l$ are considered as left-censored, and the value of Y is ignored. If right-censoring is specified, then PROC SEVERITY treats an observation with $Y \leq C^r$ as uncensored and ignores the value of C^r . The observations with $Y > C^r$ are considered as right-censored, and the value of Y is ignored. If both left-censoring and right-censoring are specified, it is referred to as interval-censoring. If $C^r < C^l$ is satisfied for an observation, then it is considered as interval-censored and the value of the response variable is ignored. If $C^r = C^l$ for an observation, then PROC SEVERITY assumes that observation to be uncensored. If all the observations in a data set are censored in some form, then the specification of the response variable in the LOSS statement

is optional, because the actual value of the response variable is not required for the purposes of estimating a model.

Specification of censoring and truncation affects the likelihood of the data (see the section “[Likelihood Function](#)” on page 1606) and how the empirical distribution function (EDF) is estimated (see the section “[Empirical Distribution Function Estimation Methods](#)” on page 1613).

Probability of Observability

For left-truncated data, PROC SEVERITY also enables you to provide additional information in the form of *probability of observability* by using the `PROBOBSERVED=` option. It is defined as the probability that the underlying severity event gets observed (and recorded) for the specified left-truncation threshold value. For example, if you specify a value of 0.75, then for every 75 observations recorded above a specified threshold, 25 more events have happened with a severity value less than or equal to the specified threshold. Although the exact severity value of those 25 events is not known, PROC SEVERITY can use the information about the number of those events.

In particular, for each left-truncated observation, PROC SEVERITY assumes a presence of $(1 - p)/p$ additional observations with $y_i = t_i$. These additional observations are then used for computing the likelihood (see the section “[Probability of Observability and Likelihood](#)” on page 1607) and an unconditional estimate of the empirical distribution function (see the section “[EDF Estimates and Truncation](#)” on page 1618).

Truncation and Conditional CDF Estimates

If left-truncation is specified without the probability of observability or if right-truncation is specified, then the EDF estimates that are computed by all methods except the STANDARD method are conditional on the truncation information. See the section “[EDF Estimates and Truncation](#)” on page 1618 for more information. In such cases, PROC SEVERITY uses conditional estimates of the CDF whenever they are used for computational or visual comparison with the EDF estimates.

Let $t_{\min}^l = \min_i \{t_i^l\}$ be the smallest value of the left-truncation threshold (t_i^l is the left-truncation threshold for observation i) and $t_{\max}^r = \max_i \{t_i^r\}$ be the largest value of the right-truncation threshold (t_i^r is the right-truncation threshold for observation i). If $\hat{F}(y)$ denotes the unconditional estimate of the CDF at y , then the conditional estimate $\hat{F}^c(y)$ is computed as follows:

- If probability of observability is not specified, then the EDF estimates are conditional on the left-truncation information. If an observation is both left-truncated and right-truncated, then

$$\hat{F}^c(y) = \frac{\hat{F}(y) - \hat{F}(t_{\min}^l)}{\hat{F}(t_{\max}^r) - \hat{F}(t_{\min}^l)}$$

If an observation is left-truncated but not right-truncated, then

$$\hat{F}^c(y) = \frac{\hat{F}(y) - \hat{F}(t_{\min}^l)}{1 - \hat{F}(t_{\min}^l)}$$

If an observation is right-truncated but not left-truncated, then

$$\hat{F}^c(y) = \frac{\hat{F}(y)}{\hat{F}(t_{\max}^r)}$$

- If probability of observability is specified, then EDF estimates are not conditional on the left-truncation information. If an observation is not right-truncated, then the conditional estimate is the same as the unconditional estimate. If an observation is right-truncated, then the conditional estimate is computed as

$$\hat{F}^c(y) = \frac{\hat{F}(y)}{\hat{F}(t_{\max}^r)}$$

If regressors are specified, then $\hat{F}(y)$, $\hat{F}(t_{\min}^l)$, and $\hat{F}(t_{\max}^r)$ are all computed from a mixture distribution, as described in the section “CDF and PDF Estimates with Regression Effects” on page 1611.

Parameter Estimation Method

If you have not specified a custom objective function by specifying programming statements and the **OBJECTIVE=** option in the PROC SEVERITY statement, then PROC SEVERITY uses the maximum likelihood (ML) method to estimate the parameters of each model. A nonlinear optimization process is used to maximize the log of the likelihood function. If you have specified a custom objective function, then PROC SEVERITY uses a nonlinear optimization algorithm to estimate the parameters of each model that minimize the value of your specified objective function. For more information, see the section “Custom Objective Functions (Experimental)” on page 1641.

Likelihood Function

Let $f_{\Theta}(x)$ and $F_{\Theta}(x)$ denote the PDF and CDF, respectively, evaluated at x for a set of parameter values Θ . Let Y denote the random response variable, and let y denote its value recorded in an observation in the input data set. Let T^l and T^r denote the random variables for the left-truncation and right-truncation threshold, respectively, and let t^l and t^r denote their values for an observation, respectively. If there is no left-truncation, then $t^l = \tau^l$, where τ^l is the smallest value in the support of the distribution; so $F(t^l) = 0$. If there is no right-truncation, then $t^r = \tau_h$, where τ_h is the largest value in the support of the distribution; so $F(t^r) = 1$. Let C^l and C^r denote the random variables for the left-censoring and right-censoring limit, respectively, and let c^l and c^r denote their values for an observation, respectively. If there is no left-censoring, then $c^l = \tau_h$, so $F(c^l) = 1$. If there is no right-censoring, then $c^r = \tau^l$, so $F(c^r) = 0$.

The set of input observations can be categorized into the following four subsets within each BY group:

- E is the set of uncensored and untruncated observations. The likelihood of an observation in E is

$$l_E = \Pr(Y = y) = f_{\Theta}(y)$$

- E_t is the set of uncensored observations that are truncated. The likelihood of an observation in E_t is

$$l_{E_t} = \Pr(Y = y | t^l < Y \leq t^r) = \frac{f_{\Theta}(y)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)}$$

- C is the set of censored observations that are not truncated. The likelihood of an observation in C is

$$l_C = \Pr(c^r < Y \leq c^l) = F_{\Theta}(c^l) - F_{\Theta}(c^r)$$

- C_t is the set of censored observations that are truncated. The likelihood of an observation C_t is

$$l_{C_t} = \Pr(c^r < Y \leq c^l | t^l < Y \leq t^r) = \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)}$$

Note that $(E \cup E_t) \cap (C \cup C_t) = \emptyset$. Also, the sets E_t and C_t are empty when no truncation is specified, and the sets C and C_t are empty when no censoring is specified.

Given this, the likelihood of the data L is as follows:

$$L = \prod_E f_{\Theta}(y) \prod_{E_t} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)} \prod_C F_{\Theta}(c^l) - F_{\Theta}(c^r) \prod_{C_t} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r) - F_{\Theta}(t^l)}$$

The maximum likelihood procedure used by PROC SEVERITY finds an optimal set of parameter values $\hat{\Theta}$ that maximizes $\log(L)$ subject to the boundary constraints on parameter values. For a distribution *dist*, such boundary constraints can be specified by using the *dist_LOWERBOUNDS* and *dist_UPPERBOUNDS* subroutines. See the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1623 for more information. Some aspects of the optimization process can be controlled by using the *NLOPTIONS* statement.

Probability of Observability and Likelihood

If probability of observability is specified for the left-truncation, then PROC SEVERITY uses a modified likelihood function for each truncated observation. If the probability of observability is $p \in (0.0, 1.0]$, then for each left-truncated observation with truncation threshold t^l , there exist $(1 - p)/p$ observations with a response variable value less than or equal to t^l . Each such observation has a probability of $\Pr(Y \leq t^l) = F_{\Theta}(t^l)$. The right-truncation and censoring information does not apply to these added observations. Thus, following the notation of the section “[Likelihood Function](#)” on page 1606, the likelihood of the data is as follows:

$$L = \prod_E f_{\Theta}(y) \prod_{E_t, t^l = \tau^l} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r)} \prod_{E_t, t^l > \tau^l} \frac{f_{\Theta}(y)}{F_{\Theta}(t^r)} F_{\Theta}(t^l)^{\frac{1-p}{p}} \\ \prod_C F_{\Theta}(c^l) - F_{\Theta}(c^r) \prod_{C_t, t^l = \tau^l} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r)} \prod_{C_t, t^l > \tau^l} \frac{F_{\Theta}(c^l) - F_{\Theta}(c^r)}{F_{\Theta}(t^r)} F_{\Theta}(t^l)^{\frac{1-p}{p}}$$

Note that the likelihood of the observations that are not left-truncated (observations in sets E and C , and observations in sets E_t and C_t for which $t^l = \tau^l$) is not affected.

If you have specified a custom objective function, then PROC SEVERITY accounts for the probability of observability only while computing the empirical distribution function estimate. The parameter estimates are affected only by your custom objective function.

Estimating Covariance and Standard Errors

PROC SEVERITY computes an estimate of the covariance matrix of the parameters by using the asymptotic theory of the maximum likelihood estimators (MLE). If N denotes the number of observations used for estimating a parameter vector θ , then the theory states that as $N \rightarrow \infty$, the distribution of $\hat{\theta}$, the estimate of θ , converges to a normal distribution with mean θ and covariance \hat{C} such that $\mathbf{I}(\theta) \cdot \hat{C} \rightarrow 1$, where $\mathbf{I}(\theta) = -E[\nabla^2 \log(L(\theta))]$ is the information matrix for the likelihood of the data, $L(\theta)$. The covariance estimate is obtained by using the inverse of the information matrix.

In particular, if $\mathbf{G} = \nabla^2(-\log(L(\theta)))$ denotes the Hessian matrix of the negative of log likelihood, then the covariance estimate is computed as

$$\hat{C} = \frac{N}{d} \mathbf{G}^{-1}$$

where d is a denominator that is determined by the **VARDEF=** option. If **VARDEF=N**, then $d = N$, which yields the asymptotic covariance estimate. If **VARDEF=DF**, then $d = N - k$, where k is number of parameters (the model's degrees of freedom). The **VARDEF=DF** option is the default, because it attempts to correct the potential bias introduced by the finite sample.

The standard error s_i of the parameter θ_i is computed as the square root of the i th diagonal element of the estimated covariance matrix; that is, $s_i = \sqrt{\hat{C}_{ii}}$.

If you have specified a custom objective function, then the covariance matrix of the parameters is still computed by inverting the information matrix, except that the Hessian matrix \mathbf{G} is computed as $\nabla^2 \log(U(\theta))$, where U denotes your custom objective function that is minimized by the optimizer.

Covariance and standard error estimates might not be available if the Hessian matrix is found to be singular at the end of the optimization process. This can especially happen if the optimization process stops without converging.

Parameter Initialization

PROC SEVERITY enables you to initialize parameters of a model in different ways. There can be two kinds of parameters in a model: distribution parameters and regression parameters.

The distribution parameters can be initialized by using one of the following three methods:

INIT= option	You can use the INIT= option in the DIST statement.
INEST= data set	You can use the INEST= data set.
PARMINIT subroutine	You can define a <i>dist_PARMINIT</i> subroutine in the distribution model. See the section “ Defining a Distribution Model with the FCMP Procedure ” on page 1623 for more information.

Note that only one of the initialization methods is used. You cannot combine them. They are used in the following order:

- The method that uses the **INIT=** option takes the highest precedence. If you use the **INIT=** option to provide an initial value for at least one parameter, then other initialization methods (**INEST=** and

PARMINIT) are not used. If you specify initial values for some but not all the parameters by using the INIT= option, then the uninitialized parameters are initialized to the default value of 0.001.

If this option is used when regression effects are specified, then the value of the first distribution parameter must be related to the initial value for the *base* value of the scale or log-transformed scale parameter. See the section “[Estimating Regression Effects](#)” on page 1609 for more information.

- The method that uses the INEST= data set takes the second precedence. If there is a nonmissing value specified for even one distribution parameter, then the PARMINIT method is not used and any uninitialized parameters are initialized to the default value of 0.001.
- If none of the distribution parameters are initialized by using the INIT= option or the INEST= data set, but the distribution model defines a PARMINIT subroutine, then PROC SEVERITY invokes that subroutine with appropriate inputs to initialize the parameters. If the PARMINIT subroutine returns missing values for some parameters, then those parameters are initialized to the default value of 0.001.
- If none of the initialization methods are used, each distribution parameter is initialized to the default value of 0.001.

See the section “[Estimating Regression Effects](#)” on page 1609 for more information about regression models and initialization of regression parameters.

Estimating Regression Effects

The SEVERITY procedure enables you to estimate the effects of regressor (exogenous) variables while fitting a distribution if the distribution has a scale parameter or a log-transformed scale parameter.

Let x_j ($j = 1, \dots, k$) denote the k regressor variables. Let β_j denote the regression parameter that corresponds to the regressor x_j . If regression effects are not specified, then the model for the response variable Y is of the form

$$Y \sim \mathcal{F}(\Theta)$$

where \mathcal{F} is the distribution of Y with parameters Θ . This model is typically referred to as the error model. The regression effects are modeled by extending the error model to the following form:

$$Y \sim \exp\left(\sum_{j=1}^k \beta_j x_j\right) \cdot \mathcal{F}(\Theta)$$

Under this model, the distribution of Y is valid and belongs to the same parametric family as \mathcal{F} if and only if \mathcal{F} has a scale parameter. Let θ denote the scale parameter and Ω denote the set of nonscale distribution parameters of \mathcal{F} . Then the model can be rewritten as

$$Y \sim \mathcal{F}(\theta, \Omega)$$

such that θ is affected by the regressors as

$$\theta = \theta_0 \cdot \exp\left(\sum_{j=1}^k \beta_j x_j\right)$$

where θ_0 is the *base* value of the scale parameter. Thus, the regression model consists of the following parameters: θ_0 , Ω , and β_j ($j = 1, \dots, k$).

Given this form of the model, distributions without a scale parameter cannot be considered when regression effects are to be modeled. If a distribution does not have a direct scale parameter, then PROC SEVERITY accepts it only if it has a log-transformed scale parameter — that is, if it has a parameter $p = \log(\theta)$.

Parameter Initialization for Regression Models

The regression parameters are initialized either by using the values you specify or by the default method.

- If you provide initial values for the regression parameters, then you must provide valid, nonmissing initial values for θ_0 and β_j parameters for all j .

You can specify the initial value for θ_0 using either the INEST= data set or the INIT= option in the DIST statement. If the distribution has a direct scale parameter (no transformation), then the initial value for the first parameter of the distribution is used as an initial value for θ_0 . If the distribution has a log-transformed scale parameter, then the initial value for the first parameter of the distribution is used as an initial value for $\log(\theta_0)$.

You can use only the INEST= data set to specify the initial values for β_j . The INEST= data set must contain nonmissing initial values for all the regressors specified in the SCALEMODEL statement. The only missing value allowed is the special missing value .R, which indicates that the regressor is linearly dependent on other regressors. If you specify .R for a regressor for one distribution in a BY group, you must specify it so for all the distributions in that BY group.

- If you do not specify valid initial values for θ_0 or β_j parameters for all j , then PROC SEVERITY initializes those parameters using the following method:

Let a random variable Y be distributed as $\mathcal{F}(\theta, \Omega)$, where θ is the scale parameter. By definition of the scale parameter, a random variable $W = Y/\theta$ is distributed as $\mathcal{G}(\Omega)$ such that $\mathcal{G}(\Omega) = \mathcal{F}(1, \Omega)$. Given a random error term e that is generated from a distribution $\mathcal{G}(\Omega)$, a value y from the distribution of Y can be generated as

$$y = \theta \cdot e$$

Taking the logarithm of both sides and using the relationship of θ with the regressors yields:

$$\log(y) = \log(\theta_0) + \sum_{j=1}^k \beta_j x_j + \log(e)$$

PROC SEVERITY makes use of the preceding relationship to initialize parameters of a regression model with distribution *dist* as follows:

1. The following linear regression problem is solved to obtain initial estimates of β_0 and β_j :

$$\log(y) = \beta_0 + \sum_{j=1}^k \beta_j x_j$$

The estimates of β_j ($j = 1, \dots, k$) in the solution of this regression problem are used to initialize the respective regression parameters of the model. The estimate of β_0 is later used to initialize the value of θ_0 .

The results of this regression are also used to detect whether any regressors are linearly dependent on the other regressors. If any such regressors are found, then a warning is written to the SAS log and the corresponding regressor is eliminated from further analysis. The estimates for linearly dependent regressors are denoted by a special missing value of .R in the OUTEST= data set and in any displayed output.

2. Let s_0 denote the initial value of the scale parameter.

If the distribution model of *dist* does not contain the *dist_PARMINIT* subroutine, then s_0 and all the nonscale distribution parameters are initialized to the default value of 0.001.

However, it is strongly recommended that each distribution's model contain the *dist_PARMINIT* subroutine. See the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1623 for more information. If that subroutine is defined, then s_0 is initialized as follows:

Each input value y_i of the response variable is transformed to its scale-normalized version w_i as

$$w_i = \frac{y_i}{\exp(\beta_0 + \sum_{j=1}^k \beta_j x_{ij})}$$

where x_{ij} denotes the value of j th regressor in the i th input observation. These w_i values are used to compute the input arguments for the *dist_PARMINIT* subroutine. The values that are computed by the subroutine for nonscale parameters are used as their respective initial values. If the distribution has an untransformed scale parameter, then s_0 is set to the value of the scale parameter that is computed by the subroutine. If the distribution has a log-transformed scale parameter P , then s_0 is computed as $s_0 = \exp(l_0)$, where l_0 is the value of P computed by the subroutine.

3. The value of θ_0 is initialized as

$$\theta_0 = s_0 \cdot \exp(\beta_0)$$

Reporting Estimates of Regression Parameters

When you request estimates to be written to the output (either ODS displayed output or in the OUTEST= data set), the estimate of the base value of the first distribution parameter is reported. If the first parameter is the log-transformed scale parameter, then the estimate of $\log(\theta_0)$ is reported; otherwise, the estimate of θ_0 is reported. The transform of the first parameter of a distribution *dist* is controlled by the *dist_SCALETRANSFORM* function that is defined for it.

CDF and PDF Estimates with Regression Effects

When regression effects are estimated, the estimate of the scale parameter depends on the values of the regressors and the estimates of the regression parameters. This dependency results in a potentially different distribution for each observation. To make estimates of the cumulative distribution function (CDF) and probability density function (PDF) comparable across distributions and comparable to the empirical distribution function (EDF), PROC SEVERITY reports the CDF and PDF estimates from a representative distribution. The *representative distribution* is a mixture of a certain number of distributions, where each distribution differs only in the value of the scale parameter. You can specify the number of distributions in the mixture and how their scale values are chosen by using the *DFMIXTURE*= option in the SCALEMODEL statement.

Let N denote the number of observations used for estimation, K denote the number of components in the mixture distribution, s_k denote the scale parameter of the k th mixture component, and d_k denote the weight associated with k th mixture component.

Let $f(y; s_k, \hat{\Omega})$ and $F(y; s_k, \hat{\Omega})$ denote the PDF and CDF, respectively, of the k th component distribution, where $\hat{\Omega}$ denotes the set of estimates of all parameters of the distribution other than the scale parameter. Then, the PDF and CDF estimates, $f^*(y)$ and $F^*(y)$, respectively, of the mixture distribution at y are computed as follows:

$$f^*(y) = \frac{1}{D} \sum_{k=1}^K d_k f(y; s_k, \hat{\Omega})$$

$$F^*(y) = \frac{1}{D} \sum_{k=1}^K d_k F(y; s_k, \hat{\Omega})$$

where D is the normalization factor ($D = \sum_{k=1}^K d_k$).

The CDF estimates reported in OUTCDF= data set, plotted in CDF plots, and used for computing the EDF-based statistics of fit are the $F^*(y)$ values. The PDF estimates plotted in PDF plots are the $f^*(y)$ values.

The scale values s_k for the K mixture components are derived from the set $\{\hat{\theta}_i\}$ ($i = 1 \dots N$) of N scale values, where $\hat{\theta}_i$ denotes the estimate of the scale parameter due to observation i . It is computed as

$$\hat{\theta}_i = \hat{\theta}_0 \cdot \exp\left(\sum_{j=1}^k \hat{\beta}_j x_{ij}\right)$$

where $\hat{\theta}_0$ is an estimate of the base value of the scale parameter, $\hat{\beta}_j$ are the estimates of regression coefficients, and x_{ij} is the value of regressor j in observation i .

Let w_i denote the weight of observation i . If the WEIGHT statement is specified, then it is equal to the value of the specified weight variable for the corresponding observation in the DATA= data set; otherwise, it is set to 1.

You can specify one of the following *method-names* in the DF MIXTURE= option in the SCALEMODEL statement to specify the method of choosing K and the corresponding s_k and d_k values:

FULL In this method, there are as many mixture components as the number of observations that are used for estimation. In other words, $K = N$, $s_k = \hat{\theta}_k$, and $d_k = w_k$ ($k = 1 \dots N$). This is the slowest method, because it requires $O(N)$ computations to compute the mixture CDF $F^*(y_i)$ or the mixture PDF $f^*(y_i)$ of one observation. For N observations, the computational complexity in terms of number of PDF or CDF evaluations is $O(N^2)$. Even for moderately large values of N , the time taken to compute the mixture CDF and PDF can significantly exceed the time taken to estimate the model parameters. So, it is recommended that you use this method only for small data sets.

MEAN In this method, the mixture contains only one distribution, whose scale value is the mean of the scale values that are implied by all the observations. In other words, s_1 is computed as

$$s_1 = \frac{1}{W} \sum_{i=1}^N w_i \hat{\theta}_i$$

where W is the total weight ($W = \sum_{i=1}^N w_i$).

This method is the fastest because it requires only one CDF or PDF evaluation per observation. The computational complexity is $O(N)$ for N observations.

If you do not specify the `DFMIXTURE=` option in the `SCALEMODEL` statement, then this is the default method.

QUANTILE

In this method, a certain number of quantiles are chosen from the set of all scale values. If you specify a value of q for the `K=` option when specifying this method, then $K = q - 1$ and s_k are set to be the $(q - 1)$ q -quantiles from the set $\{\hat{\theta}_i\}$ ($i = 1 \dots N$). The weight of each of the components (d_k) is assumed to be 1 for this method.

The default value of q is 2, which implies a one-point mixture with a distribution whose scale value is equal to the median scale value.

For this method, PROC SEVERITY needs to sort the N scale values in the set $\{\hat{\theta}_i\}$, which requires $O(N \log(N))$ computations. Then, computing mixture estimate of one observation requires $(q - 1)$ CDF or PDF evaluations. Hence, the computational complexity of this method is $O(qN) + O(N \log(N))$ for computing a mixture PDF or CDF of N observations. For $q \ll N$, it is significantly faster than the FULL method.

RANDOM

In this method, a uniform random sample of observations is chosen and the mixture contains the distributions that are implied by those observations. If you specify a value of r for the `K=` option when specifying this method, then the size of the sample is r . Hence, $K = r$. If l_j denotes the index of j th observation in the sample ($j = 1 \dots r$), such that $1 \leq l_j \leq N$, then the scale of k th component distribution in the mixture is $s_k = \hat{\theta}_{l_k}$ and the weight associated with it is $d_k = w_{l_k}$.

You can also specify the seed to be used for generating the random sample by using the `SEED=` option for this method. The same sample of observations is used for all models.

Computing a mixture estimate of one observation requires r CDF or PDF evaluations. Hence, the computational complexity of this method is $O(rN)$ for computing a mixture PDF or CDF of N observations. For $r \ll N$, it is significantly faster than the FULL method.

Empirical Distribution Function Estimation Methods

The empirical distribution function (EDF) is a nonparametric estimate of the cumulative distribution function (CDF) of the distribution. PROC SEVERITY uses EDF estimates for computing the EDF-based statistics of fit.

If you specify both right-censoring and left-censoring, then the EDF is estimated using Turnbull's method as described in the section [“EDF Estimation for Right-Censored and Left-Censored Data \(Experimental\)”](#) on page 1616. If all the observations are uncensored or there is only one type of censoring, then a choice of methods is available as described in the section [“EDF Estimation for No Censoring or Single Type of Censoring”](#) on page 1614.

Notation

Let there be a set of N observations, each containing a quintuplet of values $(y_i, t_i^l, t_i^r, c_i^r, c_i^l)$, $i = 1, \dots, N$, where y_i is the value of the response variable, t_i^l is the value of the left-truncation threshold, t_i^r is the value of the right-truncation threshold, c_i^r is the value of the right-censoring limit, and c_i^l is the value of the left-censoring limit.

If an observation is not left-truncated, then $t_i^l = \tau^l$, where τ^l is the smallest value in the support of the distribution; so $F(t_i^l) = 0$. If an observation is not right-truncated, then $t_i^r = \tau_h$, where τ_h is the largest value in the support of the distribution; so $F(t_i^r) = 1$. If an observation is not right-censored, then $c_i^r = \tau^l$; so $F(c_i^r) = 0$. If an observation is not left-censored, then $c_i^l = \tau_h$; so $F(c_i^l) = 1$.

Let w_i denote the weight associated with i th observation. If you have specified the **WEIGHT statement**, then w_i is the normalized value of the weight variable; otherwise, it is set to 1. The weights are normalized such that they sum up to N .

An indicator function $I[e]$ takes a value of 1 or 0 if the expression e is true or false, respectively.

EDF Estimation for No Censoring or Single Type of Censoring

The method descriptions assume that all observations are either uncensored or right-censored; that is, each observation is of the form $(y_i, t_i^l, t_i^r, c_i^r, \tau_h)$.

If all observations are either uncensored or left-censored, then each observation is of the form $(y_i, t_i^l, t_i^r, \tau_l, c_i^l)$. It is converted to an observation $(-y_i, -t_i^r, -t_i^l, -c_i^l, \tau_h)$; that is, the signs of all the response variable values are reversed, the new left-truncation threshold is equal to the negative of the original right-truncation threshold, the new right-truncation threshold is equal to the negative of the original left-truncation threshold, and the negative of the original left-censoring limit becomes the new right-censoring limit. With this transformation, each observation is either uncensored or right-censored. The methods described for handling uncensored or right-censored data are now applicable. After the EDF estimates are computed, the observations are transformed back to the original form and EDF estimates are adjusted such $F_n(y_i) = 1 - F_n(-y_i-)$, where $F_n(-y_i-)$ denotes the EDF estimate of the value slightly less than the transformed value $-y_i$.

A set of uncensored or right-censored observations can be converted to a set of observations of the form $(y_i, t_i^l, t_i^r, \delta_i)$, where δ_i is the indicator of right-censoring. $\delta_i = 0$ indicates a right-censored observation, in which case y_i is assumed to record the right-censoring limit c_i^r . $\delta_i = 1$ indicates an uncensored observation, and y_i records the exact observed value. In other words, $\delta_i = I[Y \leq C^r]$ and $y_i = \min(y_i, c_i^r)$.

Given this notation, the EDF is estimated as

$$F_n(y) = \begin{cases} 0 & \text{if } y < y^{(1)} \\ \hat{F}_n(y^{(k)}) & \text{if } y^{(k)} \leq y < y^{(k+1)}, k = 1, \dots, N-1 \\ \hat{F}_n(y^{(N)}) & \text{if } y^{(N)} \leq y \end{cases}$$

where $y^{(k)}$ denotes the k th order statistic of the set $\{y_i\}$ and $\hat{F}_n(y^{(k)})$ is the estimate computed at that value. The definition of \hat{F}_n depends on the estimation method. You can specify a particular method or let PROC SEVERITY choose an appropriate method by using the **EMPIRICALCDF=** option in the PROC SEVERITY statement. Each method computes \hat{F}_n as follows:

STANDARD

This method is the standard way of computing EDF. The EDF estimate at observation i is computed as follows:

$$\hat{F}_n(y_i) = \frac{1}{N} \sum_{j=1}^N w_j \cdot I[y_j \leq y_i]$$

This method ignores any censoring and truncation information, even if it is specified. When no censoring or truncation information is specified, this is the default method chosen.

The standard error of $\hat{F}_n(y_i)$ is computed by using the normal approximation method:

$$\hat{\sigma}_n(y_i) = \sqrt{\hat{F}_n(y_i)(1 - \hat{F}_n(y_i))/N}$$

KAPLANMEIER

The Kaplan-Meier (KM) estimator, also known as the product-limit estimator, was first introduced by Kaplan and Meier (1958) for censored data. Lynden-Bell (1971) derived a similar estimator for left-truncated data. PROC SEVERITY uses the definition that combines both censoring and truncation information (Klein and Moeschberger 1997, Lai and Ying 1991).

The EDF estimate at observation i is computed as

$$\hat{F}_n(y_i) = 1 - \prod_{\tau \leq y_i} \left(1 - \frac{n(\tau)}{R_n(\tau)}\right)$$

where $n(\tau)$ and $R_n(\tau)$ are defined as follows:

- $n(\tau) = \sum_{k=1}^N w_k \cdot I[y_k = \tau \text{ and } \tau \leq t_k^r \text{ and } \delta_k = 1]$, which is the number of uncensored observations ($\delta_k = 1$) for which the response variable value is equal to τ and τ is observable according to the right-truncation threshold of that observation ($\tau \leq t_k^r$).
- $R_n(\tau) = \sum_{k=1}^N w_k \cdot I[y_k \geq \tau > t_k^l]$, which is the size (cardinality) of the risk set at τ . The term *risk set* has its origins in survival analysis; it contains the events that are at risk of failure at a given time, τ . In other words, it contains the events that have survived up to time τ and might fail at or after τ . For PROC SEVERITY, *time* is equivalent to the magnitude of the event and *failure* is equivalent to an uncensored and observable event, where observable means it satisfies the truncation thresholds.

If you do not explicitly specify a method of computing EDF, then this is the default method used if you specify either right-censoring or left-censoring, but not both. This is also the default method when you specify truncation without any censoring.

The standard error of $\hat{F}_n(y_i)$ is computed by using Greenwood's formula (Greenwood, 1926):

$$\hat{\sigma}_n(y_i) = \sqrt{(1 - \hat{F}_n(y_i))^2 \cdot \sum_{\tau \leq y_i} \left(\frac{n(\tau)}{R_n(\tau)(R_n(\tau) - n(\tau))} \right)}$$

MODIFIEDKM

The product-limit estimator used by the KAPLANMEIER method does not work well if the risk set size becomes very small. For right-censored data, the size can become small towards the right tail. For left-truncated data, the size can become small at the left tail and can remain so for the entire range of data. This was demonstrated by Lai and Ying (1991). They proposed a modification to the estimator that ignores the effects due to small risk set sizes.

The EDF estimate at observation i is computed as

$$\hat{F}_n(y_i) = 1 - \prod_{\tau \leq y_i} \left(1 - \frac{n(\tau)}{R_n(\tau)} \cdot I[R_n(\tau) \geq cN^\alpha] \right)$$

where the definitions of $n(\tau)$ and $R_n(\tau)$ are identical to those used for the KAPLANMEIER method described previously.

You can specify the values of c and α by using the **C=** and **ALPHA=** options. If you do not specify a value for c , the default value used is $c = 1$. If you do not specify a value for α , the default value used is $\alpha = 0.5$.

As an alternative, you can also specify an absolute lower bound, say L , on the risk set size by using the **RSLB=** option, in which case $I[R_n(\tau) \geq cN^\alpha]$ is replaced by $I[R_n(\tau) \geq L]$ in the definition.

The standard error of $\hat{F}_n(y_i)$ is computed by using Greenwood's formula (Greenwood, 1926):

$$\hat{\sigma}_n(y_i) = \sqrt{(1 - \hat{F}_n(y_i))^2 \cdot \sum_{\tau \leq y_i} \left(\frac{n(\tau)}{R_n(\tau)(R_n(\tau) - n(\tau))} \cdot I[R_n(\tau) \geq cN^\alpha] \right)}$$

EDF Estimation for Right-Censored and Left-Censored Data (Experimental)

If the response variable is subject to both left-censoring and right-censoring effects, then the SEVERITY procedure uses a method proposed by Turnbull (1976) to compute the nonparametric estimates of the cumulative distribution function. The original Turnbull's method is modified using the suggestions made by Frydman (1994) when truncation effects are present.

Let the input data consist of N observations in the form of quintuplets of values $(y_i, t_i^l, t_i^r, c_i^r, c_i^l)$, $i = 1, \dots, N$ with notation described in the section “**Notation**” on page 1614. For each observation, let $A_i = (c_i^r, c_i^l]$ be the censoring interval; that is, the response variable value is known to lie in the interval A_i , but the exact value is not known. If an observation is uncensored, then $A_i = (y_i - \epsilon, y_i]$ for any arbitrarily small value of $\epsilon > 0$. If an observation is censored, then the value y_i is ignored. Similarly, for each observation, let $B_i = (t_i^l, t_i^r]$ be the truncation interval; that is, the observation is drawn from a truncated (conditional) distribution $F(y, B_i) = P(Y \leq y | Y \in B_i)$.

Two sets, L and R , are formed using A_i and B_i as follows:

$$\begin{aligned} L &= \{c_i^r, 1 \leq i \leq N\} \cup \{t_i^r, 1 \leq i \leq N\} \\ R &= \{c_i^l, 1 \leq i \leq N\} \cup \{t_i^l, 1 \leq i \leq N\} \end{aligned}$$

The sets L and R represent the left endpoints and right endpoints, respectively. A set of disjoint intervals $C_j = [q_j, p_j]$, $1 \leq j \leq M$ is formed such that $q_j \in L$ and $p_j \in R$ and $q_j \leq p_j$ and $p_j < q_{j+1}$.

The value of M is dependent on the nature of censoring and truncation intervals in the input data. Turnbull (1976) showed that the maximum likelihood estimate (MLE) of the EDF can increase only inside intervals C_j . In other words, the MLE estimate is constant in the interval (p_j, q_{j+1}) . The likelihood is independent of the behavior of F_n inside any of the intervals C_j . Let s_j denote the increase in F_n inside an interval C_j . Then, the EDF estimate is as follows:

$$F_n(y) = \begin{cases} 0 & \text{if } y < q_1 \\ \sum_{k=1}^j s_k & \text{if } p_j < y < q_{j+1}, 1 \leq j \leq M-1 \\ 1 & \text{if } y > p_M \end{cases}$$

PROC SEVERITY reports the estimates $F_n(p_j+) = F_n(q_{j+1}-) = \sum_{k=1}^j s_k$ at points p_j and q_{j+1} and reports $F_n(q_1-) = 0$ at point q_1 , where $F_n(x+)$ denotes the limiting estimate at a point that is infinitesimally larger than x when approaching x from values larger than x and where $F_n(x-)$ denotes the limiting estimate at a point that is infinitesimally smaller than x when approaching x from values smaller than x .

PROC SEVERITY uses the expectation-maximization (EM) algorithm proposed by Turnbull (1976), who referred to the algorithm as the self-consistency algorithm. By default, the algorithm runs until one of the following criteria is met:

- Relative-error criterion: The maximum relative error between the two consecutive estimates of s_j falls below a threshold ϵ . If l indicates an index of the current iteration, then this can be formally stated as

$$\arg \max_{1 \leq j \leq M} \left\{ \frac{|s_j^l - s_j^{l-1}|}{s_j^{l-1}} \right\} \leq \epsilon$$

You can control the value of ϵ by specifying the **EPS=** suboption of the EDF=TURNBULL option in the PROC SEVERITY statement. The default value is 1.0E-8.

- Maximum-iteration criterion: The number of iterations exceeds an upper limit specified by the **MAX-ITER=** suboption of the EDF=TURNBULL option in the PROC SEVERITY statement. The default number of maximum iterations is 500.

The self-consistent estimates obtained in this manner might not be maximum likelihood estimates. Gentleman and Geyer (1994) suggested the use of the Kuhn-Tucker conditions for the maximum likelihood problem to ensure that the estimates are MLE. If you specify the **ENSUREMLE** suboption of the EDF=TURNBULL option in the PROC SEVERITY statement, then PROC SEVERITY computes the Kuhn-Tucker conditions at the end of each iteration to determine whether the estimates $\{s_j\}$ are MLE. If no truncation effects are specified, then the Kuhn-Tucker conditions derived by Gentleman and Geyer (1994) are used. If truncation effects are specified, then PROC SEVERITY uses modified Kuhn-Tucker conditions that account for the truncation effects. An integral part of checking the conditions is to determine whether an estimate s_j is zero or whether an estimate of the Lagrange multiplier or the reduced gradient associated with the estimate s_j is zero. PROC SEVERITY declares these values to be zero if they are less than or equal to a threshold δ . You can control the value of δ by specifying the **ZEROPROB=** suboption of the EDF=TURNBULL option in the PROC SEVERITY statement. The default value is 1.0E-8. The algorithm continues until the Kuhn-Tucker conditions are satisfied or the number of iterations exceeds the upper limit. The relative-error criterion stated previously is not used when the ENSUREMLE option is specified.

The standard errors for Turnbull's EDF estimates are computed by using the asymptotic theory of the maximum likelihood estimators (MLE), even though the final estimates might not be MLE. Turnbull's estimator

essentially attempts to maximize the likelihood L , which depends on the parameters s_j ($j = 1 \dots M$). Let $\mathbf{s} = \{s_j\}$ denote the set of these parameters. If $\mathbf{G}(\mathbf{s}) = \nabla^2(-\log(L(\mathbf{s})))$ denotes the Hessian matrix of the negative of log likelihood, then the variance-covariance matrix of \mathbf{s} is estimated as $\hat{\mathbf{C}}(\mathbf{s}) = \mathbf{G}^{-1}(\mathbf{s})$. Given this matrix, the standard error of $F_n(y)$ is computed as

$$\sigma_n(y) = \sqrt{\sum_{k=1}^j \left(\hat{C}_{kk} + 2 \cdot \sum_{l=1}^{k-1} \hat{C}_{kl} \right)}, \text{ if } p_j < y < q_{j+1}, 1 \leq j \leq M-1$$

The standard error is undefined outside of these intervals.

EDF Estimates and Truncation

If truncation is specified, then the estimate $\hat{F}_n(y)$ computed by any method other than the STANDARD method is a *conditional* estimate. In other words, $\hat{F}_n(y) = \Pr(Y \leq y | \tau_G < Y \leq \tau_H)$, where G and H denote the (unknown) distribution functions of the left-truncation threshold variable T^l and the right-truncation threshold variable T^r , respectively, τ_G denotes the smallest left-truncation threshold with a nonzero cumulative probability, and τ_H denotes the largest right-truncation threshold with a nonzero cumulative probability. Formally, $\tau_G = \inf\{s : G(s) > 0\}$ and $\tau_H = \sup\{s : H(s) > 0\}$. For computational purposes, PROC SEVERITY estimates τ_G and τ_H by t_{\min}^l and t_{\max}^r , respectively, defined as

$$t_{\min}^l = \min\{t_k^l : 1 \leq k \leq N\}$$

$$t_{\max}^r = \max\{t_k^r : 1 \leq k \leq N\}$$

These estimates are used to compute conditional estimates of the CDF as described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1605.

If left-truncation is specified *with* the probability of observability p , then PROC SEVERITY uses the additional information provided by p to compute an estimate of the EDF that is not conditional on the left-truncation information. In particular, for each left-truncated observation i with response variable value y_i and truncation threshold t_i^l , an observation j is added with *weight* $w_j = (1 - p)/p$ and $y_j = t_j^l$. Each added observation is assumed to be uncensored and untruncated. Then, the specified EDF method is used by assuming no left-truncation. The EDF estimate that is obtained using this method is not conditional on the left-truncation information. For the KAPLANMEIER and MODIFIEDKM methods with uncensored or right-censored data, definitions of $n(\tau)$ and $R_n(\tau)$ are modified to account for the added observations. If N^a denotes the total number of observations including the added observations, then $n(\tau)$ is defined as $n(\tau) = \sum_{k=1}^{N^a} w_k I[y_k = \tau \text{ and } \tau \leq t_k^r \text{ and } \delta_k = 1]$, and $R_n(\tau)$ is defined as $R_n(\tau) = \sum_{k=1}^{N^a} w_k I[y_k \geq \tau]$. In the definition of $R_n(\tau)$, the left-truncation information is not used, because it was used along with p to add the observations.

If the original data are a combination of left- and right-censored data, then Turnbull’s method is applied to the appended set that contains no left-truncated observations.

Supplying EDF Estimates to Functions and Subroutines

The parameter initialization subroutines in distribution models and some predefined utility functions require EDF estimates. See the sections “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1623 and “[Predefined Utility Functions](#)” on page 1636 for more information.

PROC SEVERITY supplies the EDF estimates to these subroutines and functions by using two arrays, \mathbf{x} and \mathbf{F} , the dimension of each array, and a type of the EDF estimates. The type identifies how the EDF estimates are computed and stored. They are as follows:

- Type 1 specifies that EDF estimates are computed using the STANDARD method; that is, the data used for estimation are neither censored nor truncated.
- Type 2 specifies that EDF estimates are computed using either the KAPLANMEIER or the MODIFIEDKM method; that is, the data used for estimation are subject to truncation and one type of censoring (left or right, but not both).
- Type 3 specifies that EDF estimates are computed using the TURNBULL method; that is, the data used for estimation are subject to both left- and right-censoring. The data might or might not be truncated.

For Types 1 and 2, the EDF estimates are stored in arrays x and F of dimension N such that the following holds:

$$F_n(y) = \begin{cases} 0 & \text{if } y < x[1] \\ F[k] & \text{if } x[k] \leq y < x[k+1], k = 1, \dots, N-1 \\ F[N] & \text{if } x[N] \leq y \end{cases}$$

where $[k]$ denotes k th element of the array ($[1]$ denotes the first element of the array).

For Type 3, the EDF estimates are stored in arrays x and F of dimension N such that the following holds:

$$F_n(y) = \begin{cases} 0 & \text{if } y < x[1] \\ \text{undefined} & \text{if } x[2k-1] \leq y < x[2k], k = 1, \dots, (N-1)/2 \\ F[2k] = F[2k+1] & \text{if } x[2k] \leq y < x[2k+1], k = 1, \dots, (N-1)/2 \\ F[N] & \text{if } x[N] \leq y \end{cases}$$

Although the behavior of EDF is theoretically undefined for the interval $[x[2k-1], x[2k]]$, for computational purposes, all predefined functions and subroutines assume that the EDF increases linearly from $F[2k-1]$ to $F[2k]$ in that interval if $x[2k-1] < x[2k]$. If $x[2k-1] = x[2k]$, which can happen when the EDF is estimated from a combination of uncensored and interval-censored data, the predefined functions and subroutines assume that $F_n(x[2k-1]) = F_n(x[2k]) = F[2k]$.

Statistics of Fit

PROC SEVERITY computes and reports various statistics of fit to indicate how well the estimated model fits the data. The statistics belong to two categories: likelihood-based statistics and EDF-based statistics. Statistics Neg2LogLike, AIC, AICC, and BIC are likelihood-based statistics, and statistics KS, AD, and CvM are EDF-based statistics. The following subsections provide definitions of each.

Likelihood-Based Statistics

Let $y_i, i = 1, \dots, N$ denote the response variable values. Let L be the likelihood as defined in the section “Likelihood Function” on page 1606. Let p denote the number of model parameters estimated. Note that $p = p_d + (k - k_r)$, where p_d is the number of distribution parameters, k is the number of regressors, if any, specified in the SCALEMODEL statement, and k_r is the number of regressors found to be linearly dependent (redundant) on other regressors. Given this notation, the likelihood-based statistics are defined as follows:

Neg2LogLike The log likelihood is reported as

$$\text{Neg2LogLike} = -2 \log(L)$$

The multiplying factor -2 makes it easy to compare it to the other likelihood-based statistics. A model with a smaller value of Neg2LogLike is deemed better.

AIC The Akaike's information criterion (AIC) is defined as

$$\text{AIC} = -2 \log(L) + 2p$$

A model with a smaller value of AIC is deemed better.

AICC The corrected Akaike's information criterion (AICC) is defined as

$$\text{AICC} = -2 \log(L) + \frac{2Np}{N - p - 1}$$

A model with a smaller value of AICC is deemed better. It corrects the finite-sample bias that AIC has when N is small compared to p . AICC is related to AIC as

$$\text{AICC} = \text{AIC} + \frac{2p(p + 1)}{N - p - 1}$$

As N becomes large compared to p , AICC converges to AIC. AICC is usually recommended over AIC as a model selection criterion.

BIC The Schwarz Bayesian information criterion (BIC) is defined as

$$\text{BIC} = -2 \log(L) + p \log(N)$$

A model with a smaller value of BIC is deemed better.

EDF-Based Statistics

This class of statistics is based on the difference between the estimate of the cumulative distribution function (CDF) and the estimate of the empirical distribution function (EDF). Let $y_i, i = 1, \dots, N$ denote the sample of N values of the response variable. Let $r_i = \sum_{j=1}^N I[y_j \leq y_i]$ denote the number of observations with a value less than or equal to y_i , where I is an indicator function. Let $F_n(y_i)$ denote the EDF estimate that is computed by using the method specified in the [EMPIRICALCDF=](#) option. Let $Z_i = \hat{F}(y_i)$ denote the estimate of the CDF. Let $F_n(Z_i)$ denote the EDF estimate of Z_i values that are computed using the same method that is used to compute the EDF of y_i values. Using the probability integral transformation, if $F(y)$ is the true distribution of the random variable Y , then the random variable $Z = F(y)$ is uniformly distributed between 0 and 1 (D'Agostino and Stephens 1986, Ch. 4). Thus, comparing $F_n(y_i)$ with $\hat{F}(y_i)$ is equivalent to comparing $F_n(Z_i)$ with $\hat{F}(Z_i) = Z_i$ (uniform distribution).

Note the following two points regarding which CDF estimates are used for computing the test statistics:

- If regressor variables are specified, then the CDF estimates Z_i used for computing the EDF test statistics are from a mixture distribution. See the section [“CDF and PDF Estimates with Regression Effects”](#) on page 1611 for more information.
- If the EDF estimates are conditional because of the truncation information, then each unconditional estimate Z_i is converted to a conditional estimate using the method described in the section [“Truncation and Conditional CDF Estimates”](#) on page 1605.

In the following, it is assumed that Z_i denotes an appropriate estimate of the CDF if truncation or regression effects are specified. Given this, the EDF-based statistics of fit are defined as follows:

KS The Kolmogorov-Smirnov (KS) statistic computes the largest vertical distance between the CDF and the EDF. It is formally defined as follows:

$$KS = \sup_y |F_n(y) - F(y)|$$

If the STANDARD method is used to compute the EDF, then the following formula is used:

$$\begin{aligned} D^+ &= \max_i \left(\frac{r_i}{N} - Z_i \right) \\ D^- &= \max_i \left(Z_i - \frac{r_{i-1}}{N} \right) \\ KS &= \sqrt{N} \max(D^+, D^-) + \frac{0.19}{\sqrt{N}} \end{aligned}$$

Note that r_0 is assumed to be 0.

If the method used to compute the EDF is any method other than the STANDARD method, then the following formula is used:

$$\begin{aligned} D^+ &= \max_i (F_n(Z_i) - Z_i), \text{ if } F_n(Z_i) \geq Z_i \\ D^- &= \max_i (Z_i - F_n(Z_i)), \text{ if } F_n(Z_i) < Z_i \\ KS &= \sqrt{N} \max(D^+, D^-) + \frac{0.19}{\sqrt{N}} \end{aligned}$$

AD The Anderson-Darling (AD) statistic is a quadratic EDF statistic that is proportional to the expected value of the weighted squared difference between the EDF and CDF. It is formally defined as follows:

$$AD = N \int_{-\infty}^{\infty} \frac{(F_n(y) - F(y))^2}{F(y)(1 - F(y))} dF(y)$$

If the STANDARD method is used to compute the EDF, then the following formula is used:

$$AD = -N - \frac{1}{N} \sum_{i=1}^N [(2r_i - 1) \log(Z_i) + (2N + 1 - 2r_i) \log(1 - Z_i)]$$

If the method used to compute the EDF is any method other than the STANDARD method, then the statistic can be computed by using the following two pieces of information:

- If the EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM methods, then EDF is a step function such that the estimate $F_n(z)$ is a constant equal to $F_n(Z_{i-1})$ in interval $[Z_{i-1}, Z_i]$. If the EDF estimates are computed using the TURNBULL method, then there are two types of intervals: one in which the EDF curve is constant and the other in which the EDF curve is theoretically undefined. For computational purposes, it is assumed that the EDF curve is linear for the latter type of the interval. For each method, the EDF estimate $F_n(y)$ at y can be written as

$$F_n(z) = F_n(Z_{i-1}) + S_i(z - Z_{i-1}), \text{ for } z \in [Z_{i-1}, Z_i]$$

where S_i is the slope of the line defined as

$$S_i = \frac{F_n(Z_i) - F_n(Z_{i-1})}{Z_i - Z_{i-1}}$$

For the KAPLANMEIER or MODIFIEDKM method, $S_i = 0$ in each interval.

- Using the probability integral transform $z = F(y)$, the formula simplifies to

$$AD = N \int_{-\infty}^{\infty} \frac{(F_n(z) - z)^2}{z(1-z)} dz$$

The computation formula can then be derived from the following approximation:

$$\begin{aligned} AD &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(F_n(z) - z)^2}{z(1-z)} dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(F_n(Z_{i-1}) + S_i(z - Z_{i-1}) - z)^2}{z(1-z)} dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} \frac{(P_i - Q_i z)^2}{z(1-z)} dz \end{aligned}$$

where $P_i = F_n(Z_{i-1}) - S_i Z_{i-1}$, $Q_i = 1 - S_i$, and K is the number of points at which the EDF estimate are computed. For the TURNBULL method, $K = 2k$ for some k .

Assuming $Z_0 = 0$, $Z_{K+1} = 1$, $F_n(0) = 0$, and $F_n(Z_K) = 1$ yields the following computation formula:

$$\begin{aligned} AD &= -N(Z_1 + \log(1 - Z_1) + \log(Z_K) + (1 - Z_K)) \\ &\quad + N \sum_{i=2}^K [P_i^2 A_i - (Q_i - P_i)^2 B_i - Q_i^2 C_i] \end{aligned}$$

where $A_i = \log(Z_i) - \log(Z_{i-1})$, $B_i = \log(1 - Z_i) - \log(1 - Z_{i-1})$, and $C_i = Z_i - Z_{i-1}$.

If EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM method, then $P_i = F_n(Z_{i-1})$ and $Q_i = 1$, which simplifies the formula as

$$\begin{aligned} AD &= -N(1 + \log(1 - Z_1) + \log(Z_K)) \\ &\quad + N \sum_{i=2}^K [F_n(Z_{i-1})^2 A_i - (1 - F_n(Z_{i-1}))^2 B_i] \end{aligned}$$

CvM The Cramér-von Mises (CvM) statistic is a quadratic EDF statistic that is proportional to the expected value of the squared difference between the EDF and CDF. It is formally defined as follows:

$$CvM = N \int_{-\infty}^{\infty} (F_n(y) - F(y))^2 dF(y)$$

If the STANDARD method is used to compute the EDF, then the following formula is used:

$$CvM = \frac{1}{12N} + \sum_{i=1}^N \left(Z_i - \frac{(2r_i - 1)}{2N} \right)^2$$

If the method used to compute the EDF is any method other than the STANDARD method, then the statistic can be computed by using the following two pieces of information:

- As described previously for the AD statistic, the EDF estimates are assumed to be piecewise linear such that the estimate $F_n(y)$ at y is

$$F_n(z) = F_n(Z_{i-1}) + S_i(z - Z_{i-1}), \text{ for } z \in [Z_{i-1}, Z_i]$$

where S_i is the slope of the line defined as

$$S_i = \frac{F_n(Z_i) - F_n(Z_{i-1})}{Z_i - Z_{i-1}}$$

For the KAPLANMEIER or MODIFIEDKM method, $S_i = 0$ in each interval.

- Using the probability integral transform $z = F(y)$, the formula simplifies to:

$$\text{CvM} = N \int_{-\infty}^{\infty} (F_n(z) - z)^2 dz$$

The computation formula can then be derived from the following approximation:

$$\begin{aligned} \text{CvM} &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} (F_n(z) - z)^2 dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} (F_n(Z_{i-1}) + S_i(z - Z_{i-1}) - z)^2 dz \\ &= N \sum_{i=1}^{K+1} \int_{Z_{i-1}}^{Z_i} (P_i - Q_i z)^2 dz \end{aligned}$$

where $P_i = F_n(Z_{i-1}) - S_i Z_{i-1}$, $Q_i = 1 - S_i$, and K is the number of points at which the EDF estimate are computed. For the TURNBULL method, $K = 2k$ for some k .

Assuming $Z_0 = 0$, $Z_{K+1} = 1$, and $F_n(0) = 0$ yields the following computation formula:

$$\text{CvM} = N \frac{Z_1^3}{3} + N \sum_{i=2}^{K+1} \left[P_i^2 A_i - P_i Q_i B_i - \frac{Q_i^2}{3} C_i \right]$$

where $A_i = Z_i - Z_{i-1}$, $B_i = Z_i^2 - Z_{i-1}^2$, and $C_i = Z_i^3 - Z_{i-1}^3$.

If EDF estimates are computed using the KAPLANMEIER or MODIFIEDKM method, then $P_i = F_n(Z_{i-1})$ and $Q_i = 1$, which simplifies the formula as

$$\text{CvM} = \frac{N}{3} + N \sum_{i=2}^{K+1} [F_n(Z_{i-1})^2 (Z_i - Z_{i-1}) - F_n(Z_{i-1}) (Z_i^2 - Z_{i-1}^2)]$$

which is similar to the formula proposed by Koziol and Green (1976).

Defining a Distribution Model with the FCMP Procedure

A severity *distribution model* consists of a set of functions and subroutines that are defined using the FCMP procedure. The FCMP procedure is part of Base SAS software. Each function or subroutine must be

named as *<distribution-name>_<keyword>*, where *distribution-name* is the identifying short name of the distribution and *keyword* identifies one of the functions or subroutines. The total length of the name should not exceed 32. Each function or subroutine must have a specific signature, which consists of the number of arguments, sequence and types of arguments, and return value type. The summary of all the recognized function and subroutine names and their expected behavior is given in [Table 23.4](#).

Consider following points when you define a distribution model:

- When you define a function or subroutine requiring parameter arguments, the names and order of those arguments must be the same. Arguments other than the parameter arguments can have any name, but they must satisfy the requirements on their type and order.
- When the SEVERITY procedure invokes any function or subroutine, it provides the necessary input values according to the specified signature, and expects the function or subroutine to prepare the output and return it according to the specification of the return values in the signature.
- You can typically use most of the SAS programming statements and SAS functions that you can use in a DATA step for defining the FCMP functions and subroutines. However, there are a few differences in the capabilities of the DATA step and the FCMP procedure. Refer to the documentation of the FCMP procedure to learn more.
- You must specify either the PDF or the LOGPDF function. Similarly, you must specify either the CDF or the LOGCDF function. All other functions are optional, except when necessary for correct definition of the distribution. It is strongly recommended that you define the PARMINIT subroutine to provide a good set of initial values for the parameters. The information provided by PROC SEVERITY to the PARMINIT subroutine enables you to use popular initialization approaches based on the method of moments and the method of percentile matching, but you can implement any algorithm to initialize the parameters by using the values of the response variable and the estimate of its empirical distribution function.
- The LOWERBOUNDS subroutines should be defined if the lower bound on at least one distribution parameter is different from the default lower bound of 0. If you define a LOWERBOUNDS subroutine but do not set a lower bound for some parameter inside the subroutine, then that parameter is assumed to have no lower bound (or a lower bound of $-\infty$). Hence, it is recommended that you explicitly return the lower bound for each parameter when you define the LOWERBOUNDS subroutine.
- The UPPERBOUNDS subroutines should be defined if the upper bound on at least one distribution parameter is different from the default upper bound of ∞ . If you define an UPPERBOUNDS subroutine but do not set an upper bound for some parameter inside the subroutine, then that parameter is assumed to have no upper bound (or a upper bound of ∞). Hence, it is recommended that you explicitly return the upper bound for each parameter when you define the UPPERBOUNDS subroutine.

- If you want to use the distribution in a model with regression effects, then make sure that the first parameter of the distribution is the scale parameter itself or a log-transformed scale parameter. If the first parameter is a log-transformed scale parameter, then you must define the SCALETRANSFORM function.
- In general, it is not necessary to define the gradient and Hessian functions, because PROC SEVERITY uses an internal system to evaluate the required derivatives. The internal system typically computes the derivatives analytically. But it might not be able to do so if your function definitions use other functions that it cannot differentiate analytically. In such cases, derivatives are approximated using a finite difference method and a note is written to the SAS log to indicate the components that are differentiated using such approximations. PROC SEVERITY does reasonably well with these finite difference approximations. But, if you know of a way to compute the derivatives of such components analytically, then you should define the gradient and Hessian functions.

In order to use your distribution with PROC SEVERITY, you need to record the FCMP library that contains the functions and subroutines for your distribution and other FCMP libraries that contain FCMP functions or subroutines used within your distribution's functions and subroutines. Specify all those libraries in the CMPLIB= system option by using the OPTIONS global statement. For more information about the OPTIONS statement, see the *SAS Statements: Reference*. For more information about the CMPLIB= system option, see the *SAS System Options: Reference*.

Each predefined distribution mentioned in the section “[Predefined Distributions](#)” on page 1594 has a distribution model associated with it. The functions and subroutines of all those models are available in the Sashelp.Svrtldist library. The order of the parameters in the signatures of the functions and subroutines is the same as listed in [Table 23.2](#). You do not need to use the CMPLIB= option in order to use the predefined distributions with PROC SEVERITY. However, if you need to use the functions or subroutines of the predefined distributions in SAS statements other than the PROC SEVERITY step (such as in a DATA step), then specify the Sashelp.Svrtldist library in the CMPLIB= system option by using the OPTIONS global statement prior to using them.

[Table 23.4](#) shows functions and subroutines that define a distribution model, and subsections after the table provide more detail. The functions are listed in alphabetical order of the keyword suffix.

Table 23.4 List of Functions and Subroutines That Define a Distribution Model

Name	Type	Required	Expected to Return
<i>dist_CDF</i>	Function	YES ¹	Cumulative distribution function value
<i>dist_CDFGRADIENT</i>	Subroutine	NO	Gradient of the CDF
<i>dist_CDFHESSIAN</i>	Subroutine	NO	Hessian of the CDF
<i>dist_CONSTANTPARM</i>	Subroutine	NO	Constant parameters
<i>dist_DESCRIPTION</i>	Function	NO	Description of the distribution
<i>dist_LOGCDF</i>	Function	YES ¹	Log of cumulative distribution function value
<i>dist_LOGCDFGRADIENT</i>	Subroutine	NO	Gradient of the LOGCDF
<i>dist_LOGCDFHESSIAN</i>	Subroutine	NO	Hessian of the LOGCDF
<i>dist_LOGPDF</i>	Function	YES ²	Log of probability density function value
<i>dist_LOGPDFGRADIENT</i>	Subroutine	NO	Gradient of the LOGPDF
<i>dist_LOGPDFHESSIAN</i>	Subroutine	NO	Hessian of the LOGPDF
<i>dist_LOGSDF</i>	Function	NO	Log of survival function value
<i>dist_LOGSDFGRADIENT</i>	Subroutine	NO	Gradient of the LOGSDF
<i>dist_LOGSDFHESSIAN</i>	Subroutine	NO	Hessian of the LOGSDF
<i>dist_LOWERBOUNDS</i>	Subroutine	NO	Lower bounds on parameters
<i>dist_PARMINIT</i>	Subroutine	NO	Initial values for parameters
<i>dist_PDF</i>	Function	YES ²	Probability density function value
<i>dist_PDFGRADIENT</i>	Subroutine	NO	Gradient of the PDF
<i>dist_PDFHESSIAN</i>	Subroutine	NO	Hessian of the PDF
<i>dist_QUANTILE</i>	Function	NO	Quantile for a given CDF value
<i>dist_SCALETRANSFORM</i>	Function	NO	Type of relationship between the first distribution parameter and the scale parameter
<i>dist_SDF</i>	Function	NO	Survival function value
<i>dist_SDFGRADIENT</i>	Subroutine	NO	Gradient of the SDF
<i>dist_SDFHESSIAN</i>	Subroutine	NO	Hessian of the SDF
<i>dist_UPPERBOUNDS</i>	Subroutine	NO	Upper bounds on parameters

Notes:

1. Either the *dist_CDF* or the *dist_LOGCDF* function must be defined.
2. Either the *dist_PDF* or the *dist_LOGPDF* function must be defined.

The signature syntax and semantics of each function or subroutine are as follows:

dist_CDF

defines a function that returns the value of the cumulative distribution function (CDF) of the distribution at the specified values of the random variable and distribution parameters.

- *Type*: Function

- *Required:* YES
- *Number of arguments:* $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments:*
 - x Numeric value of the random variable at which the CDF value should be evaluated
 - p_1 Numeric value of the first parameter
 - p_2 Numeric value of the second parameter
 -
 - p_m Numeric value of the m th parameter
- *Return value:* Numeric value that contains the CDF value $F(x; p_1, p_2, \dots, p_m)$

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

$$F(x; p_1, p_2, \dots, p_m) = F\left(\frac{x}{p_1}; 1, p_2, \dots, p_m\right)$$

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

$$F(x; p_1, p_2, \dots, p_m) = F\left(\frac{x}{\exp(p_1)}; 0, p_2, \dots, p_m\right)$$

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_CDF(x, P1, P2);
  /* Code to compute CDF by using x, P1, and P2 */

  F = <computed CDF>;
  return (F);
endsub;
```

*dist_***CONSTANTPARM**

defines a subroutine that specifies constant parameters. A parameter is *constant* if it is required for defining a distribution but is not subject to optimization in PROC SEVERITY. Constant parameters are required to be part of the model in order to compute the PDF or the CDF of the distribution. Typically, values of these parameters are known a priori or estimated using some means other than the maximum likelihood method used by PROC SEVERITY. You can estimate them inside the *dist_PARMINIT* subroutine. Once initialized, the parameters remain constant in the context of PROC SEVERITY; that is, they retain their initial value. PROC SEVERITY estimates only the nonconstant parameters.

- *Type:* Subroutine
- *Required:* NO
- *Number of arguments:* k , where k is the number of constant parameters
- *Sequence and type of arguments:*

constant parameter 1 Name of the first constant parameter

 constant parameter k Name of the k th constant parameter

- *Return value:* None

Here is a sample structure of the subroutine for a distribution named 'FOO' that has P3 and P5 as its constant parameters, assuming that distribution has at least three parameters:

```
subroutine FOO_CONSTANTPARM(p5, p3);
endsub;
```

The following points should be noted while specifying the constant parameters:

- At least one distribution parameter must be free to be optimized; that is, if a distribution has total m parameters, then k must be strictly less than m .
- If you want to use this distribution for modeling regression effects, then the first parameter must not be a constant parameter.
- The order of arguments in the signature of this subroutine does not matter as long as each argument's name matches the name of one of the parameters that are defined in the signature of the *dist_PDF* function.
- The constant parameters must be specified in signatures of all the functions and subroutines that accept distribution parameters as their arguments.
- You must provide a nonmissing initial value for each constant parameter by using one of the supported parameter initialization methods.

*dist_***DESCRIPTION**

defines a function that returns a description of the distribution.

- *Type:* Function
- *Required:* NO
- *Number of arguments:* None
- *Sequence and type of arguments:* Not applicable
- *Return value:* Character value containing a description of the distribution

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_DESCRIPTION() $48;
  length desc $48;
  desc = "A model for a continuous distribution named foo";
  return (desc);
endsub;
```

There is no restriction on the length of the description (the length of 48 used in the previous example is for illustration purposes only). However, if the length is greater than 256, then only the first 256 characters appear in the displayed output and in the `_DESCRIPTION_` variable of the `OUTMODELINFO=` data set. Hence, the recommended length of the description is less than or equal to 256.

dist_LOGcore

defines a function that returns natural logarithm of the specified *core* function of the distribution at the specified values of the random variable and distribution parameters. The *core* keyword can be PDF, CDF, or SDF.

- *Type*: Function
- *Required*: YES only if *core* is PDF or CDF and you have not defined that *core* function; otherwise, NO
- *Number of arguments*: $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments*:
 - x Numeric value of the random variable at which the natural logarithm of the *core* function should be evaluated
 - p1 Numeric value of the first parameter
 - p2 Numeric value of the second parameter
 -
 - pm Numeric value of the m th parameter
- *Return value*: Numeric value that contains the natural logarithm of the *core* function

Here is a sample structure of the function for the core function PDF of a distribution named 'FOO':

```
function FOO_LOGPDF(x, P1, P2);
  /* Code to compute LOGPDF by using x, P1, and P2 */

  l = <computed LOGPDF>;
  return (l);
endsub;
```

dist_LOWERBOUNDS

defines a subroutine that returns lower bounds for the parameters of the distribution. If this subroutine is not defined for a given distribution, then the SEVERITY procedure assumes a lower bound of 0 for each parameter. If a lower bound of l_i is returned for a parameter p_i , then the SEVERITY procedure assumes that $l_i < p_i$ (strict inequality). If a missing value is returned for some parameter, then the SEVERITY procedure assumes that there is no lower bound for that parameter (equivalent to a lower bound of $-\infty$).

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: m , where m is the number of distribution parameters
- *Sequence and type of arguments*:
 - p1 Output argument that returns the lower bound on the first parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.
 - p2 Output argument that returns the lower bound on the second parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.
 -

pm Output argument that returns the lower bound on the *m*th parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.

- *Return value:* The results, lower bounds on parameter values, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named 'FOO':

```
subroutine FOO_LOWERBOUNDS(p1, p2);
    outargs p1, p2;

    p1 = <lower bound for P1>;
    p2 = <lower bound for P2>;
endsub;
```

*dist_*PARMINIT

defines a subroutine that returns the initial values for the distribution's parameters given an empirical distribution function (EDF) estimate.

- *Type:* Subroutine
- *Required:* NO
- *Number of arguments:* $m + 4$, where m is the number of distribution parameters
- *Sequence and type of arguments:*

<i>dim</i>	Input numeric value that contains the dimension of the <i>x</i> , <i>nx</i> , and <i>F</i> array arguments.
<i>x</i> {*}	Input numeric array of dimension <i>dim</i> that contains values of the random variables at which the EDF estimate is available. It can be assumed that <i>x</i> contains values in an increasing order. In other words, if $i < j$, then $x[i] < x[j]$.
<i>nx</i> {*}	Input numeric array of dimension <i>dim</i> . Each <i>nx</i> [<i>i</i>] contains the number of observations in the original data that have the value <i>x</i> [<i>i</i>].
<i>F</i> {*}	Input numeric array of dimension <i>dim</i> . Each <i>F</i> [<i>i</i>] contains the EDF estimate for <i>x</i> [<i>i</i>]. This estimate is computed by the SEVERITY procedure based on the EMPIRICALCDF= option.
<i>Ftype</i>	Input numeric value that contains the type of the EDF estimate that is stored in <i>x</i> and <i>F</i> . See the section “ Supplying EDF Estimates to Functions and Subroutines ” on page 1618 for definition of types.
<i>p1</i>	Output argument that returns the initial value of the first parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.
<i>p2</i>	Output argument that returns the initial value of the second parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.
....	
<i>pm</i>	Output argument that returns the initial value of the <i>m</i> th parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.

- *Return value:* The results, initial values of the parameters, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named 'FOO':

```
subroutine FOO_PARMINIT(dim, x{*}, nx{*}, F{*}, Ftype, p1, p2);
    outargs p1, p2;

    /* Code to initialize values of P1 and P2 by using
       dim, x, nx, and F */

    p1 = <initial value for p1>;
    p2 = <initial value for p2>;
endsub;
```

dist_PDF

defines a function that returns the value of the probability density function (PDF) of the distribution at the specified values of the random variable and distribution parameters.

- *Type*: Function
- *Required*: YES
- *Number of arguments*: $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments*:

x Numeric value of the random variable at which the PDF value should be evaluated

$p1$ Numeric value of the first parameter

$p2$ Numeric value of the second parameter

.....

pm Numeric value of the m th parameter

- *Return value*: Numeric value that contains the PDF value $f(x; p_1, p_2, \dots, p_m)$

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

$$f(x; p_1, p_2, \dots, p_m) = \frac{1}{p_1} f\left(\frac{x}{p_1}; 1, p_2, \dots, p_m\right)$$

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

$$f(x; p_1, p_2, \dots, p_m) = \frac{1}{\exp(p_1)} f\left(\frac{x}{\exp(p_1)}; 0, p_2, \dots, p_m\right)$$

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_PDF(x, P1, P2);
    /* Code to compute PDF by using x, P1, and P2 */

    f = <computed PDF>;
    return (f);
endsub;
```

dist_QUANTILE

defines a function that returns the quantile of the distribution at the specified value of the CDF for the specified values of distribution parameters.

- *Type:* Function
- *Required:* NO
- *Number of arguments:* $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments:*
 - cdf Numeric value of the cumulative distribution function (CDF) for which the quantile should be evaluated
 - p1 Numeric value of the first parameter
 - p2 Numeric value of the second parameter
 -
 - pm Numeric value of the m th parameter
- *Return value:* Numeric value that contains the quantile $F^{-1}(\text{cdf}; p_1, p_2, \dots, p_m)$

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_QUANTILE(c, P1, P2);
  /* Code to compute Quantile by using c, P1, and P2 */

  Q = <computed quantile>;
  return (Q);
endsub;
```

dist_SCALETRANSFORM

defines a function that returns a keyword to identify the transform that needs to be applied to the scale parameter to convert it to the first parameter of the distribution.

If you want to use this distribution for modeling regression effects, then the first parameter of this distribution must be a scale parameter. However, for some distributions, a typical or convenient parameterization might not have a scale parameter, but one of the parameters can be a simple transform of the scale parameter. As an example, consider a typical parameterization of the lognormal distribution with two parameters, location μ and shape σ , for which the PDF is defined as follows:

$$f(x; \mu, \sigma) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2}$$

You can reparameterize this distribution to contain a parameter θ instead of the parameter μ such that $\mu = \log(\theta)$. The parameter θ would then be a scale parameter. However, if you want to specify the distribution in terms of μ and σ (which is a more recognized form of the lognormal distribution) and still allow it as a candidate distribution for estimating regression effects, then instead of writing another distribution with parameters θ and σ , you can simply define the distribution with μ as the first parameter and specify that it is the logarithm of the scale parameter.

- *Type*: Function
- *Required*: NO
- *Number of arguments*: None
- *Sequence and type of arguments*: Not applicable
- *Return value*: Character value that contains one of the following keywords:

LOG	specifies that the first parameter is the logarithm of the scale parameter.
IDENTITY	specifies that the first parameter is a scale parameter without any transformation.

If this function is not specified, then the IDENTITY transform is assumed.

Here is a sample structure of the function for a distribution named 'FOO':

```
function FOO_SCALETRANSFORM() $8;
  length xform $8;
  xform = "IDENTITY";
  return (xform);
endsub;
```

dist_SDF

defines a function that returns the value of the survival distribution function (SDF) of the distribution at the specified values of the random variable and distribution parameters.

- *Type*: Function
- *Required*: NO
- *Number of arguments*: $m + 1$, where m is the number of distribution parameters
- *Sequence and type of arguments*:

x	Numeric value of the random variable at which the SDF value should be evaluated
p1	Numeric value of the first parameter
p2	Numeric value of the second parameter
.....	
pm	Numeric value of the m th parameter
- *Return value*: Numeric value that contains the SDF value $S(x; p_1, p_2, \dots, p_m)$

If you want to consider this distribution as a candidate distribution when estimating a response variable model with regression effects, then the first parameter of this distribution must be a scale parameter or log-transformed scale parameter. In other words, if the distribution has a scale parameter, then the following equation must be satisfied:

$$S(x; p_1, p_2, \dots, p_m) = S\left(\frac{x}{p_1}; 1, p_2, \dots, p_m\right)$$

If the distribution has a log-transformed scale parameter, then the following equation must be satisfied:

$$S(x; p_1, p_2, \dots, p_m) = S\left(\frac{x}{\exp(p_1)}; 0, p_2, \dots, p_m\right)$$

Here is a sample structure of the function for a distribution named 'FOO':

```

function FOO_SDF(x, P1, P2);
  /* Code to compute SDF by using x, P1, and P2 */

  S = <computed SDF>;
  return (S);
endsub;

```

*dist_***UPPERBOUNDS**

defines a subroutine that returns upper bounds for the parameters of the distribution. If this subroutine is not defined for a given distribution, then the SEVERITY procedure assumes that there is no upper bound for any of the parameters. If an upper bound of u_i is returned for a parameter p_i , then the SEVERITY procedure assumes that $p_i < u_i$ (strict inequality). If a missing value is returned for some parameter, then the SEVERITY procedure assumes that there is no upper bound for that parameter (equivalent to an upper bound of ∞).

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: m , where m is the number of distribution parameters
- *Sequence and type of arguments*:

$p1$	Output argument that returns the upper bound on the first parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.
$p2$	Output argument that returns the upper bound on the second parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.
.....	
pm	Output argument that returns the upper bound on the m th parameter. This must be specified in the OUTARGS statement inside the subroutine's definition.
- *Return value*: The results, upper bounds on parameter values, should be returned in the parameter arguments of the subroutine.

Here is a sample structure of the subroutine for a distribution named 'FOO':

```

subroutine FOO_UPPERBOUNDS(p1, p2);
  outargs p1, p2;

  p1 = <upper bound for P1>;
  p2 = <upper bound for P2>;
endsub;

```

*dist_core***GRADIENT**

defines a subroutine that returns the gradient vector of the specified *core* function of the distribution at the specified values of the random variable and distribution parameters. The *core* keyword can be PDF, CDF, SDF, LOGPDF, LOGCDF, or LOGSDF.

- *Type*: Subroutine
- *Required*: NO
- *Number of arguments*: $m + 2$, where m is the number of distribution parameters
- *Sequence and type of arguments*:

<i>x</i>	Numeric value of the random variable at which the gradient should be evaluated
<i>p1</i>	Numeric value of the first parameter
<i>p2</i>	Numeric value of the second parameter
.....	
<i>pm</i>	Numeric value of the <i>m</i> th parameter
<i>grad{*}</i>	Output numeric array of size <i>m</i> that contains the gradient vector evaluated at the specified values. If <i>h</i> denotes the value of the <i>core</i> function, then the expected order of the values in the array is as follows: $\frac{\partial h}{\partial p_1} \frac{\partial h}{\partial p_2} \cdots \frac{\partial h}{\partial p_m}$

- *Return value:* Numeric array that contains the gradient evaluated at *x* for the parameter values (*p1*, *p2*, ..., *pm*)

Here is a sample structure of the function for the core function CDF of a distribution named 'FOO':

```
subroutine FOO_CDFGRADIENT(x, P1, P2, grad{*});
    outargs grad;

    /* Code to compute gradient by using x, P1, and P2 */
    grad[1] = <partial derivative of CDF w.r.t. P1
              evaluated at x, P1, P2>;
    grad[2] = <partial derivative of CDF w.r.t. P2
              evaluated at x, P1, P2>;
endsub;
```

*dist_core*HESSIAN

defines a subroutine that returns the Hessian matrix of the specified *core* function of the distribution at the specified values of the random variable and distribution parameters. The *core* keyword can be PDF, CDF, SDF, LOGPDF, LOGCDF, or LOGSDF.

- *Type:* Subroutine
- *Required:* NO
- *Number of arguments:* *m* + 2, where *m* is the number of distribution parameters
- *Sequence and type of arguments:*

<i>x</i>	Numeric value of the random variable at which the Hessian matrix should be evaluated
<i>p1</i>	Numeric value of the first parameter
<i>p2</i>	Numeric value of the second parameter
.....	
<i>pm</i>	Numeric value of the <i>m</i> th parameter
<i>hess{*}</i>	Output numeric array of size $m(m + 1)/2$ that contains the lower triangular portion of the Hessian matrix in a packed vector form, evaluated at the specified values. If <i>h</i> denotes the value of the <i>core</i> function, then the expected order of the values in the array is as follows: $\frac{\partial^2 h}{\partial p_1^2} \mid \frac{\partial^2 h}{\partial p_1 \partial p_2} \frac{\partial^2 h}{\partial p_2^2} \mid \cdots \mid \frac{\partial^2 h}{\partial p_1 \partial p_m} \frac{\partial^2 h}{\partial p_2 \partial p_m} \cdots \frac{\partial^2 h}{\partial p_m^2}$

- *Return value:* Numeric array that contains the lower triangular portion of the Hessian matrix evaluated at x for the parameter values (p_1, p_2, \dots, p_m)

Here is a sample structure of the subroutine for the core function LOGSDF of a distribution named 'FOO':

```
subroutine FOO_LOGSDFHESSIAN(x, P1, P2, hess{*});
    outargs hess;

    /* Code to compute Hessian by using x, P1, and P2 */
    hess[1] = <second order partial derivative of LOGSDF
              w.r.t. P1 evaluated at x, P1, P2>;
    hess[2] = <second order partial derivative of LOGSDF
              w.r.t. P1 and P2 evaluated at x, P1, P2>;
    hess[3] = <second order partial derivative of LOGSDF
              w.r.t. P2 evaluated at x, P1, P2>;
endsub;
```

Predefined Utility Functions

The following predefined utility functions are provided with the SEVERITY procedure and are available in the Sashelp.Svrtdist library:

SVRTUTIL_EDF:

This function computes the empirical distribution function (EDF) estimate at the specified value of the random variable given the EDF estimate for a sample.

- *Type:* Function
- *Signature:* SVRTUTIL_EDF(y, n, x{*}, F{*}, Ftype)
- *Argument Description:*

y	Value of the random variable at which the EDF estimate is desired.
n	Dimension of the x and F input arrays.
x{*}	Input numeric array of dimension n that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.
F{*}	Input numeric array of dimension n in which each $F[i]$ contains the EDF estimate for $x[i]$. These values must be sorted in nondecreasing order.
Ftype	Type of the empirical estimate that is stored in the x and F arrays. See the section “Supplying EDF Estimates to Functions and Subroutines” on page 1618 for definition of types.

- *Return value:* The EDF estimate at y .

The type of the sample EDF estimate determines how the EDF estimate at y is computed. See the section [“Supplying EDF Estimates to Functions and Subroutines”](#) on page 1618 for more information.

SVRTUTIL_EMPLIMMOMENT:

This function computes the empirical estimate of the limited moment of specified order for the specified upper limit, given the EDF estimate for a sample.

- *Type:* Function
- *Signature:* SVRTUTIL_EMPLIMMOMENT(k, u, n, x{ * }, F{ * }, Ftype)
- *Argument Description:*

k	Order of the desired empirical limited moment.
u	Upper limit on the value of the random variable to be used in the computation of the desired empirical limited moment.
n	Dimension of the x and F input arrays.
x{ * }	Input numeric array of dimension n that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.
F{ * }	Input numeric array of dimension n in which each $F[i]$ contains the EDF estimate for $x[i]$. These values must be sorted in nondecreasing order.
Ftype	Type of the empirical estimate that is stored in the x and F arrays. See the section “ Supplying EDF Estimates to Functions and Subroutines ” on page 1618 for definition of types.
- *Return value:* The desired empirical limited moment.

The empirical limited moment is computed by using the empirical estimate of the CDF. If $F_n(x)$ denotes the EDF at x , then the empirical limited moment of order k with upper limit u is defined as

$$E_n[(X \wedge u)^k] = k \int_0^u (1 - F_n(x))x^{k-1} dx$$

The SVRTUTIL_EMPLIMMOMENT function uses the piecewise linear nature of $F_n(x)$ as described in the section “[Supplying EDF Estimates to Functions and Subroutines](#)” on page 1618 to compute the integration.

SVRTUTIL_HILLCUTOFF:

This function computes an estimate of the value where the right tail of a distribution is expected to begin. The function implements the algorithm described in Danielsson et al. 2001. The description of the algorithm uses the following notation:

- | | |
|-----------------|--|
| n | number of observations in the original sample |
| B | number of bootstrap samples to draw |
| m_1 | size of the bootstrap sample in the first step of the algorithm ($m_1 < n$) |
| $x_{(i)}^{j,m}$ | i th order statistic of j th bootstrap sample of size m ($1 \leq i \leq m, 1 \leq j \leq B$) |
| $x_{(i)}$ | i th order statistic of the original sample ($1 \leq i \leq n$) |

Given the input sample x and values of B and m_1 , the steps of the algorithm are as follows:

1. Take B bootstrap samples of size m_1 from the original sample.

- Find the integer k_1 that minimizes the bootstrap estimate of the mean squared error:

$$k_1 = \arg \min_{1 \leq k < m_1} Q(m_1, k)$$

- Take B bootstrap samples of size $m_2 = m_1^2/n$ from the original sample.
- Find the integer k_2 that minimizes the bootstrap estimate of the mean squared error:

$$k_2 = \arg \min_{1 \leq k < m_2} Q(m_2, k)$$

- Compute the integer k_{opt} , which is used for computing the cutoff point:

$$k_{\text{opt}} = \frac{k_1^2}{k_2} \left(\frac{\log(k_1)}{2 \log(m_1) - \log(k_1)} \right)^{2 - 2 \log(k_1) / \log(m_1)}$$

- Set the cutoff point equal to $x_{(k_{\text{opt}}+1)}$.

The bootstrap estimate of the mean squared error is computed as

$$Q(m, k) = \frac{1}{B} \sum_{j=1}^B \text{MSE}_j(m, k)$$

The mean squared error of j th bootstrap sample is computed as

$$\text{MSE}_j(m, k) = (M_j(m, k) - 2(\gamma_j(m, k))^2)^2$$

where $M_j(m, k)$ is a control variate proposed by Danielsson et al. 2001,

$$M_j(m, k) = \frac{1}{k} \sum_{i=1}^k \left(\log(x_{(m-i+1)}^{j,m}) - \log(x_{(m-k)}^{j,m}) \right)^2$$

and $\gamma_j(m, k)$ is the Hill's estimator of the tail index (Hill 1975),

$$\gamma_j(m, k) = \frac{1}{k} \sum_{i=1}^k \log(x_{(m-i+1)}^{j,m}) - \log(x_{(m-k)}^{j,m})$$

This algorithm has two tuning parameters, B and m_1 . The number of bootstrap samples B is chosen based on the availability of computational resources. The optimal value of m_1 is chosen such that the following ratio, $R(m_1)$, is minimized:

$$R(m_1) = \frac{(Q(m_1, k_1))^2}{Q(m_2, k_2)}$$

The SVRTUTIL_HILLCUTOFF utility function implements the preceding algorithm. It uses the grid search method to compute the optimal value of m_1 .

- *Type:* Function
- *Signature:* SVRTUTIL_HILLCUTOFF(n, x{*}, b, s, status)
- *Argument Description:*

- | | |
|----------|---|
| n | Dimension of the array x . |
| $x\{*\}$ | Input numeric array of dimension n that contains the sample. |
| b | Number of bootstrap samples used to estimate the mean squared error. If b is less than 10, then a default value of 50 is used. |
| s | Approximate number of steps used to search the optimal value of m_1 in the range $[n^{0.75}, n - 1]$. If s is less than or equal to 1, then a default value of 10 is used. |
| status | Output argument that contains the status of the algorithm. If the algorithm succeeds in computing a valid cutoff point, then <i>status</i> is set to 0. If the algorithm fails, then <i>status</i> is set to 1. |
- *Return value:* The cutoff value where the right tail is estimated to start. If the size of the input sample is inadequate ($n \leq 5$), then a missing value is returned and *status* is set to a missing value. If the algorithm fails to estimate a valid cutoff value (*status* = 1), then the fifth largest value in the input sample is returned.

SVRTUTIL_PERCENTILE:

This function computes the specified empirical percentile given the EDF estimates.

- *Type:* Function
- *Signature:* SVRTUTIL_PERCENTILE(p, n, $x\{*\}$, $F\{*\}$, Ftype)
- *Argument Description:*

p	Desired percentile. The value must be in the interval (0,1). The function returns the 100 p th percentile.
n	Dimension of the x and F input arrays.
$x\{*\}$	Input numeric array of dimension n that contains values of the random variable observed in the sample. These values are sorted in nondecreasing order.
$F\{*\}$	Input numeric array of dimension n in which each $F[i]$ contains the EDF estimate for $x[i]$. These values must be sorted in nondecreasing order.
Ftype	Type of the empirical estimate that is stored in the x and F arrays. See the section “ Supplying EDF Estimates to Functions and Subroutines ” on page 1618 for definition of types.
- *Return value:* The 100 p th percentile of the input sample.

The method used to compute the percentile depends on the type of the EDF estimate (Ftype argument).

- | | |
|-----------|---|
| Ftype = 1 | Smoothed empirical estimates are computed using the method described in Klugman, Panjer, and Willmot (1998). Let $\lfloor x \rfloor$ denote the greatest integer less than or equal to x . Define $g = \lfloor p(n + 1) \rfloor$ and $h = p(n + 1) - g$. Then the empirical percentile $\hat{\pi}_p$ is defined as |
|-----------|---|

$$\hat{\pi}_p = (1 - h)x[g] + hx[g + 1]$$

This method does not work if $p < 1/(n + 1)$ or $p > n/(n + 1)$. If $p < 1/(n + 1)$, then the function returns $\hat{\pi}_p = x[1]/2$, which assumes that the EDF is 0 in the interval $[0, x[1])$. If $p > n/(n + 1)$, then $\hat{\pi}_p = x[n]$.

Ftype = 2 If $p < F[1]$, then $\hat{\pi}_p = x[1]/2$, which assumes that the EDF is 0 in the interval $[0, x[1])$. If $|p - F[i]| < \epsilon$ for some value of i and $i < n$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = \frac{x[i] + x[i + 1]}{2}$$

where ϵ is a machine-precision constant as returned by the SAS function `CONSTANT('MACEPS')`. If $F[i - 1] < p < F[i]$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = x[i]$$

If $p \geq F[n]$, then $\hat{\pi}_p = x[n]$.

Ftype = 3 If $p < F[1]$, then $\hat{\pi}_p = x[1]/2$, which assumes that the EDF is 0 in the interval $[0, x[1])$. If $|p - F[i]| < \epsilon$ for some value of i and $i < n$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = \frac{x[i] + x[i + 1]}{2}$$

where ϵ is a machine-precision constant as returned by the SAS function `CONSTANT('MACEPS')`. If $F[i - 1] < p < F[i]$, then $\hat{\pi}_p$ is computed as

$$\hat{\pi}_p = x[i - 1] + (p - F[i - 1]) \frac{x[i] - x[i - 1]}{F[i] - F[i - 1]}$$

If $p \geq F[n]$, then $\hat{\pi}_p = x[n]$.

SVRTUTIL_RAWMOMENTS:

This subroutine computes the raw moments of a sample.

- *Type:* Subroutine
- *Signature:* SVRTUTIL_RAWMOMENTS(*n*, *x*{*}, *nx*{*}, *nRaw*, *raw*{*})
- *Argument Description:*

<i>n</i>	Dimension of the <i>x</i> and <i>nx</i> input arrays.
<i>x</i> {*}	Input numeric array of dimension <i>n</i> that contains distinct values of the random variable that are observed in the sample.
<i>nx</i> {*}	Input numeric array of dimension <i>n</i> in which each <i>nx</i> [<i>i</i>] contains the number of observations in the sample that have the value <i>x</i> [<i>i</i>].
<i>nRaw</i>	Desired number of raw moments. The output array <i>raw</i> contains the first <i>nRaw</i> raw moments.
<i>raw</i> {*}	Output array of raw moments. The <i>k</i> th element in the array (<i>raw</i> { <i>k</i> }) contains the <i>k</i> th raw moment, where $1 \leq k \leq nRaw$.
- *Return value:* Numeric array *raw* that contains the first *nRaw* raw moments. The array contains missing values if the sample has no observations (that is, if all the values in the *nx* array add up to zero).

SVRTUTIL_SORT:

This function sorts the given array of numeric values in an ascending or descending order.

- *Type:* Subroutine
- *Signature:* SVRTUTIL_SORT(*n*, *x*{*}, *flag*)
- *Argument Description:*

- | | |
|----------|---|
| n | Dimension of the input array x . |
| $x\{*\}$ | Numeric array that contains the values to be sorted at input. The subroutine uses the same array to return the sorted values. |
| flag | A numeric value that controls the sort order. If <i>flag</i> is 0, then the values are sorted in an ascending order. If <i>flag</i> has any value other than 0, then the values are sorted in descending order. |
- *Return value*: Numeric array x , which is sorted in place (that is, the sorted array is stored in the same storage area occupied by the input array x).

You can use the following predefined functions when you define functions and subroutines using the FCMP procedure. They are summarized here for your information. See the FCMP procedure documentation in *Base SAS Procedures Guide* for more information.

INVCDF:

This function computes the quantile from any continuous probability distribution by numerically inverting the CDF of that distribution. You need to specify the CDF function of the distribution, the values of its parameters, and the cumulative probability to compute the quantile.

LIMMOMENT:

This function computes the limited moment of order k with upper limit u for any continuous probability distribution. The limited moment is defined as

$$\begin{aligned} E[(X \wedge u)^k] &= \int_0^u x^k f(x) dx + \int_u^\infty u^k f(x) dx \\ &= \int_0^u x^k f(x) dx + u^k (1 - F(u)) \end{aligned}$$

where $f(x)$ and $F(x)$ denote the PDF and the CDF of the distribution, respectively. The LIMMOMENT function uses the following alternate definition, which can be derived using integration-by-parts:

$$E[(X \wedge u)^k] = k \int_0^u (1 - F(x)) x^{k-1} dx$$

You need to specify the CDF function of the distribution, the values of its parameters, and the values of k and u to compute the limited moment.

Custom Objective Functions (Experimental)

You can use a series of programming statements that use variables in the input data set specified by DATA= option in the PROC SEVERITY statement to assign a value to an objective function symbol. The objective function symbol must be specified using the OBJECTIVE= option in the PROC SEVERITY statement.

The objective function can be programmed such that it is applicable to any distribution that is used in the model. For that purpose, PROC SEVERITY recognizes the following *keyword* functions in the programming statements:

<code>_PDF_(x)</code>	returns the probability density function (PDF) of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_CDF_(x)</code>	returns the cumulative distribution function (CDF) of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_SDF_(x)</code>	returns the survival distribution function (SDF) of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_LOGPDF_(x)</code>	returns the natural logarithm of the PDF of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_LOGCDF_(x)</code>	returns the natural logarithm of the CDF of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_LOGSDF_(x)</code>	returns the natural logarithm of the SDF of a distribution evaluated at the current value of a data set variable <i>x</i> .
<code>_EDF_(x)</code>	returns the empirical distribution function (EDF) estimate evaluated at the current value of a data set variable <i>x</i> . Internally, PROC SEVERITY computes the estimate using the SVRTUTIL_EDF function as described in the section “ Predefined Utility Functions ” on page 1636. The EDF estimate required by the SVRTUTIL_EDF function is computed using the response variable values in the current BY group or in the entire input data set if no BY statement is specified.
<code>_EMPLIMMOMENT_(k, u)</code>	returns the empirical limited moment of order <i>k</i> evaluated at the current value of a data set variable <i>u</i> that represents the upper limit of the limited moment. The order <i>k</i> can also be a data set variable. Internally, PROC SEVERITY computes the moment using the SVRTUTIL_EMPLIMMOMENT function as described in the section “ Predefined Utility Functions ” on page 1636. The EDF estimate required by the SVRTUTIL_EMPLIMMOMENT function is computed using the response variable values in the current BY group or in the entire input data set if no BY statement is specified.
<code>_LIMMOMENT_(k, u)</code>	returns the limited moment of order <i>k</i> evaluated at the current value of a data set variable <i>u</i> that represents the upper limit of the limited moment. The order <i>k</i> can be a data set variable or a constant. Internally, for each candidate distribution, PROC SEVERITY computes the moment using the LIMMOMENT function as described in the section “ Predefined Utility Functions ” on page 1636.

All the preceding functions are right-hand side functions. They act as placeholders for distribution-specific functions, with the exception of `_EDF_` and `_EMPLIMMOMENT_` functions. As an example, let the data set `Work.Test` contain a response variable *Y* and a left-truncation threshold variable *T*. The following statements use the values in this data set to fit a model with distribution *D* such that the parameters of the model minimize the value of the objective function symbol `MYOBJ`:

```
options cmplib=(work.mydist);
proc severity data=work.test objective=myobj;
    loss y / lt=t;

    myobj = -_LOGPDF_(y);
    if (not(missing(t))) then
        myobj = myobj + log(1-_CDF_(t));
```

```
dist d;
run;
```

The symbol MYOBJ is designated as an objective function symbol by using the **OBJECTIVE=** option in the PROC SEVERITY statement. The response variable Y and left-truncation variable T are specified in the LOSS statement. The distribution D is specified in the DIST statement. The remaining statements constitute a program that computes the value of the MYOBJ symbol.

Let the distribution D have parameters P1 and P2. In order to estimate the model for this distribution, PROC SEVERITY internally converts the generic program to the following program specific to distribution D:

```
myobj = -D_LOGPDF(y, p1, p2);
if (not(missing(t))) then
    myobj = myobj + log(1-D_CDF(t, p1, p2));
```

Note that the generic keyword functions `_LOGPDF_` and `_CDF_` have been replaced with distribution-specific functions `D_LOGPDF` and `D_CDF`, respectively, with appropriate distribution parameters. The `D_LOGPDF` and `D_CDF` functions must have been defined previously and are assumed to be available in the `Work.Mydist` library specified in the `CMPLIB=` option.

The program is executed for each observation in `Work.Test` to compute the value of MYOBJ by using the values of variables Y and T in that observation and internally computed values of the model parameters P1 and P2. The values of MYOBJ are then added over all the observations of the data set or over all the observations of the current BY group if a BY statement is specified. The resulting aggregate value is the value of the objective function, and it is supplied to the optimizer. If the optimizer requires derivatives of the objective function, then PROC SEVERITY automatically differentiates MYOBJ with respect to the parameters P1 and P2. The optimizer iterates over various combinations of the values of parameters P1 and P2, each time computing a new value of the objective function and the needed derivatives of it, until it finds a combination that minimizes the objective function.

Note the following points when you define your own program to compute the custom objective function:

- The value of the objective function is always minimized by PROC SEVERITY. If you want to maximize the value of a certain objective, then add a statement that assigns the negated value of the maximization objective to the objective function symbol specified in the **OBJECTIVE=** option. Minimization of the negated objective is equivalent to the maximization of the original objective.
- The contributions of individual observations are always added to compute the overall objective function in a given iteration of the optimizer. If you have specified the **WEIGHT** statement, then the contribution of each observation is weighted by multiplying it with the normalized value of the weight variable for that observation.
- If you are fitting multiple distributions in one PROC SEVERITY step and use any of the keyword functions in your program, then it is recommended that you do not explicitly use the parameters of any of the specified distributions in your programming statements.
- If you use a specific keyword function in your programming statements, then the corresponding distribution functions must be defined in a library specified in the **CMPLIB=** system option or in `Sashelp.Svrtdist`, the predefined functions library. In the preceding example, it is assumed that the

functions D_LOGPDF and D_CDF are defined in the Work.Mydist library specified in the CMPLIB= option.

- You can use most DATA step statements and functions in your program. The DATA step file and the data set I/O statements (for example, INPUT, FILE, SET, and MERGE) are not available. However, some functionality of the PUT statement is supported. See the section “PROC FCMP and DATA Step Differences” in *Base SAS Procedures Guide* for more information. In addition to the differences listed in that section, the following differences exist:
 - Only numeric-valued variables can be used in PROC SEVERITY programming statements. This restriction also implies that you cannot use SAS functions or call routines that require character-valued arguments, unless you pass those arguments as constant (literal) strings or characters.
 - You cannot use functions that create lagged versions of a variable in PROC SEVERITY programming statements. If you need lagged versions, then you can use a DATA step prior to the PROC SEVERITY step to add those versions to the input data set.
- When coding your programming statements, avoid defining variables that begin with an underscore (_), because they might conflict with internal variables created by PROC SEVERITY.

Custom Objective Functions and Regression Effects

If you have specified regressors using the SCALEMODEL statement, then PROC SEVERITY automatically adds a statement prior to your programming statements to compute the value of the scale parameter or the log-transformed scale parameter of the distribution using the values of the regression variables and internally created regression parameters. For example, if you have specified three regressors x1, x2, and x3 in the SCALEMODEL statement, then for a model that contains the distribution D with scale parameter S, PROC SEVERITY prepends your program with a statement that is equivalent to the following statement:

```
S = _SEVTHETA0 * exp(_SEVBETA1 * x1 + _SEVBETA2 * x2 + _SEVBETA3 * x3);
```

If a model contains a distribution D1 with a log-transformed scale parameter M, PROC SEVERITY prepends your program with a statement that is equivalent to the following statement:

```
M = _SEVTHETA0 + _SEVBETA1 * x1 + _SEVBETA2 * x2 + _SEVBETA3 * x3;
```

The _SEVTHETA0, _SEVBETA1, _SEVBETA2, and _SEVBETA3 are the internal regression parameters associated with the intercept and the regressors x1, x2, and x3, respectively.

Since the names of the internal regression parameters start with a prefix _SEV, if you use a variable in your program with a name that begins with _SEV, then PROC SEVERITY writes an error message to the SAS log and stops processing.

Multithreaded Computation

PROC SEVERITY attempts to use all the computational resources of the machine where SAS is running in order to complete the estimation tasks as fast as possible. This section describes the options that control the use of multithreading by PROC SEVERITY.

Threading refers to the organization of computational work into multiple tasks (processing units that can be scheduled by the operating system). A task is associated with a thread. Multithreading refers to the concurrent execution of threads. When multithreading is possible, substantial performance gains can be realized compared to sequential (single-threaded) execution.

The number of threads spawned by the SEVERITY procedure is determined by the number of CPUs on a machine. You can control the number of threads by specifying either the CPUCOUNT= or the NOTHEADS SAS system option.

- You can specify the CPU count with the CPUCOUNT= SAS system option. For example, if you specify the following statement, then PROC SEVERITY schedules threads as if it executed on a system with four CPUs, regardless of the actual CPU count:

```
options cpucount=4;
```

On most systems, the default value of the CPUCOUNT= system option is set to the number of actual CPU cores available for processing.

- If you do not want PROC SEVERITY to use multithreading, then you can turn off the THREADS SAS system option by specifying the following statement:

```
options nothreads;
```

On most systems, the THREADS option is turned on by default.

You can examine the current settings of these system options in the SAS log by submitting the following PROC OPTIONS step:

```
proc options option=(threads cpucount);  
run;
```

Input Data Sets

PROC SEVERITY accepts DATA= and INEST= data sets as input data sets. This section details the information they are expected to contain.

DATA= Data Set

The DATA= data set is expected to contain the values of the analysis variables specified in the [LOSS statement](#) and the [SCALEMODEL statement](#).

If BY variables are specified in the BY statement, then the DATA= data set must contain all the variables specified in the BY statement and the data set must be sorted by the BY variables unless the NOTSORTED option is used in the BY statement.

INEST= Data Set

The INEST= data set is expected to contain the initial values of the parameters for the parameter estimation process.

If BY variables are specified in the BY statement, then the INEST= data set must contain all the variables specified in the BY statement. If the NOTSORTED option is not specified in the BY statement, then the INEST= data set must be sorted by the BY variables. However, it is not required to contain all the BY groups present in the DATA= data set. For the BY groups that are not present in the INEST= data set, the default parameter initialization method is used. If the NOTSORTED option is specified in the BY statement, then the INEST= data set must contain all the BY groups that are present in the DATA= data set and they must appear in the same order as they appear in the DATA= data set.

In addition to any variables specified in the BY statement, the data set must contain the following variables:

<code>_MODEL_</code>	identifying name of the distribution for which the estimates are provided.
<code>_TYPE_</code>	type of the estimate. The value of this variable must be EST for an observation to be valid.

`<Parameter 1> ... <Parameter M>`

M variables, named after the parameters of all candidate distributions, that contain initial values of the respective parameters. M is the cardinality of the union of parameter name sets from all candidate distributions. In an observation, estimates are read only from variables for parameters that correspond to the distribution specified by the `_MODEL_` variable.

If you specify a missing value for some parameters, then default initial values are used unless the parameter is initialized by using the `INIT=` option in the DIST statement. If you want to use the `dist_PARMINIT` subroutine for initializing the parameters of a model, then you should either not specify the model in the INEST= data set or specify missing values for all the distribution parameters in the INEST= data set and not use the `INIT=` option in the DIST statement.

If regressors are specified, then the initial value provided for the first parameter of each distribution must be the base value of the scale or log-transformed scale parameter. See the section “[Estimating Regression Effects](#)” on page 1609 for more information.

`<Regressor 1> ... <Regressor K>`

If K regressors are specified in the [SCALEMODEL statement](#), then the INEST= data set must contain K variables that are named for each regressor. The variables contain initial values of the respective regression coefficients. If a regressor is linearly dependent on other regressors for a given BY group, then you can indicate this by providing a special missing value of `.R` for the respective variable. In a given BY group, if a variable is marked as linearly dependent for one model, then it must be marked so for all the models. Similarly, if a variable is not marked as linearly dependent for one model, then it must be marked so for all the models.

Output Data Sets

PROC SEVERITY writes OUTCDF=, OUTEST=, OUTMODELINFO=, and OUTSTAT= data sets when requested with respective options. The data sets and their contents are described in the following sections.

OUTCDF= Data Set

The OUTCDF= data set records the estimates of the cumulative distribution function (CDF) of each of the specified model distributions and an estimate of the empirical distribution function (EDF).

If BY variables are specified, then the data are organized in BY groups and the data set contains variables specified in the BY statement. In addition, it contains the following variables:

<response variable>

value of the response variable. The values are sorted. If there are multiple BY groups, the values are sorted within each BY group.

OBSNUM observation number in the DATA= data set.

EDF estimate of the empirical distribution function (EDF). This estimate is computed by using the [EMPIRICALCDF=](#) option specified in the PROC SEVERITY statement.

_EDF_STD estimate of the standard error of EDF. This estimate is computed by using a method that is appropriate for the [EMPIRICALCDF=](#) option specified in the PROC SEVERITY statement.

_EDF_LOWER estimate of the lower confidence limit of EDF for a pointwise $100(1 - \alpha)\%$ confidence interval, where α is the value of the [EDFALPHA=](#) option specified in the PROC SEVERITY statement (default is $\alpha = 0.05$). For an EDF estimate F_n with standard error σ_n , it is computed as $\text{MAX}(0, F_n - z_{(1-\alpha/2)}\sigma_n)$, where z_p is the p th quantile from the standard normal distribution.

_EDF_UPPER estimate of the upper confidence limit of EDF for a pointwise $100(1 - \alpha)\%$ confidence interval, where α is the value of the [EDFALPHA=](#) option specified in the PROC SEVERITY statement (default is $\alpha = 0.05$). For an EDF estimate F_n with standard error σ_n , it is computed as $\text{MIN}(1, F_n + z_{(1-\alpha/2)}\sigma_n)$, where z_p is the p th quantile from the standard normal distribution.

<distribution1>_CDF ... <distributionD>_CDF

estimate of the cumulative distribution function (CDF) for each of the D candidate distributions, computed by using the final parameter estimates for that distribution. This value is missing if parameter estimation process does not converge for the given distribution.

If regressor variables are specified, then the reported estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1611 for more information.

If truncation is specified, then the data set contains the following additional variables:

<distribution1>_COND_CDF ... <distributionD>_COND_CDF

estimate of the conditional CDF for each of the D candidate distributions, computed by using the final parameter estimates for that distribution. This value is missing if parameter estimation process does not converge for the distribution. The conditional estimates are computed using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1605.

OUTEST= Data Set

The OUTEST= data set records the estimates of the model parameters. It also contains estimates of their standard errors and optionally, their covariance structure. If BY variables are specified, then the data are organized in BY groups and the data set contains variables specified in the BY statement.

If the COVOUT option is not specified, then the data set contains the following variables:

<code>_MODEL_</code>	identifying name of the distribution model. The observation contains information about this distribution.
<code>_TYPE_</code>	type of the estimates reported in this observation. It can take one of the following two values:
EST	point estimates of model parameters
STDERR	standard error estimates of model parameters
<code>_STATUS_</code>	status of the reported estimates. The possible values are listed in the section “ _STATUS_ Variable Values ” on page 1650.

<Parameter 1> ... <Parameter M>

M variables, named after the parameters of all candidate distributions, containing estimates of the respective parameters. M is the cardinality of the union of parameter name sets from all candidate distributions. In an observation, estimates are populated only for parameters that correspond to the distribution specified by the `_MODEL_` variable. If `_TYPE_` is EST, then the estimates are missing if the model does not converge. If `_TYPE_` is STDERR, then the estimates are missing if covariance estimates cannot be obtained.

If regressors are specified, then the estimate reported for the first parameter of each distribution is the estimate of the base value of the scale or log-transformed scale parameter. See the section “[Estimating Regression Effects](#)” on page 1609 for more information.

<Regressor 1> ... <Regressor K>

If K regressors are specified in the [SCALEMODEL](#) statement, then the OUTEST= data set contains K variables that are named for each regressor. The variables contain estimates for their respective regression coefficients. If a regressor is deemed to be linearly dependent on other regressors for a given BY group, then a warning message is printed to the SAS log and a special missing value of .R is written in the respective variable. If `_TYPE_` is EST, then the estimates are missing if the model does not converge. If `_TYPE_` is STDERR, then the estimates are missing if covariance estimates cannot be obtained.

If the COVOUT option is specified, then the OUTEST= data set contains additional observations that contain the estimates of the covariance structure. Given the symmetric nature of the covariance structure, only the lower triangular portion is reported. In addition to the variables listed and described previously, the data set contains the following variables that are either new or have a modified description:

<code>_TYPE_</code>	type of the estimates reported in this observation. For observations that contain rows of the covariance structure, the value is COV.
---------------------	---

<code>_STATUS_</code>	status of the reported estimates. For observations that contain rows of the covariance structure, the status is 0 if covariance estimation was successful. If estimation fails, the status is 1 and a single observation is reported with <code>_TYPE_=COV</code> and missing values for all the parameter variables.
<code>_NAME_</code>	Name of the parameter for the row of covariance matrix reported in the current observation.

OUTMODELINFO= Data Set

The OUTMODELINFO= data set records the information about each specified distribution. If BY variables are specified, then the data are organized in BY groups and the data set contains variables specified in the BY statement. In addition, it contains the following variables:

<code>_MODEL_</code>	identifying name of the distribution model. The observation contains information about this distribution.
<code>_DESCRIPTION_</code>	descriptive name of the model. This has a nonmissing value only if the DESCRIPTION function has been defined for this model.
<code>_PARMNAME1 ... _PARMNAMEM</code>	M variables that contain names of parameters of the distribution model, where M is the maximum number of parameters across all the specified distribution models. For a given distribution with m parameters, values of variables <code>_PARMNAMEj</code> ($j > m$) are missing.

OUTSTAT= Data Set

The OUTSTAT= data set records statistics of fit and model selection information. If BY variables are specified, then the data are organized in BY groups and the data set contains variables specified in the BY statement. The data set contains the following variables:

<code>_MODEL_</code>	identifying name of the distribution model. The observation contains information about this distribution.
<code>_NMODELPRM_</code>	number of parameters in the distribution.
<code>_NESTPRM_</code>	number of estimated parameters. This includes the regression parameters, if any regressors are specified.
<code>_NOBS_</code>	number of nonmissing observations used for parameter estimation.
<code>_STATUS_</code>	status of the parameter estimation process for this model. The possible values are listed in the section “ _STATUS_ Variable Values ” on page 1650.
<code>_SELECTED_</code>	indicator of the best distribution model. If the value is 1, then this model is the best model for the current BY group according to the specified model selection criterion. This value is missing if parameter estimation process does not converge for this model.
Neg2LogLike	value of the log likelihood, multiplied by -2 , that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.

AIC	value of the Akaike's information criterion (AIC) that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
AICC	value of the corrected Akaike's information criterion (AICC) that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
BIC	value of the Schwarz Bayesian information criterion (BIC) that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
KS	value of the Kolmogorov-Smirnov (KS) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
AD	value of the Anderson-Darling (AD) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.
CVM	value of the Cramér-von Mises (CvM) statistic that is attained at the end of the parameter estimation process. This value is missing if parameter estimation process does not converge for this model.

STATUS Variable Values

The `_STATUS_` variable in the `OUTEST=` and `OUTSTAT=` data sets contains a value that indicates the status of the parameter estimation process for the respective distribution model. The variable can take the following values in the `OUTEST=` data set for `_TYPE_=EST` observations and in the `OUTSTAT=` data set:

- 0 The parameter estimation process converged for this model.
- 301 The parameter estimation process might not have converged for this model because there is no improvement in the objective function value. This might indicate that the initial values of the parameters are optimal, or you can try different convergence criteria in the **NLOPTIONS** statement.
- 302 The parameter estimation process might not have converged for this model because the number of iterations exceeded the maximum allowed value. You can try setting a larger value for the `MAXITER=` options in the **NLOPTIONS** statement.
- 303 The parameter estimation process might not have converged for this model because the number of objective function evaluations exceeded the maximum allowed value. You can try setting a larger value for the `MAXFUNC=` options in the **NLOPTIONS** statement.
- 304 The parameter estimation process might not have converged for this model because the time taken by the process exceeded the maximum allowed value. You can try setting a larger value for the `MAXTIME=` option in the **NLOPTIONS** statement.
- 400 The parameter estimation process did not converge for this model.

The `_STATUS_` variable can take the following values in the `OUTEST=` data set for `_TYPE_=STDERR` and `_TYPE_=COV` observations:

- 0 The covariance and standard error estimates are available and valid.
- 1 The covariance and standard error estimates are not available, because the process of computing covariance estimates failed.

Displayed Output

The SEVERITY procedure optionally produces displayed output by using the Output Delivery System (ODS). All output is controlled by the PRINT= option in the PROC SEVERITY statement. [Table 23.5](#) relates the PRINT= options to ODS tables.

Table 23.5 ODS Tables Produced in PROC SEVERITY

ODS Table Name	Description	Option
AllFitStatistics	Statistics of fit for all the distribution models	PRINT=ALLFITSTATS
ConvergenceStatus	Convergence status of parameter estimation process	PRINT=CONVSTATUS
DescStats	Descriptive statistics for the response variable	PRINT=DESCSTATS
DistributionInfo	Distribution information	PRINT=DISTINFO
InitialValues	Initial parameter values and bounds	PRINT=INITIALVALUES
IterationHistory	Optimization iteration history	PRINT=NLOHISTORY
ModelSelection	Model selection summary	PRINT=SELECTION
OptimizationSummary	Optimization summary	PRINT=NLOSUMMARY
ParameterEstimates	Final parameter estimates	PRINT=ESTIMATES
RegDescStats	Descriptive statistics for the regressor variables	PRINT=DESCSTATS
StatisticsOfFit	Statistics of fit	PRINT=STATISTICS
TurnbullSummary	Turnbull EDF estimation summary	PRINT=ALL

If PRINT= option is not specified, then by default PROC SEVERITY produces ModelSelection, ConvergenceStatus, OptimizationSummary, StatisticsOfFit, and ParameterEstimates ODS tables.

The TurnbullSummary table is produced only if you specify PRINT=ALL and Turnbull's method is used for computing EDF estimates.

AllFitStatistics (PRINT=ALLFITSTATS)

displays the comparison of all the statistics of fit for all the models in one table. The table does not include the models whose parameter estimation process does not converge. If all the models fail to converge, then this table is not produced. If the table contains more than one model, then the best model according to each statistic is indicated with an asterisk (*) in that statistic's column.

ConvergenceStatus (PRINT=CONVSTATUS)

displays the convergence status of the parameter estimation process.

DescStats (PRINT=DESCSTATS)

displays the descriptive statistics for the response variable.

DistributionInfo (PRINT=DISTINFO)

displays the information about all the candidate distribution. It includes the name, the description, the number of distribution parameters, and whether the distribution is valid for the specified modeling task.

InitialValues (PRINT=INITIALVALUES)

displays the initial values and bounds used for estimating each model.

IterationHistory (PRINT=NLOHISTORY)

displays the iteration history of the nonlinear optimization process used for estimating the parameters.

ModelSelection (PRINT=SELECTION)

displays the model selection table. The table shows the convergence status of each candidate model, and the value of the selection criterion along with an indication of the selected model.

OptimizationSummary (PRINT=NLOSUMMARY)

displays the summary of the nonlinear optimization process used for estimating the parameters.

ParameterEstimates (PRINT=ESTIMATES)

displays the final estimates of parameters. The estimates are not displayed for models whose parameter estimation process does not converge.

RegDescStats (PRINT=DESCSTATS)

displays the descriptive statistics for the regressor variables, if you have specified the SCALEMODEL statement.

StatisticsOfFit (PRINT=STATISTICS)

displays the statistics of fit for each model. The statistics of fit are not displayed for models whose parameter estimation process does not converge.

TurnbullSummary (PRINT=ALL)

displays the summary of Turnbull's estimation process if Turnbull's method is used for computing EDF estimates. The summary includes whether the nonlinear optimization converged, the number of iterations, the maximum absolute relative error, the maximum absolute reduced gradient, and whether the final estimates are maximum likelihood estimates.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the SEVERITY procedure.

ODS Graph Names

PROC SEVERITY assigns a name to each graph it creates by using ODS. You can use these names to selectively reference the graphs. The names are listed in [Table 23.6](#).

Table 23.6 ODS Graphics Produced by PROC SEVERITY

ODS Graph Name	Plot Description	PLOTS= Option
CDFPlot	Comparative CDF Plot	CDF
CDFDistPlot	CDF Plot per Distribution	CDFPERDIST
PDFPlot	Comparative PDF Plot	PDF
PDFDistPlot	PDF Plot per Distribution	PDFPERDIST
PPPlot	P-P Plot of CDF and EDF	PP
QQPlot	Q-Q Plot	QQ

Comparative CDF Plot

The comparative CDF plot helps you visually compare the cumulative distribution function (CDF) estimates of all the candidate distribution models and the empirical distribution function (EDF) estimate. The plot does not contain CDF estimates for models whose parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the CDF or EDF estimates.

If truncation is specified, then conditional CDF estimates are plotted. Otherwise, unconditional CDF estimates are plotted. The conditional estimates are computed using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1605.

If regressor variables are specified, then the plotted CDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1611 for more information.

CDF Plot per Distribution

The CDF plot per distribution shows the CDF estimates of each candidate distribution model unless that model's parameter estimation process does not converge. The plot also contains estimates of the EDF. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the CDF or EDF estimates.

This plot shows the lower and upper pointwise confidence limits for the EDF estimates. For an EDF estimate F_n with standard error σ_n , they are computed as $\text{MAX}(0, F_n - z_{(1-\alpha/2)}\sigma_n)$ and $\text{MIN}(1, F_n + z_{(1-\alpha/2)}\sigma_n)$ respectively, where z_p is the p th quantile from the standard normal distribution and α denotes the confidence level that you specified in the `EDFALPHA=` option (the default is $\alpha = 0.05$).

If truncation is specified, then conditional CDF estimates are plotted. Otherwise unconditional CDF estimates are plotted. The conditional estimates are computed using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1605.

If regressor variables are specified, then the plotted CDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1611 for more information.

Comparative PDF Plot

The comparative PDF plot helps you visually compare the probability density function (PDF) estimates of all the candidate distribution models. The plot does not contain PDF estimates for models whose parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the PDF estimates.

If the `HISTOGRAM` option is specified, then the plot also contains the histogram of response variable values. If the `KERNEL` option is specified, then the plot also contains the kernel density estimate for the response variable values.

If regressor variables are specified, then the plotted PDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1611 for more information.

PDF Plot per Distribution

The PDF plot per distribution shows the PDF estimates of each candidate distribution model unless that model's parameter estimation process does not converge. The horizontal axis represents the values of the response variable. The vertical axis represents the values of the PDF estimates.

If the `HISTOGRAM` option is specified, then the plot also contains the histogram of response variable values. If the `KERNEL` option is specified, then the plot also contains the kernel density estimate for the response variable values.

If regressor variables are specified, then the plotted PDF estimates are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1611 for more information.

P-P Plot of CDF and EDF

The P-P plot of CDF and EDF is the probability-probability plot that compares the CDF estimates of a distribution with the EDF estimates. A plot is not prepared for models whose parameter estimation process does not converge. The horizontal axis represents the CDF estimates of a candidate distribution and the vertical axis represents the EDF estimates.

This plot can be interpreted as displaying the data that are used for computing the EDF-based statistics of fit for the given candidate distribution. As described in the section “[EDF-Based Statistics](#)” on page 1620, these statistics are computed by comparing the EDF, denoted by $F_n(y)$, and the CDF, denoted by $F(y)$, at each of the response variable values y . Using the probability inverse transform $z = F(y)$, this is equivalent to comparing the EDF of the z , denoted by $F_n(z)$, and the CDF of z , denoted by $F(z)$ (D’Agostino and Stephens 1986, Ch. 4). Given that the CDF of z is a uniform distribution ($F(z) = z$), the EDF-based statistics can be computed by comparing the EDF estimate of z with the estimate of z . The horizontal axis of the plot represents the estimated CDF $\hat{z} = \hat{F}(y)$. The vertical axis represents the estimated EDF of z , $\hat{F}_n(z)$. The plot contains a scatter plot of $(\hat{z}, \hat{F}_n(z))$ points and a reference line $F_n(z) = z$ that represents the expected uniform distribution of z . Points scattered closer to the reference line indicate a better fit than the points scattered away from the reference line.

If truncation is specified, then the EDF estimates are conditional as described in the section “[EDF Estimates and Truncation](#)” on page 1618. So, conditional estimates of CDF are displayed, which are computed using the method described in the section “[Truncation and Conditional CDF Estimates](#)” on page 1605.

If regressor variables are specified, then the displayed CDF estimates, both unconditional and conditional, are from a mixture distribution. See the section “[CDF and PDF Estimates with Regression Effects](#)” on page 1611 for more information.

Q-Q Plot

The Q-Q plot is a quantile-quantile scatter plot that compares the empirical quantiles with the quantiles from a candidate distribution. A plot is not prepared for models whose parameter estimation process does not converge. The horizontal axis represents the quantiles from a candidate distribution, and the vertical axis represents the empirical quantiles.

Each point in the plot corresponds to a specific value of EDF estimate, F_n . The Y coordinate is the value of the response variable for which F_n is computed. The X coordinate is computed by using one of two following methods for a candidate distribution named *dist*:

- If you have defined the *dist_QUANTILE* function that satisfies the requirements listed in the section “[dist_QUANTILE](#)” on page 1632, then that function is invoked with F_n and estimated distribution parameters as arguments. The QUANTILE function is defined in the Sashelp.Svrtldist library for all the predefined distributions except for the Burr distribution.
- If the *dist_QUANTILE* function is not defined, then PROC SEVERITY numerically inverts the *dist_CDF* function at the CDF value of F_n for the estimated distribution parameters. If the *dist_CDF* function is not defined, then the *exp(dist_LOGCDF)* function is inverted. If the inversion fails, the corresponding point is not plotted in the Q-Q plot.

If truncation is specified, then the EDF estimates are conditional as described in the section “[EDF Estimates and Truncation](#)” on page 1618. The CDF inversion process, whether done numerically or by evaluating the *dist_QUANTILE* function, needs to accept an unconditional CDF value. So, the F_n value is first transformed to an unconditional estimate F_n^u as

$$F_n^u = F_n \cdot (\hat{F}(t_{\max}^r) - \hat{F}(t_{\min}^l)) + \hat{F}(t_{\min}^l)$$

where $\hat{F}(t_{\max}^r)$ and $\hat{F}(t_{\min}^l)$ are as defined in the section “[Truncation and Conditional CDF Estimates](#)” on page 1605.

If regressor variables are specified, then the value of the first distribution parameter is the mean scale value computed from the scale values that are implied by all the observations in the current BY group (or in the entire DATA= data set if the BY statement is not specified).

Examples: SEVERITY Procedure

Example 23.1: Defining a Model for Gaussian Distribution

Suppose you want to fit a distribution model other than one of the predefined ones available to you. Suppose you want to define a model for the Gaussian distribution with the following typical parameterization of the PDF (f) and CDF (F):

$$f(x; \mu, \sigma) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(x - \mu)^2}{2\sigma^2}\right)$$

$$F(x; \mu, \sigma) = \frac{1}{2} \left(1 + \operatorname{erf}\left(\frac{x - \mu}{\sigma\sqrt{2}}\right)\right)$$

For PROC SEVERITY, a *distribution model* consists of a set of functions and subroutines that are defined with the FCMP procedure. Each function and subroutine should be written following certain rules. For more information, see the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1623.

NOTE: The Gaussian distribution is not a commonly used severity distribution. It is used in this example primarily to illustrate the process of defining your own distribution models. Although the distribution has a support over the entire real line, you can fit the distribution with PROC SEVERITY only if the input sample contains nonnegative values.

The following SAS statements define a distribution model named NORMAL for the Gaussian distribution. The OUTLIB= option in the PROC FCMP statement stores the compiled versions of the functions and subroutines in the ‘models’ package of the Work.Sevevxmpl library. The LIBRARY= option in the PROC FCMP statement enables this PROC FCMP step to use the SVRTUTIL_RAWMOMENTS utility subroutine that is available in the Sashelp.Svrtldist library. The subroutine is described in the section “[Predefined Utility Functions](#)” on page 1636.

```
/*----- Define Normal Distribution with PROC FCMP -----*/
proc fcmp library=sashelp.svrtldist outlib=work.sevevxmpl.models;
  function normal_pdf(x,Mu,Sigma);
    /* Mu      : Location */
    /* Sigma   : Standard Deviation */
    return ( exp(-(x-Mu)**2/(2 * Sigma**2)) /
              (Sigma * sqrt(2*constant('PI'))) );
  endsub;

  function normal_cdf(x,Mu,Sigma);
    /* Mu      : Location */
    /* Sigma   : Standard Deviation */
    z = (x-Mu)/Sigma;
    return (0.5 + 0.5*erf(z/sqrt(2)));
  endsub;
```

```

endsub;

subroutine normal_parminit(dim, x[*], nx[*], F[*], Ftype, Mu, Sigma);
    outargs Mu, Sigma;
    array m[2] / nosymbols;

    /* Compute estimates by using method of moments */
    call svrtutil_rawmoments(dim, x, nx, 2, m);
    Mu = m[1];
    Sigma = sqrt(m[2] - m[1]**2);
endsub;

subroutine normal_lowerbounds(Mu, Sigma);
    outargs Mu, Sigma;
    Mu = .; /* Mu has no lower bound */
    Sigma = 0; /* Sigma > 0 */
endsub;
quit;

```

The statements define the two functions required of any distribution model (NORMAL_PDF and NORMAL_CDF) and two optional subroutines (NORMAL_PARMINIT and NORMAL_LOWERBOUNDS). The name of each function or subroutine must follow a specific structure. It should start with the model's short or identifying name, which is 'NORMAL' in this case, followed by an underscore '_', followed by a keyword suffix such as 'PDF'. Each function or subroutine has a specific purpose. For more information about all the functions and subroutines that you can define for a distribution model, see the section “[Defining a Distribution Model with the FCMP Procedure](#)” on page 1623. Following is the description of each function and subroutine defined in this example:

- The PDF and CDF suffixes define functions that return the probability density function and cumulative distribution function values, respectively, given the values of the random variable and the distribution parameters.
- The PARMINIT suffix defines a subroutine that returns the initial values for the parameters by using the sample data or the empirical distribution function (EDF) estimate computed from it. In this example, the parameters are initialized by using the method of moments. Hence, you do not need to use the EDF estimates, which are available in the F array. The first two raw moments of the Gaussian distribution are as follows:

$$E[x] = \mu, E[x^2] = \mu^2 + \sigma^2$$

Given the sample estimates, m_1 and m_2 , of these two raw moments, you can solve the equations $E[x] = m_1$ and $E[x^2] = m_2$ to get the following estimates for the parameters: $\hat{\mu} = m_1$ and $\hat{\sigma} = \sqrt{m_2 - m_1^2}$. The NORMAL_PARMINIT subroutine implements this solution. It uses the SVRTUTIL_RAWMOMENTS utility subroutine to compute the first two raw moments.

- The LOWERBOUNDS suffix defines a subroutine that returns the lower bounds on the parameters. PROC SEVERITY assumes a default lower bound of 0 for all the parameters when a LOWERBOUNDS subroutine is not defined. For the parameter μ (*Mu*), there is no lower bound, so you need to define the NORMAL_LOWERBOUNDS subroutine. It is recommended that you assign bounds

for all the parameters when you define the LOWERBOUNDS subroutine or its counterpart, the UPPERBOUNDS subroutine. Any unassigned value is returned as a missing value, which is interpreted by PROC SEVERITY to mean that the parameter is unbounded, and that might not be what you want.

You can now use this distribution model with PROC SEVERITY. Let the following DATA step statements simulate a normal sample with $\mu = 10$ and $\sigma = 2.5$.

```
/*----- Simulate a Normal sample -----*/
data testnorm(keep=y);
  call streaminit(12345);
  do i=1 to 100;
    y = rand('NORMAL', 10, 2.5);
    output;
  end;
run;
```

Prior to using your distribution with PROC SEVERITY, you must communicate the location of the library that contains the definition of the distribution and the locations of libraries that contain any functions and subroutines used by your distribution model. The following OPTIONS statement sets the CMPLIB= system option to include the FCMP library Work.Sevexmpl in the search path used by PROC SEVERITY to find FCMP functions and subroutines.

```
/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);
```

Now, you are ready to fit the NORMAL distribution model with PROC SEVERITY. The following statements fit the model to the values of Y in the Work.Testnorm data set:

```
/*--- Fit models with PROC SEVERITY ---*/
proc severity data=testnorm print=all;
  loss y;
  dist Normal;
run;
```

The DIST statement specifies the identifying name of the distribution model, which is 'NORMAL'. Neither is the INEST= option specified in the PROC SEVERITY statement nor is the INIT= option specified in the DIST statement. So, PROC SEVERITY initializes the parameters by invoking the NORMAL_PARMINIT subroutine.

Some of the results prepared by the preceding PROC SEVERITY step are shown in [Output 23.1.1](#) and [Output 23.1.2](#). The descriptive statistics of variable Y and the “Model Selection Table”, which includes just the normal distribution, are shown in [Output 23.1.1](#).

Output 23.1.1 Summary of Results for Fitting the Normal Distribution

The SEVERITY Procedure	
Input Data Set	
Name	WORK.TESTNORM

Output 23.1.1 *continued*

Descriptive Statistics for Variable y			
Number of Observations			100
Number of Observations Used for Estimation			100
Minimum			3.88249
Maximum			16.00864
Mean			10.02059
Standard Deviation			2.37730
Model Selection Table			
Distribution	Converged	-2 Log Likelihood	Selected
Normal	Yes	455.97541	Yes

The initial values for the parameters, the optimization summary, and the final parameter estimates are shown in [Output 23.1.2](#). No iterations are required to arrive at the final parameter estimates, which are identical to the initial values. This confirms the fact that the maximum likelihood estimates for the Gaussian distribution are identical to the estimates obtained by the method of moments that was used to initialize the parameters in the NORMAL_PARMINIT subroutine.

Output 23.1.2 Details of the Fitted Normal Distribution Model

Output 23.1.2 continued

Parameter Estimates for Normal Distribution				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Mu	10.02059	0.23894	41.94	<.0001
Sigma	2.36538	0.16896	14.00	<.0001

The NORMAL distribution defined and illustrated here has no scale parameter, because all the following inequalities are true:

$$f(x; \mu, \sigma) \neq \frac{1}{\mu} f\left(\frac{x}{\mu}; 1, \sigma\right)$$

$$f(x; \mu, \sigma) \neq \frac{1}{\sigma} f\left(\frac{x}{\sigma}; \mu, 1\right)$$

$$F(x; \mu, \sigma) \neq F\left(\frac{x}{\mu}; 1, \sigma\right)$$

$$F(x; \mu, \sigma) \neq F\left(\frac{x}{\sigma}; \mu, 1\right)$$

This implies that you cannot estimate the effect of regressors on a model for the response variable based on this distribution.

Example 23.2: Defining a Model for Gaussian Distribution with a Scale Parameter

If you want to estimate the effects of regressors, then the model needs to be parameterized to have a scale parameter. While this might not be always possible, for the case of the Gaussian distribution it is possible by replacing the location parameter μ with another parameter, $\alpha = \mu/\sigma$, and defining the PDF (f) and the CDF (F) as follows:

$$f(x; \sigma, \alpha) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{1}{2}\left(\frac{x}{\sigma} - \alpha\right)^2\right)$$

$$F(x; \sigma, \alpha) = \frac{1}{2} \left(1 + \operatorname{erf}\left(\frac{1}{\sqrt{2}}\left(\frac{x}{\sigma} - \alpha\right)\right)\right)$$

It can be verified that σ is the scale parameter, because both of the following equalities are true:

$$f(x; \sigma, \alpha) = \frac{1}{\sigma} f\left(\frac{x}{\sigma}; 1, \alpha\right)$$

$$F(x; \sigma, \alpha) = F\left(\frac{x}{\sigma}; 1, \alpha\right)$$

NOTE: The Gaussian distribution is not a commonly used severity distribution. It is used in this example primarily to illustrate the concept of parameterizing a distribution such that it has a scale parameter.

Although the distribution has a support over the entire real line, you can fit the distribution with PROC SEVERITY only if the input sample contains nonnegative values.

The following statements use the alternate parameterization to define a new model named NORMAL_S. The definition is stored in the Work.Sevexmpl library.

```

/*----- Define Normal Distribution With Scale Parameter -----*/
proc fcmp library=sashelp.svrtldist outlib=work.sevexmpl.models;
  function normal_s_pdf(x, Sigma, Alpha);
    /* Sigma : Scale & Standard Deviation */
    /* Alpha : Scaled mean */
    return ( exp(-(x/Sigma - Alpha)**2/2) /
              (Sigma * sqrt(2*constant('PI')) ) );
  endsub;

  function normal_s_cdf(x, Sigma, Alpha);
    /* Sigma : Scale & Standard Deviation */
    /* Alpha : Scaled mean */
    z = x/Sigma - Alpha;
    return (0.5 + 0.5*erf(z/sqrt(2)));
  endsub;

  subroutine normal_s_parminit(dim, x[*], nx[*], F[*], Ftype, Sigma, Alpha);
    outargs Sigma, Alpha;
    array m[2] / nosymbols;

    /* Compute estimates by using method of moments */
    call svrtutil_rawmoments(dim, x, nx, 2, m);
    Sigma = sqrt(m[2] - m[1]**2);
    Alpha = m[1]/Sigma;
  endsub;

  subroutine normal_s_lowerbounds(Sigma, Alpha);
    outargs Sigma, Alpha;
    Alpha = .; /* Alpha has no lower bound */
    Sigma = 0; /* Sigma > 0 */
  endsub;
quit;

```

An important point to note is that the scale parameter *Sigma* is the first distribution parameter (after the 'x' argument) listed in the signatures of NORMAL_S_PDF and NORMAL_S_CDF functions. *Sigma* is also the first distribution parameter listed in the signatures of other subroutines. This is required by PROC SEVERITY, so that it can identify which is the scale parameter. When regressor variables are specified, PROC SEVERITY checks whether the first parameter of each candidate distribution is a scale parameter (or a log-transformed scale parameter if *dist_SCALETRANSFORM* subroutine is defined for the distribution with LOG as the transform). If it is not, then an appropriate message is written the SAS log and that distribution is not fitted.

Let the following DATA step statements simulate a sample from the normal distribution where the parameter σ is affected by the regressors as follows:

$$\sigma = \exp(1 + 0.5 X_1 + 0.75 X_3 - 2 X_4 + X_5)$$

The sample is simulated such that the regressor X_2 is linearly dependent on regressors X_1 and X_3 .

```

/*--- Simulate a Normal sample affected by Regressors ---*/
data testnorm_reg(keep=y x1-x5 Sigma);
  array x{*} x1-x5;
  array b{6} _TEMPORARY_ (1 0.5 . 0.75 -2 1);
  call streaminit(34567);
  label y='Normal Response Influenced by Regressors';

  do n = 1 to 100;
    /* simulate regressors */
    do i = 1 to dim(x);
      x(i) = rand('UNIFORM');
    end;
    /* make x2 linearly dependent on x1 and x3 */
    x(2) = x(1) + 5 * x(3);

    /* compute log of the scale parameter */
    logSigma = b(1);
    do i = 1 to dim(x);
      if (i ne 2) then
        logSigma = logSigma + b(i+1) * x(i);
      end;

    Sigma = exp(logSigma);
    y = rand('NORMAL', 25, Sigma);

    output;
  end;
run;

```

The following statements use PROC SEVERITY to fit the NORMAL_S distribution model along with some of the predefined distributions to the simulated sample:

```

/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);

/*----- Fit models with PROC SEVERITY -----*/
proc severity data=testnorm_reg print=all plots=none;
  loss y;
  scalemodel x1-x5;
  dist Normal_s burr logn pareto weibull;
run;

```

The “Model Selection Table” in [Output 23.2.1](#) indicates that all the models, except the Burr distribution model, have converged. Also, only three models, Normal_s, Burr, and Weibull, seem to have a good fit for the data. The table that compares all the fit statistics indicates that Normal_s model is the best according to the likelihood-based statistics; however, the Burr model is the best according to the EDF-based statistics.

Output 23.2.1 Summary of Results for Fitting the Normal Distribution with Regressors

The SEVERITY Procedure					
Input Data Set					
Name	WORK.TESTNORM_REG				
Model Selection Table					
Distribution	Converged	-2 Log Likelihood	Selected		
Normal_s	Yes	603.95786	Yes		
Burr	Maybe	612.80861	No		
Logn	Yes	749.20125	No		
Pareto	Yes	841.07013	No		
Weibull	Yes	612.77496	No		
All Fit Statistics Table					
Distribution	-2 Log Likelihood	AIC	AICC	BIC	KS
Normal_s	603.95786*	615.95786*	616.86108*	631.58888*	1.52388
Burr	612.80861	626.80861	628.02600	645.04480	1.50356*
Logn	749.20125	761.20125	762.10448	776.83227	2.88110
Pareto	841.07013	853.07013	853.97336	868.70115	4.83810
Weibull	612.77496	624.77496	625.67819	640.40598	1.50490
All Fit Statistics Table					
Distribution	AD		CvM		
Normal_s	4.00152		0.70769		
Burr	3.90098*		0.63396*		
Logn	16.20558		3.04825		
Pareto	31.60567		6.84045		
Weibull	3.90559		0.63458		

This prompts for further evaluation of why the model with Burr distribution has not converged. The initial values, convergence status, and the optimization summary for the Burr distribution are shown in [Output 23.2.2](#). The initial values table indicates that the regressor X2 is redundant, which is expected. More importantly, the convergence status indicates that it requires more than 50 iterations. PROC SEVERITY enables you to change several settings of the optimizer by using the [NLOPTIONS](#) statement. In this case, you can increase the limit of 50 on the iterations, change the convergence criterion, or change the technique to something other than the default trust-region technique.

Output 23.2.2 Details of the Fitted Burr Distribution Model

The SEVERITY Procedure			
Distribution Information			
Name	Burr		
Description	Burr Distribution

x2	Redundant	.	.
x3	-0.14056	-709.78271	709.78271
x4	0.27064	-709.78271	709.78271
x5	-0.23230	-709.78271	709.78271
Convergence Status for Burr Distribution			
Needs more than 50 iterations.			
Optimization Summary for Burr Distribution			
Optimization Technique	Trust Region		
Number of Iterations	50		
Number of Function Evaluations	132		
Log Likelihood	-306.40430		

The following PROC SEVERITY step uses the NLOPTIONS statement to change the convergence criterion and the limits on the iterations and function evaluations, exclude the lognormal and Pareto distributions that have been confirmed previously to fit the data poorly, and exclude the redundant regressor X2 from the model:

```

/*--- Refit and compare models with higher limit on iterations ---*/
proc severity data=testnorm_reg print=all plots=pp;
  loss y;
  scalemodel x1 x3-x5;
  dist Normal_s burr weibull;
  nloptions absfconv=2.0e-5 maxiter=100 maxfunc=500;
run;

```

The results shown in [Output 23.2.3](#) indicate that the Burr distribution has now converged and that the Burr and Weibull distributions have an almost identical fit for the data. The NORMAL_S distribution is still the best distribution according to the likelihood-based criteria.

Output 23.2.3 Summary of Results after Changing Maximum Number of Iterations

The SEVERITY Procedure					
Input Data Set					
Name	WORK.TESTNORM_REG				
Model Selection Table					
Distribution	Converged	-2 Log Likelihood		Selected	
Normal_s	Yes	603.95786		Yes	
Burr	Yes	612.78605		No	
Weibull	Yes	612.77496		No	
All Fit Statistics Table					
Distribution	-2 Log Likelihood	AIC	AICC	BIC	KS
Normal_s	603.95786*	615.95786*	616.86108*	631.58888*	1.52388
Burr	612.78605	626.78605	628.00344	645.02224	1.50479*
Weibull	612.77496	624.77496	625.67819	640.40598	1.50490
All Fit Statistics Table					
Distribution	AD		CvM		
Normal_s	4.00152		0.70769		
Burr	3.90430*		0.63442*		
Weibull	3.90559		0.63458		

The comparison of the PDF estimates of all the candidates is shown in [Output 23.2.4](#). Each plotted PDF estimate is an average computed over the N PDF estimates that are obtained with the scale parameter determined by each of the N observations in the input data set. The PDF plot shows that the Burr and Weibull models result in almost identical estimates. All the estimates have a slight left skew with the mode closer to $Y=25$, which is the mean of the simulated sample.

Output 23.2.4 Comparison of EDF and CDF Estimates of the Fitted Models

The P-P plots for the Normal_s and Burr distributions are shown in [Output 23.2.5](#). These plots show how the EDF estimates compare against the CDF estimates. Each plotted CDF estimate is an average computed over the N CDF estimates that are obtained with the scale parameter determined by each of the N observations in the input data set. Comparing the P-P plots of Normal_s and Burr distributions indicates that both fit the data almost similarly, but the Burr distribution fits the right tail slightly better, which explains why the EDF-based statistics prefer it over the Normal_s distribution.

Output 23.2.5 Comparison of EDF and CDF Estimates of NORMAL_S and BURR Models**Example 23.3: Defining a Model for Mixed-Tail Distributions**

In some applications, a few severity values tend to be extreme as compared to the typical values. The extreme values represent the worst case scenarios and cannot be discarded as outliers. Instead, their distribution must be modeled to prepare for their occurrences. In such cases, it is often useful to fit one distribution to the non-extreme values and another distribution to the extreme values. The *mixed-tail* distribution mixes two distributions: one for the *body* region, which contains the non-extreme values, and another for the *tail* region, which contains the extreme values. The *mixed-tail* distribution typically uses a generalized Pareto distribution (GPD) for the tail, because it is usually good for modeling the conditional excess severity above a threshold. The body distribution can be any distribution. The following definitions are used in describing a generic formulation of a mixed-tail distribution:

$g(x)$	PDF of the body distribution
$G(x)$	CDF of the body distribution
$h(x)$	PDF of the tail distribution
$H(x)$	CDF of the tail distribution
θ	scale parameter for the body distribution
Ω	set of nonscale parameters for the body distribution
ξ	shape parameter for the GPD tail distribution
x_r	normalized value of the response variable at which the tail starts
p_n	mixing probability

Given these notations, the PDF $f(x)$ and the CDF $F(x)$ of the mixed-tail distribution are defined as

$$f(x) = \begin{cases} \frac{p_n}{G(x_b)} g(x) & \text{if } x \leq x_b \\ (1 - p_n) h(x - x_b) & \text{if } x > x_b \end{cases}$$

$$F(x) = \begin{cases} \frac{p_n}{G(x_b)} G(x) & \text{if } x \leq x_b \\ p_n + (1 - p_n)H(x - x_b) & \text{if } x > x_b \end{cases}$$

where $x_b = \theta_{x_r}$ is the value of the response variable at which the tail starts.

These definitions indicate the following:

- The body distribution is conditional on $X \leq x_b$, where X denotes the random response variable.
- The tail distribution is the generalized Pareto distribution of the $(X - x_b)$ values.
- The probability that a response variable value belongs to the body is p_n . Consequently the probability that the value belongs to the tail is $(1 - p_n)$.

The parameters of this distribution are θ , Ω , ξ , x_r , and p_n . The scale of the GPD tail distribution θ_t is computed as

$$\theta_t = \frac{G(x_b; \theta, \Omega) (1 - p_n)}{g(x_b; \theta, \Omega) p_n} = \theta \frac{G(x_r; \theta = 1, \Omega) (1 - p_n)}{g(x_r; \theta = 1, \Omega) p_n}$$

The parameter x_r is typically estimated using a tail index estimation algorithm. One such algorithm is the Hill's algorithm (Danielsson et al. 2001), which is implemented by the predefined utility function SVRTUTIL_HILLCUTOFF available to you in the Sashelp.Svrtldist library. The algorithm and the utility function are described in detail in the section “[Predefined Utility Functions](#)” on page 1636. The function computes an estimate of x_b , which can be used to compute an estimate of x_r because $x_r = x_b / \hat{\theta}$, where $\hat{\theta}$ is the estimate of the scale parameter of the body distribution.

The parameter p_n is typically determined by the domain expert based on the fraction of losses that are expected to belong to the tail.

The following SAS statements define the LOGNGPD distribution model for a mixed-tail distribution with the lognormal distribution as the body distribution and GPD as the tail distribution:

```
/*----- Define Lognormal Body-GPD Tail Mixed Distribution -----*/
proc fcmp library=sashelp.svrtldist outlib=work.sevexmpl.models;
  function LOGNGPD_DESCRIPTION() $256;
    length desc $256;
    desc1 = "Lognormal Body-GPD Tail Distribution.";
    desc2 = " Mu, Sigma, and Xi are free parameters.";
    desc3 = " Xr and Pn are constant parameters.";
    desc = desc1 || desc2 || desc3;
    return(desc);
  endsub;

  function LOGNGPD_SCALETRANSFORM() $3;
    length xform $3;
    xform = "LOG";
    return (xform);
  endsub;

  subroutine LOGNGPD_CONSTANTPARM(Xr, Pn);
  endsub;
```

```

function LOGNGPD_PDF(x, Mu, Sigma, Xi, Xr, Pn);
  cutoff = exp(Mu) * Xr;
  p = CDF('LOGN', cutoff, Mu, Sigma);
  if (x < cutoff + constant('MACEPS')) then do;
    return ((Pn/p)*PDF('LOGN', x, Mu, Sigma));
  end;
  else do;
    gpd_scale = p*((1-Pn)/Pn)/PDF('LOGN', cutoff, Mu, Sigma);
    h = (1+Xi*(x-cutoff)/gpd_scale)**(-1-(1/Xi))/gpd_scale;
    return ((1-Pn)*h);
  end;
endsub;

function LOGNGPD_CDF(x, Mu, Sigma, Xi, Xr, Pn);
  cutoff = exp(Mu) * Xr;
  p = CDF('LOGN', cutoff, Mu, Sigma);
  if (x < cutoff + constant('MACEPS')) then do;
    return ((Pn/p)*CDF('LOGN', x, Mu, Sigma));
  end;
  else do;
    gpd_scale = p*((1-Pn)/Pn)/PDF('LOGN', cutoff, Mu, Sigma);
    H = 1 - (1 + Xi*((x-cutoff)/gpd_scale))**(-1/Xi);
    return (Pn + (1-Pn)*H);
  end;
endsub;

subroutine LOGNGPD_PARMINIT(dim, x[*], nx[*], F[*], Ftype,
                           Mu, Sigma, Xi, Xr, Pn);
  outargs Mu, Sigma, Xi, Xr, Pn;
  array xe[1] / nosymbols;
  array nxe[1] / nosymbols;

  eps = constant('MACEPS');

  Pn = 0.8; /* Set mixing probability */
  _status_ = .;
  call streaminit(56789);
  Xb = svrtutil_hillcutoff(dim, x, 100, 25, _status_);
  if (missing(_status_) or _status_ = 1) then
    Xb = svrtutil_percentile(Pn, dim, x, F, Ftype);

  /* prepare arrays for excess values */
  i = 1;
  do while (i <= dim and x[i] < Xb+eps);
    i = i + 1;
  end;
  dime = dim-i+1;
  call dynamic_array(xe, dime);
  call dynamic_array(nxe, dime);
  j = 1;
  do while(i <= dim);
    xe[j] = x[i] - Xb;
    nxe[j] = nx[i];
    i = i + 1;
  end;

```

```

        j = j + 1;
    end;

    /* Initialize lognormal parameters */
    call logn_parminit(dim, x, nx, F, Ftype, Mu, Sigma);
    if (not(missing(Mu))) then
        Xr = Xb/exp(Mu);
    else
        Xr = .;

    /* Initialize GPD's shape parameter using excess values */
    call gpd_parminit(dime, xe, nxe, F, Ftype, theta_gpd, Xi);
endsub;

subroutine LOGNGPD_LOWERBOUNDS(Mu, Sigma, Xi, Xr, Pn);
    outargs Mu, Sigma, Xi, Xr, Pn;

    Mu = .; /* Mu has no lower bound */
    Sigma = 0; /* Sigma > 0 */
    Xi = 0; /* Xi > 0 */
endsub;
quit;

```

The following points should be noted regarding the LOGNGPD definition:

- The parameters x_r and p_n are not estimated with the maximum likelihood method used by PROC SEVERITY, so you need to specify them as *constant* parameters by defining the [dist_CONSTANTPARM](#) subroutine. The signature of LOGNGPD_CONSTANTPARM subroutine lists only the constant parameters Xr and Pn .
- The parameter x_r is estimated by first using the SVRTUTIL_HILLCUTOFF utility function to compute an estimate of the cutoff point \hat{x}_b and then computing $x_r = \hat{x}_b/e^{\hat{\mu}}$. If SVRTUTIL_HILLCUTOFF fails to compute a valid estimate, then the SVRTUTIL_PERCENTILE utility function is used to set \hat{x}_b to the p_n th percentile of the data. The parameter p_n is fixed to 0.8.
- The Sashelp.Svrtldist library is specified with the LIBRARY= option in the PROC FCMP statement to enable the LOGNGPD_PARMINIT subroutine to use the predefined utility functions (SVRTUTIL_HILLCUTOFF and SVRTUTIL_PERCENTILE) and parameter initialization subroutines (LOGN_PARMINIT and GPD_PARMINIT).
- The LOGNGPD_LOWERBOUNDS subroutine defines the lower bounds for all parameters. This subroutine is required because the parameter Mu has a non-default lower bound. The bounds for $Sigma$ and Xi must be specified. If they are not specified, they are returned as missing values, which get interpreted as having no lower bound by PROC SEVERITY. You need not specify any bounds for the constant parameters Xr and Pn , because they are not subject to optimization.

The following DATA step statements simulate a sample from a mixed-tail distribution with a lognormal body and GPD tail. The parameter p_n is fixed to 0.8, the same value used in the LOGNGPD_PARMINIT subroutine defined previously:

```

/*----- Simulate a sample for the mixed-tail distribution -----*/
data testmixdist(keep=y label='Lognormal Body-GPD Tail Sample');
  call streaminit(45678);
  label y='Response Variable';
  N = 100;
  Mu = 1.5;
  Sigma = 0.25;
  Xi = 1.5;
  Pn = 0.8;

  /* Generate data comprising the lognormal body */
  Nbody = N*Pn;
  do i=1 to Nbody;
    y = exp(Mu) * rand('LOGNORMAL')**Sigma;
    output;
  end;

  /* Generate data comprising the GPD tail */
  cutoff = quantile('LOGNORMAL', Pn, Mu, Sigma);
  gpd_scale = (1-Pn) / pdf('LOGNORMAL', cutoff, Mu, Sigma);
  do i=Nbody+1 to N;
    y = cutoff + ((1-rand('UNIFORM'))**(-Xi) - 1)*gpd_scale/Xi;
    output;
  end;
run;

```

The following statements use PROC SEVERITY to fit the LOGNGPD distribution model to the simulated sample. They also fit three other predefined distributions (BURR, LOGN, and GPD). The final parameter estimates are written to the Work.Parmest data set.

```

/*--- Set the search path for functions defined with PROC FCMP ---*/
options cmplib=(work.sevexmpl);

/*----- Fit LOGNGPD model with PROC SEVERITY -----*/
proc severity data=testmixdist print=all plots(histogram kernel)=all
  outest=parmest;
  loss y;
  dist logngpd burr logn gpd;
run;

```

Some of the results prepared by PROC SEVERITY are shown in [Output 23.3.1](#) through [Output 23.3.4](#). The “Model Selection Table” in [Output 23.3.1](#) indicates that all models converged. The last table in [Output 23.3.1](#) shows that the model with LOGNGPD distribution has the best fit according to almost all the statistics of fit. The Burr distribution model is the closest contender to the LOGNGPD model, but the GPD distribution model fits the data very poorly.

Output 23.3.1 Summary of Fitting Mixed-Tail Distribution

The SEVERITY Procedure

Logn	3.27122		0.48448		
Gpd	16.74156		3.31860		

The plots in [Output 23.3.2](#) show that both the lognormal and GPD distributions fit the data poorly, GPD being the worst. The Burr distribution fits the data as well as the LOGNGPD distribution in the body region, but has a poorer fit in the tail region than the LOGNGPD distribution.

Output 23.3.2 Comparison of the CDF and PDF Estimates of the Fitted Models

Output 23.3.2 continued

The P-P plots of [Output 23.3.3](#) provide a better visual confirmation that the LOGNGPD distribution fits the tail region better than the Burr distribution.

Output 23.3.3 P-P Plots for the LOGNGPD and BURR Distribution Models

The detailed results for the LOGNGPD distribution are shown in [Output 23.3.4](#). The initial values table indicates the values computed by LOGNGPD_PARMINIT subroutine for the Xr and Pn parameters. It also uses the bounds columns to indicate the constant parameters. The last table in the figure shows the final parameter estimates. The estimates of all free parameters are significantly different than 0. As expected, the final estimates of the constant parameters Xr and Pn have not changed from their initial values.

Output 23.3.4 Detailed Results for the LOGNGPD Distribution

Pn              0.80000      Constant      .          .

```

The following SAS statements use the parameter estimates to compute the value where the tail region is estimated to start ($x_b = e^{\hat{\mu}} \hat{x}_r$) and the scale of the GPD tail distribution ($\theta_t = \frac{G(x_b)(1-p_n)}{g(x_b)p_n}$):

```

/*----- Compute tail cutoff and tail distribution's scale -----*/
data xb_thetat(keep=x_b theta_t);
  set parmesest(where=(_MODEL_='logngpd' and _TYPE_='EST'));
  x_b = exp(Mu) * Xr;
  theta_t = (CDF('LOGN',x_b,Mu,Sigma)/PDF('LOGN',x_b,Mu,Sigma)) *
            ((1-Pn)/Pn);
run;

proc print data=xb_thetat noobs;
run;

```

Output 23.3.5 Start of the Tail and Scale of the GPD Tail Distribution

x_b	theta_t
6.18005	1.27865

The computed values of x_b and θ_t are shown as `x_b` and `theta_t` in [Output 23.3.5](#). Equipped with this additional derived information, you can now interpret the results of fitting the mixed-tail distribution as follows:

- The tail starts at $y \approx 6.18$. The primary benefit of using the scale-normalized cutoff (x_r) as the constant parameter instead of using the actual cutoff (x_b) is that the absolute cutoff gets optimized by virtue of optimizing the scale of the body region ($\theta = e^\mu$).
- The values $y \leq 6.18$ follow the lognormal distribution with parameters $\mu \approx 1.58$ and $\sigma \approx 0.32$. These parameter estimates are reasonably close to the parameters used for simulating the sample.
- The values $y_t = y - 6.18$ ($y_t > 0$) follow the GPD distribution with scale $\theta_t \approx 1.28$ and shape $\xi \approx 1.04$.

Example 23.4: Estimating Parameters Using Cramér-von Mises Estimator

PROC SEVERITY enables you to estimate model parameters by minimizing your own objective function. This example illustrates how you can use PROC SEVERITY to implement the Cramér-von Mises estimator. Let $F(y_i; \Theta)$ denote the estimate of CDF at y_i for a distribution with parameters Θ , and let $F_n(y_i)$ denote the empirical estimate of CDF (EDF) at y_i that is computed from a sample y_i , $1 \leq i \leq N$. Then, the Cramér-von Mises estimator of the parameters is defined as

$$\hat{\Theta} = \arg \min_{\Theta} \sum_{i=1}^N (F(y_i; \Theta) - F_n(y_i))^2$$

This estimator belongs to the class of minimum distance estimators. It attempts to estimate the parameters such that the squared distance between the CDF and EDF estimates is minimized.

The following PROC SEVERITY step uses the Cramér-von Mises estimator to fit four candidate distribution models, including the LOGNGPD mixed-tail distribution model that was defined in “[Example 23.3: Defining a Model for Mixed-Tail Distributions](#)” on page 1667. The input sample is the same as is used in that example.

```
options cmplib=(work.sevexmpl);

proc severity data=testmixdist obj=cvmobj print=all plots=pp;
  loss y;
  dist logngpd burr logn gpd;

  * Cramer-von Mises estimator (minimizes the distance *
  * between parametric and nonparametric estimates)    *;
  cvmobj = _cdf_(y);
  cvmobj = (cvmobj -_edf_(y))**2;
run;
```

The OBJ= option in the PROC SEVERITY statement specifies that the objective function cvmobj should be minimized. The programming statements compute the contribution of each observation in the input data set to the objective function cvmobj. The use of keyword functions _CDF_ and _EDF_ makes the program applicable to all the distributions.

Some of the key results prepared by PROC SEVERITY are shown in [Output 23.4.1](#). The “Model Selection Table” indicates that all models converged. When you specify a custom objective function, the default selection criterion is the value of the custom objective function. The “All Fit Statistics Table” indicates that LOGNGPD is the best distribution according to all the statistics of fit. Comparing the fit statistics of [Output 23.4.1](#) with those of [Output 23.3.1](#) indicates that the use of the Cramér-von Mises estimator has resulted in smaller values for all the EDF-based statistics of fit for all the models, which is expected from a minimum distance estimator.

Output 23.4.1 Summary of Cramér-von Mises Estimation

The P-P plots in [Output 23.4.2](#) provide a visual confirmation that the CDF estimates match the EDF estimates more closely when compared to the estimates that are obtained with the maximum likelihood estimator.

Output 23.4.2 P-P Plots for LOGNGPD Model with Maximum Likelihood (Left) and Cramér-von Mises (Right) Estimators

Example 23.5: Fitting a Scaled Tweedie Model with Regressors

The Tweedie distribution is often used in the insurance industry to explain the effect of independent variables (regressors) on the distribution of losses. PROC SEVERITY provides a predefined scaled Tweedie distribution (STWEEDIE) that enables you to model the regression effects on the scale parameter. The scale regression model has its own advantages such as the ability to easily account for inflation effects. This example illustrates how that model can be used to evaluate the effect of regressors on the *mean* of the Tweedie distribution, which is useful in problems such rate-making and pure premium modeling.

Assume a Tweedie process, whose mean μ is affected by k regressors x_j , $j = 1, \dots, k$ as follows:

$$\mu = \mu_0 \exp \left(\sum_{j=1}^k \beta_j x_j \right)$$

where μ_0 represents the base value of the mean (you can think of μ_0 as $\exp(\beta_0)$, where β_0 is the intercept). This model for the mean is identical to the popular generalized linear model for the mean with a logarithmic link function. More interestingly, it parallels the model used by PROC SEVERITY for the scale parameter θ , which is as follows

$$\theta = \theta_0 \exp \left(\sum_{j=1}^k \beta_j x_j \right)$$

where θ_0 represents the base value of the scale parameter. As described in the section “[Tweedie Distributions](#)” on page 1596, for the parameter range $p \in (1, 2)$, the mean of the Tweedie distribution is given by

$$\mu = \theta \lambda \frac{2-p}{p-1}$$

where λ is the Poisson mean parameter of the scaled Tweedie distribution. This relationship enables you to use the scale regression model to infer the effect of regressors on the mean of the distribution.

Let the data set `Work.Test_Sevtw` contain a sample generated from a Tweedie distribution with dispersion parameter $\phi = 0.5$, index parameter $p = 1.75$, and the mean parameter that is affected by three regression variables `x1`, `x2`, and `x3` as follows:

$$\mu = 5 \exp(0.25 x_1 - x_2 + 3 x_3)$$

Thus, the population values of regression parameters are $\mu_0 = 5$, $\beta_1 = 0.25$, $\beta_2 = -1$, and $\beta_3 = 3$. You can find the code used to generate the sample in the PROC SEVERITY sample program `sevex05.sas`.

The following PROC SEVERITY step uses the sample in `Work.Test_Sevtw` data set to estimate the parameters of the scale regression model for the predefined scaled Tweedie distribution (STWEEDIE) with the dual quasi-Newton (QUANEW) optimization technique:

```
proc severity data=test_sevtw outest=estw covout print=all plots=none;
  loss y;
  scalemodel x1-x3;

  dist stweedie;
  nloptions tech=quanew;
run;
```

The dual quasi-Newton technique is used because it requires only the first-order derivatives of the objective function, and it is harder to compute reasonably accurate estimates of the second-order derivatives of Tweedie distribution's PDF with respect to the parameters.

Some of the key results prepared by PROC SEVERITY are shown in [Output 23.5.1](#) and [Output 23.5.2](#). The distribution information and the convergence results are shown in [Output 23.5.1](#).

Output 23.5.1 Convergence Results for the STWEEDIE Model with Regressors

The SEVERITY Procedure	
Distribution Information	
Name	stweedie
Description	Tweedie Distribution with Scale Parameter
Number of Distribution Parameters	3
Number of Regression Parameters	3
Convergence Status for stweedie Distribution	
Convergence criterion (FCONV=2.220446E-16) satisfied.	
Optimization Summary for stweedie Distribution	
Optimization Technique	Dual Quasi-Newton
Number of Iterations	41
Number of Function Evaluations	156
Log Likelihood	-1044.3

The final parameter estimates of the STWEEDIE regression model are shown in [Output 23.5.2](#). The estimate that is reported for the parameter Theta is the estimate of the base value θ_0 . The estimates of regression coefficients β_1 , β_2 , and β_3 are indicated by the rows of x1, x2, and x3, respectively.

Output 23.5.2 Parameter Estimates for the STWEEDIE Model with Regressors

Parameter Estimates for stweedie Distribution				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
Theta	0.82532	0.42135	1.96	0.0511
Lambda	16.40072	21.40657	0.77	0.4442
P	1.75168	0.33675	5.20	<.0001
x1	0.27991	0.09906	2.83	0.0050
x2	-0.76666	0.10338	-7.42	<.0001
x3	3.03252	0.10169	29.82	<.0001

If your goal is to explain the effect of regressors on the scale parameter, then the output displayed in [Output 23.5.2](#) is sufficient. But, if you want to compute the effect of regressors on the mean of the distribution, then some postprocessing needs to be done. Using the relationship between μ and θ , μ can be written in terms of the parameters of the STWEEDIE model as

$$\mu = \theta_0 \exp \left(\sum_{j=1}^k \beta_j x_j \right) \lambda \frac{2-p}{p-1}$$

This shows that the parameters β_j are identical for the mean and the scale model, and the base value μ_0 of the mean model is

$$\mu_0 = \theta_0 \lambda \frac{2-p}{p-1}$$

The estimate of μ_0 and the standard error associated with it can be computed by using the property of the functions of maximum likelihood estimators (MLE). If $g(\Omega)$ represents a totally differentiable function of parameters Ω , then the MLE of g has an asymptotic normal distribution with mean $g(\hat{\Omega})$ and covariance $C = (\partial g)' \Sigma (\partial g)$, where $\hat{\Omega}$ is the MLE of Ω , Σ is the estimate of covariance matrix of Ω , and ∂g is the gradient vector of g with respect to Ω evaluated at $\hat{\Omega}$. For μ_0 , the function is $g(\Omega) = \theta_0 \lambda (2-p)/(p-1)$. The gradient vector is

$$\begin{aligned} \partial g &= \left(\frac{\partial g}{\partial \theta_0} \quad \frac{\partial g}{\partial \lambda} \quad \frac{\partial g}{\partial p} \quad \frac{\partial g}{\partial \beta_1} \cdots \frac{\partial g}{\partial \beta_k} \right) \\ &= \left(\frac{\mu_0}{\theta_0} \quad \frac{\mu_0}{\lambda} \quad \frac{-\mu_0}{(p-1)(2-p)} \quad 0 \dots 0 \right) \end{aligned}$$

You can write a DATA step that implements these computations by using the parameter and covariance estimates prepared by PROC SEVERITY step. The DATA step program is available in the sample program `sevex05.sas`. The estimates of μ_0 prepared by that program are shown in [Output 23.5.3](#). These estimates and the estimates of β_j as shown in [Output 23.5.2](#) are reasonably close (that is, within one or two standard errors) to the parameters of the population from which the sample in `Work.Test_Sevtw` data set was drawn.

Output 23.5.3 Estimate of the Base Value μ_0 of the Mean Parameter

Parameter	Estimate	Standard Error	t Value	Approx Pr > t
μ_0	4.47156	0.42283	10.5752	0

Another effect of using the scaled Tweedie distribution to model the regression effects is that the regressors also affect the variance V of the Tweedie distribution. The variance is related to the mean as $V = \phi\mu^p$, where ϕ is the dispersion parameter. Using the relationship between the parameters TWEEDIE and STWEEDIE distributions as described in the section “[Tweedie Distributions](#)” on page 1596, the regression model for the dispersion parameter is

$$\begin{aligned}\log(\phi) &= (2 - p) \log(\mu) - \log(\lambda(2 - p)) \\ &= ((2 - p) \log(\mu_0) - \log(\lambda(2 - p))) + (2 - p) \sum_{j=1}^k \beta_j x_j\end{aligned}$$

Subsequently, the regression model for the variance is

$$\begin{aligned}\log(V) &= 2 \log(\mu) - \log(\lambda(2 - p)) \\ &= (2 \log(\mu_0) - \log(\lambda(2 - p))) + 2 \sum_{j=1}^k \beta_j x_j\end{aligned}$$

In summary, PROC SEVERITY enables you to estimate regression effects on various parameters and statistics of the Tweedie model.

Example 23.6: Fitting Distributions to Interval-Censored Data

In some applications, the data available for modeling might not be exact. A commonly encountered scenario is the use of grouped data from an external agency, which for several reasons, including privacy, does not provide information about individual loss events. The losses are grouped into disjoint bins, and you know only the range and number of values in each bin. Each group is essentially interval-censored, because you know that a loss magnitude is in certain interval, but you do not know the exact magnitude. This example illustrates how you can use PROC SEVERITY to model such data.

The following DATA step generates sample grouped data for dental insurance claims, which is taken from Klugman, Panjer, and Willmot (1998).

```
/* Grouped dental insurance claims data
   (Klugman, Panjer, and Willmot, 1998) */
data gdental;
  input lowerbd upperbd count @@;
  datalines;

500 1000 45 1000 1500 10 1500 2500 11 2500 4000 3
;
run;
```

Often, when you do not know the nature of the data, it is recommended that you first explore the nature of the sample distribution by examining the nonparametric estimates of PDF and CDF. The following PROC SEVERITY step prepares the nonparametric estimates, but it does not fit any distribution because there is no DIST statement specified:

```
/* Prepare nonparametric estimates */
proc severity data=gdenat print=all plots(histogram kernel)=all;
  loss / rc=lowerbd lc=upperbd;
  weight count;
run;
```

The LOSS statement specifies the left and right boundary of each group as the right-censoring and left-censoring limits, respectively. The variable count records the number of losses in each group and is specified in the WEIGHT statement. Note that there is no response or loss variable specified in the LOSS statement, which is allowed as long as each observation in the input data set is censored. The nonparametric estimates prepared by this step are shown in [Output 23.6.1](#). The histogram, kernel density, and EDF plots all indicate that the data is heavy-tailed. For interval-censored data, PROC SEVERITY uses Turnbull's algorithm to compute the EDF estimates. The plot of Turnbull's EDF estimates is shown to be linear between the endpoints of a censored group. The linear relationship is chosen for convenient visualization and ease of computation of EDF-based statistics, but you should note that theoretically the behavior of Turnbull's EDF estimates is undefined within a group.

Output 23.6.1 Nonparametric Distribution Estimates for Interval-Censored Data

With the PRINT=ALL option, PROC SEVERITY prints the summary of the Turnbull EDF estimation process as shown in [Output 23.6.2](#). It indicates that the final EDF estimates have converged and are in fact maximum likelihood (ML) estimates. If they were not ML estimates, then you could have used the ENSUREMLE option to force the algorithm to search for ML estimates.

Output 23.6.2 Turnbull EDF Estimation Summary for Interval-Censored Data

Turnbull EDF Estimation Summary	
Technique	EM with Maximum Likelihood Check
Convergence Status	Converged
Number of Iterations	2
Maximum Absolute Relative Error	1.8406E-16
Maximum Absolute Reduced Gradient	1.7764E-15
Estimates	Maximum Likelihood

After exploring the nature of the data, you can now fit a set of heavy-tailed distributions to this data. The following PROC SEVERITY step fits all the predefined distributions to the data in Work.Gdental data set:

```

/* Fit all predefined distributions */
proc severity data=gdental print=all plots(histogram kernel)=all
    criterion=ad;
    loss / rc=lowerbd lc=upperbd;
    weight count;
    dist _predef_;
run;

```

Some of the key results prepared by PROC SEVERITY are shown in [Output 23.6.3](#) through [Output 23.6.4](#). According to the “Model Selection Table” in [Output 23.6.3](#), all distribution models have converged. The “All Fit Statistics Table” in [Output 23.6.3](#) indicates that the generalized Pareto distribution (GPD) has the best fit for data according to a majority of the likelihood-based statistics and that the Burr distribution (BURR) has the best fit according to all the EDF-based statistics.

Output 23.6.3 Statistics of Fit for Interval-Censored Data

The SEVERITY Procedure			
Input Data Set			
Name	WORK.GDENTAL		
Model Selection Table			
Distribution	Converged	Anderson-Darling Statistic	Selected
Burr	Yes	0.00103	Yes
Exp	Yes	0.09936	No
Gamma	Yes	0.04608	No
Igauss	Yes	0.12301	No
Logn	Yes	0.01884	No
Pareto	Yes	0.00739	No
Gpd	Yes	0.00739	No
Weibull	Yes	0.03293	No

Output 23.6.3 *continued*

All Fit Statistics Table					
Distribution	-2 Log Likelihood	AIC	AICC	BIC	KS
Burr	41.41112*	47.41112	51.41112	48.31888	0.08974*
Exp	42.14768	44.14768*	44.64768*	44.45026*	0.26412
Gamma	41.92541	45.92541	47.63969	46.53058	0.19569
Igauss	42.34445	46.34445	48.05874	46.94962	0.34514
Logn	41.62598	45.62598	47.34027	46.23115	0.16853
Pareto	41.45480	45.45480	47.16908	46.05997	0.11423
Gpd	41.45480	45.45480	47.16908	46.05997	0.11423
Weibull	41.76272	45.76272	47.47700	46.36789	0.17238

All Fit Statistics Table		
Distribution	AD	CvM
Burr	0.00103*	0.0000816*
Exp	0.09936	0.01866
Gamma	0.04608	0.00759
Igauss	0.12301	0.02562
Logn	0.01884	0.00333
Pareto	0.00739	0.0009084
Gpd	0.00739	0.0009084
Weibull	0.03293	0.00472

The P-P plots of [Output 23.6.4](#) show that both GPD and BURR have a close fit between EDF and CDF estimates, although BURR has slightly better fit, which is also indicated by the EDF-based statistics. Given that BURR is a generalization of the GPD and that the plots do not offer strong evidence in support of the more complex distribution, GPD seems like a good choice for this data.

Output 23.6.4 P-P Plots of Burr and GPD for Interval-Censored Data

Overview: SIMILARITY Procedure

The SIMILARITY procedure computes similarity measures associated with time-stamped data, time series, and other sequentially ordered numeric data. PROC SIMILARITY computes similarity measures for time-stamped transactional data (transactions) with respect to time by accumulating the data into a time series format, and it computes similarity measures for sequentially ordered numeric data (sequences) by respecting the ordering of the data.

Given two ordered numeric sequences (input and target), a similarity measure is a metric that measures the distance between the input and target sequences while taking into account the ordering of the data. The SIMILARITY procedure computes similarity measures between an input sequence and a target sequence, in addition to similarity measures that “slide” the target sequence with respect to the input sequence. The “slides” can be by observation index (sliding-sequence similarity measures) or by seasonal index (seasonal-sliding-sequence similarity measures).

In order to compare the raw input and the raw target time-stamped data, the raw data must be accumulated to a time series format. After the input and target time series are formed, the two accumulated time series can be compared as two ordered numeric sequences.

For raw time-stamped data, after the transactional data are accumulated to form time series and any missing values are interpreted, each accumulated time series can be functionally transformed, if desired. Transformations are useful when you want to stabilize the time series before computing the similarity measures. Transformations performed by the SIMILARITY procedure include the following:

- log (LOG)
- square-root (SQRT)
- logistic (LOGISTIC)
- Box-Cox (BOXCOX)
- user-defined transformations

Each time series can be transformed further by using simple differencing or seasonal differencing or both. Additional time series transformations can be performed by using various time series transformation and analysis techniques provided by this procedure or other SAS/ETS procedures.

After optionally transforming each time series, the accumulated and transformed time series can be stored in an output data set (OUT= data set).

After optional accumulation and transformation, each of these time series are the “working series,” which can now be analyzed as sequences of numeric data. Each of these sequences can be a target sequence, an input sequence, or both a target and an input sequence. Throughout the remainder of this chapter, the term “original sequence” applies to both the original input and target sequence. The term “working sequence” applies to a version of both the original input and target sequence under investigation.

Each original sequence can be normalized prior to similarity analysis. Normalizations are useful when you want to compare the “shape” or “profile” of the time series. Normalizations performed by the SIMILARITY procedure include the following:

- standard (STANDARD)
- absolute (ABSOLUTE)
- user-defined normalizations

After each original sequence is optionally normalized, each working input sequence can be scaled to the target sequence prior to similarity analysis. Scaling is useful when you want to compare the input sequence to the target sequence while discounting the variation of the target sequence. Input sequence scaling performed by the SIMILARITY procedure include the following:

- standard (STANDARD)
- absolute (ABSOLUTE)
- user-defined scaling

After the working input sequence is optionally scaled to the target sequence, similarity measures can be computed. Similarity measures computed by the SIMILARITY procedure include:

- squared deviation (SQRDEV)
- absolute deviation (ABSDEV)
- mean square deviation (MSQRDEV)
- mean absolute deviation (MABSDEV)
- user-defined similarity measures

In computing the similarity measure between two time series, tasks are needed for transforming time series, normalizing sequences, scaling sequences, and computing metrics or measures. The SIMILARITY procedure provides built-in routines to perform these tasks. The SIMILARITY procedure also enables you to extend the procedure with user-defined routines.

All results of the similarity analysis can be stored in output data sets, printed, or graphed using the Output Delivery System (ODS).

The SIMILARITY procedure can process large amounts of time-stamped transactional data, time series, or sequential data. Therefore, the analysis results are useful for large-scale time series analysis, analogous time series forecasting, new product forecasting, or time series (temporal) data mining.

The SAS/ETS EXPAND procedure can be used for frequency conversion and transformations of time series. The TIMESERIES procedure can be used for large-scale time series analysis. The SAS/STAT DISTANCE procedure can be used to compute various measures of distance, dissimilarity, or similarity between observations (rows) of a SAS data set.

Getting Started: SIMILARITY Procedure

This section outlines the use of the SIMILARITY procedure and gives a cursory description of some of the analysis techniques that can be performed on time-stamped transactional data, time series, or sequentially ordered numeric data.

Given an input data set that contains numerous transaction variables recorded over time at no specific frequency, the SIMILARITY procedure can form equally spaced input and target time series as follows:

```
PROC SIMILARITY DATA=<input-data-set>
                OUT=<output-data-set>
                OUTSUM=<summary-data-set>;
  ID <time-ID-variable> INTERVAL=<frequency>
                ACCUMULATE=<statistic>;
  INPUT <input-time-stamp-variables>;
  TARGET <target-time-stamp-variables>;
RUN;
```

The SIMILARITY procedure forms time series from the input time-stamped transactional data. It can provide results in output data sets or in other output formats using the Output Delivery System (ODS). The examples in this section are more fully illustrated in the section “[Examples: SIMILARITY Procedure](#)” on page 1731.

Time-stamped transactional data are often recorded at no fixed interval. Analysts often want to use time series analysis techniques that require fixed-time intervals. Therefore, the transactional data must be accumulated to form a fixed-interval time series.

Suppose that a bank wants to analyze the transactions that are associated with each of its customers over time. Further, suppose that the data set WORK.TRANSACTIONS contains three variables that are related to the customer transactions (CUSTOMER, DATE, and WITHDRAWAL) and one variable that contains an example fraudulent behavior (FRAUD).

The following statements illustrate how to use the SIMILARITY procedure to accumulate time-stamped transactional data to form a daily time series based on the accumulated daily totals of each type of transaction (WITHDRAWALS and FRAUD):

```
proc similarity data=transactions out=timedata;
  by customer;
  id date interval=day accumulate=total;
  input withdrawals;
  target fraud;
run;
```

The OUT=TIMEDATA option specifies that the resulting time series data for each customer are to be stored in the data set WORK.TIMEDATA. The INTERVAL=DAY option specifies that the transactions are to be accumulated on a daily basis. The ACCUMULATE=TOTAL option specifies that the sum of the transactions are to be accumulated. After the transactional data are accumulated into a time series format, the time series data can be normalized so that the “shape” or “profile” is analyzed.

For example, the following statements build on the previous statements and demonstrate normalization of the accumulated time series:

```
proc similarity data=transactions out=timedata;
  by customer;
  id date interval=day accumulate=total;
  input withdrawals / NORMALIZE=STANDARD;
  target fraud      / NORMALIZE=STANDARD;
run;
```

The NORMALIZE=STANDARD option specifies that each accumulated time series observation is normalized by subtracting the mean and then dividing by the standard deviation of the accumulated time series. The WORK.TIMEDATA data set now contains the accumulated and normalized time series data for each customer.

After the transactional data are accumulated into a time series format and normalized to a mean of zero and standard deviation of one, similarity analysis can be performed on the accumulated and normalized time series.

For example, the following statements build on the previous statements and demonstrate similarity analysis of the accumulated and normalized time series:

```
proc similarity data=transactions
  out=timedata OUTSUM=SUMMARY;
  by customer;
  id date interval=day accumulate=total;
  input withdrawals / normalize=standard;
  target fraud      / normalize=standard MEASURE=MABSDEV;
run;
```

The MEASURE=MABSDEV option specifies the accumulated and normalized time series data that are associated with the variables WITHDRAWALS and FRAUD are to be compared by using mean absolute deviation. The OUTSUM=SUMMARY option specifies that the similarity analysis summary for each customer is to be stored in the data set WORK.SUMMARY.

Syntax: SIMILARITY Procedure

The following statements are used with the SIMILARITY procedure.

```
PROC SIMILARITY options ;
  BY variables ;
  ID variable INTERVAL= interval options ;
  FCMPOPT options ;
  INPUT variable-list / options ;
  TARGET variable-list / options ;
```

Functional Summary

The statements and options that control the SIMILARITY procedure are summarized in the following table.

Table 24.1 SIMILARITY Functional Summary

Description	Statement	Option
Statements		
Specifies BY-group processing	BY	
Specifies the time ID variable	ID	
Specifies the FCMP options	FCMPOPT	
Specifies input variables to analyze	INPUT	
Specifies target variables to analyze	TARGET	
Data Set Options		
Specifies the input data set	PROC SIMILARITY	DATA=
Specifies the time series output data set	PROC SIMILARITY	OUT=
Specifies the measure summary output data set	PROC SIMILARITY	OUTMEASURE=
Specifies the path output data set	PROC SIMILARITY	OUTPATH=
Specifies the sequence output data set	PROC SIMILARITY	OUTSEQUENCE=
Specifies the summary output data set	PROC SIMILARITY	OUTSUM=
User-Defined Functions and Subroutine Options		
Specifies FCMP quiet mode	FCMPOPT	QUIET=
Specifies FCMP trace mode	FCMPOPT	TRACE=

Description	Statement	Option
Accumulation and Seasonality Options		
Specifies the accumulation frequency	ID	INTERVAL=
Specifies the length of seasonal cycle	PROC SIMILARITY	SEASONALITY=
Specifies the interval alignment	ID	ALIGN=
Specifies that the time ID variable values are not sorted	ID	NOTSORTED
Specifies the starting time ID value	ID	START=
Specifies the ending time ID value	ID	END=
Specifies the accumulation statistic	ID, INPUT, TARGET	ACCUMULATE=
Specifies the missing value interpretation	ID, INPUT, TARGET	SETMISS=
Specifies the zero value interpretation	ID, INPUT, TARGET	ZEROMISS=
Specifies the type of missing value trimming	INPUT, TARGET	TRIMMISS=
Time Series Transformation Options		
Specifies simple differencing	INPUT, TARGET	DIF=
Specifies seasonal differencing	INPUT, TARGET	SDIF=
Specifies the transformation	INPUT, TARGET	TRANSFORM=
Input Sequence Options		
Specifies normalization	INPUT	NORMALIZE=
Specifies scaling	INPUT	SCALE=
Target Sequence Options		
Specifies normalization	TARGET	NORMALIZE=
Similarity Measure Options		
Specifies the compression limits	TARGET	COMPRESS=
Specifies the expansion limits	TARGET	EXPAND=
Specifies the similarity measure	TARGET	MEASURE=
Specifies the similarity measure and path	TARGET	PATH=
Specifies the sequence slide	TARGET	SLIDE=
Printing and Graphical Control Options		
Specifies the time ID format	ID	FORMAT=
Specifies printed output	PROC SIMILARITY	PRINT=
Specifies detailed printed output	PROC SIMILARITY	PRINTDETAILS
Specifies graphical output	PROC SIMILARITY	PLOTS=
Miscellaneous Options		
Specifies that analysis variables are processed in ascending order	PROC SIMILARITY	SORTNAMES
Specifies the ordering of the processing of the input and target variables	PROC SIMILARITY	ORDER=

PROC SIMILARITY Statement

PROC SIMILARITY *options* ;

The following options can be used in the PROC SIMILARITY statement.

DATA=SAS-data-set

names the SAS data set that contains the time series, transactional, or sequence input data for the procedure. If the DATA= option is not specified, the most recently created SAS data set is used.

ORDER=order-option

specifies the order in which the variables listed in the INPUT and TARGET statements are to be processed. This ordering affects the OUTSEQUENCE=, OUTPATH=, OUTMEASURE=, and OUTSUM= data sets, in addition to the printed and graphical output. The SORTNAMES option also affects the ordering of the analysis. You must specify one of the following *order-options*:

INPUT	specifies that each INPUT variable be processed and then the TARGET variables be processed. The results are stored and printed based only on the INPUT variables.
INPUTTARGET	specifies that each INPUT variable be processed and then the TARGET variables be processed. The results are stored and printed based on both the INPUT and TARGET variables. This is the default.
TARGET	specifies that each TARGET variable be processed and then the INPUT variables be processed. The results are stored and printed based only on the TARGET variables.
TARGETINPUT	specifies that each TARGET variable be processed and then the INPUT variables be processed. The results are stored and printed based on both the TARGET and INPUT variables.

OUT=SAS-data-set

names the output data set to contain the time series variables specified in the subsequent INPUT and TARGET statements. If an ID variable is specified in the ID statement, it is also included in the OUT= data set. The values are accumulated based on the ID statement INTERVAL= option or the ACCUMULATE= options or both. The values are transformed based on the INPUT or TARGET statement TRANSFORM=, DIF=, and SDIF= options in this order. The OUT= data set is particularly useful when you want to further analyze, model, or forecast the resulting time series with other SAS/ETS procedures.

OUTMEASURE=SAS-data-set

names the output data set to contain the detailed similarity measures by time ID value. The form of the OUTMEASURE= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

OUTPATH=SAS-data-set

names the output data set to contain the path used to compute the similarity measures for each slide and warp. The form of the OUTPATH= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options. If a user-defined similarity measure is specified, the path cannot be determined; therefore, the OUTPATH= data set does not contain information related to this measure.

OUTSEQUENCE=SAS-data-set

names the output data set to contain the sequences used to compute the similarity measures for each slide and warp. The form of the OUTSEQUENCE= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

OUTSUM=SAS-data-set

names the output data set to contain the similarity measure summary. The OUTSUM= data set is particularly useful when analyzing large numbers of series and only the summary of the results are needed. The form of the OUTSUM= data set is determined by the PROC SIMILARITY statement SORTNAMES and ORDER= options.

PLOTS=option**PLOTS=(options ...)**

specifies the graphical output desired. To specify multiple *options*, separate them by spaces and enclose the group in parentheses. By default, the SIMILARITY procedure produces no graphical output. The following graphical *options* are available:

COSTS	plots graphics for time warp costs.
DISTANCES	plots graphics for similarity absolute and relative distances (OUTPATH= data set).
INPUTS	plots graphics for input variable time series (OUT= data set).
MAPS	plots graphics for time warp maps (OUTPATH= data set).
MEASURES	plots graphics for similarity measures (OUTMEASURE= data set).
NORMALIZED	plots graphics for both the input and target variable normalized sequence. These plots are displayed only when the INPUT or TARGET statement NORMALIZE= option is specified.
PATHS	plots time warp paths graphics (OUTPATH= data set).
SCALED	plots graphics for both the input variable scaled sequence. These plots are displayed only when the INPUT statement SCALE= option is specified.
SEQUENCES	plots graphics for both the input and target variable sequence (OUTSEQUENCE= data set).
TARGETS	plots graphics for the target variable time series (OUT= data set).
WARPS	plots graphics for time warps (OUTPATH= data set).
ALL	is the same as PLOTS=(INPUTS TARGETS SEQUENCES NORMALIZED SCALED DISTANCES PATHS MAPS WARPS COST MEASURES).

PRINT=option**PRINT=(options ...)**

specifies the printed output desired. To specify multiple *options*, separate them by spaces and enclose the group in parentheses. By default, the SIMILARITY procedure produces no printed output. The following printing options are available:

DESCSTATS	prints the descriptive statistics for the working time series.
PATHS	prints the path statistics table. If a user-defined similarity measure is specified, the path cannot be determined; therefore, the PRINT=PATHS table is not printed for this measure.

COSTS	prints the cost statistics table.
WARPS	prints the warp summary table.
SLIDES	prints the slides summary table.
SUMMARY	prints the similarity measure summary table.
ALL	is the same as PRINT=(DESCSTATS PATHS COSTS WARPS SLIDES SUMMARY).

PRINTDETAILS

specifies that the output requested with the PRINT= option be printed in greater detail.

SEASONALITY=integer

specifies the length of the seasonal cycle where *integer* ranges from one to 10,000. For example, SEASONALITY=3 means that every group of three time periods forms a seasonal cycle. By default, the length of the seasonal cycle is 1 (no seasonality) or the length implied by the INTERVAL= option specified in the ID statement. For example, INTERVAL=MONTH implies that the length of the seasonal cycle is 12.

SORTNAMES

specifies that the variables specified in the INPUT and TARGET statements be processed in alphabetical order of the variable names. By default, the SIMILARITY procedure processes the variables in the order in which they are listed. The ORDER= option also affects the ordering in which the analysis is performed.

BY Statement

A BY statement can be used with PROC SIMILARITY to obtain separate dummy variable definitions for groups of observations defined by the BY variables.

When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the option NOTSORTED or DESCENDING in the BY statement for the SIMILARITY procedure. The NOTSORTED option does not mean that the data are unsorted, but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY-group processing, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FCMPOPT Statement

FCMPOPT *options* ;

The FCMPOPT statement specifies the following *options* that are related to user-defined functions and subroutines:

QUIET=ON | OFF

specifies whether the nonfatal errors and warnings that are generated by the user-defined SAS language functions and subroutines are printed to the log. Nonfatal errors are usually associated with operations with missing values. The default is QUIET=ON.

TRACE=ON | OFF

specifies whether the user-defined SAS language functions and subroutines tracings are printed to the log. Tracings are the results of every operation executed. This option is generally used for debugging. The default is TRACE=OFF.

ID Statement

ID *variable* **INTERVAL=** *interval options* ;

The ID statement names a numeric variable that identifies observations in the input and output data sets. The ID variable's values are assumed to be SAS date, time, or datetime values. In addition, the ID statement specifies the (desired) frequency associated with the time series. The ID statement options also specify how the observations are accumulated and how the time ID values are aligned to form the time series. The options specified affect all variables listed in subsequent INPUT and TARGET statements. If an ID statement is specified, the INTERVAL= option must also be specified. The other ID statement options are optional. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID.

The following options can be used with the ID statement:

ACCUMULATE=*option*

specifies how the data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option. The ID variable contains the time ID values. Each time ID variable value corresponds to a specific time period. The accumulated values form the time series, which is used in subsequent analysis.

The ACCUMULATE= option is particularly useful when there are zero or more than one input observations that coincide with a particular time period (for example, time-stamped transactional data). The EXPAND procedure offers additional frequency conversions and transformations that can also be useful in creating a time series.

The following *options* determine how the observations are accumulated within each time period based on the ID variable and the frequency specified by the INTERVAL= option:

NONE	No accumulation occurs; the ID variable values must be equally spaced with respect to the frequency. This is the default option.
TOTAL	Observations are accumulated based on the total sum of their values.

AVERAGE AVG	Observations are accumulated based on the average of their values.
MINIMUM MIN	Observations are accumulated based on the minimum of their values.
MEDIAN MED	Observations are accumulated based on the median of their values.
MAXIMUM MAX	Observations are accumulated based on the maximum of their values.
N	Observations are accumulated based on the number of nonmissing observations.
NMISS	Observations are accumulated based on the number of missing observations.
NOBS	Observations are accumulated based on the number of observations.
FIRST	Observations are accumulated based on the first of their values.
LAST	Observations are accumulated based on the last of their values.
STDDEV STD	Observations are accumulated based on the standard deviation of their values.
CSS	Observations are accumulated based on the corrected sum of squares of their values.
USS	Observations are accumulated based on the uncorrected sum of squares of their values.

If the `ACCUMULATE=` option is specified, the `SETMISSING=` option is useful for specifying how accumulated missing values are treated. If missing values should be interpreted as zero, then `SETMISSING=0` should be used. The section “[Details: SIMILARITY Procedure](#)” on page 1709 describes accumulation in greater detail.

ALIGN=option

controls the alignment of SAS dates that are used to identify output observations. The `ALIGN=` option accepts the following values: `BEGINNING` | `BEG` | `B`, `MIDDLE` | `MID` | `M`, and `ENDING` | `END` | `E`. `ALIGN=BEGINNING` is the default.

END=option

specifies a SAS date, datetime, or time value that represents the end of the data. If the last time ID variable value is less than the `END=` value, the series is extended with missing values. If the last time ID variable value is greater than the `END=` value, the series is truncated. For example, `END=&sysdate` uses the automatic macro variable `SYSDATE` to extend or truncate the series to the current date. The `START=` and `END=` options can be used to ensure that data that are associated within each `BY` group contain the same number of observations.

FORMAT=format

specifies the SAS format for the time ID values. If the `FORMAT=` option is not specified, the default format is implied by the `INTERVAL=` option. For example, `FORMAT=DATE9.` specifies that the `DATE9.` SAS format be used. Notice that the terminating “.” is required when specifying a SAS format.

INTERVAL= *interval*

specifies the frequency of the accumulated time series. For example, if the input data set consists of quarterly observations, then INTERVAL=QTR should be used. If the SEASONALITY= option is not specified, the length of the seasonal cycle is implied from the INTERVAL= option. For example, INTERVAL=QTR implies a seasonal cycle of length 4. If the ACCUMULATE= option is also specified, the INTERVAL= option determines the time periods for the accumulation of observations.

NOTSORTED

specifies that the time ID values are not in sorted order. The SIMILARITY procedure sorts the data with respect to the time ID prior to analysis if the NOTSORTED option is specified.

SETMISSING= *option* | *number*

specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series. If a *number* is specified, missing values are set to that number. If a missing value indicates an unknown value, the SETMISSING= option should not be used. If a missing value indicates no value, then SETMISSING=0 should be used. You typically use SETMISSING=0 for transactional data, because no recorded data usually implies no activity. The following *options* can also be used to determine how missing values are assigned:

MISSING	Missing values are set to missing. This is the default option.
AVERAGE AVG	Missing values are set to the accumulated average value.
MINIMUM MIN	Missing values are set to the accumulated minimum value.
MEDIAN MED	Missing values are set to the accumulated median value.
MAXIMUM MAX	Missing values are set to the accumulated maximum value.
FIRST	Missing values are set to the accumulated first nonmissing value.
LAST	Missing values are set to the accumulated last nonmissing value.
PREVIOUS PREV	Missing values are set to the previous period's accumulated nonmissing value. Missing values at the beginning of the accumulated series remain missing.
NEXT	Missing values are set to the next period's accumulated nonmissing value. Missing values at the end of the accumulated series remain missing.

START= *option*

specifies a SAS date, datetime, or time value that represents the beginning of the data. If the first time ID variable value is greater than the START= value, the series is prepended with missing values. If the first time ID variable value is less than the START= value, the series is truncated. The START= and END= options can be used to ensure that data that are associated with each BY group contain the same number of observations.

ZEROMISS= *option*

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series. The following *options* can also be used to determine how beginning and ending zero values are assigned:

NONE	Beginning and ending zeros are unchanged. This is the default.
LEFT	Beginning zeros are set to missing.
RIGHT	Ending zeros are set to missing.
BOTH	Both beginning and ending zeros are set to missing.

If the accumulated series is all missing or zero, the series is not changed.

INPUT Statement

INPUT *variable-list* < / *options* > ;

The INPUT statement lists the input numeric variables in the DATA= data set whose values are to be accumulated to form the time series or represent ordered numeric sequences (when no ID statement is specified).

An input data set variable can be specified in only one INPUT or TARGET statement. Any number of INPUT statements can be used. The following *options* can be used with an INPUT statement:

ACCUMULATE=*option*

specifies how the data set observations are accumulated within each time period for the variables listed in the INPUT statement. If the ACCUMULATE= option is not specified in the INPUT statement, accumulation is determined by the ACCUMULATE= option of the ID statement. If the ACCUMULATE= option is not specified in the ID statement or the INPUT statement, no accumulation is performed. See the ID statement ACCUMULATE= option for more details.

DIF=(*numlist*)

specifies the differencing to be applied to the accumulated time series. The list of differencing orders must be separated by spaces or commas. For example, DIF=(1,3) specifies first, then third order, differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the DIF= option. Simple differencing is useful when you want to detrend the time series before computing the similarity measures.

NORMALIZE=*option*

specifies the sequence normalization to be applied to the working input sequence. The following normalization *options* are provided:

NONE	No normalization is applied. This option is the default.
ABSOLUTE	Absolute normalization is applied.
STANDARD	Standard normalization is applied.
<i>User-Defined</i>	Normalization is computed by a user-defined subroutine that is created using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

Normalization is applied to the working input sequence, which can be a subset of the working input time series if the SLIDE=INDEX or SLIDE=SEASON option is specified.

SCALE=option

specifies the scaling of the working input sequence with respect to the working target sequence. Scaling is performed after normalization. The following scaling *options* are provided:

NONE	No scaling is applied. This option is the default.
ABSOLUTE	Absolute scaling is applied.
STANDARD	Standard scaling is applied.
<i>User-Defined</i>	Scaling is computed by a user-defined subroutine that is created using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

Scaling is applied to the working input sequence, which can be a subset of the working input time series if the SLIDE=INDEX or SLIDE=SEASON option is specified.

SDIF=(numlist)

specifies the seasonal differencing to be applied to the accumulated time series. The list of seasonal differencing orders must be separated by spaces or commas. For example, SDIF=(1,3) specifies first, then third, order seasonal differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the SDIF= option. Seasonal differencing is useful when you want to deseasonalize the time series before computing the similarity measures.

SETMISSING=option | number**SETMISS=option | number**

specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the INPUT statement. If the SETMISSING= option is not specified in the INPUT statement, missing values are set based on the SETMISSING= option in the ID statement. If the SETMISSING= option is not specified in the ID statement or the INPUT statement, no missing value interpretation is performed. See the ID statement SETMISSING= option for more details.

TRANSFORM=option

specifies the time series transformation to be applied to the accumulated time series. The following transformations are provided:

NONE	No transformation is applied. This option is the default.
LOG	Logarithmic transformation is applied.
SQRT	Square-root transformation is applied.
LOGISTIC	Logistic transformation is applied.
BOXCOX(<i>number</i>)	Box-Cox transformation with parameter is applied, where the real <i>number</i> is between -5 and 5.
<i>User-Defined</i>	Transformation is computed by a user-defined subroutine that is created using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

When the TRANSFORM= option is specified, the time series must be strictly positive unless a user-defined function is used.

TRIMMISSING=option**TRIMMISSING=option**

specifies how missing values (either actual or accumulated) are trimmed from the accumulated time series or ordered sequence for variables that are listed in the INPUT statement. The following trimming options are provided:

NONE	No missing value trimming is applied.
LEFT	Beginning missing values are trimmed.
RIGHT	Ending missing values are trimmed.
BOTH	Both beginning and ending missing value are trimmed. This is the default.

ZEROMISS=option

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the INPUT statement. If the ZEROMISS= option is not specified in the INPUT statement, beginning and ending zero values are set based on the ZEROMISS= option of the ID statement. If the ZERO= option is not specified in the ID statement or the INPUT statement, no zero value interpretation is performed. See the ID statement ZEROMISS= option for more details.

TARGET Statement

TARGET *variable-list* < / *options* > ;

The TARGET statement lists the numeric target variables in the DATA= data set whose values are to be accumulated to form the time series or represent ordered numeric sequences (when no ID statement is specified).

An input data set variable can be specified in only one INPUT or TARGET statement. Any number of TARGET statements can be used. The following *options* can be used with a TARGET statement:

ACCUMULATE=option

specifies how the data set observations are accumulated within each time period for the variables listed in the TARGET statement. If the ACCUMULATE= option is not specified in the TARGET statement, accumulation is determined by the ACCUMULATE= option in the ID statement. If the ACCUMULATE= option is not specified in the ID statement or the TARGET statement, no accumulation is performed. See the ID statement ACCUMULATE= option for more details.

COMPRESS=option | (options)

specifies the sliding sequence (global) and warping (local) compression range of the target sequence with respect to the input sequence. Compression of the target sequence is the same as expansion of the input sequence and vice versa. The compression limits are defined based on the length of the target sequence and are imposed on the target sequence. The following compression options are provided:

GLOBALABS=*integer* specifies the absolute global compression, where *integer* ranges from zero to 10,000. GLOBALABS=0 implies no global compression, which is the default unless the GLOBALPCT= option is specified.

GLOBALPCT=number specifies global compression as a percentage of the length of the target sequence, where *number* ranges from zero to 100. GLOBALPCT=0 implies no global compression, which is the default. GLOBALPCT=100 implies maximum allowable compression.

LOCALABS=integer specifies the absolute local compression, where *integer* ranges from zero to 10,000. The default is maximum allowable absolute local compression unless the LOCALPCT= option is specified.

LOCALPCT=number specifies local compression as a percentage of the length of the target sequence, where *number* ranges from zero to 100. The percentage specified by the LOCALPCT= option must be less than the GLOBALPCT= option. LOCALPCT=0 implies no local compression. LOCALPCT=100 implies maximum allowable local compression. The default is LOCALPCT=100.

If the SLIDE=NONE or the SLIDE=SEASON option is specified in the TARGET statement, the global compression options are ignored. To disallow local compression, use the option COMPRESS=(LOCALPCT=0 LOCALABS=0).

If the SLIDE=INDEX option is specified, the global compression options are not ignored. To completely disallow both global and local compression, use the option COMPRESS=(GLOBALPCT=0 LOCALPCT=0) or COMPRESS=(GLOBALABS=0 LOCALABS=0). To allow only local compression, use the option COMPRESS=(GLOBALPCT=0 GLOBALABS=0). These are the default compression options.

The preceding options can be used in combination to specify the desired amount of global and local compression as the following examples illustrate, where L_c denotes the global compression limit and l_c denotes the local compression limit:

- COMPRESS=(GLOBALPCT=20) allows the global and local compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$.
- COMPRESS=(GLOBALPCT=20 GLOBALABS=10) allows the global and local compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$.
- COMPRESS=(LOCALPCT=10) allows the local compression to range from zero to $l_c = \min(\lfloor 0.1N_y \rfloor, (N_y - 1))$.
- COMPRESS=(LOCALPCT=20 LOCALABS=5) allows the local compression to range from zero to $l_c = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 5))$.
- COMPRESS=(GLOBALPCT=20 LOCALPCT=20) allows the global compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$ and allows the local compression to range from zero to $l_c = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$.
- COMPRESS=(GLOBALPCT=20 GLOBALABS=10 LOCALPCT=10 LOCALABS=5) allows the global compression to range from zero to $L_c = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$ and allows the local compression to range from zero to $l_c = \min(\lfloor 0.1N_y \rfloor, \min((N_y - 1), 5))$.

Suppose T_z is the length of the input time series and N_y is the length of the target sequence. The *valid* global compression limit, L_c , is always limited by the length of the target sequence: $0 \leq L_c < N_y$.

Suppose N_x is the length of the input sequence and N_y is the length of the target sequence. The *valid* local compression limit, l_c , is always limited by the lengths of the input and target sequence: $\max(0, (N_y - N_x)) \leq l_c < N_y$.

DIF=(numlist)

specifies the differencing to be applied to the accumulated time series. The list of differencing orders must be separated by spaces or commas. For example, DIF=(1,3) specifies first, then third, order differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the DIF= option. Simple differencing is useful when you want to detrend the time series before computing the similarity measures.

EXPAND=option | (options)

specifies the sliding sequence (global) and warping (local) expansion range of the target sequence with respect to the input sequence. Expansion of the target sequence is the same as compression of the input sequence and vice versa. The expansion limits are defined based on the length of the input sequence, but are imposed on the target sequence. The following expansion options are provided:

GLOBALABS=integer specifies the absolute global expansion, where *integer* ranges from zero to 10,000. GLOBALABS=0 implies no global expansion, which is the default unless the GLOBALPCT= option is specified.

GLOBALPCT=number specifies global expansion as a percentage of the length of the target sequence, where *number* ranges from zero to 100. GLOBALPCT=0 implies no global expansion, which is the default unless the GLOBALABS= option is specified. GLOBALPCT=100 implies maximum allowable global expansion.

LOCALABS=integer specifies the absolute local expansion, where *integer* ranges from zero to 10,000. The default is the maximum allowable absolute local expansion unless the LOCALPCT= option is specified.

LOCALPCT=number specifies local expansion as a percentage of the length of the target sequence, where *number* ranges from zero to 100. LOCALPCT=0 implies no local expansion. LOCALPCT=100 implies maximum allowable local expansion. The default is LOCALPCT=100.

If the SLIDE=NONE or the SLIDE=SEASON option is specified in the TARGET statement, the global expansion options are ignored. To disallow local expansion, use the option EXPAND=(LOCALPCT=0 LOCALABS=0).

If the SLIDE=INDEX option is specified, the global expansion options are not ignored. To completely disallow both global and local expansion, use the option EXPAND=(GLOBALPCT=0 LOCALPCT=0) or EXPAND=(GLOBALABS=0 LOCALABS=0). To allow only local expansion, use the option EXPAND=(GLOBALPCT=0 GLOBALABS=0). These are the default expansion options.

The preceding options can be used in combination to specify the desired amount of global and local expansion as the following examples illustrate, where L_e denotes the global expansion limit and l_e denotes the local expansion limit:

- EXPAND=(GLOBALPCT=20) allows the global and local expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$.
- EXPAND=(GLOBALPCT=20 GLOBALABS=10) allows the global and local expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$.
- EXPAND=(LOCALPCT=10) allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, (N_y - 1))$.

- EXPAND=(LOCALPCT=10 LOCALABS=5) allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, \min((N_y - 1), 5))$.
- EXPAND=(GLOBALPCT=20 LOCALPCT=10) allows the global expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, (N_y - 1))$ and allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, (N_y - 1))$.
- EXPAND=(GLOBALPCT=20 GLOBALABS=10 LOCALPCT=10 LOCALABS=5) allows the global expansion to range from zero to $L_e = \min(\lfloor 0.2N_y \rfloor, \min((N_y - 1), 10))$ and allows the local expansion to range from zero to $l_e = \min(\lfloor 0.1N_y \rfloor, \min((N_y - 1), 5))$.

Suppose T_z is the length of the input time series and N_y is the length of the target sequence. The *valid* global expansion limit, L_e , is always limited by the length of the input time series: $0 \leq L_e < T_z$.

Suppose N_x is the length of the input sequence and N_y is the length of the target sequence. The *valid* local expansion limit, l_e , is always limited by the lengths of the input and target sequence: $\max(0, (N_x - N_y)) \leq l_e < N_x$.

MEASURE=option

specifies the similarity measure to be computed by using the working input and target sequences. The following similarity measures are provided:

SQRDEV	squared deviation. This option is the default.
ABSDEV	absolute deviation
MSQRDEV	mean squared deviation
MSQRDEVINP	mean squared deviation relative to the length of the input sequence
MSQRDEVTAR	mean squared deviation relative to the length of the target sequence
MSQRDEVMIN	mean squared deviation relative to the minimum valid path length
MSQRDEVMAX	mean squared deviation relative to the maximum valid path length
MABSDEV	mean absolute deviation
MABSDEVINP	mean absolute deviation relative to the length of the input sequence
MABSDEVTAR	mean absolute deviation relative to the length of the target sequence
MABSDEVMIN	mean absolute deviation relative to the minimum valid path length
MABSDEVMAX	mean absolute deviation relative to the maximum valid path length
<i>User-Defined</i>	The measure is computed by a user-defined function created by using the FCMP procedure, where <i>User-Defined</i> is the function name.

NORMALIZE=option

specifies the sequence normalization to be applied to the working target sequence. The following normalization options are provided:

NONE	No normalization is applied. This option is the default.
ABSOLUTE	Absolute normalization is applied.
STANDARD	Standard normalization is applied.
<i>User-Defined</i>	Normalization is computed by a user-defined subroutine that is created by using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

PATH=option

specifies the similarity measure and warping path information to be computed using the working input and target sequences. The following similarity measures and warping path are provided:

User-Defined The measure and path are computed by a user-defined subroutine that is created by using the FCMP procedure, where *User-Defined* is the subroutine name

For computational efficiency, the PATH= option should be only used when you want to compute both the similarity measure and the warping path information. If only the similarity measure is needed, use the MEASURE= option. If you specify both the MEASURE= and PATH= option in the TARGET statement, the PATH= option takes precedence.

SDIF=(numlist)

specifies the seasonal differencing to be applied to the accumulated time series. The list of seasonal differencing orders must be separated by spaces or commas. For example, SDIF=(1,3) specifies first, then third, order seasonal differencing. Differencing is applied after time series transformation. The TRANSFORM= option is applied before the SDIF= option. Seasonal differencing is useful when you want to deseasonalize the time series before computing the similarity measures.

SETMISSING=option | number**SETMISS=option | number**

option specifies how missing values (either actual or accumulated) are interpreted in the accumulated time series for variables that are listed in the TARGET statement. If the SETMISSING= option is not specified in the TARGET statement, missing values are set based on the SETMISSING= option in the ID statement. If the SETMISSING= option is not specified in the ID statement or the TARGET statement, no missing value interpretation is performed. See the ID statement SETMISSING= option for more details.

SLIDE=option

specifies the sliding of the target sequence with respect to the input sequence. The following slides are provided:

NONE	No sequence sliding. The input time series is compared with the target sequence directly with no sliding. This option is the default.
INDEX	Slide by time index. The input time series is compared with the target sequence by observation index.
SEASON	Slide by seasonal index. The input time series is compared with the target sequence by seasonal index.

The SLIDE= option takes precedence over the COMPRESS= and EXPAND= options.

TRANSFORM=option

specifies the time series transformation to be applied to the accumulated time series. The following transformations are provided:

NONE	No transformation is applied. This option is the default.
LOG	Logarithmic transformation is applied.
SQRT	Square-root transformation is applied.

LOGISTIC	Logistic transformation is applied.
BOXCOX(<i>number</i>)	Box-Cox transformation with parameter is applied, where the real <i>number</i> is between -5 and 5
<i>User-Defined</i>	Transformation is computed by a user-defined subroutine that is created by using the FCMP procedure, where <i>User-Defined</i> is the subroutine name.

When the TRANSFORM= option is specified, the time series must be strictly positive unless a user-defined function is used.

TRIMMISSING=option

TRIMMISS= option

specifies how missing values (either actual or accumulated) are trimmed from the accumulated time series or ordered sequence for variables that are listed in the TARGET statement. The following trimming options are provided:

NONE	No missing value trimming is applied.
LEFT	Beginning missing values are trimmed.
RIGHT	Ending missing values are trimmed.
BOTH	Both beginning and ending missing values are trimmed. This is the default.

ZEROMISS=option

specifies how beginning and ending zero values (either actual or accumulated) are interpreted in the accumulated time series or ordered sequence for variables listed in the TARGET statement. If the ZEROMISS= option is not specified in the TARGET statement, beginning and ending values are set based on the ZEROMISS= option in the ID statement. See the ID statement ZEROMISS= option for more details.

Details: SIMILARITY Procedure

You can use the SIMILARITY procedure to do the following functions, which are done in the order shown. First, you can form time series data from transactional data with the options shown:

1. accumulation ACCUMULATE= option
2. missing value interpretation SETMISSING= option
3. zero value interpretation ZEROMISS= option

Next, you can transform the accumulated time series to form the working time series with the following options. Transformations are useful when you want to stabilize the time series before computing the similarity measures. Simple and seasonal differencing are useful when you want to detrend or deseasonalize the time series before computing the similarity measures. Often, but not always, the TRANSFORM=, DIF=, and SDIF= options should be specified in the same way for both the target and input variables.

- 4. time series transformation TRANSFORM= option
- 5. time series differencing DIF= and SDIF= option
- 6. time series missing value trimming TRIMMISSING= option
- 7. time series descriptive statistics PRINT=DESCSTATS option

After the working series is formed, you can treat it as an ordered sequence that can be normalized or scaled. Normalizations are useful when you want to compare the “shape” or “profile” of the time series. Scaling is useful when you want to compare the input sequence to the target sequence while discounting the variation of the target sequence.

- 8. normalization NORMALIZE= option
- 9. scaling SCALE= option

After the working sequences are formed, you can compute similarity measures between input and target sequences:

- 10. sliding SLIDE= option
- 11. warping COMPRESS= and EXPAND= option
- 12. similarity measure MEASURE= and PATH= option

The SLIDE= option specifies observation-index sliding, seasonal-index sliding, or no sliding. The COMPRESS= and EXPAND= options specify the warping limits. The MEASURE= and PATH= options specify how the similarity measures are computed.

Accumulation

If the ACCUMULATE= option is specified in the ID, INPUT, or TARGET statement, data set observations are accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option in the ID statement. The ID variable contains the time ID values. Each time ID value corresponds to a specific time period. Accumulation is particularly useful when the input data set contains transactional data, whose observations are not spaced with respect to any particular time interval. The accumulated values form the time series, which is used in subsequent analyses.

For example, suppose a data set contains the following observations:

19MAR1999	10
19MAR1999	30
11MAY1999	50
12MAY1999	20
23MAY1999	20

If the INTERVAL=MONTH is specified, all of the preceding observations fall within three time periods of March 1999, April 1999, and May 1999. The observations are accumulated within each time period as follows:

If the ACCUMULATE=NONE option is specified, an error is generated because the ID variable values are not equally spaced with respect to the specified frequency (MONTH).

If the ACCUMULATE=TOTAL option is specified, the data are accumulated as follows:

O1MAR1999	40
O1APR1999	.
O1MAY1999	90

If the ACCUMULATE=AVERAGE option is specified, the data are accumulated as follows:

O1MAR1999	20
O1APR1999	.
O1MAY1999	30

If the ACCUMULATE=MINIMUM option is specified, the data are accumulated as follows:

O1MAR1999	10
O1APR1999	.
O1MAY1999	20

If the ACCUMULATE=MEDIAN option is specified, the data are accumulated as follows:

O1MAR1999	20
O1APR1999	.
O1MAY1999	20

If the ACCUMULATE=MAXIMUM option is specified, the data are accumulated as follows:

O1MAR1999	30
O1APR1999	.
O1MAY1999	50

If the ACCUMULATE=FIRST option is specified, the data are accumulated as follows:

O1MAR1999	10
O1APR1999	.
O1MAY1999	50

If the ACCUMULATE=LAST option is specified, the data are accumulated as follows:

O1MAR1999	30
O1APR1999	.
O1MAY1999	20

If the ACCUMULATE=STDDEV option is specified, the data are accumulated as follows:

```
O1MAR1999    14.14
O1APR1999    .
O1MAY1999    17.32
```

As can be seen from the preceding examples, even though the data set observations contain no missing values, the accumulated time series can have missing values.

Missing Value Interpretation

Sometimes missing values should be interpreted as unknown values. But sometimes missing values are known, such as when missing values are created from accumulation and no observations should be interpreted as no (zero) value. In the former case, the SETMISSING= option in the ID, INPUT, or TARGET statement can be used to interpret how missing values are treated. The SETMISSING=0 option should be used when missing observations are to be treated as no (zero) values. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and interpreted time series is used in subsequent analyses.

The SETMISSING=0 option should be used with missing observations are to be treated as a zero value. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and interpreted time series is then used in subsequent analyses.

Zero Value Interpretation

When querying certain databases for time-stamped data based on a particular time range, time periods that contain no data are sometimes assigned zero values. For certain analyses, it is more desirable to assign these values to missing. Often, these beginning or ending zero values need to be interpreted as missing values. The ZEROMISS= option in the ID, INPUT, or TARGET statement specifies that the beginning, ending, or both the beginning and ending values are to be interpreted as zero values.

Time Series Transformation

Transformations are useful when you want to stabilize the time series before computing the similarity measures. There are four transformations available, for strictly positive series only. Let $y_t > 0$ be the original time series, and let w_t be the transformed series. The transformations are defined as follows:

Log is the logarithmic transformation,

$$w_t = \ln(y_t)$$

Logistic is the logistic transformation,

$$w_t = \ln(cy_t / (1 - cy_t))$$

where the scaling factor c is

$$c = (1 - e^{-6})10^{-\text{ceil}(\log_{10}(\max(y_t)))}$$

and $\text{ceil}(x)$ is the smallest integer greater than or equal to x .

Square root is the square root transformation,

$$w_t = \sqrt{y_t}$$

Box-Cox is the Box-Cox transformation,

$$w_t = \begin{cases} \frac{y_t^\lambda - 1}{\lambda} & \lambda \neq 0 \\ \ln(y_t) & \lambda = 0 \end{cases}$$

User-Defined is the transformation computed by a user-defined subroutine that is created by using the FCMP procedure, where *User-Defined* is the subroutine name.

Other time series transformations can be performed prior to invoking the SIMILARITY procedure by using the SAS/ETS EXPAND procedure or the DATA step.

Time Series Differencing

After optionally transforming the series, the accumulated series can be simply or seasonally differenced using the INPUT or TARGET statement DIF= and SDIF= options. Simple and seasonal differencing are useful when you want to detrend or deseasonalize the time series before computing the similarity measures.

For example, suppose y_t is a monthly time series. The following examples of the DIF= and SDIF= options demonstrate how to simply and seasonally difference the time series: DIF=(1,3) specifies first, then third, order differencing; SDIF=(1,3) specifies first, then third, order seasonal differencing.

Additionally, assuming that y_t is strictly positive, the INPUT or TARGET statement TRANSFORM= option and the DIF= and SDIF= options can be combined.

Time Series Missing Value Trimming

In some instances, missing values should be interpreted as an unknown observation, but other times, missing values are known and should be interpreted as a zero value. This is the case when missing values are created from accumulation, and a missing observation should be interpreted as having no value (meaning a value of zero). In the former case, the SETMISSING=option in the ID, INPUT, or TARGET, statement can be used to interpret how missing observations should be treated. By default, missing values, at the beginning and ending of the data set, are trimmed from the data set prior to analysis. This can be performed using TRIMMISS=both.

Time Series Descriptive Statistics

After a series has been optionally accumulated and transformed with missing values interpreted, descriptive statistics can be computed for the resulting working series by specifying the PRINT=DESCSTATS option. This option produces an ODS table that contains the sum, mean, minimum, maximum, and standard deviation of the working series.

Input and Target Sequences

After the input and target working series are formed, they can be treated as two ordered sequences. Given an input time sequence, x_i , for $i = 1$ to N_x , where i is the input sequence index, and a target time sequence, y_j , for $j = 1$ to N_y , where j is the target sequence index, these sequences are analyzed for similarity.

Sliding Sequences

Similarity measures can be computed between the target sequence and any contiguous subsequences of the input time series.

There are three types of sequence sliding:

- no sliding
- slide by time index
- slide by season index

For more information, see Leonard, Elsheimer, and Sloan (2008).

Time Warping

Time warping allows for the comparison between target and input sequences of differing lengths by compressing or expanding the input sequence with respect to the target sequence while respecting the order of the sequence elements.

For more information, see Leonard, Elsheimer, and Sloan (2008).

Sequence Normalization

The working (input or target) sequence can be normalized prior to further analysis. Let q_i be the original sequence with mean μ_q and standard deviation σ_q , and let r_i be the normalized sequence. The normalizations are defined as follows:

- Standard is the standard normalization

$$r_i = (q_i - \mu_q) / \sigma_q$$

- Absolute is the absolute normalization

$$r_i = (q_i - \min(q_i)) / (\max(q_i) - \min(q_i))$$

- User-defined is a user-defined normalization created by the FCMP procedure.

Sequence Scaling

The working input sequence can be scaled to the working target sequence. Sequence scaling is applied after normalization. Let y_j be the working target sequence with mean μ_y and standard deviation σ_y . Let x_i be the working input sequence and let q_i be the scaled sequence. The scaling is defined as follows:

- Standard is the standard normalization

$$q_i = (x_i - \mu_y) / \sigma_y$$

- Absolute is the absolute scaling

$$q_i = (x_i - \min(y_j)) / (\max(y_j) - \min(y_j))$$

- User-defined is a user-defined scaling created by the FCMP procedure.

Similarity Measures

The working input sequence can be compared to the working target sequence to create a similarity.

For more information, see Leonard, Elsheimer, and Sloan (2008).

User-Defined Functions and Subroutines

A user-defined routine can be written in the SAS language by using the FCMP procedure or in the C language by using both the FCMP procedure and the PROTO procedure, respectively. The SIMILARITY procedure cannot use C language routines directly. The procedure can use only SAS language routines that might or might not call C language routines. Creating user-defined routines is more completely described in the FCMP procedure and the PROTO procedure documentation. The FCMP and PROTO procedures are part of Base SAS software.

The SAS language provides integrated memory management and exception handling such as operations on missing values. The C language provides flexibility and allows the integration of existing C language libraries. However, proper memory management and exception handling are solely the responsibility of

the user. Additionally, the support for standard C libraries is restricted. If you have a choice, it is highly recommended that you write user-defined functions and subroutines in the SAS language using the FCMP procedure.

For each of the tasks previously described, the following sections describe the required subroutine or function signature and provide examples of using a user-defined routine with the SIMILARITY procedure.

Time Series Transformations

A user-defined transformation subroutine has the following subroutine signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*] );
```

where the array-name is the time series to be transformed.

For example, to duplicate the functionality of the built-in TRANSFORM=LOG option in the INPUT and TARGET statement, the following SAS statements create a user-defined version of this transformation called MYTRANSFORM and store this subroutine in the catalog SASUSER.MYSIMILAR.

```
proc fcmp outlib=sasuser.mysimilar.package;

  subroutine mytransform( series[*] );

    outargs series;

    length = DIM(series);

    do i = 1 to length;
      value = series[i];
      if value > 0 then do;
        series[i] = log( value );
      end;
      else do;
        series[i] = .;
      end;
    end;

  endsub;

run;
```

This user-defined subroutine can be specified in the TRANSFORM= option in the INPUT or TARGET statement as follows:

```
options cmplib = sasuser.mysimilar;

proc similarity ...;
...
input myinput / transform=mytransform;
target mytarget / transform=mytransform;
...
run;
```

Sequence Normalizations

A user-defined normalization subroutine has the following signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*] );
```

where the array-name is the sequence to be normalized.

For example, to duplicate the functionality of the built-in NORMALIZE=ABSOLUTE option in the INPUT and TARGET statement, the following SAS statements create a user-defined version of this normalization called MYNORMALIZE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```
proc fcmp outlib=sasuser.mysimilar.package;

  subroutine mynormalize( sequence[*] );

    outargs sequence;

    length = DIM(sequence);
    minimum = .; maximum = .;

    do i = 1 to length;
      value = sequence[i];
      if nmiss(minimum) | nmiss(maximum) then do;
        minimum = value;
        maximum = value;
      end;
      if nmiss(value) = 0 then do;
        if value < minimum then minimum = value;
        if value > maximum then maximum = value;
      end;
    end;

    do i = 1 to length;
      value = sequence[i];
      if nmiss( value ) | minimum > maximum then do;
        sequence[i] = .;
      end;
      else do;
        sequence[i] = (value - minimum) / (maximum - minimum);
      end;
    end;

  endsub;

run;
```

This user-defined subroutine can be specified in the NORMALIZE= option in the INPUT or TARGET statement as follows:

```
options cmplib = sasuser.mysimilar;
```

```

proc similarity ...;
  ...
  input  myinput  / normalize=mynormalize;
  target mytarget / normalize=mynormalize;
  ...
run;

```

Sequence Scaling

A user-defined scaling subroutine has the following signature:

```
SUBROUTINE <SUBROUTINE-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*] );
```

where the first array-name is the target sequence and the second array-name is the input sequence to be scaled.

For example, to duplicate the functionality of the built-in SCALE=ABSOLUTE option in the INPUT statement, the following SAS statements create a user-defined version of this scaling called MYSCALE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```

proc fcmp outlib=sasuser.mysimilar.package;

  subroutine myscale( target[*], input[*] );

    outargs input;

    length = DIM(target);
    minimum = .; maximum = .;

    do i = 1 to length;
      value = target[i];
      if nmiss(minimum) | nmiss(maximum) then do;
        minimum = value;
        maximum = value;
      end;
      if nmiss(value) = 0 then do;
        if value < minimum then minimum = value;
        if value > maximum then maximum = value;
      end;
    end;

    do i = 1 to length;
      value = input[i];
      if nmiss( value ) | minimum > maximum then do;
        input[i] = .;
      end;
      else do;
        input[i] = (value - minimum) / (maximum - minimum);
      end;
    end;
  end;

```

```
endsub;

run;
```

This user-defined subroutine can be specified in the SCALE= option in the INPUT statement as follows:

```
options cmplib=sasuser.mysimilar;

proc similarity ...;
  ...
  input myinput / scale=myscale;
  ...
run;
```

Similarity Measures

A user-defined similarity measure function has the following signature:

```
FUNCTION <FUNCTION-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*] );
```

where the first array-name is the target sequence and the second array-name is the input sequence. The return value of the function is the similarity measure associated with the target sequence and the input sequence.

For example, to duplicate the functionality of the built-in MEASURE=ABSDEV option in the TARGET statement with no warping, the following SAS statements create a user-defined version of this measure called MYMEASURE and store this subroutine in the catalog SASUSER.MYSIMILAR.

```
proc fcmp outlib=sasuser.mysimilar.package;

  function mymeasure( target[*], input[*] );

    length = min(DIM(target), DIM(input));
    sum = 0; num = 0;

    do i = 1 to length;
      x = input[i];
      w = target[i];
      if nmiss(x) = 0 & nmiss(w) = 0 then do;
        d = x - w;
        sum = sum + abs(d);
        num = num + 1;
      end;
    end;

    if num <= 0 then return(.);

    return(sum);

  endsub;

run;
```

This user-defined function can be specified in the MEASURE= option in the TARGET statement as follows:

```
options cmplib=sasuser.mysimilar;

proc similarity ...;
    ...
    target mytarget / measure=mymmeasure;
    ...
run;
```

For another example, to duplicate the functionality of the built-in MEASURE=SQRDEV and MEASURE=ABSDEV options by using the C language, the following SAS statements create a user-defined C language version of these measures called DTW_SQRDEV_C and DTW_ABSDEV_C and store these functions in the catalog SASUSER.CSIMIL.CFUNCS. DTW refers to dynamic time warping. These C language functions can be then called by SAS language functions and subroutines.

```
proc proto package=sasuser.csimil.cfuncs;

mapmiss double = 999999999;

double dtw_sqrdev_c( double * target / iotype=input,
                    int      targetLength,
                    double * input / iotype=input,
                    int      inputLength );

externc dtw_sqrdev_c;
double dtw_sqrdev_c( double * target,
                    int      targetLength,
                    double * input,
                    int      inputLength )
{
    int      i,j;
    double   x,w,d;
    double * prev = (double *)malloc( sizeof(double)*targetLength);
    double * curr = (double *)malloc( sizeof(double)*inputLength);
    if ( prev == 0 || curr == 0 ) return 999999999;

    x = input[0];
    for ( j=0; j<targetLength; j++ ) {
        w = target[j];
        d = x - w;
        d = d*d;
        if ( j == 0 ) prev[j] = d;
        else          prev[j] = d + prev[j-1];
    }

    for ( i=1; i<inputLength; i++ ) {
        x = input[i];

        j = 0;
        w = target[j];
        d = x - w;
```

```

    d = d*d;
    curr[j] = d + prev[j];

    for (j=1; j<targetLength; j++ ) {
        w = target[j];
        d = x - w;
        d = d*d;
        curr[j] = d + fmin( prev[j],
                           fmin( prev[j-1], curr[j]));
    }

    if ( i < targetLength ) {
        for( j=0; j<inputLength; j++ )
            prev[j] = curr[j];
    }
}

d = curr[inputLength-1];
free( (char*) prev);
free( (char*) curr);
return( d );
}
externcend;

double dtw_absdev_c( double * target / iotype=input,
                    int      targetLength,
                    double * input / iotype=input,
                    int      inputLength );
externc dtw_absdev_c;
double dtw_absdev_c( double * target,
                    int      targetLength,
                    double * input,
                    int      inputLength )
{
    int      i,j;
    double   x,w,d;
    double * prev = (double *)malloc( sizeof(double)*targetLength);
    double * curr = (double *)malloc( sizeof(double)*inputLength);
    if ( prev == 0 || curr == 0 ) return 999999999;

    x = input[0];
    for ( j=0; j<targetLength; j++ ) {
        w = target[j];
        d = x - w;
        d = fabs(d);
        if (j == 0) prev[j] = d;
        else prev[j] = d + prev[j-1];
    }

    for (i=1; i<inputLength; i++ ) {
        x = input[i];

        j = 0;
        w = target[j];

```

```

    d = x - w;
    d = fabs(d);
    curr[j] = d + prev[j];

    for (j=1; j<targetLength; j++) {
        w = target[j];
        d = x - w;
        d = fabs(d);
        curr[j] = d + fmin( prev[j],
                           fmin( prev[j-1], curr[j] ));
    }

    if ( i < inputLength) {
        for ( j=0; j<targetLength; j++ )
            prev[j] = curr[j];
    }

    }

    d = curr[inputLength-1];
    free( (char*) prev);
    free( (char*) curr);
    return( d );
}
extern cend;

run;

```

The preceding SAS statements create two C language functions which can then be used in SAS language functions or subroutines or both. However, these functions cannot be directly used by the SIMILARITY procedure. In order to use these C language functions in the SIMILARITY procedure, two SAS language functions must be created that call these two C language functions. The following SAS statements create two user-defined SAS language versions of these measures called DTW_SQRDEV and DTW_ABSDEV and stores these functions in the catalog SASUSER.MYSIMILAR.FUNCS. These SAS language functions use the previously created C language function; the SAS language functions can then be used by the SIMILARITY procedure.

```

proc fcmp outlib=sasuser.mysimilar.funcs
    inlib=sasuser.cfuncs;

    function dtw_sqrdev( target[*], input[*] );
        dev = dtw_sqrdev_c(target,DIM(target),input,DIM(input));
        return( dev );
    endsub;

    function dtw_absdev( target[*], input[*] );
        dev = dtw_absdev_c(target,DIM(target),input,DIM(input));
        return( dev );
    endsub;

run;

```

This user-defined function can be specified in the MEASURE= option in the TARGET statement as follows:

```
options cmlib=sasuser.mysimilar;

proc similarity ...;
  ...
  target  mytarget      / measure=dtw_sqrdev;
  target  yourtarget    / measure=dtw_absdev;
  ...
run;
```

Similarity Measures and Warping Path

A user-defined similarity measure and warping path information function has the following signature:

```
FUNCTION <FUNCTION-NAME> ( <ARRAY-NAME>[*], <ARRAY-NAME>[*],
                           <ARRAY-NAME>[*], <ARRAY-NAME>[*],
                           <ARRAY-NAME>[*] );
```

where the first array-name is the target sequence, the second array-name is the input sequence, the third array-name is the returned target sequence indices, the fourth array-name is the returned input sequence indices, the fifth array-name is the returned path distances. The returned value of the function is the similarity measure. The last three returned arrays are used to compute the path and cost statistics.

The returned sequence indices must represent a valid warping path; that is, integers greater than zero and less than or equal to the sequence length and recorded in ascending order. The returned path distances must be nonnegative numbers.

Output Data Sets

The SIMILARITY procedure can create the OUT=, OUTMEASURE=, OUTPATH=, OUTSEQUENCE=, and OUTSUM= data sets. In general, these data sets contain the variables listed in the BY statement. The ID statement time ID variable is also included in the data sets when the time dimension is important. If an analysis step related to an output data step fails, then the values of this step are not recorded or are set to missing in the related output data set, and appropriate error and warning messages are recorded in the SAS log.

OUT= Data Set

The OUT= data set contains the variables that are specified in the BY, ID, INPUT, and TARGET statements. If the ID statement is specified, the ID variable values are aligned and extended based on the ALIGN=, INTERVAL=, START=, and END= options. The values of the variables specified in the INPUT and TARGET statements are accumulated based on the ACCUMULATE= option, missing values are interpreted based on the SETMISSING= option, and zero values are interpreted using the ZEROMISS= option. The accumulated time series is transformed based on the TRANSFORM=, DIF=, and SDIF= options.

OUTMEASURE= Data Set

The OUTMEASURE= data set records the similarity measures between each INPUT and TARGET statement variable with respect to each time ID value. The form of the OUTMEASURE= data set depends on the SORTNAMES and ORDER= options. The OUTMEASURE= data set contains the variables specified in the BY statement in addition to the variables listed below.

For ORDER=INPUTTARGET and ORDER=TARGETINPUT, the OUTMEASURE= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_INPSEQ_</code>	input sequence values
<code>_TARSEQ_</code>	target sequence values
<code>_SIM_</code>	similarity measures

The OUTMEASURE= data set is ordered by the variables `_INPUT_`, then `_TARGET_`, then `_TIMEID_` when ORDER=INPUTTARGET. The OUTMEASURE= data set is ordered by the variables `_TARGET_`, then `_INPUT_`, then `_TIMEID_` when ORDER=TARGETINPUT.

For ORDER=INPUT, the OUTMEASURE= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_TIMEID_</code>	time ID values
<code>_INPSEQ_</code>	input sequence values
<i>target-names</i>	similarity measures that are associated with each TARGET statement variable name

The OUTMEASURE= data set is ordered by the variables `_INPUT_`, then `_TIMEID_`.

For ORDER=TARGET, the OUTMEASURE= data set has the following form:

<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_TARSEQ_</code>	target sequence values
<i>input-names</i>	similarity measures that are associated with each INPUT statement variable name

The OUTMEASURE= data set is ordered by the variables `_TARGET_`, then `_TIMEID_`.

OUTPATH= Data Set

The OUTPATH= data set records the path analysis between each INPUT and TARGET statement variable. This data set records the path sequences for each slide index and for each warp index associated with the

slide index. The sequence values recorded are normalized and scaled based on the NORMALIZE= and SCALE= options.

The OUTPATH= data set contains the variables specified in the BY statement and the following variables:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_SLIDE_</code>	slide index
<code>_WARP_</code>	warp index
<code>_INPSEQ_</code>	input sequence values
<code>_TARSEQ_</code>	target sequence values
<code>_INPPTH_</code>	input path index
<code>_TARPTH_</code>	target path index
<code>_METRIC_</code>	distance metric values

The Warp Index indicates the total amount of warping for each slide. A negative number represents compression of the target sequence. A positive number represents expansion of the target sequence. The Warp Index is always zero for SLIDE=NONE and SLIDE=SEASON.

The sorting of the OUTPATH= data set depends on the SORTNAMES and the ORDER= option.

The OUTPATH= data set is ordered by the variables `_INPUT_`, then `_TARGET_`, then `_TIMEID_` when ORDER=INPUTTARGET or ORDER=INPUT. The OUTPATH= data set is ordered by the variables `_TARGET_`, then `_INPUT_`, then `_TIMEID_` when ORDER=TARGETINPUT or ORDER=TARGET.

If there are a large number of slides or warps or both, this data set might be large.

OUTSEQUENCE= Data Set

The OUTSEQUENCE= data set records the input and target sequences that are associated with each INPUT and TARGET statement variable. This data set records the input and target sequence values for each slide index and for each warp index that is associated with the slide index. The sequence values that are recorded are normalized and scaled based on the NORMALIZE= and SCALE= options. This data set also contains the similarity measure associated with the two sequences.

The OUTSEQUENCE= data set contains the variables specified in the BY statement in addition to the following variables:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_TIMEID_</code>	time ID values
<code>_SLIDE_</code>	slide index
<code>_WARP_</code>	warp index

<code>_INPSEQ_</code>	input sequence values
<code>_TARSEQ_</code>	target sequence values
<code>_SIM_</code>	similarity measure
<code>_STATUS_</code>	sequence status

The sorting of the OUTSEQUENCE= data set depends on the SORTNAMES and the ORDER= option.

The OUTSEQUENCE= data set is ordered by the variables `_INPUT_`, then `_TARGET_`, then `_TIMEID_` when `ORDER=INPUTTARGET` or `ORDER=INPUT`. The OUTSEQUENCE= data set is ordered by the variables `_TARGET_`, then `_INPUT_`, then `_TIMEID_` when `ORDER=TARGETINPUT` or `ORDER=TARGET`.

If there are a large number of slides or warps or both, this data set might be large.

OUTSUM= Data Set

The OUTSUM= data set summarizes the similarity measures between each INPUT and TARGET statement variable. The form of the OUTSUM= data set depends on the SORTNAMES and ORDER= option. If the SORTNAMES option is specified, each variable (INPUT or TARGET) is analyzed in ascending order. The OUTSUM= data set contains the variables specified in the BY statement in addition to the variables listed below.

For `ORDER=INPUTTARGET` and `ORDER=TARGETINPUT`, the OUTSUM= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_TARGET_</code>	target variable name
<code>_STATUS_</code>	status flag that indicates whether the requested analyses were successful
<code>_TIMEID_</code>	time ID values
<code>_SIM_</code>	similarity measure summary

The OUTSUM= data set is ordered by the variables `_INPUT_`, then `_TARGET_` when `ORDER=INPUTTARGET`. The OUTSUM= data set is ordered by the variables `_TARGET_`, then `_INPUT_` when `ORDER=TARGETINPUT`.

For `ORDER=INPUT`, the OUTSUM= data set has the following form:

<code>_INPUT_</code>	input variable name
<code>_STATUS_</code>	status flag that indicates whether the requested analyses were successful
<i>target-names</i>	similarity measure summary that is associated with each TARGET statement variable name

The OUTSUM= data set is ordered by the variable `_INPUT_`.

For `ORDER=TARGET`, the OUTSUM= data set has the following form:

<code>_TARGET_</code>	target variable name
<code>_STATUS_</code>	status flag that indicates whether the requested analyses were successful
<i>input-names</i>	similarity measure summary that is associated with each INPUT statement variable name

The OUTSUM= data set is ordered by the variable `_TARGET_`.

`_STATUS_` Variable Values

The `_STATUS_` variable contains a code that specifies whether the similarity analysis has been successful or not. The `_STATUS_` variable can take the following values:

0	Success
3000	Accumulation failure
4000	Missing value interpretation failure
6000	Series is all missing
7000	Transformation failure
8000	Differencing failure
9000	Unable to compute descriptive statistics
10000	Normalization failure
11000	Input contains imbedded missing values
12000	Target contains imbedded missing values
13000	Scaling failure
14000	Measure failure
15000	Path failure
16000	Slide summarization failure

Printed Output

The SIMILARITY procedure optionally produces printed output by using the Output Delivery System (ODS). By default, the procedure produces no printed output. All output is controlled by the PRINT= and PRINTDETAILS options in the PROC SIMILARITY statement.

The sort, order, and form of the printed output depends on both the SORTNAMES option and the ORDER= option. If the SORTNAMES option is specified, each variable (INPUT or TARGET) is analyzed in ascending order. For ORDER=INPUTTARGET, the printed output is ordered by the INPUT statement variables (row) and then by the TARGET statement variables (row). For ORDER=TARGETINPUT, the printed output is ordered by the TARGET statement variables (row) and then by the INPUT statement variables (row). For ORDER=INPUT, the printed output is ordered by the INPUT statement variables (row) and then by the TARGET statement variables (column). For ORDER=TARGET, the printed output is ordered by the TARGET statement variables (row) and then by the INPUT statement variables (column).

In general, if an analysis step related to printed output fails, the values of that step are not printed and appropriate error and warning messages are recorded in the SAS log. The printed output is similar to the output data set; these similarities are described as follows:

PRINT=COSTS

prints the costs statistics.

PRINT=DESCSTATS

prints the descriptive statistics.

PRINT=PATHS

prints the path statistics.

PRINT=SLIDES

prints the sliding sequence summary.

PRINT=SUMMARY

prints the summary of similarity measures similar to the OUTSUM= data set.

PRINT=WARPS

prints the warp summary.

PRINTDETAILS

prints each table with greater detail.

ODS Table Names

The following table relates the PRINT= options to ODS tables.

Table 24.2 ODS Tables Produced in PROC SIMILARITY

ODS Table Name	Description	Option
CostStatistics	Cost statistics	PRINT=COSTS
DescStats	Descriptive statistics	PRINT=DESCSTATS
PathLimits	Path limits	PRINT=PATHS
PathStatistics	Path statistics	PRINT=PATHS
SlideMeasuresSummary	Summary of measure per slide	PRINT=SLIDES
MeasuresSummary	Measures summary	PRINT=SUMMARY
InputMeasuresSummary	Measures summary	PRINT=SUMMARY
TargetMeasuresSummary	Measures summary	PRINT=SUMMARY
WarpMeasuresSummary	Summary of measure per warp	PRINT=WARPS

The tables are related to a single series within a BY group.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS for creating graphics with the SIMILARITY procedure.

ODS Graph Names

PROC SIMILARITY assigns a name to each graph it creates by using ODS. You can use these names to selectively reference the graphs. The names are listed in [Table 24.3](#).

Table 24.3 ODS Graphics Produced by PROC SIMILARITY

ODS Graph Name	Plot Description	Statement	PLOTS= Option
CostsPlot	Costs plot	SIMILARITY	PLOTS=COSTS
NormalizedSequencePlot	Normalized Sequence Plot	SIMILARITY	PLOTS=NORMALIZED
PathDistancePlot	Path distances plot	SIMILARITY	PLOTS=DISTANCES
PathDistanceHistogram	Path distances histogram	SIMILARITY	PLOTS=DISTANCES
PathRelativeDistancePlot	Path relative distances plot	SIMILARITY	PLOTS=DISTANCES
PathRelativeDistanceHistogram	Path relative distances histogram	SIMILARITY	PLOTS=DISTANCES
PathPlot	Path plot	SIMILARITY	PLOTS=PATHS
PathSequencesPlot	Path sequences plot	SIMILARITY	PLOTS=MAPS
PathSequencesScaledPlot	Scaled path sequences map plot	SIMILARITY	PLOTS=MAPS
ScaledSequencePlot	Scaled Sequence plot	SIMILARITY	PLOTS=SCALED
SequencePlot	Sequence plot	SIMILARITY	PLOTS=SEQUENCES
SeriesPlot	Input time series plot	SIMILARITY	PLOTS=INPUTS
SimilarityPlot	Similarity measures plot	SIMILARITY	PLOTS=MEASURES
TargetSequencePlot	Target sequence plot	SIMILARITY	PLOTS=TARGETS
WarpPlot	Warping plot	SIMILARITY	PLOTS=WARPS
WarpScaledPlot	Scaled warping plot	SIMILARITY	PLOTS=WARPS

Time Series Plots

The time series plots (SeriesPlot) illustrate the input time series to be compared. The horizontal axis represents the input series time ID values, and the vertical axis represents the input series values.

Sequence Plots

The sequence plots (SequencePlot) illustrate the target and input sequences to be compared. The horizontal axis represents the (target or input) sequence index, and the vertical axis represents the (target or input) sequence values.

Path Plots

The path plot (PathPlot) and path limits plot (PathLimitsPlot) illustrate the path through the distance matrix. The horizontal axis represents the input sequence index, and the vertical axis represents the target sequence index. The dots represent the path coordinates. The upper parallel line represents the compression limit, and the lower parallel line represents the expansion limit. These plots visualize the path through the distance matrix. Vertical movements indicate compression, and horizontal movements represent expansion of the target sequence with respect to the input sequence. These plots are useful for visualizing the amount of expansion and compression along the path.

Time Warp Plots

The time warp plot (WarpPlot) and scaled time warp plot (WarpScaledPlot) illustrate the time warping. The horizontal axis represents the (input and target) sequence index. The upper line plot represents the target sequence. The lower line plot represents the input sequence. The lines that connect the input and target sequence values represent the mapping between the input and target sequence indices along the optimal path. These plots visualize the warping of the time index with respect to the input and target sequence values. Expansion of a single target sequence value occurs when it is mapped to more than one input sequence value. Expansion of a single input sequence value occurs when it is mapped to more than one target sequence value. The plots are useful for visualizing the mapping between the input and target sequence values along the path. The plots are useful for comparing the path sequences or input and target sequence after time warping.

Path Sequence Plots

The path sequence plot (PathSequencesPlot) and scaled path sequence plot (PathSequencesScaledPlot) illustrate the sequence mapping along the optimal path. The horizontal axis represents the path index. The dashed line represents the time warped input sequence. The solid line represents the time warped target sequence. These plots visualize the mapping between the input and target sequence values with respect to the path index. The scaled plot with the input and target sequence values are scaled and evenly separated for visual convenience.

Path Distance Plots

The path distance plots (PathDistancePlot) and path relative distance plots (PathRelativeDistancePlot) illustrate the path (relative) distances. The horizontal axis represents the path index. The vertical needles represent the (relative) distances. The horizontal reference lines indicate one and two standard deviations.

The path distance histogram (PathDistanceHistogram) and path relative distance histogram (PathDistanceRelativeHistogram) illustrate the distribution of the path (relative) distances. The bars represent the histogram, and the solid line represents a normal distribution with the same mean and variance.

Cost Plots

The cost plot (CostPlot) and cost limits plot (CostPlot) illustrate the cost of traversing the distance matrix. The horizontal axis represents the input sequence index, and the vertical axis represents the target sequence index. The colors and shading within the plot illustrate the incremental cost of traversing the distance matrix. The upper parallel line represents the compression limit, and the lower parallel line represents the expansion limit.

Examples: SIMILARITY Procedure

Example 24.1: Accumulating Transactional Data into Time Series Data

This example uses the SIMILARITY procedure to illustrate the accumulation of time-stamped transactional data that has been recorded at no particular frequency into time series data at a specific frequency. After the time series is created, the various SAS/ETS procedures related to time series analysis, similarity analysis, seasonal adjustment and decomposition, modeling, and forecasting can be used to further analyze the time series data.

Suppose that the input data set WORK.RETAIL contains variables STORE and TIMESTAMP and numerous other numeric transaction variables. The BY variable STORE contains values that break up the transactions into groups (BY groups). The time ID variable TIMESTAMP contains SAS date values recorded at no particular frequency. The other data set variables contain the numeric transaction values to be analyzed. It is further assumed that the input data set is sorted by the variables STORE and TIMESTAMP.

The following statements form monthly time series from the transactional data based on the median value (ACCUMULATE=MEDIAN) of the transactions recorded with each time period. The accumulated time series values for time periods with no transactions are set to zero instead of missing (SETMISS=0). Only transactions recorded between the first day of 1998 (START='01JAN1998'D) and last day of 2000 (END='31DEC2000'D) are considered and if needed are extended to include this range.

```
proc similarity data=work.retail out=mseries;
  by store;
  id timestamp interval=month
      accumulate=median
      setmiss=0
      start='01jan1998'd
      end  ='31dec2000'd;
  target _NUMERIC_;
run;
```

The monthly time series data are stored in the data WORK.MSERIES. Each BY group associated with the BY variable STORE contains an observation for each of the 36 months associated with the years 1998, 1999,

and 2000. Each observation contains the variable STORE, TIMESTAMP, and each of the analysis variables in the input DATA= data set.

After each set of transactions has been accumulated to form the corresponding time series, the accumulated time series can be analyzed by using various time series analysis techniques. For example, exponentially weighted moving averages can be used to smooth each series. The following statements use the EXPAND procedure to smooth the analysis variable named STOREITEM.

```
proc expand data=mseries
            out=smoothed
            from=month;
  by store;
  id timestamp;
  convert storeitem=smooth / transform=(ewma 0.1);
run;
```

The smoothed series is stored in the data set WORK.SMOOTHED. The variable SMOOTH contains the smoothed series.

If the time ID variable TIMESTAMP contains SAS datetime values instead of SAS date values, the INTERVAL=, START=, and END= options in the SIMILARITY procedure must be changed accordingly, and the following statements could be used to accumulate the datetime transactions to a monthly interval:

```
proc similarity data=work.retail
              out=tseries;
  by store;
  id timestamp interval=dtmonth
              accumulate=median
              setmiss=0
              start='01jan1998:00:00:00'dt
              end  ='31dec2000:00:00:00'dt;
  target _NUMERIC_;
run;
```

The monthly time series data are stored in the data WORK.TSERIES, and the time ID values use a SAS datetime representation.

Example 24.2: Similarity Analysis

This simple example illustrates how to use similarity analysis to compare two time sequences. The following statements create an example data set that contains two time sequences of differing lengths:

```
data test;
input i y x;
datalines;
1  2  3
2  4  5
3  6  3
4  7  3
5  3  3
6  8  6
7  9  3
```

```

8   3   8
9  10   .
10 11   .
;
run;

```

The following statements perform similarity analysis on the example data set:

```

proc similarity data=test out=_null_
  print=all plot=all;
  input x;
  target y / measure=absdev;
run;

```

The DATA=TEST option specifies that the input data set WORK.TEST is to be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The PRINT=ALL and PLOTS=ALL options specify that all ODS tables and graphs are to be produced. The INPUT statement specifies that the input variable is X. The TARGET statement specifies that the target variable is Y and that the similarity measure is computed using absolute deviation (MEASURE=ABSDEV).

Output 24.2.1 Description Statistics of the Input Variable, x

Output 24.2.16 Time Warp Plot

Output 24.2.17 Time Warp Scaled Plot

The following statements repeat the preceding similarity analysis on the example data set with warping limits:

```
proc similarity data=test out=_null_
  print=all plot=all;
  input x;
  target y / measure=absdev
             compress=(localabs=2)
             expand=(localabs=2);
run;
```

The COMPRESS=(LOCALABS=2) option limits local absolute compression to 2. The EXPAND=(LOCALABS=2) option limits local absolute expansion to 2.

Output 24.2.18 Path Plot with Warping Limits

Output 24.2.19 Warped Path Limits

Path Limits					
Limit	Specified Absolute	Specified Percentage	Minimum Allowed	Maximum Allowed	Applied
Compression	2	None	2	9	2
Expansion	2	None	0	7	2

Output 24.2.20 Cost Plot with Warping Limits

The following statements repeat the preceding similarity analysis on the example data set but store the results in output data sets:

```
proc similarity data=test out=series
  outsequence=sequences outpath=path outsum=summary;
  input x;
  target y / measure=absdev
             compress=(localabs=2)
             expand=(localabs=2);
run;
```

The OUT=SERIES, OUTSEQUENCE=SEQUENCES, OUTPATH=PATH, and OUTSUM=SUMMARY options specify that the output time series, time sequences, path analysis, and summary data sets be created, respectively.

Example 24.3: Sliding Similarity Analysis

This example illustrates how to use sliding similarity analysis to compare two time sequences. The SASHELP.WORKERS data set contains two similar time series variables (ELECTRIC and MASONRY), which represent employment over time. The following statements create an example data set that contains two time series of differing lengths, where the variable MASONRY has the first 12 and last 7 observations set to missing to simulate the lack of data associated with the target series:

```
data workers; set sashelp.workers;
  if '01JAN1978'D <= date < '01JAN1982'D then masonry = masonry;
  else masonry = .;
run;
```

The goal of sliding similarity measures analysis is find the slide index that corresponds to the most similar subsequence of the input series when compared to the target sequence. The following statements perform sliding similarity analysis on the example data set:

```
proc similarity data=workers out=_NULL_ print=(slides summary);
  id date interval=month;
  input electric;
  target masonry / slide=index measure=msqrdev
                  expand=(localabs=3 globalabs=3)
                  compress=(localabs=3 globalabs=3);
run;
```

The DATA=WORKERS option specifies that the input data set WORK.WORKERS is to be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The PRINT=(SLIDES SUMMARY) option specifies that the ODS tables related to the sliding similarity measures and their summary be produced. The INPUT statement specifies that the input variable is ELECTRIC. The TARGET statement specifies that the target variable is MASONRY and that the similarity measure be computed using mean squared deviation (MEASURE=MSQRDEV). The SLIDE=INDEX option specifies observation index sliding. The COMPRESS=(LOCALABS=3 GLOBALABS=3) option limits local and global absolute compression to 3. The EXPAND=(LOCALABS=3 GLOBALABS=3) option limits local and global absolute expansion to 3.

Output 24.3.1 Summary of the Slide Measures

The SIMILARITY Procedure					
Slide Measures Summary for Input=ELECTRIC and Target=MASONRY					
Slide Index	DATE	Slide Target Sequence Length	Slide Input Sequence Length	Slide Warping Amount	Slide Minimum Measure
0	JAN1977	48	51	3	497.6737
1	FEB1977	48	51	1	482.6777
2	MAR1977	48	51	0	474.1251
3	APR1977	48	51	0	490.7792
4	MAY1977	48	51	-2	533.0788
5	JUN1977	48	51	-3	605.8198
6	JUL1977	48	51	-3	701.7138
7	AUG1977	48	51	3	646.5918
8	SEP1977	48	51	3	616.3258
9	OCT1977	48	51	3	510.9836
10	NOV1977	48	51	3	382.1434
11	DEC1977	48	51	3	340.4702
12	JAN1978	48	51	2	327.0572
13	FEB1978	48	51	1	322.5460
14	MAR1978	48	51	0	325.2689
15	APR1978	48	51	-1	351.4161
16	MAY1978	48	51	-2	398.0490
17	JUN1978	48	50	-3	471.6931
18	JUL1978	48	49	-3	590.8089
19	AUG1978	48	48	0	595.2538
20	SEP1978	48	47	-1	689.2233
21	OCT1978	48	46	-2	745.8891
22	NOV1978	48	45	-3	679.1907

Output 24.3.2 Minimum Measure

Minimum Measure Summary	
Input Variable	MASONRY
ELECTRIC	322.5460

This analysis results in 23 slides based on the observation index. The minimum measure (322.5460) occurs at slide index 13 which corresponds to the time value FEB1978. Note that the original data set SASHELP.WORKERS was modified beginning at the time value JAN1978. This similarity analysis justifies the belief the ELECTRIC lags MASONRY by one month based on the time series cross-correlation analysis despite the lack of target data (MASONRY).

The goal of seasonal sliding similarity measures is to find the seasonal slide index that corresponds to the most similar seasonal subsequence of the input series when compared to the target sequence. The following statements repeat the preceding similarity analysis on the example data set with seasonal sliding:

```
proc similarity data=workers out=_NULL_ print=(slides summary);
  id date interval=month;
  input electric;
  target masonry / slide=season measure=msqrdev;
run;
```

Output 24.3.3 Summary of the Seasonal Slide Measures

The SIMILARITY Procedure					
Slide Measures Summary for Input=ELECTRIC and Target=MASONRY					
Slide Index	DATE	Slide Target Sequence Length	Slide Input Sequence Length	Slide Warping Amount	Slide Minimum Measure
0	JAN1977	48	48	0	1040.086
12	JAN1978	48	48	0	641.927

Output 24.3.4 Seasonal Minimum Measure

Minimum Measure Summary	
Input Variable	MASONRY
ELECTRIC	641.9273

The analysis differs from the previous analysis in that the slides are performed based on the seasonal index (SLIDE=SEASON) with no warping. With a seasonality of 12, two seasonal slides are considered at slide indices 0 and 12 with the minimum measure (641.9273) occurring at slide index 12 which corresponds to the time value JAN1978. Note that the original data set SASHELP.WORKERS was modified beginning at the time value JAN1978. This similarity analysis justifies the belief that ELECTRIC and MASONRY have similar seasonal properties based on seasonal decomposition analysis despite the lack of target data (MASONRY).

Example 24.4: Searching for Historical Analogies

This example illustrates how to search for historical analogies by using seasonal sliding similarity analysis of transactional time-stamped data. The SASHELP.TIMEDATA data set contains the variable (VOLUME), which represents activity over time. The following statements create an example data set that contains two time series of differing lengths, where the variable HISTORY represents the historical activity and RECENT represents the more recent activity:

```
data timedata; set sashelp.timedata;
  drop volume;
  recent = .;
  history = volume;
  if datetime >= '20AUG2000:00:00:00'DT then do;
    recent = volume;
    history = .;
  end;
run;
```

The goal of seasonal sliding similarity measures is to find the seasonal slide index that corresponds to the most similar seasonal subsequence of the input series when compared to the target sequence. The following statements perform similarity analysis on the example data set with seasonal sliding:

```
proc similarity data=timedata out=_NULL_ outsequence=sequences
  outsum=summary;
  id datetime interval=dtday accumulate=total
  start='27JUL1997:00:00:00'dt
  end='21OCT2000:11:59:59'DT;
  input history / normalize=absolute;
  target recent / slide=season normalize=absolute measure=mabsdev;
run;
```

The DATA=TIMEDATA option specifies that the input data set WORK.TIMEDATA be used in the analysis. The OUT=_NULL_ option specifies that no output time series data set is to be created. The OUTSEQUENCE=SEQUENCES and OUTSUM=SUMMARY options specify the output sequences and summary data sets, respectively. The ID statement specifies that the time ID variable is DATETIME, which is to be accumulated on a daily basis (INTERVAL=DTDAY) by summing the transactions (ACCUMULATE=TOTAL). The ID statement also specifies that the data is accumulated on the weekly boundaries starting on the week of 27JUL1997 and ending on the week of 15OCT2000 (START='27JUL1997:00:00:00'DT END='21OCT2000:11:59:59'DT'). The INPUT statement specifies that the input variable is HISTORY, which is to be normalized using absolute normalization (NORMALIZE=ABSOLUTE). The TARGET statement specifies that the target variable is RECENT, which is to be normalized by using absolute normalization (NORMALIZE=ABSOLUTE) and that the similarity measure be computed by using mean absolute deviation (MEASURE=MABSDEV). The SLIDE=SEASON options specifies season index sliding.

To illustrate the results of the similarity analysis, the output sequence data set must be subset by using the output summary data set.

```
data _NULL_; set summary;
  call symput('MEASURE', left(trim(putn(recent, 'BEST20.'))));
run;
```

```

data result; set sequences;
  by _SLIDE_;
  retain flag 0;
  if first._SLIDE_ then do;
    if (&measure - 0.00001 < _SIM_ < &measure + 0.00001)
      then flag = 1;
  end;
  if flag then output;
  if last._SLIDE_ then flag = 0;
run;

```

The following statements generate a cross series plot of the results:

```

proc timeseries data=result out=_NULL_ crossplot=series;
  id datetime interval=dtday;
  var _TARSEQ_;
  crossvar _INPSEQ_;
run;

```

The cross series plot illustrates that the historical time series analogy most similar to the most recent time series data that started on 20AUG2000 occurred on 02AUG1998.

Output 24.4.1 Cross Series Plot of the Historical Time Series

Example 24.5: Clustering Time Series

This example illustrates how to cluster time series using a similarity matrix. The WORK.APPLIANCES data set contains 24 variables that record sales histories. The following statements create a similarity matrix and store the matrix in the WORK.SIMMATRIX data set:

```
proc similarity data=sashelp.applianceseries out=_null_ outsum=simmatrix;  
    target units_1--units_24 / measure=mabsdev normalize=absolute;  
run;
```

The following statements cluster the rows of the similarity matrix.

```
proc cluster data=simmatrix(drop=_status_) outtree=tree method=ward noprint;  
    id _input_;  
run;
```

The following statements plot the dendrogram:

```
proc tree data=tree horizontal;  
run;
```

Overview: SIMLIN Procedure

The SIMLIN procedure reads the coefficients for a set of linear structural equations, which are usually produced by the SYSLIN procedure. PROC SIMLIN then computes the reduced form and, if input data are given, uses the reduced form equations to generate predicted values. PROC SIMLIN is especially useful

when dealing with sets of structural difference equations. The SIMLIN procedure can perform simulation or forecasting of the endogenous variables.

The SIMLIN procedure can be applied only to models that are:

- linear with respect to the parameters
- linear with respect to the variables
- square (as many equations as endogenous variables)
- nonsingular (the coefficients of the endogenous variables form an invertible matrix)

Getting Started: SIMLIN Procedure

The SIMLIN procedure processes the coefficients in a data set created by the SYSLIN procedure using the OUTEST= option or by another regression procedure such as PROC REG. To use PROC SIMLIN you must first produce the coefficient data set and then specify this data set on the EST= option of the PROC SIMLIN statement. You must also tell PROC SIMLIN which variables are endogenous and which variables are exogenous. List the endogenous variables in an ENDOGENOUS statement, and list the exogenous variables in an EXOGENOUS statement.

The following example illustrates the creation of an OUTEST= data set with PROC SYSLIN and the computation and printing of the reduced form coefficients for the model with PROC SIMLIN.

```
proc syslin data=in outest=e;
    model y1 = y2 x1;
    model y2 = y1 x2;
run;

proc simlin est=e;
    endogenous y1 y2;
    exogenous x1 x2;
run;
```

If the model contains lagged endogenous variables you must also use a LAGGED statement to tell PROC SIMLIN which variables contain lagged values, which endogenous variables they are lags of, and the number of periods of lagging. For dynamic models, the TOTAL and INTERIM= options can be used on the PROC SIMLIN statement to compute and print total and impact multipliers. (See "Dynamic Multipliers" later in this section for an explanation of multipliers.)

In the following example the variables Y1LAG1, Y2LAG1, and Y2LAG2 contain lagged values of the endogenous variables Y1 and Y2. Y1LAG1 and Y2LAG1 contain values of Y1 and Y2 for the previous observation, while Y2LAG2 contains 2 period lags of Y2. The LAGGED statement specifies the lagged relationships, and the TOTAL and INTERIM= options request multiplier analysis. The INTERIM=2 option prints matrices showing the impact that changes to the exogenous variables have on the endogenous variables after 1 and 2 periods.

```

data in; set in;
  y1lag1 = lag(y1);
  y2lag1 = lag(y2);
  y2lag2 = lag2(y2);
run;

proc syslin data=in outest=e;
  model y1 = y2 y1lag1 y2lag2 x1;
  model y2 = y1 y2lag1 x2;
run;

proc simlin est=e total interim=2;
  endogenous y1 y2;
  exogenous x1 x2;
  lagged y1lag1 y1 1 y2lag1 y2 1 y2lag2 y2 2;
run;

```

After the reduced form of the model is computed, the model can be simulated by specifying an input data set on the PROC SIMLIN statement and using an OUTPUT statement to write the simulation results to an output data set. The following example modifies the PROC SIMLIN step from the preceding example to simulate the model and stores the results in an output data set.

```

proc simlin est=e total interim=2 data=in;
  endogenous y1 y2;
  exogenous x1 x2;
  lagged y1lag1 y1 1 y2lag1 y2 1 y2lag2 y2 2;
  output out=sim predicted=y1hat y2hat
         residual=y1resid y2resid;
run;

```

Prediction and Simulation

If an input data set is specified with the DATA= option in the PROC SIMLIN statement, the procedure reads the data and uses the reduced form equations to compute predicted and residual values for each of the endogenous variables. (If no data set is specified with the DATA= option, no simulation of the system is performed, and only the reduced form and multipliers are computed.)

The character of the prediction is based on the START= value. Until PROC SIMLIN encounters the START= observation, actual endogenous values are found and fed into the lagged endogenous terms. Once the START= observation is reached, dynamic simulation begins, where predicted values are fed into lagged endogenous terms until the end of the data set is reached.

The predicted and residual values generated here are different from those produced by the SYSLIN procedure since PROC SYSLIN uses the structural form with actual endogenous values. The predicted values computed by the SIMLIN procedure solve the simultaneous equation system. These reduced-form predicted values are functions only of the exogenous and lagged endogenous variables and do not depend on actual values of current period endogenous variables.

Syntax: SIMLIN Procedure

The following statements can be used with PROC SIMLIN:

```
PROC SIMLIN options ;
  BY variables ;
  ENDOGENOUS variables ;
  EXOGENOUS variables ;
  ID variables ;
  LAGGED lag-var endogenous-var number ellipsis ;
  OUTPUT OUT=SAS-data-set options ;
```

Functional Summary

The statements and options controlling the SIMLIN procedure are summarized in the following table.

Description	Statement	Option
Data Set Options		
specify input data set containing structural coefficients	PROC SIMLIN	EST=
specify type of estimates read from EST= data set	PROC SIMLIN	TYPE=
write reduced form coefficients and multipliers to an output data set	PROC SIMLIN	OUTEST=
specify the input data set for simulation	PROC SIMLIN	DATA=
write predicted and residual values to an output data set	OUTPUT	
Printing Control Options		
print the structural coefficients	PROC SIMLIN	ESTPRINT
suppress printing of reduced form coefficients	PROC SIMLIN	NORED
suppress all printed output	PROC SIMLIN	NOPRINT
Dynamic Multipliers		
compute interim multipliers	PROC SIMLIN	INTERIM=
compute total multipliers	PROC SIMLIN	TOTAL
Declaring the Role of Variables		
specify BY-group processing	BY	
specify the endogenous variables	ENDOGENOUS	
specify the exogenous variables	EXOGENOUS	
specify identifying variables	ID	
specify lagged endogenous variables	LAGGED	

Description	Statement	Option
Controlling the Simulation		
specify the starting observation for dynamic simulation	PROC SIMLIN	START=

PROC SIMLIN Statement

PROC SIMLIN *options* ;

The following options can be used in the PROC SIMLIN statement:

DATA= *SAS-data-set*

specifies the SAS data set containing input data for the simulation. If the DATA= option is used, the data set specified must supply values for all exogenous variables throughout the simulation. If the DATA= option is not specified, no simulation of the system is performed, and only the reduced form and multipliers are computed.

EST= *SAS-data-set*

specifies the input data set containing the structural coefficients of the system. If EST= is omitted the most recently created SAS data set is used. The EST= data set is normally a "TYPE=EST" data set produced by the OUTEST= option of PROC SYSLIN. However, you can also build the EST= data set with a SAS DATA step. See "The EST= Data Set" later in this chapter for details.

ESTPRINT

prints the structural coefficients read from the EST= data set.

INTERIM= *n*

requests that interim multipliers be computed for interims 1 through *n*. If not specified, no interim multipliers are computed. This feature is available only if there are no lags greater than 1.

NOPRINT

suppresses all printed output.

NORED

suppresses the printing of the reduced form coefficients.

OUTEST= *SAS-data-set*

specifies an output SAS data set to contain the reduced form coefficients and multipliers, in addition to the structural coefficients read from the EST= data set. The OUTEST= data set has the same form as the EST= data set. If the OUTEST= option is not specified, the reduced form coefficients and multipliers are not written to a data set.

START= *n*

specifies the observation number in the DATA= data set where the dynamic simulation is to be started. By default, the dynamic simulation starts with the first observation in the DATA= data set for which all variables (including lags) are not missing.

TOTAL

requests that the total multipliers be computed. This feature is available only if there are no lags greater than 1.

TYPE= value

specifies the type of estimates to be read from the EST= data set. The TYPE= value must match the value of the `_TYPE_` variable for the observations that you want to select from the EST= data set (TYPE=2SLS, for example).

BY Statement

BY variables ;

A BY statement can be used with PROC SIMLIN to obtain separate analyses for groups of observations defined by the BY variables.

The BY statement can be applied to one or both of the EST= and the DATA= input data set. When a BY statement is used and both an EST= and a DATA= input data set are specified, PROC SIMLIN checks to see if one or both of the data sets contain the BY variables.

Thus, there are three ways of using the BY statement with PROC SIMLIN:

1. If the BY variables are found in the EST= data set only, PROC SIMLIN simulates over the entire DATA= data set once for each set of coefficients read from the BY groups in the EST= data set.
2. If the BY variables are found in the DATA= data set only, PROC SIMLIN performs separate simulations over each BY group in the DATA= data set, using the single set of coefficients in the EST= data set.
3. If the BY variables are found in both the EST= and the DATA= data sets, PROC SIMLIN performs separate simulations over each BY group in the DATA= data set using the coefficients from the corresponding BY group in the EST= data set.

ENDOGENOUS Statement

ENDOGENOUS variables ;

List the names of the endogenous (jointly dependent) variables in the ENDOGENOUS statement. The ENDOGENOUS statement can be abbreviated as ENDOG or ENDO.

EXOGENOUS Statement

EXOGENOUS variables ;

List the names of the exogenous (independent) variables in the EXOGENOUS statement. The EXOGENOUS statement can be abbreviated as EXOG or EXO.

ID Statement

ID *variables ;*

The ID statement can be used to restrict the variables copied from the DATA= data set to the OUT= data set. Use the ID statement to list the variables you want copied to the OUT= data set besides the exogenous, endogenous, lagged endogenous, and BY variables. If the ID statement is omitted, all the variables in the DATA= data set are copied to the OUT= data set.

LAGGED Statement

LAGGED *lag-var endogenous-var number ellipsis ;*

For each lagged endogenous variable, specify the name of the lagged variable, the name of the endogenous variable that was lagged, and the degree of the lag. Only one LAGGED statement is allowed.

The following is an example of the use of the LAGGED statement:

```
proc simlin est=e;
  endog y1 y2;
  lagged y1lag1 y1 1   y2lag1 y2 1   y2lag3 y2 3;
run;
```

This statement specifies that the variable Y1LAG1 contains the values of the endogenous variable Y1 lagged one period; the variable Y2LAG1 refers to the values of Y2 lagged one period; and the variable Y2LAG3 refers to the values of Y2 lagged three periods.

OUTPUT Statement

OUTPUT *OUT= SAS-data-set options ;*

The OUTPUT statement specifies that predicted and residual values be put in an output data set. A DATA= input data set must be supplied if the OUTPUT statement is used, and only one OUTPUT statement is allowed. The following options can be used in the OUTPUT statement:

OUT= *SAS-data-set*

names the output SAS data set to contain the predicted values and residuals. If OUT= is not specified, the output data set is named using the DATA*n* convention.

PREDICTED= *names*

P= *names*

names the variables in the output data set that contain the predicted values of the simulation. These variables correspond to the endogenous variables in the order in which they are specified in the ENDOGENOUS statement. Specify up to as many names as there are endogenous variables. If you specify names on the PREDICTED= option for only some of the endogenous variables, predicted values for the remaining variables are not output. The names must not match any variable name in the input data set.

RESIDUAL= *names*

R= *names*

names names the variables in the output data set that contain the residual values from the simulation. The residuals are the differences between the actual values of the endogenous variables from the DATA= data set and the predicted values from the simulation. These variables correspond to the endogenous variables in the order in which they are specified in the ENDOGENOUS statement. Specify up to as many names as there are endogenous variables. The names must not match any variable name in the input data set.

The following is an example of the use of the OUTPUT statement. This example outputs predicted values for Y1 and Y2 and outputs residuals for Y1.

```
proc simlin est=e;
  endog y1 y2;
  output out=b predicted=y1hat y2hat
          residual=y1resid;
run;
```

Details: SIMLIN Procedure

The following sections explain the structural and reduced forms, dynamic multipliers, input data sets, and the model simulation process in more detail.

Defining the Structural Form

An EST= input data set supplies the coefficients of the equation system. The data set containing the coefficients is normally a "TYPE=EST" data set created by the OUTEST= option of PROC SYSLIN or another regression procedure. The data set contains the special variables _TYPE_, _DEPVAR_, and INTERCEPT. You can also supply the structural coefficients of the system to PROC SIMLIN in a data set produced by a SAS DATA step as long as the data set is of the form TYPE=EST. Refer to SAS/STAT software documentation for a discussion of the special TYPE=EST type of SAS data set.

Suppose that there is a $g \times 1$ vector of endogenous variables \mathbf{y}_t , an $l \times 1$ vector of lagged endogenous variables \mathbf{y}_t^L , and a $k \times 1$ vector of exogenous variables \mathbf{x}_t , including the intercept. Then, there are g structural equations in the simultaneous system that can be written

$$\mathbf{G}\mathbf{y}_t = \mathbf{C}\mathbf{y}_t^L + \mathbf{B}\mathbf{x}_t$$

where \mathbf{G} is the matrix of coefficients of current period endogenous variables, \mathbf{C} is the matrix of coefficients of lagged endogenous variables, and \mathbf{B} is the matrix of coefficients of exogenous variables. \mathbf{G} is assumed to be nonsingular.

Computing the Reduced Form

First, the SIMLIN procedure computes reduced form coefficients by premultiplying by \mathbf{G}^{-1} :

$$\mathbf{y}_t = \mathbf{G}^{-1}\mathbf{C}\mathbf{y}_t^L + \mathbf{G}^{-1}\mathbf{B}\mathbf{x}_t$$

This can be written as

$$\mathbf{y}_t = \Pi_1\mathbf{y}_t^L + \Pi_2\mathbf{x}_t$$

where $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$ and $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$ are the reduced form coefficient matrices.

The reduced form matrices $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$ and $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$ are printed unless the NORED option is specified in the PROC SIMLIN statement. The structural coefficient matrices \mathbf{G} , \mathbf{C} , and \mathbf{B} are printed when the ESTPRINT option is specified.

Dynamic Multipliers

For models that have only first-order lags, the equation of the reduced form of the system can be rewritten

$$\mathbf{y}_t = \mathbf{D}\mathbf{y}_{t-1} + \Pi_2\mathbf{x}_t$$

\mathbf{D} is a matrix formed from the columns of Π_1 plus some columns of zeros, arranged in the order in which the variables meet the lags. The elements of Π_2 are called *impact multipliers* because they show the immediate effect of changes in each exogenous variable on the values of the endogenous variables. This equation can be rewritten as

$$\mathbf{y}_t = \mathbf{D}^2\mathbf{y}_{t-2} + \mathbf{D}\Pi_2\mathbf{x}_{t-1} + \Pi_2\mathbf{x}_t$$

The matrix formed by the product $\mathbf{D}\Pi_2$ shows the effect of the exogenous variables one lag back; the elements in this matrix are called *interim multipliers* and are computed and printed when the INTERIM= option is specified in the PROC SIMLIN statement. The i th period interim multipliers are formed by $\mathbf{D}^i\Pi_2$.

The series can be expanded as

$$\mathbf{y}_t = \mathbf{D}^\infty\mathbf{y}_{t-\infty} + \sum_{i=0}^{\infty} \mathbf{D}^i \Pi_2\mathbf{x}_{t-i}$$

A permanent and constant setting of a value for x has the following cumulative effect:

$$\left(\sum_{i=0}^{\infty} \mathbf{D}^i \right) \Pi_2\mathbf{x} = (\mathbf{I} - \mathbf{D})^{-1} \Pi_2\mathbf{x}$$

The elements of $(\mathbf{I} - \mathbf{D})^{-1} \Pi_2$ are called the *total multipliers*. Assuming that the sum converges and that $(\mathbf{I} - \mathbf{D})$ is invertible, PROC SIMLIN computes the total multipliers when the TOTAL option is specified in the PROC SIMLIN statement.

Multipliers for Higher Order Lags

The dynamic multiplier options require the system to have no lags of order greater than one. This limitation can be circumvented, since any system with lags greater than one can be rewritten as a system where no lag is greater than one by forming new endogenous variables that are single-period lags.

For example, suppose you have the third-order single equation

$$y_t = ay_{t-3} + b\mathbf{x}_t$$

This can be converted to a first-order three-equation system by introducing two additional endogenous variables, $y_{1,t}$ and $y_{2,t}$, and computing corresponding first-order lagged variables for each endogenous variable: y_{t-1} , $y_{1,t-1}$, and $y_{2,t-1}$. The higher order lag relations are then produced by adding identities to link the endogenous and identical lagged endogenous variables:

$$y_{1,t} = y_{t-1}$$

$$y_{2,t} = y_{1,t-1}$$

$$y_t = ay_{2,t-1} + b\mathbf{X}_t$$

This conversion using the SYSLIN and SIMLIN procedures requires three steps:

1. Add the extra endogenous and lagged endogenous variables to the input data set using a DATA step. Note that two copies of each lagged endogenous variable are needed for each lag reduced, one to serve as an endogenous variable and one to serve as a lagged endogenous variable in the reduced system.
2. Add IDENTITY statements to the PROC SYSLIN step to equate each added endogenous variable to its lagged endogenous variable copy.
3. In the PROC SIMLIN step, declare the added endogenous variables in the ENDOGENOUS statement and define the lag relations in the LAGGED statement.

See [Example 25.2](#) for an illustration of how to convert an equation system with higher-order lags into a larger system with only first-order lags.

EST= Data Set

Normally, PROC SIMLIN uses an EST= data set produced by PROC SYSLIN with the OUTEST= option. This data set is in the form expected by PROC SIMLIN. If there is more than one set of estimates produced by PROC SYSLIN, you must use the TYPE= option in the PROC SIMLIN statement to select the set to be simulated. Then PROC SIMLIN reads from the EST= data set only those observations with a _TYPE_ value corresponding to the TYPE= option (for example, TYPE=2SLS) or with a _TYPE_ value of IDENTITY.

The SIMLIN procedure can only solve square, nonsingular systems. If you have fewer equations than endogenous variables, you must specify IDENTITY statements in the PROC SYSLIN step to bring the system up to full rank. If there are g endogenous variables and $m < g$ stochastic equations with unknown

parameters, then you use m MODEL statements to specify the equations with parameters to be estimated and you must use $g-m$ IDENTITY statements to complete the system.

You can build your own EST= data set with a DATA step rather than use PROC SYSLIN. The EST= data set must contain the endogenous variables, the lagged endogenous variables (if any), and the exogenous variables in the system (if any). If any of the equations have intercept terms, the variable INTERCEPT must supply these coefficients. The EST= data set should also contain the special character variable comp _DEPVAR_ to label the equations.

The EST= data set must contain one observation for each equation in the system. The values of the lagged endogenous variables must contain the **C** coefficients. The values of the exogenous variables and the INTERCEPT variable must contain the **B** coefficients. The values of the endogenous variables, however, must contain the negatives of the **G** coefficients. This is because the SYSLIN procedure writes the coefficients to the OUTEST= data set in the form

$$0 = \mathbf{H}\mathbf{y}_t + \mathbf{C}\mathbf{y}_t^L + \mathbf{B}\mathbf{x}_t$$

where $\mathbf{H} = -\mathbf{G}$.

See "Multipliers for Higher Order Lags" and [Example 25.2](#) later in this chapter for more information on building the EST= data set.

DATA= Data Set

The DATA= data set must contain all of the exogenous variables. Values for all of the exogenous variables are required for each observation for which predicted endogenous values are desired. To forecast past the end of the historical data, the DATA= data set should contain nonmissing values for all of the exogenous variables and missing values for the endogenous variables for the forecast periods, in addition to the historical data. (See [Example 25.1](#) for an illustration.)

In order for PROC SIMLIN to output residuals and compute statistics of fit, the DATA= data set must also contain the endogenous variables with nonmissing actual values for each observation for which residuals and statistics are to be computed.

If the system contains lags, initial values must be supplied for the lagged variables. This can be done by including either the lagged variables or the endogenous variables, or both, in the DATA= data set. If the lagged variables are not in the DATA= data set or if they have missing values in the early observations, PROC SIMLIN prints a warning and uses the endogenous variable values from the early observations to initialize the lags.

OUTEST= Data Set

The OUTEST= data set contains all the variables read from the EST= data set. The variables in the OUTEST= data set are as follows.

- the BY statement variables, if any
- _TYPE_, a character variable that identifies the type of observation

- `_DEPVAR_`, a character variable containing the name of the dependent variable for the observation
- the endogenous variables
- the lagged endogenous variables
- the exogenous variables
- `INTERCEPT`, a numeric variable containing the intercept values
- `_MODEL_`, a character variable containing the name of the equation
- `_SIGMA_`, a numeric variable containing the estimated error variance of the equation (output only if present in the `EST=` data set)

The observations read from the `EST=` data set that supply the structural coefficients are copied to the `OUT=` data set, except that the signs of endogenous coefficients are reversed. For these observations, the `_TYPE_` variable values are the same as in the `EST=` data set.

In addition, the `OUTEST=` data set contains observations with the following `_TYPE_` values:

REDUCED	the reduced form coefficients. The endogenous variables for this group of observations contain the inverse of the endogenous coefficient matrix \mathbf{G} . The lagged endogenous variables contain the matrix $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$. The exogenous variables contain the matrix $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$.
IMULT<i>i</i>	the interim multipliers, if the <code>INTERIM=</code> option is specified. There are gn observations for the interim multipliers, where g is the number of endogenous variables and n is the value of the <code>INTERIM=n</code> option. For these observations the <code>_TYPE_</code> variable has the value <code>IMULT<i>i</i></code> , where the interim number i ranges from 1 to n . The exogenous variables in groups of g observations that have a <code>_TYPE_</code> value of <code>IMULT<i>i</i></code> contain the matrix $\mathbf{D}^i \Pi_2$ of multipliers at interim i . The endogenous and lagged endogenous variables for this group of observations are set to missing.
TOTAL	the total multipliers, if the <code>TOTAL</code> option is specified. The exogenous variables in this group of observations contain the matrix $(\mathbf{I} - \mathbf{D})^{-1} \Pi_2$. The endogenous and lagged endogenous variables for this group of observations are set to missing.

OUT= Data Set

The `OUT=` data set normally contains all of the variables in the input `DATA=` data set, plus the variables named in the `PREDICTED=` and `RESIDUAL=` options in the `OUTPUT` statement.

You can use an `ID` statement to restrict the variables that are copied from the input data set. If an `ID` statement is used, the `OUT=` data set contains only the `BY` variables (if any), the `ID` variables, the endogenous and lagged endogenous variables (if any), the exogenous variables, plus the `PREDICTED=` and `RESIDUAL=` variables.

The `OUT=` data set contains an observation for each observation in the `DATA=` data set. When the actual value of an endogenous variable is missing in the `DATA=` data set, or when the `DATA=` data set does not contain the endogenous variable, the corresponding residual is missing.

Printed Output

Structural Form

The following items are printed as they are read from the EST= input data set. Structural zeros are printed as dots in the listing of these matrices.

1. Structural Coefficients for Endogenous Variables. This is the **G** matrix, with g rows and g columns.
2. Structural Coefficients for Lagged Endogenous Variables. These coefficients make up the **C** matrix, with g rows and l columns.
3. Structural Coefficients for Exogenous Variables. These coefficients make up the **B** matrix, with g rows and k columns.

Reduced Form

1. The reduced form coefficients are obtained by inverting **G** so that the endogenous variables can be directly expressed as functions of only lagged endogenous and exogenous variables.
2. Inverse Coefficient Matrix for Endogenous Variables. This is the inverse of the **G** matrix.
3. Reduced Form for Lagged Endogenous Variables. This is $\Pi_1 = \mathbf{G}^{-1}\mathbf{C}$, with g rows and l columns. Each value is a dynamic multiplier that shows how past values of lagged endogenous variables affect values of each of the endogenous variables.
4. Reduced Form for Exogenous Variables. This is $\Pi_2 = \mathbf{G}^{-1}\mathbf{B}$, with g rows and k columns. Its values are called *impact multipliers* because they show the immediate effect of each exogenous variable on the value of the endogenous variables.

Multipliers

Interim and total multipliers show the effect of a change in an exogenous variable over time.

1. Interim Multipliers. These are the interim multiplier matrices. They are formed by multiplying Π_2 by powers of **D**. The d th interim multiplier is $\mathbf{D}^d \Pi_2$. The interim multiplier of order d shows the effects of a change in the exogenous variables after d periods. Interim multipliers are only available if the maximum lag of the endogenous variables is 1.
2. Total Multipliers. This is the matrix of total multipliers, $\mathbf{T} = (\mathbf{I} - \mathbf{D})^{-1} \Pi_2$. This matrix shows the cumulative effect of changes in the exogenous variables. Total multipliers are only available if the maximum lag is one.

Statistics of Fit

If the DATA= option is used and the DATA= data set contains endogenous variables, PROC SIMLIN prints a statistics-of-fit report for the simulation. The statistics printed include the following. (Summations are over the observations for which both y_t and \hat{y}_t are nonmissing.)

1. the number of nonmissing errors. (Number of observations for which both y_t and \hat{y}_t are nonmissing.)
2. the mean error: $\frac{1}{n} \sum (y_t - \hat{y}_t)$
3. the mean percent error: $\frac{100}{n} \sum \frac{(y_t - \hat{y}_t)}{y_t}$
4. the mean absolute error: $\frac{1}{n} \sum |y_t - \hat{y}_t|$
5. the mean absolute percent error $\frac{100}{n} \sum \frac{|y_t - \hat{y}_t|}{y_t}$
6. the root mean square error: $\sqrt{\frac{1}{n} \sum (y_t - \hat{y}_t)^2}$
7. the root mean square percent error: $\sqrt{\frac{100}{n} \sum \left(\frac{(y_t - \hat{y}_t)}{y_t}\right)^2}$

ODS Table Names

PROC SIMLIN assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 25.2 ODS Tables Produced in PROC SIMLIN

ODS Table Name	Description	Option
Endogenous	Structural Coefficients for Endogenous Variables	default
LaggedEndogenous	Structural Coefficients for Lagged Endogenous Variables	default
Exogenous	Structural Coefficients for Exogenous Variables	default

TotalMult	Total Multipliers	TOTAL= option
FitStatistics	Fit statistics	default

Examples: SIMLIN Procedure

Example 25.1: Simulating Klein's Model I

In this example, the SIMLIN procedure simulates a model of the U.S. economy called Klein's Model I. The SAS data set KLEIN is used as input to the SYSLIN and SIMLIN procedures.

```
data klein;
  input year c p w i x wp g t k wsum;
  date=mdy(1,1,year);
  format date year.;
  y  = c + i + g - t;
  yr = year - 1931;
  klag = lag( k );
  plag = lag( p );
  xlag = lag( x );
  if year >= 1921;
  label c    ='consumption'
        p    ='profits'
        w    ='private wage bill'
        i    ='investment'
        k    ='capital stock'
        y    ='national income'
        x    ='private production'
        wsum ='total wage bill'
        wp   ='govt wage bill'
        g    ='govt demand'
        t    ='taxes'
        klag ='capital stock lagged'
        plag ='profits lagged'
        xlag ='private product lagged'
        yr   ='year-1931';
datalines;
1920      .  12.7      .      .  44.9      .      .      .  182.8      .
1921  41.9  12.4  25.5 -0.2  45.6  2.7    3.9    7.7  182.6  28.2

... more lines ...
```

First, the model is specified and estimated using the SYSLIN procedure, and the parameter estimates are written to an OUTEST= data set. The printed output produced by the SYSLIN procedure is not shown here; see [Example 29.1](#) in [Chapter 29](#) for the printed output of the PROC SYSLIN step.

```

title1 'Simulation of Klein''s Model I using SIMLIN';
proc syslin 3sls data=klein outest=a;

    instruments klag plag xlag wp g t yr;
    endogenous c p w i x wsum k y;

    consume: model    c = p plag wsum;
    invest:  model    i = p plag klag;
    labor:   model    w = x xlag yr;

    product: identity x = c + i + g;
    income:  identity y = c + i + g - t;
    profit:  identity p = x - w - t;
    stock:   identity k = klag + i;
    wage:    identity wsum = w + wp;
run;

```

The OUTEST= data set A created by the SYSLIN procedure contains parameter estimates to be used by the SIMLIN procedure. The OUTEST= data set is shown in [Output 25.1.1](#).

Using the OUTEST= data set A produced by the SYSLIN procedure, the SIMLIN procedure can now compute the reduced form and simulate the model. The following statements perform the simulation.

```

title1 'Simulation of Klein''s Model I using SIMLIN';
proc simlin data=klein
    est=a type=3sls
    estprint
    total interim=2
    outest=b;
    endogenous c p w i x wsum k y;
    exogenous wp g t yr;
    lagged klag k 1   plag p 1   xlag x 1;
    id year;
    output out=c p=chat phat what ihat xhat wsumhat khat yhat
           r=cres pres wres ires xres wsumres kres yres;
run;

```

The reduced form coefficients and multipliers are added to the information read from EST= data set A and written to the OUTEST= data set B. The predicted and residual values from the simulation are written to the OUT= data set C specified in the OUTPUT statement.

The SIMLIN procedure first prints the structural coefficient matrices read from the EST= data set, as shown in [Output 25.1.2](#) through [Output 25.1.4](#).

Output 25.1.2 SIMLIN Procedure Output – Endogenous Structural Coefficients

Simulation of Klein's Model I using SIMLIN				
The SIMLIN Procedure				
Structural Coefficients for Endogenous Variables				
Variable	c	p	w	i
c	1.0000	-0.1249	.	.
i	.	0.0131	.	1.0000
w	.	.	1.0000	.
x	-1.0000	.	.	-1.0000
y	-1.0000	.	.	-1.0000
p	.	1.0000	1.0000	.
k	.	.	.	-1.0000
wsum	.	.	-1.0000	.
Structural Coefficients for Endogenous Variables				
Variable	x	wsum	k	y
c	.	-0.7901	.	.
i
w	-0.4005	.	.	.
x	1.0000	.	.	.
y	.	.	.	1.0000
p	-1.0000	.	.	.
k	.	.	1.0000	.
wsum	.	1.0000	.	.

Output 25.1.3 SIMLIN Procedure Output – Lagged Endogenous Structural Coefficients

Structural Coefficients for Lagged Endogenous Variables			
Variable	klag	plag	xlag
c	.	0.1631	.
i	-0.1948	0.7557	.
w	.	.	0.1813
x	.	.	.
y	.	.	.
p	.	.	.
k	1.0000	.	.
wsum	.	.	.

Output 25.1.4 SIMLIN Procedure Output – Exogenous Structural Coefficients

Structural Coefficients for Exogenous Variables					
Variable	wp	g	t	yr	Intercept
c	16.4408
i	28.1778
w	.	.	.	0.1497	1.7972
x	.	1.0000	.	.	0
y	.	1.0000	-1.0000	.	0
p	.	.	-1.0000	.	0
k	0
wsum	1.0000	.	.	.	0

The SIMLIN procedure then prints the inverse of the endogenous variables coefficient matrix, as shown in [Output 25.1.5](#).

Output 25.1.5 SIMLIN Procedure Output – Inverse Coefficient Matrix

Inverse Coefficient Matrix for Endogenous Variables				
Variable	c	i	w	x
c	1.6347	0.6347	1.0957	0.6347
p	0.9724	0.9724	-0.3405	0.9724
w	0.6496	0.6496	1.4406	0.6496
i	-0.0127	0.9873	0.004453	-0.0127
x	1.6219	1.6219	1.1001	1.6219
wsum	0.6496	0.6496	1.4406	0.6496
k	-0.0127	0.9873	0.004453	-0.0127
y	1.6219	1.6219	1.1001	0.6219

Inverse Coefficient Matrix for Endogenous Variables				
Variable	y	p	k	wsum
c	0	0.1959	0	1.2915

The actual and predicted values for the variable C are plotted in [Output 25.1.11](#).

```
title2 'Plots of Simulation Results';
proc sgplot data=c;
  scatter x=year y=c;
  series x=year y=chat / markers markerattrs=(symbol=plus);
  refline 1941.5 / axis=x;
run;
```

Output 25.1.11 Plot of Actual and Predicted Consumption

Example 25.2: Multipliers for a Third-Order System

This example shows how to fit and simulate a single equation dynamic model with third-order lags. It then shows how to convert the third-order equation into a three equation system with only first-order lags, so that the SIMLIN procedure can compute multipliers. (See the section "Multipliers for Higher Order Lags" earlier in this chapter for more information.)

The input data set TEST is created from simulated data. A partial listing of the data set TEST produced by PROC PRINT is shown in [Output 25.2.1](#).

Output 25.2.1 Partial Listing of Input Data Set

Simulate Equation with Third-Order Lags Listing of Simulated Input Data

Overview: SPECTRA Procedure

The SPECTRA procedure performs spectral and cross-spectral analysis of time series. You can use spectral analysis techniques to look for periodicities or cyclical patterns in data.

The SPECTRA procedure produces estimates of the spectral and cross-spectral densities of a multivariate time series. Estimates of the spectral and cross-spectral densities of a multivariate time series are produced using a finite Fourier transform to obtain periodograms and cross-periodograms. The periodogram ordinates are smoothed by a moving average to produce estimated spectral and cross-spectral densities. PROC SPECTRA can also test whether or not the data are white noise.

PROC SPECTRA uses the finite Fourier transform to decompose data series into a sum of sine and cosine waves of different amplitudes and wavelengths. The finite Fourier transform decomposition of the series x_t is

$$x_t = \frac{a_0}{2} + \sum_{k=1}^{m-1} f_k (a_k \cos \omega_k t + b_k \sin \omega_k t)$$

$$f_k = \begin{cases} 1/2 & \text{if } n \text{ is even and } k = m - 1 \\ 1 & \text{otherwise} \end{cases}$$

where

t	is the time subscript, $t = 0, 1, 2, \dots, n - 1$
x_t	are the equally spaced time series data
n	is the number of observations in the time series
m	is the number of frequencies in the Fourier decomposition: $m = \frac{n+2}{2}$ if n is even, $m = \frac{n+1}{2}$ if n is odd
k	is the frequency subscript, $k = 0, 1, 2, \dots, m - 1$
a_0	is the mean term: $a_0 = 2\bar{x}$
a_k	are the cosine coefficients
b_k	are the sine coefficients
ω_k	are the Fourier frequencies: $\omega_k = \frac{2\pi k}{n}$

Functions of the Fourier coefficients a_k and b_k can be plotted against frequency or against wave length to form *periodograms*. The amplitude periodogram J_k is defined as follows:

$$J_k = \frac{n}{2}(a_k^2 + b_k^2)$$

Several definitions of the term periodogram are used in the spectral analysis literature. The following discussion refers to the J_k sequence as the periodogram.

The periodogram can be interpreted as the contribution of the k th harmonic ω_k to the total sum of squares (in an analysis of variance sense) in the decomposition of the process into two-degree-of-freedom components for each of the m frequencies. When n is even, $\sin(\omega_{\frac{n}{2}})$ is zero, and thus the last periodogram value is a one-degree-of-freedom component.

The periodogram is a volatile and inconsistent estimator of the spectrum. The spectral density estimate is produced by smoothing the periodogram. Smoothing reduces the variance of the estimator but introduces a bias. The weight function used for the smoothing process, $W()$, often called the kernel or spectral window, is specified with the WEIGHTS statement. It is related to another weight function, $w()$, the lag window, that is used in other methods to taper the correlogram rather than to smooth the periodogram. Many specific weighting functions have been suggested in the literature (Fuller 1976, Jenkins and Watts 1968, Priestly 1981). Table 26.3 later in this chapter gives the relevant formulas when the WEIGHTS statement is used.

Letting i represent the imaginary unit $\sqrt{-1}$, the cross-periodogram is defined as follows:

$$J_k^{xy} = \frac{n}{2}(a_k^x a_k^y + b_k^x b_k^y) + i \frac{n}{2}(a_k^x b_k^y - b_k^x a_k^y)$$

The cross-spectral density estimate is produced by smoothing the cross-periodogram in the same way as the periodograms are smoothed using the spectral window specified by the WEIGHTS statement.

The SPECTRA procedure creates an output SAS data set whose variables contain values of the periodograms, cross-periodograms, estimates of spectral densities, and estimates of cross-spectral densities. The form of the output data set is described in the section “[OUT= Data Set](#)” on page 1797.

Getting Started: SPECTRA Procedure

To use the SPECTRA procedure, specify the input and output data sets and options for the analysis you want in the PROC SPECTRA statement, and list the variables to analyze in the VAR statement. The procedure produces no printed output unless the WHITESTEST option is specified in the PROC SPECTRA statement. The periodogram, spectral density, and other results are written to the OUT= data set, depending on the options used.

For example, to compute the Fourier transform of a variable X in a data set A, use the following statements:

```
proc spectra data=a out=b coef;
  var x;
run;
```

This PROC SPECTRA step writes the Fourier coefficients a_k and b_k to the variables COS_01 and SIN_01 in the output data set B.

When a WEIGHTS statement is specified, the periodogram is smoothed by a weighted moving average to produce an estimate of the spectral density of the series. The following statements write a spectral density estimate for X to the variable S_01 in the output data set B.

```
proc spectra data=a out=b s;
  var x;
  weights 1 2 3 4 3 2 1;
run;
```

When the VAR statement specifies more than one variable, you can perform cross-spectral analysis by specifying the CROSS option in the PROC SPECTRA statement. The CROSS option by itself produces the cross-periodograms for all two-way combinations of the variables listed in the VAR statement. For example, the following statements write the real and imaginary parts of the cross-periodogram of X and Y to the variables RP_01_02 and IP_01_02 in the output data set B.

```
proc spectra data=a out=b cross;
  var x y;
run;
```

To produce cross-spectral density estimates, specify both the CROSS option and the S option. The cross-periodogram is smoothed using the weights specified by the WEIGHTS statement in the same way as the spectral density. The squared coherency and phase estimates of the cross-spectrum are computed when the K and PH options are used.

The following example computes cross-spectral density estimates for the variables X and Y.

```
proc spectra data=a out=b cross s;
  var x y;
  weights 1 2 3 4 3 2 1;
run;
```

The real part and imaginary part of the cross-spectral density estimates are written to the variables CS_01_02 and QS_01_02, respectively.

Syntax: SPECTRA Procedure

The following statements are used with the SPECTRA procedure:

```
PROC SPECTRA options ;
BY variables ;
VAR variables ;
WEIGHTS < weights> < kernel> ;
```

Functional Summary

Table 26.1 summarizes the statements and options that control the SPECTRA procedure.

Table 26.1 SPECTRA Functional Summary

Description	Statement	Option
Statements		
specify BY-group processing	BY	
specify the variables to be analyzed	VAR	
specify weights for spectral density estimates	WEIGHTS	
Data Set Options		
specify the input data set	PROC SPECTRA	DATA=

output the amplitudes of the cross-spectrum	PROC SPECTRA	A
output the Fourier coefficients	PROC SPECTRA	COEF
output the periodogram	PROC SPECTRA	P
output the spectral density estimates	PROC SPECTRA	S
output cross-spectral analysis results	PROC SPECTRA	CROSS
output squared coherency of the cross-spectrum	PROC SPECTRA	K
output the phase of the cross-spectrum	PROC SPECTRA	PH
Smoothing Options		
specify the Bartlett kernel	WEIGHTS	BART

Table 26.1 *continued*

Description	Statement	Option
specify the Parzen kernel	WEIGHTS	PARZEN
specify the quadratic spectral kernel	WEIGHTS	QS
specify the Tukey-Hanning kernel	WEIGHTS	TUKEY
specify the truncated kernel	WEIGHTS	TRUNCAT
Other Options		
subtract the series mean	PROC SPECTRA	ADJMEAN
specify an alternate quadrature spectrum estimate	PROC SPECTRA	ALTW
request tests for white noise	PROC SPECTRA	WHITESTEST

PROC SPECTRA Statement

PROC SPECTRA *options* ;

The following options can be used in the PROC SPECTRA statement:

A

outputs the amplitude variables (A_{nn_mm}) of the cross-spectrum.

ADJMEAN

CENTER

subtracts the series mean before performing the Fourier decomposition. This sets the first periodogram ordinate to 0 rather than $2n$ times the squared mean. This option is commonly used when the periodograms are to be plotted to prevent a large first periodogram ordinate from distorting the scale of the plot.

ALTW

specifies that the quadrature spectrum estimate is computed at the boundaries in the same way as the spectral density estimate and the cospectrum estimate are computed.

COEF

outputs the Fourier cosine and sine coefficients of each series.

CROSS

is used with the P and S options to output cross-periodograms and cross-spectral densities when more than one variable is listed in the VAR statement.

DATA=SAS-data-set

names the SAS data set that contains the input data. If the DATA= option is omitted, the most recently created SAS data set is used.

K

outputs the squared coherency variables (K_{nn_mm}) of the cross-spectrum. The K_{nn_mm} variables are identically 1 unless weights are given in the WEIGHTS statement and the S option is specified.

OUT=SAS-data-set

names the output data set created by PROC SPECTRA to store the results. If the OUT= option is omitted, the output data set is named by using the DATA n convention.

P

outputs the periodogram variables. The variables are named P_{nn} , where nn is an index of the original variable with which the periodogram variable is associated. When both the P and CROSS options are specified, the cross-periodogram variables RP_{nn_mm} and IP_{nn_mm} are also output.

PH

outputs the phase variables (PH_{nn_mm}) of the cross-spectrum.

S

outputs the spectral density estimates. The variables are named S_{nn} , where nn is an index of the original variable with which the estimate variable is associated. When both the S and CROSS options are specified, the cross-spectral variables CS_{nn_mm} and QS_{nn_mm} are also output.

WHITETEST

prints two tests of the hypothesis that the data are white noise. See the section “[White Noise Test](#)” on page 1797 for details.

Note that the CROSS, A, K, and PH options are meaningful only if more than one variable is listed in the VAR statement.

BY Statement

BY *variables* ;

A BY statement can be used with PROC SPECTRA to obtain separate analyses for groups of observations defined by the BY variables.

VAR Statement

VAR *variables* ;

The VAR statement specifies one or more numeric variables that contain the time series to analyze. The order of the variables in the VAR statement list determines the index, nn , used to name the output variables. The VAR statement is required.

WEIGHTS Statement

WEIGHTS *weight-constants / kernel-specification* ;

The WEIGHTS statement specifies the relative weights used in the moving average applied to the periodogram ordinates to form the spectral density estimates. A WEIGHTS statement must be used to produce smoothed spectral density estimates. You can specify the relative weights in two ways: you can specify them explicitly as explained in the section “[Using Weight Constants Specification](#)” on page 1793, or you can specify them implicitly by using the kernel specification as explained in the section “[Using Kernel Specifications](#)” on page 1793. If the WEIGHTS statement is not used, only the periodogram is produced.

Using Weight Constants Specification

Any number of weighting constants can be specified. The constants should be positive and symmetric about the middle weight. The middle constant (or the constant to the right of the middle if an even number of weight constants are specified) is the relative weight of the current periodogram ordinate. The constant immediately following the middle one is the relative weight of the next periodogram ordinate, and so on. The actual weights used in the smoothing process are the weights specified in the WEIGHTS statement scaled so that they sum to $\frac{1}{4\pi}$.

The moving average reflects at each end of the periodogram. The first periodogram ordinate is not used; the second periodogram ordinate is used in its place.

For example, a simple triangular weighting can be specified using the following WEIGHTS statement:

```
weights 1 2 3 2 1;
```

Using Kernel Specifications

You can specify five different kernels in the WEIGHTS statement. The syntax for the statement is

WEIGHTS [PARZEN][BART][TUKEY][TRUNCAT][QS] [*c e*] ;

where $c \geq 0$ and $e \geq 0$ are used to compute the bandwidth parameter as

$$l(q) = cq^e$$

and q is the number of periodogram ordinates + 1:

$$q = \text{floor}(n/2) + 1$$

To specify the bandwidth explicitly, set $c =$ to the desired bandwidth and $e = 0$.

For example, a Parzen kernel can be specified using the following WEIGHTS statement:

```
weights parzen 0.5 0;
```

For details, see the section “[Kernels](#)” on page 1794.

Details: SPECTRA Procedure

Input Data

Observations in the data set analyzed by the SPECTRA procedure should form ordered, equally spaced time series. No more than 99 variables can be included in the analysis.

Data are often detrended before analysis by the SPECTRA procedure. This can be done by using the residuals output by a SAS regression procedure. Optionally, the data can be centered using the ADJMEAN option in the PROC SPECTRA statement, since the zero periodogram ordinate corresponding to the mean is of little interest from the point of view of spectral analysis.

Missing Values

Missing values are excluded from the analysis by the SPECTRA procedure. If the SPECTRA procedure encounters missing values for any variable listed in the VAR statement, the procedure determines the longest contiguous span of data that has no missing values for the variables listed in the VAR statement and uses that span for the analysis.

Computational Method

If the number of observations n factors into prime integers that are less than or equal to 23, and the product of the square-free factors of n is less than 210, then PROC SPECTRA uses the fast Fourier transform developed by Cooley and Tukey and implemented by Singleton (1969). If n cannot be factored in this way, then PROC SPECTRA uses a Chirp-Z algorithm similar to that proposed by Monro and Branch (1976). To reduce memory requirements, when n is small, the Fourier coefficients are computed directly using the defining formulas.

Kernels

Kernels are used to smooth the periodogram by using a weighted moving average of nearby points. A smoothed periodogram is defined by the following equation.

$$\hat{J}_i(l(q)) = \sum_{\tau=-l(q)}^{l(q)} w\left(\frac{\tau}{l(q)}\right) \tilde{J}_{i+\tau}$$

where $w(x)$ is the kernel or weight function. At the endpoints, the moving average is computed cyclically; that is,

$$\tilde{J}_{i+\tau} = \begin{cases} J_{i+\tau} & 0 \leq i + \tau \leq q \\ J_{-(i+\tau)} & i + \tau < 0 \\ J_{q-(i+\tau)} & i + \tau > q \end{cases}$$

The SPECTRA procedure supports the following kernels. They are listed with their default bandwidth functions.

Bartlett: KERNEL BART

$$\begin{aligned} w(x) &= \begin{cases} 1 - |x| & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(q) &= \frac{1}{2}q^{1/3} \end{aligned}$$

Parzen: KERNEL PARZEN

$$\begin{aligned} w(x) &= \begin{cases} 1 - 6|x|^2 + 6|x|^3 & 0 \leq |x| \leq \frac{1}{2} \\ 2(1 - |x|)^3 & \frac{1}{2} \leq |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(q) &= q^{1/5} \end{aligned}$$

Quadratic spectral: KERNEL QS

$$\begin{aligned} w(x) &= \frac{25}{12\pi^2 x^2} \left(\frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right) \\ l(q) &= \frac{1}{2}q^{1/5} \end{aligned}$$

Tukey-Hanning: KERNEL TUKEY

$$\begin{aligned} w(x) &= \begin{cases} (1 + \cos(\pi x))/2 & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(q) &= \frac{2}{3}q^{1/5} \end{aligned}$$

Truncated: KERNEL TRUNCAT

$$\begin{aligned} w(x) &= \begin{cases} 1 & |x| \leq 1 \\ 0 & \text{otherwise} \end{cases} \\ l(q) &= \frac{1}{4}q^{1/5} \end{aligned}$$

A summary of the default values of the bandwidth parameters, c and e , associated with the kernel smoothers in PROC SPECTRA are listed below in Table 26.2:

Table 26.2 Bandwidth Parameters

Kernel	c	e
Bartlett	$1/2$	$1/3$
Parzen	1	$1/5$
quadratic	$1/2$	$1/5$
Tukey-Hanning	$2/3$	$1/5$
truncated	$1/4$	$1/5$

Figure 26.1 Kernels for Smoothing

See Andrews (1991) for details about the properties of these kernels.

White Noise Test

PROC SPECTRA prints two test statistics for white noise when the WHITETEST option is specified: Fisher's Kappa (Davis 1941, Fuller 1976) and Bartlett's Kolmogorov-Smirnov statistic (Bartlett 1966, Fuller 1976, Durbin 1967).

If the time series is a sequence of independent random variables with mean 0 and variance σ^2 , then the periodogram, J_k , will have the same expected value for all k . For a time series with nonzero autocorrelation, each ordinate of the periodogram, J_k , will have different expected values. The Fisher's Kappa statistic tests whether the largest J_k can be considered different from the mean of the J_k . Critical values for the Fisher's Kappa test can be found in Fuller 1976.

The Kolmogorov-Smirnov statistic reported by PROC SPECTRA has the same asymptotic distribution as Bartlett's test (Durbin 1967). The Kolmogorov-Smirnov statistic compares the normalized cumulative periodogram with the cumulative distribution function of a uniform(0,1) random variable. The normalized cumulative periodogram, F_j , of the series is

$$F_j = \frac{\sum_{k=1}^j J_k}{\sum_{k=1}^m J_k}, j = 1, 2, \dots, m-1$$

where $m = \frac{n}{2}$ if n is even or $m = \frac{n-1}{2}$ if n is odd. The test statistic is the maximum absolute difference of the normalized cumulative periodogram and the uniform cumulative distribution function. Approximate p -values for Bartlett's Kolmogorov-Smirnov test statistics are provided with the test statistics. Small p -values cause you to reject the null-hypothesis that the series is white noise.

Transforming Frequencies

The variable FREQ in the data set created by the SPECTRA procedure ranges from 0 to π . Sometimes it is preferable to express frequencies in cycles per observation period, which is equal to $\frac{1}{2\pi}$ FREQ.

To express frequencies in cycles per unit time (for example, in cycles per year), multiply FREQ by $\frac{d}{2\pi}$, where d is the number of observations per unit of time. For example, for monthly data, if the desired time unit is years then d is 12. The period of the cycle is $\frac{2\pi}{d \times \text{FREQ}}$, which ranges from $\frac{2}{d}$ to infinity.

OUT= Data Set

The OUT= data set contains $\frac{n}{2} + 1$ observations, if n is even, or $\frac{n+1}{2}$ observations, if n is odd, where n is the number of observations in the time series or the span of data being analyzed if missing values are present in the data. See the section “[Missing Values](#)” on page 1794 for details.

The variables in the new data set are named according to the following conventions. Each variable to be analyzed is associated with an index. The first variable listed in the VAR statement is indexed as 01, the second variable as 02, and so on. Output variables are named by combining indexes with prefixes. The prefix always identifies the nature of the new variable, and the indices identify the original variables from which the statistics were obtained.

Variables that contain spectral analysis results have names that consist of a prefix, an underscore, and the index of the variable analyzed. For example, the variable S_01 contains spectral density estimates for the

first variable in the VAR statement. Variables that contain cross-spectral analysis results have names that consist of a prefix, an underscore, the index of the first variable, another underscore, and the index of the second variable. For example, the variable A_01_02 contains the amplitude of the cross-spectral density estimate for the first and second variables in the VAR statement.

Table 26.3 shows the formulas and naming conventions used for the variables in the OUT= data set. Let X be variable number *nn* in the VAR statement list and let Y be variable number *mm* in the VAR statement list. Table 26.3 shows the output variables that contain the results of the spectral and cross-spectral analysis of X and Y.

In Table 26.3 the following notation is used. Let W_j be the vector of $2p + 1$ smoothing weights given by the WEIGHTS statement, normalized to sum to $\frac{1}{4\pi}$. Note that the weights are either explicitly provided using the constant specification or are implicitly determined by the kernel specification in the WEIGHTS statement.

The subscript of W_j runs from W_{-p} to W_p , so that W_0 is the middle weight in the list. Let $\omega_k = \frac{2\pi k}{n}$, where $k = 0, 1, \dots, \text{floor}(\frac{n}{2})$.

Table 26.3 Variables Created by PROC SPECTRA

Variable	Description
FREQ	frequency in radians from 0 to π (Note: Cycles per observation is $\frac{\text{FREQ}}{2\pi}$.)
PERIOD	period or wavelength: $\frac{2\pi}{\text{FREQ}}$ (Note: PERIOD is missing for FREQ=0.)
COS_nn	cosine transform of X: $a_k^x = \frac{2}{n} \sum_{t=1}^n X_t \cos(\omega_k(t-1))$
SIN_nn	sine transform of X: $b_k^x = \frac{2}{n} \sum_{t=1}^n X_t \sin(\omega_k(t-1))$
P_nn	periodogram of X: $J_k^x = \frac{n}{2} [(a_k^x)^2 + (b_k^x)^2]$
S_nn	spectral density estimate of X: $F_k^x = \sum_{j=-p}^p W_j J_{k+j}^x$ (except across endpoints)
RP_nn_mm	real part of cross-periodogram X and Y: $\text{real}(J_k^{xy}) = \frac{n}{2} (a_k^x a_k^y + b_k^x b_k^y)$
IP_nn_mm	imaginary part of cross-periodogram of X and Y: $\text{imag}(J_k^{xy}) = \frac{n}{2} (a_k^x b_k^y - b_k^x a_k^y)$
CS_nn_mm	cospectrum estimate (real part of cross-spectrum) of X and Y: $C_k^{xy} = \sum_{j=-p}^p W_j \text{real}(J_{k+j}^{xy})$ (except across endpoints)

Table 26.3 *continued*

Variable	Variable
QS _{nn mm}	quadrature spectrum estimate (imaginary part of cross-spectrum) of X and Y: $Q_k^{xy} = \sum_{j=-p}^p W_j \text{imag}(J_{k+j}^{xy}) \text{(except across end-points)}$
A _{nn mm}	amplitude (modulus) of cross-spectrum of X and Y: $A_k^{xy} = \sqrt{(C_k^{xy})^2 + (Q_k^{xy})^2}$
K _{nn mm}	coherency squared of X and Y: $K_k^{xy} = (A_k^{xy})^2 / (F_k^x F_k^y)$
PH _{nn mm}	phase spectrum in radians of X and Y: $\Phi_k^{xy} = \arctan(Q_k^{xy} / C_k^{xy})$

Printed Output

By default PROC SPECTRA produces no printed output.

When the WHITETEST option is specified, the SPECTRA procedure prints the following statistics for each variable in the VAR statement:

1. the name of the variable
2. M-1, the number of two-degree-of-freedom periodogram ordinates used in the test
3. MAX(P(*)), the maximum periodogram ordinate
4. SUM(P(*)), the sum of the periodogram ordinates
5. Fisher's Kappa statistic
6. Bartlett's Kolmogorov-Smirnov test statistic
7. Approximate *p*-value for Bartlett's Kolmogorov-Smirnov test statistic

See the section “[White Noise Test](#)” on page 1797 for details.

ODS Table Names: SPECTRA procedure

PROC SPECTRA assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 26.4 ODS Tables Produced in PROC SPECTRA

ODS Table Name	Description	Option
WhiteNoiseTest	white noise test	WHITETEST
Kappa	Fishers Kappa statistic	WHITETEST
Bartlett	Bartletts Kolmogorov-Smirnov statistic	WHITETEST

Examples: SPECTRA Procedure

Example 26.1: Spectral Analysis of Sunspot Activity

This example analyzes Wolfer's sunspot data (Anderson 1971). The following statements read and plot the data.

```

title "Wolfer's Sunspot Data";
data sunspot;
    input year wolfer @@;
datalines;
1749  809 1750  834 1751  477 1752  478 1753  307 1754  122 1755   96

... more lines ...

proc sgplot data=sunspot;
    series x=year y=wolfer / markers markerattrs=(symbol=circlefilled);
    xaxis values=(1740 to 1930 by 10);
    yaxis values=(0 to 1600 by 200);
run;

```

The plot of the sunspot series is shown in [Output 26.1.1](#).

Output 26.1.1 Plot of Original Sunspot Data

The spectral analysis of the sunspot series is performed by the following statements:

```
proc spectra data=sunspot out=b p s adjmean whitetest;
  var wolfer;
  weights 1 2 3 4 3 2 1;
run;

proc print data=b(obs=12);
run;
```

The PROC SPECTRA statement specifies the P and S options to write the periodogram and spectral density estimates to the OUT= data set B. The WEIGHTS statement specifies a triangular spectral window for smoothing the periodogram to produce the spectral density estimate. The ADJMEAN option zeros the frequency 0 value and avoids the need to exclude that observation from the plots. The WHITETEST option prints tests for white noise.

The Fisher's Kappa test statistic of 16.070 is larger than the 5% critical value of 7.2, so the null hypothesis that the sunspot series is white noise is rejected (see the table of critical values in Fuller (1976)).

The Bartlett's Kolmogorov-Smirnov statistic is 0.6501, and its approximate p -value is < 0.0001 . The small p -value associated with this test leads to the rejection of the null hypothesis that the spectrum represents white noise.

The printed output produced by PROC SPECTRA is shown in [Output 26.1.2](#). The output data set B created by PROC SPECTRA is shown in part in [Output 26.1.3](#).

The following statements plot the periodogram and spectral density estimate by the frequency and period.

```

proc sgplot data=b;
  series x=freq y=p_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
  series x=period y=p_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
  series x=freq y=s_01 / markers markerattrs=(symbol=circlefilled);
run;

proc sgplot data=b;
  series x=period y=s_01 / markers markerattrs=(symbol=circlefilled);
run;

```

The periodogram is plotted against the frequency in [Output 26.1.4](#) and plotted against the period in [Output 26.1.5](#). The spectral density estimate is plotted against the frequency in [Output 26.1.6](#) and plotted against the period in [Output 26.1.7](#).

Output 26.1.4 Plot of Periodogram by Frequency

Output 26.1.5 Plot of Periodogram by Period

Output 26.1.6 Plot of Spectral Density Estimate by Frequency

Output 26.1.7 Plot of Spectral Density Estimate by Period

Since PERIOD is the reciprocal of frequency, the plot axis for PERIOD is stretched for low frequencies and compressed at high frequencies. One way to correct for this is to use a WHERE statement to restrict the plots and exclude the low frequency components. The following statements plot the spectral density for periods less than 50.

```
proc sgplot data=b;
  where period < 50;
  series x=period y=s_01 / markers markerattrs=(symbol=circlefilled);
  refline 11 / axis=x;
run;
title;
```

The spectral analysis of the sunspot series confirms a strong 11-year cycle of sunspot activity. The plot makes this clear by drawing a reference line at the 11 year period, which highlights the position of the main peak in the spectral density.

Output 26.1.8 shows the plot. Contrast Output 26.1.8 with Output 26.1.7.

Output 26.1.8 Plot of Spectral Density Estimate by Period to 50 Years

Example 26.2: Cross-Spectral Analysis

This example uses simulated data to show cross-spectral analysis for two variables X and Y . X is generated by an AR(1) process; Y is generated as white noise plus an input from X lagged 2 periods. All output options are specified in the PROC SPECTRA statement. PROC CONTENTS shows the contents of the OUT= data set.

```
data a;
  x1 = 0; x11 = 0;
  do i = - 10 to 100;
    x = .4 * x1 + rannor(123);
    y = .5 * x11 + rannor(123);
    if i > 0 then output;
    x11 = x1; x1 = x;
  end;
run;
```

```
proc spectra data=a out=b cross coef a k p ph s;
  var x y;
  weights 1 1.5 2 4 8 9 8 4 2 1.5 1;
run;

proc contents data=b position;
run;
```

The PROC CONTENTS report for the output data set B is shown in [Output 26.2.1](#).

Output 26.2.1 Contents of PROC SPECTRA OUT= Data Set

Overview: SSM Procedure

State space models (SSMs) are used for analyzing continuous response variables that are recorded sequentially according to a numeric indexing variable. In many cases, the indexing variable is time and the observations are collected at regular time intervals—for example, hourly, weekly, or monthly. In such cases, the resulting data are called time series data. In other cases, the indexing variable might not be time or the observations might not be equally spaced according to the indexing variable. These more general types of sequential data are called longitudinal data. Because of their sequential nature, these types of data exhibit some characteristic features. For example, chronologically closer measurements tend to be highly correlated while measurements farther apart are essentially uncorrelated. Data can be trending in a particular direction and can have seasonal or other periodic patterns. SSMs are specially designed to model such sequential data. They apply to both univariate and multivariate response situations and can easily incorporate predictor (independent variable) information when it is available.

The SSM procedure performs state space modeling of univariate and multivariate time series and longitudinal data. You can do the following with the SSM procedure:

- analyze quite general linear state space models.
- use an expressive language to specify an SSM. An SSM specification consists of specifying a variety of matrices—for example, the state transition matrix and the covariance matrices of the state and observation disturbances. The SSM procedure provides language similar to a DATA step for specifying the elements of these matrices. The matrix elements can be user-defined functions of data variables and unknown parameters.
- easily specify several commonly needed univariate and multivariate SSMs by using only a few keywords. These SSMs include the principal univariate and multivariate structural models for regularly spaced data and a variety of trend and cycle models for the longitudinal data.
- estimate unknown model parameters by (restricted) maximum likelihood. The likelihood function is computed by using the (diffuse) Kalman filter algorithm.
- print, or output to a data set, the series forecasts, residuals, and the full-sample estimates of any linear combination of the underlying state variables. These estimates are obtained by using the (diffuse) Kalman filter and smoother algorithm.
- generate residual diagnostic plots and plots useful for detecting structural breaks.

Background

State space models are widely used in a variety of fields such as engineering, statistics, econometrics, and agriculture. There are numerous references that deal with state space modeling, particularly with the state space modeling of time series data. State space modeling of longitudinal data has received a little less attention. The primary reference for the modeling techniques implemented in the SSM procedure is Harvey (1989). It contains treatment of both the time series and longitudinal data. Other useful books about this subject are Durbin and Koopman (2001), Jones (1993), and Anderson and Moore (1979). Jones (1993) is exclusively devoted to the state space modeling of longitudinal data. In addition, the articles Wecker and Ansley (1983), Kohn and Ansley (1991), and de Jong and Mazzi (2001) are also quite informative. For the implementation details of the diffuse Kalman filter and smoother (the main computational tool used by the SSM procedure), the main references are a series of articles de Jong (1989, 1991), de Jong and Chu-Chun-Lin (2003), and the references therein.

Getting Started: SSM Procedure

This example illustrates how you can use the SSM procedure to analyze a panel of time series. The following data set, Cigar, contains information about yearly per capita cigarette sales for 46 geographic regions in the United States over the period 1963–1992. The variables `lsales`, `lprice`, `lndi`, and `lpimin` denote the per capita cigarette sales, price per pack of cigarettes, per capita disposable income, and minimum price in adjoining regions per pack of cigarettes, respectively (all in the natural log scale). The variable `year` contains the observation year, and the variable `region` contains an integer between 1 to 46 that serves as the unique identifier for the region. See Baltagi and Levin (1992) and Baltagi (1995) for additional data description. The data are sorted by year.

```
data cigar;
  input year region lsales lprice lndi lpimin;
  label lsales = 'Log cigarette sales in packs per capita';
  label lprice = 'Log price per pack of cigarettes';
  label lndi = 'Log per capita disposable income';
  label lpimin = 'Log minimum price in adjoining regions
                 per pack of cigarettes';
  year = intnx( 'year', '1jan63'd, year-63 );
  format year year.;
datalines;
63 1 4.54223 3.35341 7.3514 3.26194
63 2 4.82831 3.17388 7.5729 3.21487
63 3 4.63860 3.29584 7.3000 3.25037
63 4 4.95583 3.23080 7.9288 3.17388
63 5 5.05114 3.28840 7.9772 3.26576

... more lines ...
```

The goal of the analysis is to study the impact of the regressors on the smoking behavior and to understand the changes in the smoking patterns in different regions over the years. Consider the following model for $lsales$:

$$lsales_{i,t} = \mu_{i,t} + lprice \beta_1 + lndi \beta_2 + lpimin \beta_3 + \epsilon_{i,t}$$

This model represents $lsales$ in a region i and in a year t as a sum of region-specific trend components $\mu_{i,t}$, the regression effects due to $lprice$, $lndi$, and $lpimin$, and the observation noise $\epsilon_{i,t}$. Different variations of this model are obtained by considering different models for the trend component $\mu_{i,t}$. Proper modeling of the trend component is important because it captures differences between the regions because of unrecorded factors such as demographic changes over time, results of anti-smoking campaigns, and so on. The following statements specify and fit one such model:

```
proc ssm data=cigar plots=residual;
  id year interval=year;
  array RegionArray{46} region1-region46;
  do i=1 to 46;
    RegionArray[i] = (region=i);
  end;
  trend IrwTrend(11) cross(matchparm)=(RegionArray) levelvar=0;
  irregular wn;
  model lsales = lprice lndi lpimin IrwTrend wn;
  eval TrendPlusReg = IrwTrend + lprice + lndi + lpimin;
  output out=forCigar pdv;
run;
```

The PROC SSM statement specifies the input data set, *Cigar*, which contains analysis variables such as the response variable, $lsales$, and the predictor variables, $lprice$, $lndi$, and $lpimin$. The PLOTS=RESIDUAL option in the PROC SSM statement produces residual diagnostic plots. The optional ID statement specifies a numeric index variable (often a SAS date or datetime variable), which is *year* in this case. The INTERVAL=YEAR option in the ID statement indicates that the measurements are collected on a yearly basis. The next few statements define a 46-dimensional array of dummy variables, *RegionArray*, such that *RegionArray*[*i*] is 1 if region is i and is 0 otherwise. The next three statements, TREND, IRREGULAR, and MODEL, constitute the model specification part of the program:

- **trend IrwTrend(11) cross(matchparm)=(RegionArray) levelvar=0;** defines a trend, named *IrwTrend*, of local linear type (which is signified by the keyword *ll* used within the parenthesis after the name). A local linear trend—a trend with time-varying level and time-varying slope—depends on two parameters: the disturbance variance of the level equation and the disturbance variance of the slope equation (see the section “[Local Linear Trend](#)” on page 1855 for more information). The LEVELVAR=0 specification fixes the disturbance variance of the level equation to 0, which results in a trend model called an *integrated random walk* (IRW). An IRW model tends to produce a smoother trend than a general local linear trend. In the limiting case, if the disturbance variance of the slope equation is also 0, the IRW trend reduces to a straight line (with a fixed intercept and slope). In addition, because of the use of the 46-dimensional array, *RegionArray*, in the CROSS= option (**cross(matchparm)=(RegionArray)**), this trend specification amounts to fitting a separate IRW trend for each region. This is because, as a result of the CROSS= option, *IrwTrend* is treated as a linear combination of 46 (the number of variables in *RegionArray*) stochastically independent, integrated random walks,

$$IrwTrend_t = \sum_{i=1}^{46} RegionArray[i] \mu_{i,t}$$

where each $\mu_{i,t}$ is an integrated random walk. Note that since `RegionArray[i]` is a binary variable, `lrwTrend` equals $\mu_{i,t}$ when region is i . Lastly, the use of `MATCHPARM` option specifies that the different IRW trends $\mu_{i,t}$ use the same disturbance variance parameter for their slope equation. This is done mainly for parsimony. Based on the model diagnostics shown later, this appears to be a reasonable model simplification.

- **irregular wn;** defines the observation noise $\epsilon_{i,t}$, named `wn`, as a sequence of independent, identically distributed, zero-mean, Gaussian variables—a white noise sequence.
- **model lsales = lprice lndi lpimin lrwTrend wn;** defines the model for `lsales` as a sum of regression effects that involve `lprice`, `lndi`, and `lpimin`, a trend term, `lrwTrend`, and the observation noise `wn`.

The last two statements, `EVAL` and `OUTPUT`, control certain aspects of the procedure output. The following `EVAL` statement defines a linear combination, named `TrendPlusReg`, of selected terms in the `MODEL` statement.

```
eval TrendPlusReg = lrwTrend + lprice + lndi + lpimin;
```

This `EVAL` statement causes the SSM procedure to produce an estimate of `TrendPlusReg` (and its standard error), which can then be printed or output to a data set. `TrendPlusReg` contains all the terms in the model except for the observation noise and thus can be regarded as the *explanatory* part of the model. In the `OUTPUT` statement, you can specify an output data set that stores all the component estimates that are produced by the procedure. The following `OUTPUT` statement specifies `forCigar` as the output data set:

```
output out=forCigar pdv;
```

The `PDV` option causes variables such as `region1`–`region46`, which are defined by the `DATA` step statements within the SSM procedure, also to be included in the output data set.

All the models that are specified in the SSM procedure possess a state space representation. See the section “[State Space Model and Notation](#)” on page 1843 for more information. The SSM procedure output begins with a table (not shown here) of the input data set that provides the name and other information. Next, the “Model Summary” table, shown in [Figure 27.1](#), provides basic model information, such as the following:

- the dimension of the underlying state equation, 92 (because each of the 46 IRW trends $\mu_{i,t}$ contributes two elements to the state)
- the diffuse dimension of the model, 95 (which is equal to the three regressors plus the 92 diffuse initial states of $\mu_{i,t}$)
- the number of model parameters, 2 (which is the common disturbance variance of the slope equation in `lrwTrend` and the variance of the noise term `wn`)

This information is very useful in determining the computational complexity of the model (the larger state size, 92, explains the relatively long computing time—as much as two minutes on some desktops—for this example).

Figure 27.1 Summary of the Underlying State Space Model

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	92
Dimension of the Diffuse Initial Condition	95
Number of Parameters	2

The index variable information is shown in Figure 27.2. Among other things, it categorizes the data to be of the type *Regular with Replication*, which implies that the data are regularly spaced with respect to the ID variable and at least some observations have the same ID value. This is clearly true in this example: the data are yearly without any gaps, and there are 46 observations in each year—one per region.

Figure 27.2 Index Variable Information

ID Variable Information				
Name	Start	End	Max Delta	Type
year	1963	1992	1	Regular with Replication

Figure 27.3 provides simple summary information about the response variable. It shows that *lsales* has no missing values and no induced missing values because the predictors in the model, *lprice*, *lndi*, and *lpimin*, do not have any missing values either.

Figure 27.3 Response Variable Summary

Response Variable Information							
Name	--Number of Observations--			Minimum	Maximum	Mean	Std Deviation
	Total	Missing	Induced Missing				
lsales	1380	0	0	3.98	5.7	4.79	0.225

The regression coefficients of *lprice*, *lndi*, and *lpimin* are shown in Figure 27.4. As expected, the coefficient of *lprice* is negative and the coefficients of *lndi* and *lpimin* are positive, all being statistically significant. This is consistent with the expectation that the cigarette sales are adversely affected by the price and are positively correlated with the disposable income. The estimated effect of *lpimin*, called bootlegging effect by Baltagi and Levin (1992), is statistically significant but much smaller than the effects of *lprice* and *lndi*.

Figure 27.4 Estimated Regression Coefficients

Regression Parameter Estimates					
Response Variable	Regression Variable	Estimate	Standard Error	t Value	Pr > t
<i>lsales</i>	<i>lprice</i>	-0.3480	0.0232	-15.01	<.0001
<i>lsales</i>	<i>lndi</i>	0.1425	0.0344	4.15	<.0001
<i>lsales</i>	<i>lpimin</i>	0.0619	0.0269	2.30	0.0214

Figure 27.5 Estimated Model Parameters

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
<i>lrwTrend</i>	LL Trend	Slope Variance	0.000169	0.0000219
<i>wn</i>	Irregular	Variance	0.000592	0.0000342

Figure 27.5 shows the estimates of the disturbance variance of the slope equation in *lrwTrend* and the variance of the noise term *wn*. The estimate of the disturbance variance of the slope equation in *lrwTrend*, 0.00017, is statistically significant (being several times larger than its standard error, 0.000022). This implies that the estimated trends $\mu_{i,t}$ are not simple lines with fixed intercept and slope.

Figure 27.6 shows a panel of residual normality diagnostic plots. These plots show that the residuals are symmetrically distributed but contain slightly larger than expected number of extreme residuals. Figure 27.7 shows the plot of residuals versus time. There the residuals do not exhibit any obvious pattern; however, the plot does show that more extreme residuals appear before 1970 and after 1989. On the whole, however, these plots do not exhibit serious violations of model assumptions.

Figure 27.6 Residual Normality Check

Figure 27.7 Standardized Residuals Plotted against Time

Figure 27.8 shows the details of the likelihood computations such as the number of nonmissing response values used and the likelihood of the fitted model. See the section “Likelihood Computation and Model Fitting Phase” on page 1852 for more information. Figure 27.8 shows the likelihood-based information criteria in smaller-is-better format, which are useful for model comparison.

Figure 27.8 Likelihood Computation Details

Likelihood Computation Summary	
Statistic	Value
Nonmissing Response Values Used	1380
Estimated Parameters	2
Initialized Diffuse State Elements	95
Normalized Residual Sum of Squares	1285
Full Log Likelihood	2246.05

Figure 27.9 Information Criteria

Likelihood Based Information Criteria	
Statistic	Value
AIC (smaller is better)	-4488.1
BIC (smaller is better)	-4477.8
AICC (smaller is better)	-4488.1
HQIC (smaller is better)	-4484.2
CAIC (smaller is better)	-4475.8

In addition to the regression estimates, it is useful to analyze the estimates of different model components such as the trend component `lrwTrend` and the linear combination `TrendPlusReg`. These estimates can be printed by using the `PRINT=` option provided in the `TREND` and `EVAL` statements, or they can be output to a data set (as it is done in this illustration). This latter option is particularly useful for graphical exploration of these components by standard graphical procedures such as `SGPLOT` and `SGPANEL` procedures. The following statements produce a panel of plots that shows how well the proposed model fits the observed cigarette sales in the first three regions, which correspond to Alabama, Arizona, and Arkansas. The output data set, `forCigar`, contains all the needed information: `Smoothed_TrendPlusReg` contains the smoothed (full-sample) estimate of `TrendPlusReg`, and `Smoothed_Lower_TrendPlusReg` and `Smoothed_Upper_TrendPlusReg` contain its 95% lower and upper confidence limits. In addition, for easy readability, a user-defined format (`RegionFormat`), which is created by using the `FORMAT` procedure (not shown), is used to associate the region names to region values.

```
proc sgpanel data=forCigar noautolegend;
  where region <= 3;
  format region RegionFormat.;
  title 'Region-Specific Sales Patterns with 95% Confidence Band';
  panelby region / columns=3;
  band x=year lower=Smoothed_Lower_TrendPlusReg
  upper=Smoothed_Upper_TrendPlusReg;
  scatter x=year y=lsales;
  series x=year y= Smoothed_TrendPlusReg;
run;
```

Figure 27.10 Cigarette Sales Patterns for the First Three Regions

Figure 27.10 seems to indicate that the model fits the data reasonably well. It also shows that Arizona differs markedly from Alabama and Arkansas in its cigarette sales pattern over the years. The following statements produce a similar panel of plots that show the estimate of trend without the regression effects:

```
proc sgpanel data=forCigar noautolegend;
  where region <= 3;
  format region RegionFormat.;
  title 'Region-Specific Trend Estimates';
  panelby region / columns=3;
  series x=year y= smoothed_IrwTrend;
run;
```

Figure 27.11 Estimate of lnwTrend for the First Three Regions

The trend patterns, shown in Figure 27.11, seem to suggest that after accounting for the regression effects, per capita cigarette sales were on the rise in Alabama and Arkansas while they were declining in Arizona.

Syntax: SSM Procedure

The following statements are available in the SSM procedure:

```

PROC SSM < options > ;
  BY variables ;
  COMPONENT name = (variables) * state < / options > ;
  Eval name = expression < / options > ;
  ID variable < option > ;
  IRREGULAR name < options > ;
  MODEL response = variables < / options > ;
  OUTPUT < options > ;
  PARMS variables < / options > ;
  Programming statements ;
  STATE name(dim) < options > ;
  TREND name(type) < options > ;

```

You can specify all statements except the BY, ID, and the OUTPUT statements multiple times. The PROC SSM statement and at least one MODEL statement are required. In addition to these statements, you can use most DATA step programming statements to define new variables that are needed for specifying different parts of the state space model.

NOTE: In the statement options described throughout this section, whenever you use a list to specify the elements of the system matrices, the list elements must all be of the same type: either all of them must be variables or all of them must be numbers. In addition, if the list contains more than one variable, then they cannot be of the array type. These are not serious restrictions. When the list contains mix of variables and numbers, you can redefine the numbers as constant variables. Similarly, you can reformulate a list that contains a mix of variables of array and non-array types as just one array by combining all its elements in a new array.

Functional Summary

Table 27.1 summarizes the statements and options that control the SSM procedure. Most commonly needed scenarios are listed; see the individual statements for additional details.

Table 27.1 Functional Summary

Description	Statement	Option
Data Set Options		
Specifies the input data set	PROC SSM	DATA=
Writes series and component forecasts to an output data set	OUTPUT	OUT=
Model Specification Options		
Specifies the index variable	ID	
Defines variables as model parameters	PARMS	

Table 27.1 continued

Description	Statement	Option
Specifies a response variable and the associated observation equation	MODEL	
Specifies a state subsection	STATE	
Specifies the transition matrix of a state subsection	STATE	T
Specifies the disturbance covariance matrix of a state subsection	STATE	COV
Specifies the size of the diffuse initial condition of a state subsection	STATE	A1
Specifies the initial covariance matrix of a state subsection	STATE	COV1
Specifies a state subsection for a predefined structural model	STATE	TYPE=
Specifies the input vector in a state equation	STATE	SINPUT=
Specifies a component	COMPONENT	
Specifies a predefined trend component	TREND	
Likelihood Optimization Process Control Options		
Specifies the optimization technique	PROC SSM	OPTIMIZER(TECH=)
Limits the number of iterations	PROC SSM	OPTIMIZER(MAXITER=)
Outlier Detection Options		
Turns on the search for additive outliers (AO)		Default
Specifies the significance level for additive outlier tests	OUTPUT	AO(AOALPHA=)
Limits the number of additive outliers	OUTPUT	AO(MAXNUM=)
limit the number of additive outliers to a percentage of the series length	OUTPUT	AO(MAXPCT=)
Turns on the search for maximal state shock	OUTPUT	MAXSHOCK
Graphical Residual and Outlier Analysis Options		
Creates a panel of plots that consists of residual normality plots	PROC SSM	PLOTS=RESIDUAL(NORMAL)
Creates the standardized residual plot against time	PROC SSM	PLOTS=RESIDUAL(STD)
Creates a panel of plots that consists of prediction error normality plots	PROC SSM	PLOTS=AO(NORMAL)
Creates the standardized prediction error plot against time	PROC SSM	PLOTS=AO(STD)
Creates the plot of maximal state shock chi-square statistics against time	PROC SSM	PLOTS=MAXSHOCK

Table 27.1 *continued*

Description	Statement	Option
Output Control Options		
Specifies the significance level of the forecast confidence limits	OUTPUT	ALPHA=
Prints the prediction error sum of squares table	OUTPUT	PRESS
Specifies a linear combination of components to be output	EVAL	
Global Printing and Plotting Options		
Turns off all printing for the procedure	PROC SSM	NOPRINT
Turns on all printing options for the procedure	PROC SSM	PRINTALL
Turns off all plotting for the procedure	PROC SSM	PLOTS=NONE
Turns on all plotting options for the procedure	PROC SSM	PLOTS=ALL
Printing State Equation System Matrix Options		
Prints the transition matrix that is associated with a state subsection	STATE	PRINT=T
Prints the disturbance covariance matrix that is associated with a state subsection	STATE	PRINT=COV
Prints the initial covariance matrix that is associated with a state subsection	STATE	PRINT=COV1
Prints the autoregressive coefficient matrix that is associated with a state subsection	STATE	PRINT=AR
Prints the moving average coefficient matrix that is associated with a state subsection	STATE	PRINT=MA
Printing Component, Series Forecast, and Smoothed Estimate Options		
Prints the series forecasts	MODEL	PRINT=FILTER
Prints the full-sample estimates of missing series values	MODEL	PRINT=SMOOTH
Prints the smoothed trend estimate	TREND	PRINT=SMOOTH
Prints the filtered trend estimate	TREND	PRINT=FILTER
Prints the smoothed component estimate	COMPONENT	PRINT=SMOOTH
Prints the filtered component estimate	COMPONENT	PRINT=FILTER
Prints the smoothed component estimate	EVAL	PRINT=SMOOTH
Prints the filtered component estimate	EVAL	PRINT=FILTER
BY Groups		
Specifies BY-group processing	BY	

PROC SSM Statement

PROC SSM < options > ;

The PROC SSM statement is required. You can specify the following *options* in the PROC SSM statement:

DATA=SAS-data-set

specifies the name of the SAS data set that contains the variables needed for the analysis. If you do not specify this option, PROC SSM uses the most recently created SAS data set.

NOPRINT

turns off all the printing and plotting for the procedure. Any subsequent print options are ignored.

PLOTS < (global-plot-options) > = plot-request < (options) >

PLOTS< (global-plot-options) > = (plot-request < (options) > < ... plot-request < (options) > >)

controls the plots produced with ODS Graphics. When you specify only one *plot-request*, you can omit the parentheses around it. Here are some examples:

```
plots=none
plots=all
plots=residual
plots=residual(normal)
plots=(maxshock residual(normal))
plots(unpack)=residual
```

If you do not specify any specific *plot-request*, then by default PROC SSM produces the plot of standardized residuals against time. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Global Plot Options:

The *global-plot-options* apply to all relevant plots generated by the SSM procedure. The following *global-plot-option* is supported:

UNPACK

displays each graph separately. (By default, some graphs can appear together in a single panel.)

Specific Plot Options:

The following list describes the specific *plot-requests* and their *options*:

ALL

produces all plots appropriate for the particular analysis.

AO< (prediction-error-plot-options) >

produces the prediction error plots—one for each response variable. You can specify the following *prediction-error-plot-options*:

NORMAL

produces a summary panel of the prediction error diagnostics, which consist of the following:

- histogram of prediction errors
- normal quantile plot of prediction errors

STD

produces a scatter plot of standardized prediction errors against time.

MAXSHOCK

produces a scatter plot of maximal state shock statistics against time.

NONE

suppresses all plots.

RESIDUAL < (*residual-plot-options*) >

produces the residuals plots—one for each response variable. You can specify the following *residual-plot-options*:

NORMAL

produces a summary panel of the residual diagnostics, which consist of the following:

- histogram of residuals
- normal quantile plot of residuals

STD

produces a scatter plot of standardized residuals against time.

See the section “[Smoothing Phase](#)” on page 1853 for more information about the precise meaning of the terms *maximal state shock statistics* and *prediction errors*.

PRINTALL

turns on all the printing options for the procedure. All subsequent NOPRINT options in the procedure are ignored.

STATEINFO

prints two tables that provide information about the composition of the state vector in terms of the components specified in the model. One table describes the composition of state α_t , and the other table describes the diffuse vector δ and the regressors, which are part of the initial condition specification α_1 . See the section “[State Space Model and Notation](#)” on page 1843 for more information about the state space model notation.

OPTIMIZER(< **TECHNIQUE**=*technique* > < **MAXITER**=*integer* >)

specifies options that are associated with the optimizer used in the maximum likelihood parameter estimation. The default settings of the optimization process are adequate in most problems. However, in some cases it might be useful to change the optimization technique or to change the maximum number of iterations. You can specify one of the following *techniques*:

INTERIORPOINT	corresponds to the primal-dual interior point method.
ACTIVESET	corresponds to the active-set method.
DBLDOG	corresponds to the double-dogleg method.
NEWRAP	corresponds to the Newton-Raphson method.
QUANEW	corresponds to the (dual) quasi-Newton method.
TRUREG	corresponds to the trust region method.

The default technique is TRUREG. The INTERIORPOINT and ACTIVESET techniques are documented in Chapter 7, “The Nonlinear Programming Solver” (*SAS/OR User’s Guide: Mathematical Programming*), and the remaining techniques are documented in Chapter 6, “Nonlinear Optimization Methods.” You can alter the maximum number of iterations setting in the nonlinear optimization search by specifying a nonnegative *integer* as the MAXITER= value.

BY Statement

BY *variables* ;

A BY statement can be used in the SSM procedure to process a data set in groups of observations that are defined by the BY variables. The model specified by using the MODEL and other statements is applied to all the groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The variables are one or more variables in the input data set.

COMPONENT Statement

COMPONENT *name* = (*var1 var2 ...*) * *state* </options> ;

COMPONENT *name* = *state*[*integer*] </options> ;

COMPONENT *name* = (*Variable* | *Number*) * *state*[*integer*] </options> ;

The COMPONENT statement specifies a component (a linear combination of state elements), named *name*. You can use *name* later as a term in the right-hand side of the MODEL statement, which defines the observation equation. The estimate of *name* is output to the OUT= data set that is specified in the OUTPUT statement. In addition, you can print the component estimate by using the PRINT= option.

The first form of the COMPONENT statement defines a component as a dot product of a state subsection *state* and a row vector (*var1 var2 ...*). The value of *state* can be the name of a state subsection that is defined by using a STATE statement elsewhere in the program, or it can be the name of the state that is associated with a trend component defined by using a TREND statement elsewhere in the program (see the section “TREND Statement” on page 1839 for more information about the naming of the state that is associated with a trend component). The row vector (*var1 var2 ...*), which can be either a list of numbers or a list of variables, must be of the same dimension as the actual dimension of the state subsection. The dot product form—also called the explicit dot product form—of the component specification is unambiguous; however, it requires detailed knowledge of the state vector underlying the *state* specification. Suppose that mystate is a two-dimensional state defined by a STATE statement elsewhere in the program and that X1

and X2 are (numeric) predictor variables. The following are valid examples of the dot product form of the COMPONENT statement:

```
component c1 = (x1 x2) * mystate;
component c2 = (1 1) * mystate;
```

The second and the third forms of the COMPONENT statement are a shortened version of the first form. The second form defines the component as a particular element of *state*—for example, *state*[3] defines the component as the third element of *state*. The specified *integer* must lie between 1 and *dim*, the nominal dimension of *state*. The second form of component specification has another important use when the STATE statement that defines *state* uses the TYPE= option to set its type or when *state* is associated with a trend component. In these cases, the second form of the component specification assumes additional meaning when the nominal state dimension and the actual state dimensions differ (specifically the state types LL, SEASON, CYCLE, and VARMA and the states associated with all the trend types). For example, if *state* is a three-dimensional seasonal component, *state*[2] signifies an appropriate linear combination of *state* that results in the second of the three seasonals that constitute the three-dimensional seasonal. Similar interpretation holds for the CYCLE type. See the sections “[Multivariate Season](#)” on page 1861 and “[Predefined Structural Models](#)” on page 1857 for more information. The third form extends the second form by permitting multiplication by a variable or a number.

NOTE: A component that is based on a state associated with a trend component cannot be used as a right-hand side term in any MODEL statement. That is, it is defined purely for output purposes (either printed or output to a data set). However, it can be used as a term in the expression that is specified in an [EVAL](#) statement to build more complex linear combinations for output.

You can specify the following *options* to print the filtered or smoothed estimate of the component:

PRINT=FILTER | SMOOTH

PRINT=(*< FILTER >* *< SMOOTH >*)

requests printing of the filtered or smoothed estimate of the specified component.

EVAL Statement

EVAL *name* = *number1*variable1 + number2*variable2 + ...* *</ options >* ;

The EVAL statement defines a linear combination, named *name*, of the terms used in the right-hand side of a MODEL statement. You can specify any variables (for example, predictor variables and names of components) in the expression of the EVAL statement; however, you cannot specify in this expression any observation disturbances that are specified by the IRREGULAR statement. Suppose C1 and C2 are two components (defined by COMPONENT statements elsewhere in the program), T1 is a trend component, and X1 is a regression variable used in a model. The following are valid examples of the EVAL statement:

```
eval e1 = c1 - c2;
eval e2 = t1 + c1 + x1;
eval e2 = t1 + 2*c1 - 1.5*x1;
```

The estimates of linear combinations defined by the EVAL statement (for example, E1, E2, and E3) are output to the OUT= data set that is specified in the OUTPUT statement. In addition, you can print these estimates by using the following PRINT= options:

PRINT=FILTER | SMOOTH**PRINT=(*< FILTER >* *< SMOOTH >*)**

requests printing of the filtered or smoothed estimate of the specified linear combination.

ID Statement

ID *variable* *< option >* ;

The ID statement names a numeric variable to associate a sequence value—usually related to a time stamp—to the observations in the input data set. The observations within a BY group must be ordered in ascending order by the ID variable. Often the ID variable's values are SAS date, time, or datetime values, and each observation within a BY group has a unique ID value. Generally, however, the ID variable can be any numeric variable, and there can be multiple observations with the same ID value. If the ID values are SAS date, time, or datetime values, you can specify the frequency associated with the time series by using the INTERVAL= option. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID. Whenever an ID variable is specified, a variable, `_ID_DELTA_`, is automatically created that can be used as any input data set variable in the programming statements. `_ID_DELTA_` contains the distance between two successive ID values. The first `_ID_DELTA_` value is arbitrarily taken as one. If the INTERVAL= option is specified, the distance between the ID values is measured in terms of the number of intervals; therefore, for regularly spaced data, `_ID_DELTA_` is identically equal to one. You can specify the following *option* in the ID statement:

INTERVAL=*value*

specifies the time interval between observations. INTERVAL=*value* is used in conjunction with the ID variable to check that the input data are in proper order. For a complete discussion of the intervals supported, see Chapter 4, “[Date Intervals, Formats, and Functions](#).”

IRREGULAR Statement

IRREGULAR *name* *< options >* ;

The IRREGULAR statement specifies a one-dimensional white noise component, which can be used to specify the observation error in a MODEL statement. You can specify the following *options* in the IRREGULAR statement:

PRINT=SMOOTH

requests printing of the smoothed estimate of the specified irregular component.

VARIANCE=*variable* | *number*

specifies the variance of the white noise. Any nonnegative value, including 0, is permissible. If the *variable* contains unknown parameters, they are estimated from the data. Similarly, if the VARIANCE= option is not specified, the variance is estimated from the data.

MODEL Statement

MODEL *response* = *variables* < / *options* > ;

A MODEL statement specifies an observation equation that describes a response variable as a sum of regression effects and components that are defined in the program. The response variable must be a numeric variable from the input data set. The variables used in the right-hand side of the model expression can be numeric variables from the input data set, numeric variables defined by using programming statements, or names of components that are specified in the COMPONENT, TREND, or IRREGULAR statements.

For a multivariate model, a separate MODEL statement is needed for each of the response variables. In this case, the observation errors, which are specified in an IRREGULAR statement, must be different in each MODEL statement. You can specify the following *options* to print the filtered or smoothed estimate of the response variable:

PRINT=FILTER | SMOOTH

PRINT=(< FILTER > < SMOOTH >)

requests printing of the filtered or smoothed estimate of the specified response variable. The filtered estimate is produced during the filtering phase, and the smoothed estimate is produced by the smoothing phase of the Kalman filter and smoother algorithm. The filtered estimate is also called the one-step-ahead forecast of the response variable. The smoothed estimate corresponds to the full-sample prediction of the response variable. Since the full-sample prediction of a nonmissing response value is that value itself, full-sample predictions are printed only for the missing response values.

OUTPUT Statement

OUTPUT < *options* > ;

The OUTPUT statement specifies an output data set to store the estimates of the model components and series forecasts.

AO(< AOALPHA=number > < MAXNUM=number > < MAXPCT=number >)

controls the additive outlier search. The AOALPHA= option specifies the significance level for reporting the outliers. The default is 0.05. The MAXNUM= option limits the number of outliers to search. The default is MAXNUM=5. The MAXPCT= option is similar to the MAXNUM= option. In the MAXPCT= option you can limit the number of outliers to search for according to a percentage of the series length. The default is MAXPCT=1. When you specify both of these options, the minimum of the two search numbers is used.

ALPHA=number

specifies the significance level of the forecast confidence intervals. For example, ALPHA=0.05, which is the default, results in a 95% confidence interval.

MAXSHOCK

causes the computation of the maximal state shock chi-square statistic at each distinct time point in the input data set. These statistics are output to the data set that is specified in the OUT= option. A time series plot of these statistics is produced if the PLOTS=MAXSHOCK option is specified in the PROC SSM statement. These statistics are useful for detecting structural breaks in the observation process. This option can be computationally expensive for a model with large state size.

OUT=SAS-data-set

specifies an output data set for the forecasts. The output data set contains the ID variable (if specified), the response variables, the one-step-ahead and out-of-sample response variable forecasts, the forecast confidence intervals, the smoothed values of the response series, and the one-step-ahead and smoothed estimates of the model components—including expressions that are defined by using the EVAL statement. See the section “[OUT= Data Set](#)” on page 1869 for more information.

PDV

causes the inclusion of the variables (variables in the program data vector) that are defined by using the programming statements in the SSM procedure in the OUT= data set. The parameters defined by the PARMS statement are also included. The output data set contains the values of these variables evaluated for all the rows in the input data set that is specified in the DATA= option. The parameters in the PARMS statement contain their estimated values.

PRESS

prints the prediction error sum of squares (PRESS). The PRESS table reports the prediction error sum of squares, the number of summands used in the sum of squares, and the sum of squares of the weighted prediction errors (prediction errors normalized by their standard errors). See the section “[Smoothing Phase](#)” on page 1853 for more information about the precise meaning of the term prediction error.

PARMS Statement

PARMS *variable*<=*number*> *variable*<=*number*> < / *options*> ;

The PARMS statement declares the parameters of a model and optionally sets their initial values. You can also specify the lower and upper limits of their validity range. The parameters declared by using the PARMS statement are called *named parameters* throughout this chapter. A model can have additional parameters: any unspecified quantity in the model specification becomes part of the parameter vector. You can specify the following *options*:

LOWER=(*number1 number2 ...*)

LOWER=(*number*)

specifies the lower bounds for the specified parameters. The list can contain exactly one number, which is taken to be the lower bound for all the listed parameters in the statement, or it must contain as many values as the number of parameters specified. A missing value, denoted by ., is a permissible value, which signifies that the parameter has no lower bound.

UPPER=(*number1 number2 ...*)

UPPER=(*number*)

specifies the upper bounds for the specified parameters. The list can contain exactly one number, which is taken to be the upper bound for all the listed parameters in the statement, or it must contain as many values as the number of parameters specified. A missing value, denoted by ., is a permissible value, which signifies that the parameter has no upper bound.

Programming Statements

To define the model, you can use most of the programming statements that are allowed in the SAS DATA step. See the *SAS Language Reference: Dictionary* for more information. The syntax of programming statements used in PROC SSM is identical to that used in the MODEL procedure (see Chapter 19, “The MODEL Procedure”) and the NLMIXED procedure (see Chapter 64, “The NLMIXED Procedure” (*SAS/STAT User’s Guide*)). Additional restrictions are that the DATA step lagging and differencing functions are not allowed.

STATE Statement

STATE *name* (*dim*) < *options* > ;

The STATE statement specifies a subsection of α_t , the overall state vector at time t . For more information, see the section “State Space Model and Notation” on page 1843. Consider the state equations that define the state space model:

$$\begin{aligned}\alpha_{t+1} &= \mathbf{T}_t \alpha_t + \mathbf{c}_{t+1} + \eta_{t+1} \\ \alpha_1 &= \mathbf{c}_1 + \mathbf{A}_1 \delta + \eta_1\end{aligned}$$

You can specify multiple STATE statements, each specifying a separate subsection. It is assumed that the subsections specified by using different STATE statements are mutually independent. This independence assumption implies a block-diagonal structure for the transition matrices \mathbf{T}_t and the disturbance covariances \mathbf{Q}_t for all $t \geq 1$. An appropriate block structure also applies to \mathbf{A}_1 . The *options* in the STATE statement provide complete control over the description of the relevant blocks of \mathbf{T}_t , \mathbf{Q}_t , and \mathbf{A}_1 . The argument *dim* (a positive integer in *name* (*dim*)) specifies the nominal dimension of this subsection. In most situations the nominal dimension and the actual dimension of the state subsection are the same. However, when you specify the TYPE= option, the actual dimension of the state subsection can be different than the nominal dimension. The TYPE= option simplifies the state specification task for some commonly needed models.

NOTE: The T, COV, and COV1 options described later in this section specify the relevant blocks of \mathbf{T}_t , \mathbf{Q}_t , and \mathbf{Q}_1 , respectively. The structure of these matrix blocks is described in a similar way in the option descriptions. For example, the specification COV(I) corresponds to the identity form, COV(D) corresponds to the diagonal form, and COV(G) corresponds to the general form of the \mathbf{Q}_t block.

You can use the following *options* in the STATE statement to specify the system matrices \mathbf{T}_t , \mathbf{Q}_t , and \mathbf{A}_1 , and to request printing of their estimates:

A1(nd)

specifies that the last *nd* elements of the state subsection be treated as diffuse. This becomes the dimension of the relevant subsection of the diffuse vector δ . The \mathbf{A}_1 block is created by using appropriate columns of the identity matrix. The value of *nd* must lie between 1 and the nominal dimension, *dim*. The absence of this option signifies that this subsection of α_t is nondiffuse. If both the COV1 and A1 options are specified, the last *nd* rows and columns of the matrix specified in the COV1 option are taken to be 0. This option cannot be used together with the RANK= option of the COV1 option.

COV(D) <= (var1 var2 ...) | (number1 number2 ...)>

COV(G) <= (var1 var2 ...) | (number1 number2 ...)>

COV(I) <= (variable) | (number)>

COV(RANK=integer)

specifies the relevant block of the disturbance covariance Q_t (for $t \geq 2$) in the transition equation. Similar to the **T** option, the absence of this option signifies that this Q-block consists of only zeros. The structure of the Q-block is also similarly specified. However, the following differences exist:

- The list that is specified to form the covariance must result in a symmetric, positive semidefinite matrix. For an example, see [Example 27.5](#).
- You can specify a rank constraint on the Q-block by specifying **COV(RANK=integer)**, where the specified integer must lie between 1 and *dim*. A rank constraint is permissible only for the general form and only when its elements are not specified by using a list.
- The convention of treating unset variables as structural zeros, which is used in specifying sparsity of the T-block, is not used in the Q-block specification. Whenever you explicitly specify the entries of the Q-block by specifying a list of variables in parentheses, all variables in the list must evaluate to nonmissing values.

The following examples illustrate different ways of specifying a Q-block. It is assumed that *dim* = 2.

- **COV(G)** specifies a general-form Q-block, which contributes $(2 * (2 + 1))/2 = 3$ unspecified elements to the parameter vector θ .
- **COV(RANK=1)** specifies a rank-one Q-block.

COV1(D) <= (var1 var2 ...) | (number1 number2 ...)>

COV1(G) <= (var1 var2 ...) | (number1 number2 ...)>

COV1(I) <= (variable) | (number)>

COV1(RANK=integer)

specifies the relevant block of the initial state covariance Q_1 . The different options in this case have the same meaning as the options of the **COV** option. However, the following differences exist:

- If the elements of Q_1 are specified by a list of variables in parentheses, then these variables must evaluate to constant values. In particular, they can depend on parameters that are specified by the **PARMS** statements; however, they cannot depend on any of the input data columns.
- If the initial condition is partially diffuse (that is, the diffuse dimension *nd* specified in the **A1** option is nonzero), the last *nd* rows and columns of the matrix specified in **COV1** are taken to be zero. Moreover, if the elements of Q_1 are specified by a list, its number of elements must correspond to a matrix of dimension $(dim - nd)$.

PRINT=AR | COV | COV1 | MA | T

PRINT=(<AR> <COV> <COV1> <MA> <T>)

requests printing of the respective system matrices. You can specify **PRINT=AR** or **PRINT=MA** only if you specify the **TYPE=VARMA** option. If any of these matrices are time-varying, the matrix that corresponds to the first time instance is printed.

SINPUT = (*var1 var2 ...*) | (*number1 number2 ...*)

specifies the relevant *dim*-dimensional block of the state input vector \mathbf{c}_t . The absence of this option signifies that this block of the \mathbf{c}_t vector consists of only zeros. If the elements of \mathbf{c}_t are specified by a list of variables in parentheses, then these variables must be independent of unknown parameters. In particular, they cannot be functions of parameters that are defined by the PARMS statements.

T(D) <= (*var1 var2 ...*) | (*number1 number2 ...*)>

T(G) <= (*var1 var2 ...*) | (*number1 number2 ...*)>

T(I) <= (*variable*) | (*number*)>

specifies the relevant block of the transition matrix T_t . The absence of this option signifies that this block consists of only zeros. You can specify the structure of the T-block by specifying T(I) for the identity form, T(D) for the diagonal form, and T(G) for a general unstructured form. In addition, you can explicitly specify the entries of the T-block by specifying a list of numbers in parentheses, or by specifying in parentheses a list of variables that are defined by using the programming statements. The unspecified elements of the T-block are included in the list of parameters to be estimated from the data. If the elements of the T-block are supplied by a list in parentheses, the number of elements in the list depends on its structure. For the diagonal form, the list must contain exactly *dim* elements. In the case of the identity form—T(I)—the block is already fully specified; however, a specification T(I)=(*variable*) is understood to mean that the identity block is scaled by the specified *variable* (or a *number*). In the general case—T(G)—the list must consist of *dim* * *dim* elements, specified in a rowwise fashion. An inappropriate number of elements in the list results in a syntax error.

The following examples illustrate different ways of specifying the transition matrix. It is assumed that *dim* = 2.

- T(I) specifies that the T-block is a two-dimensional identity matrix.
- T(D) specifies that the T-block is a two-dimensional diagonal matrix. The two unspecified diagonal entries become part of the parameter vector θ .
- T(D)=(1.1 2) fully specifies the two-dimensional diagonal T-block.
- T(D)=($X_1 X_2$) specifies a two-dimensional diagonal T-block where the diagonal elements are dynamically calculated based on the values of the variables X_1 and X_2 . In this case the T-block can change with time if X_1 or X_2 changes with time.
- T(G) specifies a general form T-block (with $2^2 = 4$ unspecified elements).
- T(G)=($X_1 X_2 X_3 X_4$) specifies a general form T-block where the first row is formed by X_1 and X_2 , and the second row is formed by X_3 and X_4 .

In practice the transition matrix is often sparse—that is, many of its elements are 0. The algorithms in the SSM procedure exploit this sparsity structure for computational efficiency. Whenever you explicitly specify the entries of the T-block by specifying a list of variables in parentheses, you can leave the variables that correspond to the zero elements *unset*. These unset variables are treated as structural zeros by the SSM procedure. The section “[Sparse Transition Matrix Specification](#)” on page 1848 further explains how to use this sparsity convention.

TYPE=WN

TYPE=RW

TYPE=LL (SLOPECOV(I | D | G) <= (var1, var2, ...) | (number1, number2, ...) >)

TYPE=LL (SLOPECOV(RANK=*integer*))

TYPE=SEASON(LENGTH=*integer*)

TYPE=CYCLE <(<CT> <RHO=*variable* | *number* > <PERIOD=*variable* | *number* >) >

TYPE=VARMA (<p <(I | D)> =*integer* > <q<(D)>=*integer* >)

specifies a state subsection that corresponds to the specified type. You can specify either a number or a variable for the RHO= and PERIOD= suboptions. When TYPE=VARMA, the autoregressive and moving average orders can be at most 1 ($0 \leq p \leq 1$ and $0 \leq q \leq 1$). Moreover, by using the D and I flags with the order specification, you can impose additional structure on the autoregressive and moving average coefficient matrices—for example, specifying TYPE=VARMA(P=1) implies a VAR(1) model with general autoregressive coefficient matrix, whereas specifying TYPE=VARMA(P(D)=1) implies a VAR(1) model with diagonal autoregressive coefficient matrix. If you specify the TYPE= option, the **T**, **COV1**, **SINPUT**, and **A1** options are not needed. In fact they are ignored, since the transition matrix T_t and the matrices in the initial condition (Q_1 and A_1) are implicitly defined by the choice of the type. However, the specification of the **COV** option does play a key role in the eventual form of Q_t —the covariance of the disturbance term in the transition equation. For the types LL, CYCLE, SEASON, and VARMA, the dimension of the resulting state subsection is a certain multiple of *dim*, the nominal dimension in the STATE statement. For example, the following specification results in a state subsection, named cycleState, of dimension $2 * dim$:

```
state cycleState(dim) cov(g) type=cycle;
```

The name cycleState corresponds to the state underlying a *dim*-dimensional cycle component. All of these special state types require that the data be regular (replication is permissible); the only exception is TYPE=CYCLE(CT), which defines a continuous-time cycle and is applicable to any data type. Table 27.2 summarizes some of this information for easy reference. For more information about these state types, see the section “Predefined Structural Models” on page 1857.

The TYPE=LL specification results in a state that corresponds to a multivariate local linear trend. It is governed by two covariance matrices: the **COV** option specifies the covariance that corresponds to the level equation, and the SLOPECOV suboption specifies the covariance used in the slope equation. The form of the SLOPECOV suboption is exactly the same as that of the **COV** option.

The TYPE=CYCLE option results in a state that corresponds to a (stochastic) cycle. By default, this cycle is assumed to be for the regular data type. If TYPE=CYCLE(CT), the resulting cycle is applicable to any data type. The CT option is available only for $dim = 1$; that is, only a univariate cycle is available for the irregular data type. The cycle specification depends on a covariance matrix and two numbers: the damping factor RHO and the cycle period PERIOD. The covariance can be specified by the **COV** option. The damping factor is specified by the RHO= suboption; its value must lie between 0.0 and 1.0. The cycle period can be specified by the PERIOD= suboption. If the CT option is not included, the period value must be larger than 2.0. On the other hand, if the CT option is included, its value must be strictly positive. If these parameters are not specified, they are estimated from the data.

Table 27.2 Summary of Predefined State Types

Type	Description	Parameters	State Dimension
WN	<i>dim</i> -variate white noise	COV	<i>dim</i>
RW	<i>dim</i> -variate random walk	COV	<i>dim</i>
LL	<i>dim</i> -variate local linear	COV, SLOPECOV	2* <i>dim</i>
SEASON(LENGTH= <i>length</i>)	<i>dim</i> -variate season	COV	(<i>length</i> −1)* <i>dim</i>
CYCLE	<i>dim</i> -variate cycle	COV, RHO, PERIOD	2* <i>dim</i>
VARMA(P= <i>p</i> Q= <i>q</i>)	<i>dim</i> -variate VARMA(<i>p</i> , <i>q</i>)	COV, AR, MA	<i>dim</i> *max(<i>p</i> , <i>q</i> +1)

TREND Statement

TREND *name* (*type*) < *options* > ;

The TREND statement defines a trend term in the model. Loosely speaking, a trend is a special type of component that captures the time-varying level of the data. The *options* in the TREND statement enable you to specify a wide variety of commonly used trend patterns. Each TREND specification in effect stands for a special pair of STATE and COMPONENT statements. You can specify more than one TREND statement. Each separate trend specification defines a component that is assumed to be independent of all other component specifications in the model.

You can refer to the state associated with a TREND specification by appending the string “_state_” at the end of its name. For example, *name_state_* is the state associated with a trend named *name*. You can use *name_state_* in a COMPONENT statement to define a linear combination of its elements. The estimate of this linear combination can then be printed or output to a data set. The nominal dimension of *name_state_* is taken to be 1, or the number of variables in the list that is specified in the CROSS= option in the TREND statement that is used to define *name*.

Some of these trend specifications are applicable to all the data types—that is, they can be used for both regular data types and irregular data types, while the others require that the data be regular or regular-with-replication. Of course, the trend specification is only a part of the overall model specification. Therefore, the other parts of the model can imply additional constraints on the data type.

Table 27.3 lists the available trend models and their data requirements. The *type* column shows the admissible keywords that signify the particular trend type. For brevity, the Data Type column in Table 27.3 groups the regular and regular-with-replication data types into one category: regular. The section “Predefined Trend Models” on page 1855 provides additional details about these trend models.

Table 27.3 Summary of Trend Types

<i>type</i>	Data Type	Description	Parameters
ARIMA(P= <i>integer</i> D= <i>integer</i> ...)	Regular	ARIMA trend specification	AR and MA coefficients, and the error variance σ^2
DLL	Regular	Damped local linear	Level and slope σ_1^2, σ_2^2 , damping factor ϕ
LL	Regular	Local linear	Level and slope σ_1^2, σ_2^2
RW	Regular	Random walk	Level σ^2

Table 27.3 continued

<i>type</i>	Data Type	Description	Parameters
DECAY	Irregular	A type of decay pattern	Level σ^2 , decay rate ϕ
DECAY(OU)	Irregular	Ornstein-Uhlenbeck decay pattern	Level σ^2 , decay rate ϕ
GROWTH	Irregular	A type of growth pattern	Level σ^2 , growth rate ϕ
GROWTH(OU)	Irregular	Ornstein-Uhlenbeck growth pattern	Level σ^2 , growth rate ϕ
PS(<i>order</i>)	Irregular	Polynomial spline of order up to 3	Level σ^2

The keyword specification of different trend types, except possibly the ARIMA trend, is quite simple. For example, the following statement specifies `polySpline` as a trend of type polynomial spline of order 2:

```
trend polySpline(ps(2));
```

Similarly, the following statement defines `dampedTrend` as a damped local linear trend:

```
trend dampedTrend(dll) slopevar=x;
```

The variance parameter that governs the slope equation of this trend type is given by a variable `x`, which must be defined elsewhere in the program. The other parameters that define `dampedTrend` are left unspecified.

The ARIMA trend specification permits specification of trends that follow an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model. The specification of ARIMA models requires some notation, which is explained first.

Let B denote the backshift operator—that is, for any sequence μ_t , $B\mu_t = \mu_{t-1}$. The higher powers of B represent larger shifts (for example, $B^3\mu_t = \mu_{t-3}$). A random sequence μ_t follows an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model with nonseasonal autoregressive order p , seasonal autoregressive order P , nonseasonal differencing order d , seasonal differencing order D , nonseasonal moving average order q , and seasonal moving average order Q if it satisfies the following difference equation that is specified in terms of the polynomials in the back-shift operator, where a_t is a white noise sequence and s is the season length:

$$\phi(B)\Phi(B^s)(1-B)^d(1-B^s)^D\mu_t = \theta(B)\Theta(B^s)a_t$$

The polynomials ϕ , Φ , θ , and Θ are of orders p , P , q , and Q , respectively, which can be any nonnegative integers. The season length s must be a positive integer. For example, μ_t satisfies an $\text{ARIMA}(1,0,1)$ model (that is, $p = 1$, $d = 0$, $q = 1$, $P = 0$, $D = 0$, and $Q = 0$) if

$$\mu_t = \phi_1\mu_{t-1} + a_t - \theta_1a_{t-1}$$

for some coefficients ϕ_1 and θ_1 and a white noise sequence a_t . Similarly μ_t satisfies an $\text{ARIMA}(0,1,1) \times (0,1,1)_{12}$ model if

$$\mu_t = \mu_{t-1} + \mu_{t-12} - \mu_{t-13} + a_t - \theta_1a_{t-1} - \Theta_1a_{t-12} + \theta_1\Theta_1a_{t-13}$$

for some coefficients θ_1 and Θ_1 and a white noise sequence a_t . An ARIMA process is mean-zero, stationary, and invertible if $d = 0$, $D = 0$, and the defining polynomials ϕ , Φ , θ , and Θ have all their roots outside the unit circle—that is, their absolute values are strictly larger than 1.0. It is assumed that the coefficients of the polynomials ϕ , Φ , θ , and Θ are constrained so that the stationarity and invertibility conditions are satisfied.

The unknown coefficients of these polynomials become part of the model parameter vector that is estimated by using the data. The general form of ARIMA trend specification is as follows:

ARIMA(*<P=integer>* *<D=integer>* *<Q=integer>* *<SP=integer>* *<SD=integer>* *<SQ=integer>* *<S=integer>*)

By default, the different orders are equal to 0 and the season length is equal to 1. The following examples illustrate a few different ARIMA trend specifications:

This statement defines `ima` as an integrated moving average trend:

```
trend ima(arima(d=1 q=1));
```

This statement defines `airTrend` as a trend that satisfies the well-known Airline model (ARIMA(0,1,1)(0,1,1)₁₂ model) for monthly seasonal data:

```
trend airTrend(arima(d=1 q=1 sd=1 sq=1 s=12));
```

This statement defines `arma11` as a zero-mean ARMA(1,1) trend with autoregressive parameter fixed to 0.1:

```
trend arma11(arima(p=1 q=1)) ar=0.1;
```

For an example of the use of ARIMA trend specification, see the example [Example 27.6](#).

TREND Statement Options

You can use the following *options* in the TREND statement to specify the trend parameters and to request printing of the trend estimates. In addition, you can create a custom combination of given trend type by specifying the `CROSS=` option to create a more general trend. For an example of the use of the `CROSS=` option, see the section “[Getting Started: SSM Procedure](#)” on page 1815 and the discussion of the second model in [Example 27.4](#).

AR= $\phi_1 \phi_2 \dots \phi_p$

lists the values of the coefficients of the nonseasonal autoregressive polynomial

$$\phi(B) = 1 - \phi_1 B - \dots - \phi_p B^p$$

where the order p is specified in the ARIMA trend specification. The coefficients ϕ_i must define a stationary autoregressive polynomial.

CROSS=(*var1, var2, ...*)

CROSS(MATCHPARM)=(*var1, var2, ...*)

creates a linear combination of one or more independent trend components that is based on the variables in the list. If the parameters of the trend are specified by options such as the `LEVELVAR=` option or the `PHI=` option, these parameters are shared by these constituent trends. For example, suppose that the `CROSS=` list contains two variables (X_1 and X_2) and the trend specification is of the type RW. The effect of `CROSS=(X_1, X_2)` is to create a component $\mu_t = X_1 \mu_{1,t} + X_2 \mu_{2,t}$, where $\mu_{1,t}$ and $\mu_{2,t}$ are two independent random walk trends. Moreover, if the random walk trend specification uses the `LEVELVAR=` option to specify the variance parameter, $\mu_{1,t}$ and $\mu_{2,t}$ share the same variance parameter; otherwise, two separate variance parameters are assigned to these random walks.

If the second form of the CROSS option, CROSS(MATCHPARM)=, is used, then the constituent trends share all the relevant parameters no matter how they are specified. The CROSS= option is useful for a variety of situations. For example, suppose X is an indicator variable that is 1 before a certain time point t_0 and 0 thereafter. Then CROSS=(X) has the effect of turning off the trend component after time t_0 . Similarly, suppose G_1 and G_2 are indicators for gender—for example, $G_1 = (\text{GENDER}=\text{"M"})$ and $G_2 = (\text{GENDER}=\text{"F"})$. Then CROSS=(G_1, G_2) creates a trend that varies with the gender of the observation. The variables in the CROSS= list must be free of unknown parameters.

The CROSS= option can be computationally expensive; computationally it is equivalent to specifying as many separate trends as the number of variables in the specified list.

LEVELVAR=*variable* | *number*

specifies the disturbance variance parameter for all the trend types. For trend types LL and DLL, this option specifies σ_1^2 . Any nonnegative value, including 0, is permissible. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the LEVELVAR= option is not specified, σ^2 is estimated from the data.

MA= $\theta_1 \theta_2 \dots \theta_q$

lists the values of the coefficients of the nonseasonal moving average polynomial,

$$\theta(B) = 1 - \theta_1 B - \dots - \theta_q B^q$$

where the order q is specified in the ARIMA trend specification. The coefficients θ_i must define an invertible moving average polynomial.

NODIFFUSE

causes the diffuse elements in the initial state of the state subsection underlying the trend component to be treated as nondiffuse. This option is applicable to all trend types except ARIMA. For the ARIMA trend type, this option is ignored even if the nonseasonal or seasonal differencing orders are nonzero. The diffuse elements are assumed to be independent, zero-mean, Gaussian variables. Their variances become part of the parameter vector and are estimated by using the data. This option is useful for creating a trend component that can be interpreted as a deviation from an overall trend component (with diffuse initialization), which is defined separately.

PHI=*variable* | *number*

specifies the value of ϕ for trend types DLL, DECAY, DECAY(OU), GROWTH, and GROWTH(OU). For the type DLL, the specified value must be between 0.0 and 1.0. For types DECAY and DECAY(OU), ϕ must be strictly negative. For types GROWTH and GROWTH(OU), ϕ must be strictly positive. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the PHI= option is not specified, ϕ is estimated from the data.

PRINT=COV | COV1 | FILTER | SMOOTH | T

PRINT=(< COV > < COV1 > < FILTER > < SMOOTH > < T >)

requests printing of the respective system matrices of the state equation underlying the specified trend, and the printing of its filtered and smoothed estimates. If any of these matrices are time-varying, the matrix that corresponds to the first time instance is printed.

SAR= $\Phi_1 \Phi_2 \dots \Phi_P$

lists the values of the coefficients of the seasonal autoregressive polynomial

$$\Phi(B^s) = 1 - \Phi_1 B^s - \dots - \Phi_P B^{sP}$$

where the order P is specified by using the SP= option in the ARIMA trend specification and the season length s is specified in the S= option. The coefficients Φ_i must define a stationary autoregressive polynomial.

SMA= $\Theta_1 \Theta_2 \dots \Theta_Q$

lists the values of the coefficients of the seasonal moving average polynomial

$$\Theta(B^s) = 1 - \Theta_1 B^s - \dots - \Theta_Q B^{sQ}$$

where the order Q is specified by using the SQ= option in the ARIMA trend specification and the season length s is specified in the S= option. The coefficients Θ_i must define an invertible moving average polynomial.

SLOPEVAR=*variable | number*

specifies the second disturbance variance parameter, σ_2^2 , for trend types LL and DLL. Any nonnegative value, including 0, is permissible. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the SLOPEVAR= option is not specified, σ_2^2 is estimated from the data.

Details

Throughout this section, vectors and matrices are denoted by bold-faced letters. Generally, Greek letters (such as α , β , and ϵ) denote unobserved or latent quantities—often estimated from the data—that represent model parameters, latent states, or noise variables. Capital letters such as X , Y , and Z are used to denote the observed data variables. Whenever it is unambiguous, it is assumed that the matrices have appropriate dimensions when they are being multiplied—in particular, the vectors behave as column vectors or row vectors as the need arises. On many occasions, matrices are described inline—that is, they are described as parenthesized lists, in a rowwise fashion, with the rows separated by a comma. The term “dot product” is used to describe the scalar that results from the product of a row vector with a (conforming) column vector.

State Space Model and Notation

The (linear) state space model is described in the literature in a few different ways and with varying degree of generality. The description given in this section loosely follows the description given in Durbin and Koopman (2001, chap. 6, sec. 4). This formulation of SSM is quite general; in particular, it includes nonstationary SSMs with time-varying system matrices and state equations with a diffuse initial condition (these terms are defined later in this subsection).

Suppose that observations are collected in a sequential fashion (indexed by a numeric variable τ) on some variables: the vector $\mathbf{y} = (y_1, y_2, \dots, y_q)$, which denotes the q -variate response values, and the k -dimensional vector \mathbf{x} , which denotes the predictors. Suppose that the observation instances are $\tau_1 < \tau_2 < \dots < \tau_n$. The possibility that multiple observations are taken at a particular instance τ_i is not ruled out, and the successive observation instances do not need to be regularly spaced—that is, $(\tau_2 - \tau_1)$ does not need to equal $(\tau_3 - \tau_2)$. For $t = 1, 2, \dots, n$, suppose $p_t (\geq 1)$ denotes the number of observations recorded at instance τ_t . For notational simplicity, an integer-valued secondary index t is used to index the

data so that $t = 1$ corresponds to $\tau = \tau_1$, $t = 2$ corresponds to $\tau = \tau_2$, and so on. Consider the following model:

$$\begin{aligned} \mathbf{Y}_t &= \mathbf{Z}_t \boldsymbol{\alpha}_t + \mathbf{X}_t \boldsymbol{\beta} + \boldsymbol{\epsilon}_t && \text{Observation equation} \\ \boldsymbol{\alpha}_{t+1} &= \mathbf{T}_t \boldsymbol{\alpha}_t + \mathbf{c}_{t+1} + \boldsymbol{\eta}_{t+1} && \text{State transition equation} \\ \boldsymbol{\alpha}_1 &= \mathbf{c}_1 + \mathbf{A}_1 \boldsymbol{\delta} + \boldsymbol{\eta}_1 && \text{Initial condition} \end{aligned}$$

The following list describes these equations:

- The *observation equation* describes the relationship between the $(p_t * q)$ -dimensional response vector \mathbf{Y}_t and the unobserved vectors $\boldsymbol{\alpha}_t$, $\boldsymbol{\beta}$, and $\boldsymbol{\epsilon}_t$. The q -variate responses are vertically stacked in a column to form this $(p_t * q)$ -dimensional response vector \mathbf{Y}_t . The m -dimensional vectors $\boldsymbol{\alpha}_t$ are called *states*, the k -dimensional vector $\boldsymbol{\beta}$ is the regression coefficient vector associated with predictors \mathbf{x} , and the $(p_t * q)$ -dimensional vectors $\boldsymbol{\epsilon}_t$ are called the *observation disturbances*. The matrices \mathbf{Z}_t (of dimension $(q * p_t) \times m$) and \mathbf{X}_t (of dimension $(q * p_t) \times k$) correspond to the *state effect* and the *regression effect*, respectively. The elements of \mathbf{X}_t are assumed to be fully known. The states $\boldsymbol{\alpha}_t$ and the disturbances $\boldsymbol{\epsilon}_t$ are *random* sequences. It is assumed that $\boldsymbol{\epsilon}_t$ is a sequence of independent, zero-mean, Gaussian random vectors with diagonal covariances, with the diagonal elements denoted by $\sigma_{t,i}^2, i = 1, 2, \dots, q * p_t$.
- The state sequence $\boldsymbol{\alpha}_t$ is assumed to follow a Markovian structure described by the state transition equation and the associated initial condition.
- The *state transition equation* postulates that a new instance of the state, $\boldsymbol{\alpha}_{t+1}$, is obtained by multiplying its previous instance, $\boldsymbol{\alpha}_t$, by an m -dimensional square matrix \mathbf{T}_t (called the state transition matrix) and by adding two vectors: a known nonrandom vector \mathbf{c}_{t+1} (called the state input) and a random disturbance vector $\boldsymbol{\eta}_{t+1}$. The m -dimensional state disturbance vectors $\boldsymbol{\eta}_t$ are assumed to be independent, zero-mean, Gaussian random vectors with covariances \mathbf{Q}_t (not necessarily diagonal).
- The *initial condition* describes the starting condition of the state evolution equation. The starting state vector $\boldsymbol{\alpha}_1$ is assumed to be partially diffuse: it is the sum of a known nonrandom vector \mathbf{c}_1 , a mean-zero Gaussian vector $\boldsymbol{\eta}_1$, and a term $\mathbf{A}_1 \boldsymbol{\delta}$ that represents the contribution from a d -dimensional diffuse vector $\boldsymbol{\delta}$ (a diffuse vector is a Gaussian vector with infinite covariance). The $m \times d$ matrix \mathbf{A}_1 is assumed to be completely known.
- The observation disturbances $\boldsymbol{\epsilon}_t$ and the state disturbances $\boldsymbol{\eta}_t$ (for $t \geq 1$) are assumed to be mutually independent. Either the elements of the matrices \mathbf{Z}_t , \mathbf{T}_t , and \mathbf{Q}_t and the diagonal elements of the observation disturbance covariances $\sigma_{t,i}^2$ are assumed to be completely known, or some of them can be functions of a small set of unknown parameters (to be estimated from the data). Suppose that this unknown set of parameters is denoted by $\boldsymbol{\theta}$.
- The d -dimensional diffuse vector $\boldsymbol{\delta}$ from the state initial condition together with the k -dimensional regression coefficient vector $\boldsymbol{\beta}$ constitute the overall $(d + k)$ -dimensional diffuse initial condition of the model. See the section “[Likelihood, Filtering, and Smoothing](#)” on page 1850 for more information.

Although this description of the state space model might appear involved, it conveniently covers many variants of the SSMs that are encountered in practice and precisely describes the most general case that can be handled by the SSM procedure. An important restriction about the preceding description of the model formulation is that it assumes that the matrices \mathbf{X}_t that appear in the observation equation are free of unknown parameters and that the covariances of the observation disturbances $\boldsymbol{\epsilon}_t$ are diagonal. In most

practical situations, the model under consideration can be easily reformulated to a statistically equivalent form that conforms to this restriction.

For easy reference, Table 27.4 summarizes the information contained in the SSM equations.

Table 27.4 State Space Model: Notation

Notation	Description
$\tau_1, \tau_2, \dots, \tau_n$	Distinct index values at which the observations are recorded
n	Number of distinct index instances
p_t	Number of observations recorded at index τ_t , $t = 1, 2, \dots, n$
q	Number of response variables in the model
$\mathbf{Y}_t = (y_{t,1}, y_{t,2}, \dots, y_{t,p_t * q})$	Vertically stacked vector of response values recorded at τ_t
$N = q * \sum_{t=1}^n p_t$	Total number of response values in the data set
k	Number of predictor (regressor) variables in the observation equation
\mathbf{X}_t	$(p_t * q) \times k$ matrix of predictor values recorded at τ_t
$\boldsymbol{\beta}$	k -dimensional regression vector that is associated with the predictors
$\boldsymbol{\epsilon}_t \sim N(0, (\sigma_{t,1}^2, \dots))$	$(q * p_t)$ -dimensional observation disturbance vector with diagonal covariance
m	Dimension of the state vectors $\boldsymbol{\alpha}_t$
$\boldsymbol{\alpha}_t$	m -dimensional state vector
\mathbf{Z}_t	$(q * p_t) \times m$ matrix that is associated with $\boldsymbol{\alpha}_t$ in the observation equation
\mathbf{T}_t	$m \times m$ state transition matrix
\mathbf{c}_t	m -dimensional state input vector
$\boldsymbol{\eta}_t \sim N(0, \mathbf{Q}_t)$	m -dimensional state disturbance vector
d	Dimension of the diffuse vector $\boldsymbol{\delta}$ in the state initial condition
$\boldsymbol{\delta} \sim N(0, \kappa \Sigma), \kappa \rightarrow \infty$	Diffuse vector in the state initial condition
\mathbf{A}_1	$m \times d$ constant matrix associated with $\boldsymbol{\delta}$
$\boldsymbol{\eta}_1 \sim N(0, \mathbf{Q}_1)$	m -dimensional state disturbance vector in the initial condition
$\boldsymbol{\theta}$	Parameter vector

Types of Data Organization

The state space model specification in the SSM procedure requires proper understanding of both the data organization and the form of the model. The SSMs that are appropriate for time series data might not be appropriate for irregularly spaced longitudinal data. The SSM procedure distinguishes three types of data organization based on the way the observations are sequenced by the index variable. If an index variable is not specified, it is assumed that the observations are sequenced according to the observation number.

Regular: The observations are recorded at regularly spaced intervals; that is, $\tau_1, \tau_2, \dots, \tau_n$ are regularly spaced. Moreover, at each observation instance τ_i a single observation is recorded; that is, $p_t = 1$ for all t . The standard time series data (both univariate and multivariate) fall in this category.

Regular with Replication: The observations are recorded at regularly spaced intervals, but $p_t > 1$ for at least one t . Here the word replication is used loosely—it does not mean that the multiple observations at τ_t are replications in the precise statistical sense. The panel or cross-sectional data types fall into this category. In the panel data case with p cross-sections, $p_t = p$ for all t .

Irregular: The observations are not recorded at regular intervals, and the number of observations p_t at each index instance can be different. The longitudinal data fall into this category.

It is not always easy to decide whether the specified model is appropriate for the given data type. Whenever possible, the SSM procedure issues a note regarding the possible mismatch between the specified model and the data type being analyzed.

Overview of Model Specification Syntax

An SSM specification involves the description of the terms in the observation equation, the state transition equation, and the initial condition. For example, the response variables, the predictor variables, and the elements of the state transition matrix \mathbf{T}_t must somehow be specified. The SSM procedure syntax is designed so that little effort is needed to specify the more commonly needed models, while a highly flexible language is available for specifying more complex models. Two syntax features help achieve this goal: the ability to build a complex specification by combining simpler subspecifications, and a programming language for creating lists of variables to be used later in the model specification.

The SSM procedure statements can be divided into two classes:

- **programming statements**, which are used to create lists of variables that can be used for a variety of purposes (for example, as the elements of the model system matrices)
- statements specific to the SSM procedure that formulate the state space model and control its other aspects such as the input data specification and the resulting output

Since the matrices involved in the model specification can be specified as lists of variables, which you separately create by using the programming statements, you can finely control all aspects of the model specification. These programming statements permit the use of most DATA step language features such as the conditional logic (IF-THEN-ELSE), array type variables, and all the mathematical functions available in the DATA step. You can also use programming statements to define predictor variables on the fly.

Building a Complex Model Specification

In addition to being able to specify the system matrices in a flexible way, you can also build a complex model specification in a modular way by combining simpler subspecifications. Suppose that the state vector for the model to be specified is composed of subsections that are statistically independent, which is a common scenario in practical modeling situations. For example, suppose that $\boldsymbol{\alpha}_t$ can be divided into two disjoint subsections $\boldsymbol{\alpha}_t^a$ and $\boldsymbol{\alpha}_t^b$, which are statistically independent. This entails a corresponding block-diagonal structure to the system matrices \mathbf{T}_t and \mathbf{Q}_t that govern the state equations. In this case the term $\mathbf{Z}_t \boldsymbol{\alpha}_t$ that appears in the observation equation also splits into the sum $\mathbf{Z}_t^a \boldsymbol{\alpha}_t^a + \mathbf{Z}_t^b \boldsymbol{\alpha}_t^b$ for appropriately partitioned matrices \mathbf{Z}_t^a and \mathbf{Z}_t^b . The model specification syntax of the SSM procedure makes building an SSM from such smaller pieces easy. Throughout this chapter, the linear combinations of the state subsections (such as $\mathbf{Z}_t^a \boldsymbol{\alpha}_t^a$) that appear in the observation equation are called *components*. An SSM specification in the SSM procedure is created by combining separate component specifications. In general, you specify a component in two steps: first you define a state subsection $\boldsymbol{\alpha}_t^a$, and then you define a matching linear combination $\mathbf{Z}_t^a \boldsymbol{\alpha}_t^a$. For some special components, such as some commonly needed *trend* components, you can combine these two steps into one keyword specification.

The following list summarizes the (nonprogramming) SSM procedure syntax statements used for model specification:

- The **ID** statement specifies the index variable (τ). It is assumed that the data within each BY group are ordered (in ascending order) according to the ID variable. The SSM procedure automatically creates a variable, `_ID_DELTA_`, which contains the difference between the successive ID values. This variable is available for use by the programming statements to define time-varying system matrices. For example, in the case of SSMs used for modeling the longitudinal data, the T_t and Q_t matrices often depend on `_ID_DELTA_` (see [Example 27.5](#)).
- The **PARMS** statement specifies variables that serve as the parameters of the model. That is, it partially defines the model parameter vector θ . Other elements of θ are implicitly defined if your specification of the system matrices is not fully complete.
- The **STATE** statement specifies a subsection of the model state vector. Multiple STATE statements can be used in the model specification; each one defines a statistically independent subsection of the model state vector. For full customization, T_t and Q_t blocks that govern this subsection can be specified as lists of variables that are created by programming statements. However, you can obtain many commonly needed state subsection types simply by using the `TYPE=` option in this statement. For example, the use of `TYPE=SEASON(LENGTH=12)` results in a state subsection that can be used to define a monthly seasonal component.
- The **COMPONENT** statement specifies a linear combination that matches a state subsection that is previously defined in a STATE statement. Thus, a matching pair of STATE and COMPONENT statements define a component.
- The **TREND** statement is used for easy specification of some commonly needed trend components.
- The **IRREGULAR** statement specifies the observation disturbance for a particular response variable.
- The **MODEL** statement specifies the observation equation for one of the response variables. A separate MODEL statement is needed for each response variable in the multivariate case. The MODEL statement specifies an equation in which the left-hand side is the response variable and the right-hand side is a list that contains components and regression variables.

Model Specification Steps

To illustrate the model specification steps, suppose y is a response variable and variables x_1 and x_2 are predictors. The following statements specify a model for y that includes two components named `cycle` and `randomWalk`, predictors x_1 and x_2 , and an observation disturbance named `whiteNoise`:

```
parms lambda / lower=(1.e-6) upper=(3.14);
parms cycleVar / lower=(1.e-6);
array cycleT{4} c1-c4;
c1 = cos(lambda);
c2 = sin(lambda);
c3 = -c2;
c4 = c1;
state s_cycle(2) T(g)=(cycleT) cov(I)=(cycleVar) a1(2);
component cycle=(1 0)*s_cycle;
```

```

trend randomWalk(rw);
irregular whiteNoise;
model y = x1 x2 randomWalk cycle whiteNoise;

```

The specification begins with a PARMS statement that defines two parameters, `lambda` and `cycleVar`, along with their lower and upper bounds (essentially 0 and π for `lambda`, and 0 and infinity for `cycleVar`). Next, programming statements define an array of variables, `cycleT`, which contains four variables, `c1–c4`; these variables are used later for defining the elements of the transition matrix of a state subsection. The STATE statement specifies the two-dimensional subsection `s_cycle`; the dimension appears within the parentheses after the name (`s_cycle(2)`). The T= option specifies the transition matrix for the `s_cycle` ($\mathbf{T}(\mathbf{g}) = (\mathbf{cycleT})$); the `g` in $\mathbf{T}(\mathbf{g})$ signifies that the form of the T matrix is *general*. The COV= option (`cov(I) = (cycleVar)`) specifies the covariance of the state disturbance (\mathbf{Q}_t for $t \geq 2$); because of the use of `I` in `cov(I)`, the covariance is of the form scaled identity, essentially a two-dimensional diagonal matrix with both diagonal elements equal to `cycleVar`. The initial condition for `s_cycle` is completely diffuse because the A1= option, which specifies \mathbf{A}_1 , specifies that the dimension of the diffuse vector $\boldsymbol{\delta}$ is 2: `a1(2)`. In this case there is no need to specify the covariance \mathbf{Q}_1 in the initial condition. The COMPONENT statement specifies the component `cycle`. It specifies `cycle` as a dot product of two vectors—(1 0) and `s_cycle`, which merely selects the first element of `s_cycle`: `component cycle = (1 0) * s_cycle`. The TREND statement defines a component named `randomWalk`; its type is `rw`, which signifies random walk. The IRREGULAR statement defines an observation disturbance named `whiteNoise`. Both the `randomWalk` and `whiteNoise` specifications are only partially complete—for example, the disturbance variance of `whiteNoise` is not specified. These unspecified variances, `trendVar`, which corresponds to `randomWalk`, and `wnVar`, which corresponds to `whiteNoise`, are automatically included in the list of unknown parameters, $\boldsymbol{\theta}$, along with the parameters that are defined by the PARMS statements. Thus, the parameter vector for this model is $\boldsymbol{\theta} = (\text{lambda } \text{cycleVar } \text{trendVar } \text{wnVar})$. Finally, the model specification is completed by the MODEL statement, which specifies the components of the observation equation: the response variable `y`, the predictors `x1` and `x2`, the components `randomWalk` and `cycle`, and the irregular term `whiteNoise`.

The preceding statements result in an SSM with a three-dimensional state vector, which is the result of combining the two-dimensional state subsection, `s_cycle`, and a one-dimensional subsection underlying the trend, `randomWalk`. In this specification, the initial state is completely diffuse with \mathbf{Q}_1 a null matrix, and \mathbf{A}_1 equal to the three-dimensional identity. The other state system matrices \mathbf{T}_t and \mathbf{Q}_t are time-invariant:

$$\mathbf{T} = \begin{bmatrix} \cos(\text{lambda}) & \sin(\text{lambda}) & 0 \\ -\sin(\text{lambda}) & \cos(\text{lambda}) & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad \mathbf{Q} = \begin{bmatrix} \text{cycleVar} & 0 & 0 \\ 0 & \text{cycleVar} & 0 \\ 0 & 0 & \text{trendVar} \end{bmatrix}$$

The observation equation is obvious with $\mathbf{Z} = [1 \ 0 \ 1]$.

Sparse Transition Matrix Specification

It often happens that the transition matrix \mathbf{T} (or \mathbf{T}_t in the time-varying case) specified in a STATE statement is sparse—that is, many of its elements are zero. The algorithms in the SSM procedure exploit this sparsity for computational efficiency. In most cases the sparsity of a T-block can be inferred from the context. However, if the elements of the T-block are supplied by a list of variables in parentheses, it can be difficult to recognize elements that are structurally zero (this is because of the generality of the DATA step language used for defining the variables). To simplify the specification of such sparse transition matrix, SSM procedure has adopted a convention: the variables that correspond to structural zeros can (and should) be left *unset*—that is, these variables are declared, but no value is assigned to them. As an example, suppose that

a three-dimensional state subsection has the following form of transition matrix for some variables X1, X2, and X3 defined elsewhere in the program:

$$T = \begin{bmatrix} X1 & 0 & 0 \\ X2 & X1 & 0 \\ X3 & 0 & X1 \end{bmatrix}$$

The following (incomplete) statements show how to specify such a T-block:

```
array tMat{3,3};
do i=1 to 3;
  tMat[i, i] = x1;
end;
tMat[2,1] = x2;
tMat[3,1] = x3;
state foo(3) T(g)=(tMat) ...;
```

In this specification only the nonzero elements of the tMat array, which contains $3 \times 3 = 9$ elements, are assigned a value. On the other hand, the following statements show an alternate way of specifying the same T-block. This specification explicitly sets the zeros in the T-block (the elements above the diagonal and tMat[3,2]) to 0.

```
array tMat{3,3};
do i=1 to 3;
  do j=1 to 3;
    if i=j then tMat[i, j] = x1;
    else if j > i then tMat[i, j] = 0;
  end;
end;
tMat[2,1] = x2;
tMat[3,1] = x3;
tMat[3,2] = 0;
state foo(3) T(g)=(tMat) ...;
```

The first specification is simpler, and is preferred. The second specification is mathematically equivalent (and generates the same output) but is computationally less efficient since its sparsity structure cannot always be reliably inferred due to the generality of the DATA step language. In the first specification, the unset elements are recognized to be *structural* zeros while the set elements are treated as nonzero for sparsity purposes. See [Example 27.5](#) for a simple illustration. Proper sparsity specification can lead to significant computational savings for larger matrices.

Regression Variable Specification in Multivariate Models

Suppose that a regression variable in a multivariate model affects two or more response variables. For example, suppose that response variables y1 and y2 depend on a regression variable x. This dependence can be categorized as one of two types:

- In the more common case, the regression coefficient of x for y1 and the regression coefficient of x for y2 are different. The relationship can be described as follows:

$$\begin{aligned} y1 &= \beta_1 x + \text{other terms} \\ y2 &= \beta_2 x + \text{other terms} \end{aligned}$$

In the SSM procedure you can specify this type of relationship in two equivalent ways:

- You can specify the variable x in the MODEL statement for y_1 and specify the variable x_copy (a copy of x) in the MODEL statement for y_2 as follows:

```
x_copy = x;           /* create a copy of x */
model y1 = x ...;
model y2 = x_copy ...;
```

- You can specify the variable x in MODEL statements for both y_1 and y_2 as follows:

```
model y1 = x ...;
model y2 = x ...;
```

This specification avoids creating x_copy .

Of these two alternate ways, the first is preferred because x and x_copy can then be unambiguously used in an EVAL statement to refer to the terms $\beta_1 x$ and $\beta_2 x$, respectively.

- In the less common case, y_1 and y_2 share a common regression coefficient. The relationship can be described as follows:

$$\begin{aligned} y_1 &= \beta x + \text{other terms} \\ y_2 &= \beta x + \text{other terms} \end{aligned}$$

You can specify this type of relationship by placing the regression coefficient in the model state vector as follows:

```
state beta(1) T(I) A1(1) ;           /* beta is a constant state */
comp xeffect = beta*(x) ;
model y1 = xeffect ...;
model y2 = xeffect ...;
```

Here the STATE statement defines β as a one-dimensional, time-invariant constant (because the transition matrix is identity, the disturbance covariance is 0 and the initial state is diffuse). Next, the COMP statement defines $xeffect$ as the product between β and the variable x . Subsequently, both y_1 and y_2 use $xeffect$ in their respective MODEL statements.

Likelihood, Filtering, and Smoothing

The Kalman filter and smoother (KFS) algorithm is the main computational tool for using SSM for data analysis. This subsection briefly describes the basic quantities generated by this algorithm and their relationship to the output generated by the SSM procedure. For proper treatment of SSMs with a diffuse initial condition or when regression variables are present, a modified version of the traditional KFS, called diffuse Kalman filter and smoother (DKFS), is needed. A good discussion of the different variants of the traditional and diffuse KFS can be found in Durbin and Koopman (2001). The DKFS implemented in the SSM procedure closely follows the treatment in de Jong and Chu-Chun-Lin (2003). Additional details can be found in these references.

The state space model equations (see the section “State Space Model and Notation” on page 1843) imply that the combined response data vector $\mathbf{Y} = (\mathbf{Y}_1, \mathbf{Y}_2, \dots, \mathbf{Y}_n)$ has a Gaussian probability distribution. This

probability distribution is *proper* if d , the dimension of the diffuse vector δ in the initial condition, is 0 and if k , the number of regression variables in the observation equation, is also 0 (the regression parameter β is also treated as a diffuse vector). Otherwise, this probability distribution is *improper*. The KFS algorithm is a combination of two iterative phases: a forward pass through the data, called *filtering*, and a backward pass through the data, called *smoothing*, that uses the quantities generated during filtering. One of the advantages of using the SSM formulation to analyze the time series data is its ability to handle the missing values in the response variables. The KFS algorithm appropriately handles the missing values in \mathbf{Y} . For additional information about how PROC SSM handles missing values, see the section “Missing Values” on page 1864.

Filtering Pass

The filtering pass sequentially computes the quantities shown in Table 27.5 for $t = 1, 2, \dots, n$ and $i = 1, 2, \dots, q * p_t$.

Table 27.5 KFS: Filtering Phase

Quantity	Description
$\hat{y}_{t,i} = E(y_{t,i} y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	One-step-ahead prediction of the response values
$v_{t,i} = y_{t,i} - \hat{y}_{t,i}$	One-step-ahead prediction residuals
$F_{t,i} = \text{Var}(y_{t,i} y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	Variance of the one-step-ahead prediction
$\hat{\alpha}_{t,i} = E(\alpha_t y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	One-step-ahead prediction of the state vector
$\mathbf{P}_{t,i} = \text{Cov}(\alpha_t y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	Covariance of $\hat{\alpha}_{t,i}$
$\mathbf{b}_{t,i}$	$(d + k)$ -dimensional vector
$\mathbf{S}_{t,i}$	$(d + k)$ -dimensional symmetric matrix
$(\hat{\delta})_{t,i} = \mathbf{S}_{t,i}^{-1} \mathbf{b}_{t,i}$	Estimate of δ and β by using the data up to (t, i)
$\mathbf{S}_{t,i}^{-1}$	Covariance of $(\hat{\delta})_{t,i}$

Here the notation $E(y_{t,i} | y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$ denotes the *conditional expectation* of $y_{t,i}$ given the history up to the index $(t, i - 1)$: $(y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$. Similarly $\text{Var}(y_{t,i} | y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$ denotes the corresponding conditional variance. The quantity $v_{t,i} = y_{t,i} - \hat{y}_{t,i}$ is set to missing whenever $y_{t,i}$ is missing. Note that $\hat{y}_{t,i}$ are *one-step-ahead* forecasts only when the model has only one response variable and the data are a time series; in all other cases it is more appropriate to call them *one-measurement-ahead* forecasts (since the next measurement might be at the same time point). Despite this, $\hat{y}_{t,i}$ are called one-step-ahead predictions (and $v_{t,i}$ are called one-step-ahead residuals) throughout this document. In the diffuse case, the conditional expectations must be appropriately interpreted. The vector $\mathbf{b}_{t,i}$ and the matrix $\mathbf{S}_{t,i}$ contain some accumulated quantities that are needed for the estimation of δ and β . Of course, when $(d + k) = 0$ (the nondiffuse case), these quantities are not needed. In the diffuse case, because the matrix $\mathbf{S}_{t,i}$ is sequentially accumulated (starting at $t = 1, i = 1$), it might not be invertible until some $t = t_*, i = i_*$. The filtering process is called *initialized* after $t = t_*, i = i_*$. In some situations, this initialization might not happen even after the entire sample is processed—that is, the filtering process remains *uninitialized*. This can happen if the regression variables are collinear or if the data are not sufficient to estimate the initial condition δ for some other reason.

The filtering process is used for a variety of purposes. One important use of filtering is to compute the likelihood of the data. In the model-fitting phase, the unknown model parameters θ are estimated by maximum likelihood. This requires repeated evaluation of the likelihood at different trial values of θ . After θ is estimated, it is treated as a known vector. The filtering process is used again with the fitted model in the

forecasting phase, when the one-step-ahead forecasts and residuals based on the fitted model are provided. In addition, this filtering output is needed by the smoothing phase to produce the full-sample component estimates.

Likelihood Computation and Model Fitting Phase

In view of the Gaussian nature of the response vector, the likelihood of \mathbf{Y} , $\mathbf{L}(\mathbf{Y}, \boldsymbol{\theta})$, can be computed by using the prediction-error decomposition, which leads to the formula

$$-2 \log \mathbf{L}(\mathbf{Y}, \boldsymbol{\theta}) = N_0 * \log 2\pi + \sum_{t=1}^n \sum_{i=1}^{q * p_t} \left(\log F_{t,i} + \frac{v_{t,i}^2}{F_{t,i}} \right) - \log(|\mathbf{S}_{n,p_n}^{-1}|) - \mathbf{b}_{n,p_n}' \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$$

where $N_0 = (N - k - d)$, $|\mathbf{S}_{n,p_n}^{-1}|$ denotes the determinant of \mathbf{S}_{n,p_n}^{-1} , and \mathbf{b}_{n,p_n}' denotes the transpose of the column vector \mathbf{b}_{n,p_n} . In the preceding formula, the terms that are associated with the missing response values $y_{t,i}$ are excluded and N denotes the total number of nonmissing response values in the sample. If \mathbf{S}_{n,p_n} is not invertible, then a generalized inverse is used in place of \mathbf{S}_{n,p_n}^{-1} , and $|\mathbf{S}_{n,p_n}^{-1}|$ is computed based on the nonzero eigenvalues of \mathbf{S}_{n,p_n} . Moreover, in this case $N_0 = N - \text{Rank}(\mathbf{S}_{n,p_n})$. When \mathbf{Y} has a proper distribution (that is, when $(d + k) = 0$), the terms that involve \mathbf{S}_{n,p_n} and \mathbf{b}_{n,p_n} are absent and the preceding likelihood is proper. Otherwise, it is called the diffuse likelihood or the restricted likelihood.

When the model specification contains any unknown parameters $\boldsymbol{\theta}$, they are estimated by maximizing the preceding likelihood function. This is done by using a nonlinear optimization process that involves repeated evaluations of $\mathbf{L}(\mathbf{Y}, \boldsymbol{\theta})$ at different values of $\boldsymbol{\theta}$. The maximum likelihood (ML) estimate of $\boldsymbol{\theta}$ is denoted by $\hat{\boldsymbol{\theta}}$. When the restricted likelihood is used for computing $\hat{\boldsymbol{\theta}}$, the estimate is called the restricted maximum likelihood (REML) estimate. Approximate standard errors of $\hat{\boldsymbol{\theta}}$ are computed by taking the square root of the diagonal elements of its (approximate) covariance matrix. This covariance is computed as $-\mathbf{H}^{-1}$, where \mathbf{H} is the Hessian (the matrix of the second-order partials) of $\log \mathbf{L}(\mathbf{Y}, \boldsymbol{\theta})$ evaluated at the optimum $\hat{\boldsymbol{\theta}}$.

Let $\dim(\boldsymbol{\theta})$ denote the dimension of the parameter vector $\boldsymbol{\theta}$. After the parameter estimation is completed, a table, called “Likelihood Computation Summary” is printed. It summarizes the likelihood calculations at $\hat{\boldsymbol{\theta}}$ as shown in Table 27.6.

Table 27.6 Likelihood Computation Summary

Quantity	Formula
Nonmissing response values used	N
Estimated parameters	$\dim(\boldsymbol{\theta})$
Initialized diffuse state elements	$\text{Rank}(\mathbf{S}_{n,p_n})$
Normalized residual sum of squares	$\sum_{t=1}^n \sum_{i=1}^{q * p_t} \left(\frac{v_{t,i}^2}{F_{t,i}} \right) - \mathbf{b}_{n,p_n}' \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$
Full log likelihood	$\log \mathbf{L}(\mathbf{Y}, \hat{\boldsymbol{\theta}})$

In addition, the “Likelihood Based Information Criteria” table reports a variety of information-based criteria, which are functions of $-2 \log \mathbf{L}(\mathbf{Y}, \hat{\boldsymbol{\theta}})$, N_0 , and $\dim(\boldsymbol{\theta})$. Table 27.7 summarizes the reported information criteria in smaller-is-better form:

Table 27.7 Information Criteria

Criterion	Formula	Reference
AIC	$-2 \log \mathbf{L} + 2 \dim(\theta)$	Akaike (1974)
AICC	$-2 \log \mathbf{L} + 2 \dim(\theta) N_0 / (N_0 - \dim(\theta) - 1)$	Hurvich and Tsai (1989) Burnham and Anderson (1998)
HQIC	$-2 \log \mathbf{L} + 2 \dim(\theta) \log \log(N_0)$	Hannan and Quinn (1979)
BIC	$-2 \log \mathbf{L} + \dim(\theta) \log(N_0)$	Schwarz (1978)
CAIC	$-2 \log \mathbf{L} + \dim(\theta)(\log(N_0) + 1)$	Bozdogan (1987)

Forecasting Phase

After the model-fitting phase, the filtering process is repeated again to produce the model-based one-step-ahead response variable forecasts ($\hat{y}_{t,i}$), residuals ($v_{t,i}$), and their standard errors ($\sqrt{F_{t,i}}$). In addition, one-step-ahead forecasts of the components that are specified in the MODEL statements, and any other user-defined linear combinations of α_t , are also produced. These forecasts are set to missing as long as the index $t < t_*$ (that is, until the filtering process is initialized). If the filtering process remains uninitialized, then all the quantities that are related to the one-step-ahead forecast (such as $\hat{y}_{t,i}$ and $v_{t,i}$) are reported as missing. When the fitted model is appropriate, the one-step-ahead residuals $v_{t,i}$ form a sequence of uncorrelated normal variates. This fact can be used during model diagnostic process.

Smoothing Phase

After the filtering phase of KFS produces the one-step-ahead predictions of the response variables and the underlying state vectors, the smoothing phase of KFS produces the full-sample versions of these quantities—that is, rather than using the history up to $(t, i - 1)$, the entire sample \mathbf{Y} is used. The smoothing phase of KFS is a backward algorithm, which begins at $t = n$ and $i = q * p_n$ and goes back toward $t = 1$ and $i = 1$. It produces the following quantities:

Table 27.8 KFS: Smoothing Phase

Quantity	Description
$\tilde{y}_{t,i} = E(y_{t,i} \mathbf{Y})$	Interpolated response value
$\tilde{F}_{t,i} = \text{Var}(y_{t,i} \mathbf{Y})$	Variance of the interpolated response value
$\tilde{\alpha}_t = E(\alpha_t \mathbf{Y})$	Full-sample estimate of the state vector
$\tilde{\mathbf{P}}_t = \text{Cov}(\alpha_t \mathbf{Y})$	Covariance of $\tilde{\alpha}_t$
$\begin{pmatrix} \tilde{\delta} \\ \tilde{\beta} \end{pmatrix} = \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$	Full-sample estimate of δ and β
\mathbf{S}_{n,p_n}^{-1}	Covariance of $\begin{pmatrix} \tilde{\delta} \\ \tilde{\beta} \end{pmatrix}$
$\text{AO}_{t,i} = y_{t,i} - E(y_{t,i} \mathbf{Y}^{t,i})$	Estimate of additive outlier
$g_{t,i}$	Variance of $\text{AO}_{t,i}$
ρ_t^{*2}	Maximal state shock chi-square statistic

Note that if $y_{t,i}$ is not missing, then $\tilde{y}_{t,i} = E(y_{t,i} | \mathbf{Y}) = y_{t,i}$ and $\tilde{F}_{t,i} = \text{Var}(y_{t,i} | \mathbf{Y}) = 0$ because $y_{t,i}$ is completely known, given \mathbf{Y} . Therefore, $\tilde{y}_{t,i}$ provides nontrivial information only when $y_{t,i}$ is missing—in which case $\tilde{y}_{t,i}$ represents the best estimate of $y_{t,i}$ based on the available data. The full-sample estimates

of components that are specified in the model equations are based on the corresponding linear combinations of $\tilde{\alpha}_t$. Similarly, their standard errors are computed by using appropriate functions of $\tilde{\mathbf{P}}_t$. The estimate of the additive outlier, $\text{AO}_{t,i} = y_{t,i} - \text{E}(y_{t,i}|\mathbf{Y}^{t,i})$, is the difference between the observed response value $y_{t,i}$ and its estimate or prediction by using all the data except $y_{t,i}$, which is denoted by $\mathbf{Y}^{t,i}$. The estimate $\text{AO}_{t,i}$ is missing when $y_{t,i}$ is missing. $\text{AO}_{t,i}$ is also called the *prediction error*—as opposed to the one-step-ahead residual, $v_{t,i}$. Similar to $v_{t,i}$, the prediction errors can be used in checking the model adequacy. The prediction errors are normally distributed; however, unlike $v_{t,i}$, they are not serially uncorrelated. You can request the printing of the prediction error sum of squares (PRESS) by specifying the PRESS option in the OUTPUT statement. The maximal state shock chi-square statistic, ρ_t^{*2} , is computed at each distinct time point and is described in de Jong and Penzer (1998) (the second term in the right-hand side of Equation 14). Loosely speaking, ρ_t^{*2} is a measure of the magnitude of unexpected change in the underlying state at time t . A large value of ρ_t^{*2} , which follows chi-square distribution with degrees of freedom equal to m (the state size), can signify change in the data generation mechanism at time t . For more information about the computation, precise definitions of additive outliers and maximal state shocks, and their use in the detection of structural change in the observation process, see de Jong and Penzer (1998). The computation of ρ_t^{*2} can be expensive for large state size and is not done by default. You can turn on its computation by specifying the MAXSHOCK option in the OUTPUT statement.

If the filtering process remains uninitialized until the end of the sample (that is, if \mathbf{S}_{n,p_n} is not invertible), some linear combinations of $\boldsymbol{\delta}$ and $\boldsymbol{\beta}$ are not estimable. This, in turn, implies that some linear combinations of $\boldsymbol{\alpha}_t$ are also inestimable. These inestimable quantities are reported as missing. For more information about the estimability of the state effects, see Selukar (2010).

Contrasting PROC SSM with Other SAS Procedures

The SSM procedure complements several SAS/ETS procedures and the MIXED procedure in SAS/STAT software (see Chapter 59, “The MIXED Procedure” (*SAS/STAT User’s Guide*)). The statistical models underlying all these procedures can be formulated as state space models; however, in many cases this formulation effort can be considerable. Generally speaking, when a problem can be formulated and satisfactorily solved either by using the SSM procedure or by using one of these other procedures, the other procedures are likely to be more efficient. However, in many instances, the SSM procedure can solve more general problems or offer more detailed analysis, or both. Throughout this discussion, it is assumed that the problem being solved can be modeled as a linear statistical model. In particular, situations that require models such as autoregressive conditional heteroscedasticity (ARCH) models are not considered. The following list provides a more specific comparison of the SSM procedure with different procedures:

- All the SAS/ETS time series analysis procedures (the ARIMA, ESM, UCM, VARMAX, STATESPACE, and PANEL procedures) require time series data and are not applicable to the longitudinal data.
- For univariate time series analysis, the modeling facilities provided by the ARIMA, ESM, and UCM procedures are adequate in most cases. The SSM procedure can handle cases that do not fit neatly into one of these categories.
- For multivariate time series data analysis, you can use the VARMAX procedure for vector ARIMA modeling and the STATESPACE procedure for state space modeling. The capabilities of the SSM procedure are complementary to these procedures. In particular, the predefined multivariate structural models available in the SSM procedure cannot be specified by either of these procedures. In addition,

you can formulate a much wider range of multivariate models—for example, models for series with different frequencies, by using the SSM procedure.

- When the \mathbf{R} side effects are not too complicated (for example, if \mathbf{R} is diagonal), the model considered by the MIXED procedure is a special case of the model considered by the SSM procedure. In the case of diagonal \mathbf{R} , it is easy to see that the state vector $\boldsymbol{\alpha}_t$ is equal to \boldsymbol{y} , the MIXED random-effects vector, for all $t \geq 1$ (that is, $\boldsymbol{\alpha}_t$ is *time invariant*). Therefore, the random-effects MIXED model is obtained by setting $\mathbf{T} = \text{Identity}$, $\mathbf{Q}_t = \mathbf{0}$, $t \geq 2$, $\mathbf{Q}_1 = \mathbf{G}$ (the MIXED \mathbf{G} matrix), and $\mathbf{A}_1 = \mathbf{0}$.
- For the analysis of cross-sectional data, you can use the PANEL procedure. In this case, the SSM procedure capabilities are complementary. PROC SSM can provide alternate models, REML estimates, richer missing value support, and the estimates of the unobserved components (see the section “[Getting Started: SSM Procedure](#)” on page 1815 and the example [Example 27.2](#) for more information).

Predefined Trend Models

The statistical models that govern the predefined trend components available in the SSM procedure are divided into two groups: models that are applicable to equally spaced data (possibly with replication), and models that are applicable more generally (the irregular data type). Each trend component can be described as a dot product $\mathbf{Z}\boldsymbol{\alpha}_t$ for some (time-invariant) vector \mathbf{Z} and a state vector $\boldsymbol{\alpha}_t$. The component specification is complete after the vector \mathbf{Z} is specified and the system matrices that govern the equations of $\boldsymbol{\alpha}_t$ are specified. For trend models for regular data, all the system matrices are time-invariant. For irregular data, \mathbf{T}_t and \mathbf{Q}_t depend on the spacing between the distinct time points: $(\tau_{t+1} - \tau_t)$.

Trend Models for Regular Data

These models are applicable when the data type is either regular or regular-with-replication. A good reference for these models is Harvey (1989).

Random Walk Trend

This model provides a trend pattern in which the level of the curve changes slowly. The rapidity of this change is inversely proportional to the disturbance variance σ^2 that governs the underlying state. It can be described as $\mathbf{Z}\boldsymbol{\alpha}_t$, where $\mathbf{Z} = (1)$ and the (one-dimensional) state α_t follows a random walk:

$$\alpha_{t+1} = \alpha_t + \eta_{t+1}, \quad \eta_t \sim N(0, \sigma^2)$$

Here $\mathbf{T} = 1$ and $\mathbf{Q} = \sigma^2$. The initial condition is fully diffuse. Note that if $\sigma^2 = 0$, the resulting trend is a fixed constant.

Local Linear Trend

This model provides a trend pattern in which both the level and the slope of the curve vary slowly. This variation in the level and the slope is controlled by two parameters: σ_1^2 controls the level variation, and σ_2^2 controls the slope variation. If $\sigma_1^2 = 0$, the resulting trend is called an *integrated random walk*. If both $\sigma_1^2 = 0$ and $\sigma_2^2 = 0$, then the resulting model is the deterministic linear time trend. Here $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ 1, \ 0 \ 1)$, and $\mathbf{Q} = \text{Diag}(\sigma_1^2, \sigma_2^2)$. The initial condition is fully diffuse.

Damped Local Linear Trend

This trend pattern is similar to the local linear trend pattern. However, in the DLL trend the slope follows a first-order autoregressive model, whereas in the LL trend the slope follows a random walk. The autoregressive parameter or the damping factor, ϕ , must lie between 0.0 and 1.0, which implies that the long-run forecast according to this pattern has a slope that tends to 0. Here $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ 1, \ 0 \ \phi)$, and $\mathbf{Q} = \text{Diag}(\sigma_1^2, \sigma_2^2)$. The initial condition is partially diffuse with $\mathbf{Q}_1 = \text{Diag}(0, \sigma_2^2/(1 - \phi * \phi))$.

ARIMA Trend

This section describes the state space form for a trend that follows an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model. The notation for ARIMA models is explained in the **TREND** statement. A number of alternate state space forms are possible in this case; the one given here is based on Jones (1980). With slight abuse of notation, let $p = p + s * P + d + s * D$ denote the effective autoregressive order, and let $q = q + s * Q$ denote the effective moving average order of the model. Similarly, let ϕ be the effective autoregressive polynomial, and let θ be the effective moving average polynomial in the backshift operator with coefficients ϕ_1, \dots, ϕ_p and $\theta_1, \dots, \theta_q$, obtained by multiplying the respective nonseasonal and seasonal factors. Then, a random sequence μ_t that follows an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model with a white noise sequence a_t has a state space form with state vector of size $m = \max(p, q + 1)$. The system matrices are as follows: $\mathbf{Z} = [1 \ 0 \ \dots \ 0]$, and the transition matrix \mathbf{T} , in a blocked form, is given by

$$\mathbf{T} = \begin{bmatrix} 0 & I_{m-1} \\ \phi_m & \dots & \phi_1 \end{bmatrix}$$

where $\phi_i = 0$ if $i > p$ and I_{m-1} is an $(m - 1)$ dimensional identity matrix. The covariance of the state disturbance matrix $\mathbf{Q} = \sigma^2 \psi \psi'$, where σ^2 is the variance of the white noise sequence a_t and the vector $\psi = [\psi_0 \ \dots \ \psi_{m-1}]'$ contains the first m values of the impulse response function—that is, the first m coefficients in the expansion of the ratio θ/ϕ . The sequence μ_t is stationary if and only if $d = 0$ and $D = 0$; in this case the initial state is nondiffuse. The covariance matrix of the initial state, \mathbf{Q}_1 , in the stationary case is computed by

$$\text{vec}(\mathbf{Q}_1) = (\mathbf{I} - \mathbf{T} \otimes \mathbf{T})^{-1} \text{vec}(\mathbf{Q})$$

where \otimes denotes the Kronecker product and the *vec* operation on a matrix creates a vector formed by vertically stacking the rows of that matrix. If either d or D is nonzero, the initial state is treated as fully diffuse.

Trend Models for Irregular Data

A good reference for these models is de Jong and Mazzi (2001). Throughout this section $h_t = (\tau_{t+1} - \tau_t)$ denotes the difference between the successive time points. The system matrices \mathbf{T}_t and \mathbf{Q}_t that govern these models depend on h_t . However, whenever the notation is unambiguous, the subscript t is omitted.

Polynomial Spline Trend

This model is a general-purpose tool for extracting a smooth trend from the noisy data. The order of the spline governs the order of the local polynomial that defines the spline. In the SSM procedure, the order is restricted to be an integer 1, 2, or 3; the default order is 1. The order-1 spline corresponds to a random walk, the order-2 spline corresponds to an integrated random walk, and the order-3 spline provides a locally quadratic trend. The dimension of the state underlying this component is the same as the order of the spline. The system matrices for the different orders are described below (in all the cases the initial condition is fully diffuse):

- order-1 spline: $\mathbf{Z} = (1)$, $\mathbf{T} = (1)$, and $\mathbf{Q} = \sigma^2(h)$
- order-2 spline: $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ h, \ 0 \ 1)$, and $\mathbf{Q} = \sigma^2 \begin{pmatrix} \frac{h^3}{3} & \frac{h^2}{2} & \frac{h^2}{2} & h \end{pmatrix}$
- order-3 spline: $\mathbf{Z} = (1 \ 0 \ 0)$, $\mathbf{T} = \begin{pmatrix} 1 & h & \frac{h^2}{2} & 0 & 1 & h & 0 & 0 & 1 \end{pmatrix}$, and

$$\mathbf{Q}[i, j] = \sigma^2 * \frac{h^{6-i-j+1}}{(6-i-j+1)(3-i)!(3-j)!} \quad 1 \leq i, j \leq 3$$

Decay and Growth Trends

There are two choices for the decay trend: DECAF and DECAF(OU). Similarly, there are two choices for the growth trend: GROWTH and GROWTH(OU). The “OU” stands for the Ornstein-Uhlenbeck form of these models. The decay trend is a sum of two correlated components: one component is a random walk, and the other component is a stationary autoregression. In its Ornstein-Uhlenbeck form, the random walk component is replaced by a constant. The growth trend (and its Ornstein-Uhlenbeck variant) has the same form as the decay trend except that the autoregression is nonstationary (in fact, it is explosive). For growth trend models, floating-point errors can result for even moderately long forecast horizons because of the explosive growth in the trend values.

The system matrices for the decay and the growth types in their respective cases are identical, except for the sign of the rate parameter ϕ : $\phi < 0.0$ for the decay type, and $\phi > 0.0$ for the growth type. In addition, the initial conditions for the growth models are fully diffuse; they are only partially diffuse for the decay models. The underlying state vector for all these models is two-dimensional.

The system matrices for the DECAF type are:

$$\begin{aligned} \mathbf{Z} &= (1 \ 1) \\ \mathbf{T} &= \text{Diag}(1, \exp(h\phi)) \\ \mathbf{Q} &= \frac{\sigma^2}{\phi^3} \begin{pmatrix} h\phi & 1 - \exp(h\phi), & 1 - \exp(h\phi) & (\exp(2h\phi) - 1)/2 \end{pmatrix} \end{aligned}$$

The initial condition is partially diffuse with $\mathbf{Q}_1 = \text{Diag}(0, \frac{-\sigma^2}{2\phi^3})$. The system matrices for the GROWTH type are the same (with $\phi > 0.0$), except that the initial condition is fully diffuse; so $\mathbf{Q}_1 = 0$.

For the DECAF(OU) type, \mathbf{Z} and \mathbf{T} are the same as DECAF, whereas

$$\mathbf{Q} = \text{Diag} \left(0, \sigma^2 \frac{(\exp(2h\phi) - 1)}{2\phi} \right) \quad \text{and} \quad \mathbf{Q}_1 = \text{Diag}(0, \frac{-\sigma^2}{2\phi})$$

The system matrices for the GROWTH(OU) type are the same (with $\phi > 0.0$), except that the initial condition is fully diffuse; so $\mathbf{Q}_1 = 0$.

Predefined Structural Models

A set of predefined models is available in the SSM procedure for models called structural models in the time series literature. These predefined models can be used to model trend, seasonal, and cyclical patterns in the univariate and multivariate time series. For the most part, the multivariate models are straightforward

generalizations of the corresponding univariate models—for example, the multivariate random walk trend described later in this section generalizes the univariate random walk trend that is described in the section “Random Walk Trend” on page 1855. All of these models, with the exception of the continuous-time cycle model, are applicable only to the regular data type. The continuous-time cycle model is applicable to all the data types; however, it is available for the univariate case only.

To specify these models, you must first use the STATE statement with the correct **TYPE=** option. When you specify the **TYPE=option**, you do not need to specify other options of the STATE statement (for example, the **T** option, the **COV1** option, and the **A1** option). However, you must specify the **COV** option, which describes the covariance of the disturbance term that drives the state equation. Throughout this section, the symmetric matrix specified by using the **COV** option is denoted by Σ . For **TYPE=LL**, an additional matrix, specified by using the **SLOPECOV** suboption, also plays a role; it is denoted by Σ_{slope} . Subsequently you must specify one or more COMPONENT statements to define the (univariate) components that are based on this state subsection for their inclusion in the MODEL statement. These univariate components exhibit interesting behavior based on the structure of Σ (and Σ_{slope} , whenever applicable)—for example, imposing rank restrictions on Σ in the multivariate random walk results in these univariate trends moving together. For additional information about these models, see Harvey (1989).

The following example summarizes the steps needed to define a multivariate structural model by using a sequence of STATE and COMPONENT statements. For a full example, see [Example 27.1](#). Suppose that a three-dimensional time series is being studied with response variables y_1 , y_2 , and y_3 . Suppose you want to specify the trivariate structural model

$$y_t = \mu_t + \psi_t + \epsilon_t$$

where $y_t = (y_{1,t}, y_{2,t}, y_{3,t})$ denotes the response series, and μ_t , ψ_t , and ϵ_t denote the trivariate components, trend, cycle, and white noise, respectively. The three components of ϵ_t , the observation noise in the model, are not assumed to be independent. Therefore, you cannot specify them by using three **IRREGULAR** statements; you must include them in the state specification. The following (incomplete) statements show how to specify this model:

```
state whiteNoise(3) type=wn ...;
component wn1 = whiteNoise[1];
component wn2 = whiteNoise[2];
component wn3 = whiteNoise[3];

state randomWalk(3) type=rw ...;
component rw1 = randomWalk[1];
component rw2 = randomWalk[2];
component rw3 = randomWalk[3];

state cycleState(3) type=cycle ...;
component c1 = cycleState[1];
component c2 = cycleState[2];
component c3 = cycleState[3];

model y1 = rw1 c1 wn1;
model y2 = rw2 c2 wn2;
model y3 = rw3 c3 wn3;
```

The first STATE statement defines whiteNoise, a state subsection that is needed for defining a three-dimensional white noise component. In turn, whiteNoise is used to define the three univariate white noise

components: $wn1$, $wn2$, and $wn3$. The components $wn1$, $wn2$, and $wn3$ are correlated—their correlation structure is controlled by the covariance specification of `whiteNoise`. The second set of `STATE` and `COMPONENT` statements result in three correlated random walk trend components: $rw1$, $rw2$, and $rw3$. Finally, the last set of `STATE` and `COMPONENT` statements result in three correlated cycle components: $c1$, $c2$, and $c3$. In the end, the desired multivariate model is defined by including these (univariate) components in the appropriate `MODEL` statements.

In the preceding example, it is important to note the relationship between the nominal dimension (denoted by dim throughout this section) that is specified in the `STATE` statement and the actual dimension of the resulting state subsection. Note that the three state subsections, `whiteNoise`, `randomWalk`, and `cycleState`, are defined by using the same dim specification: 3. However, the actual dimensions of these state subsections depend on their type; they do not need to equal this specified dimension. Here, `whiteNoise` and `randomWalk` do have the same size, 3, as the specified dim . However, the size of `cycleState`, which is of `TYPE=CYCLE`, is $2 * dim = 6$. Another important point to note: no matter what the underlying size of the state subsection, the desired univariate components were obtained by using an identical specification scheme in the `COMPONENT` statement. This happens because the component specification style that is based on the element operator—`[]`—in the `COMPONENT` statement behaves differently when the `TYPE=` option is used to define the state subsection (see the section “[Multivariate Season](#)” on page 1861 for an illustration).

The system matrices for all these models are time-invariant, with the exception of the continuous-time cycle model. In this section, α_t denotes the subsection of the overall model state α_t , and T , Q , and A_1 denote the corresponding blocks of the larger system matrices.

For the multivariate cycle system matrices described in the section “[Multivariate Cycle](#)” on page 1860, the Kronecker product notation is useful: if A is an $m \times n$ matrix and B is a $p \times q$ matrix, then the Kronecker product $A \otimes B$ is an $mp \times nq$ block matrix:

$$A \otimes B = \begin{bmatrix} a_{11}B & \cdots & a_{1n}B \\ \vdots & \ddots & \vdots \\ a_{m1}B & \cdots & a_{mn}B \end{bmatrix}$$

Multivariate White Noise

The `STATE` statement option `TYPE=WN` specifies white noise of dimension dim —that is, a sequence of zero mean, independent, Gaussian vectors with covariance Σ . The specification of the associated system matrices is trivial: T is zero, $Q = \Sigma$, and the initial condition is nondiffuse ($Q_1 = \Sigma$ and $A_1 = 0$).

Multivariate white noise is needed to specify the observation equation noise term for the multivariate models for the time series data. Since the state space formulation for the SSM procedure requires the observation equation noise vector to have the diagonal form, you need to include the noise vector in the state. The noise term for the i th response variable is defined by a component that simply picks the i th element of this multivariate white noise. For example, the component `wn_i` defined as follows can be used as a noise term in the `MODEL` statement of the i th response variable:

```
state white(dim) type=wn ...;
component wn_3 = white[3];
```

Multivariate Random Walk Trend

The STATE statement option **TYPE=RW** specifies a dim -dimensional random walk

$$\boldsymbol{\alpha}_{t+1} = \boldsymbol{\alpha}_t + \boldsymbol{\eta}_{t+1}$$

where $\boldsymbol{\eta}_t$ is a sequence of zero mean, independent, Gaussian vectors with covariance $\boldsymbol{\Sigma}$. The specification of the associated system matrices is trivial: \mathbf{T} is a dim -dimensional identity matrix, \mathbf{I}_{dim} , $\mathbf{Q} = \boldsymbol{\Sigma}$, and the initial condition is fully diffuse ($\mathbf{Q}_1 = 0$ and $\mathbf{A}_1 = \mathbf{I}_{dim}$).

The multivariate random walk is a useful trend model for multivariate time series data. The trend term for the i th response variable is defined by a component that simply picks the i th ($1 \leq i \leq dim$) element of $\boldsymbol{\alpha}_t$. For example, the component `rw_i` defined as follows can be used as a trend term in the MODEL statement of the i th response variable:

```
state randomWalk(3) type=rw ...;
component rw_2 = randomWalk[2];
```

Multivariate Local Linear Trend

The STATE statement option **TYPE=LL** specifies a $(2*dim)$ -dimensional $\boldsymbol{\alpha}_t$, needed for defining a dim -dimensional local linear trend. The first dim elements of $\boldsymbol{\alpha}_t$ correspond to the needed multivariate trend, and the subsequent dim elements are needed to capture the slope vector of this trend. $\boldsymbol{\alpha}_t$ can be defined as

$$\boldsymbol{\alpha}_{t+1} = \mathbf{T}\boldsymbol{\alpha}_t + \boldsymbol{\eta}_{t+1}$$

where $\boldsymbol{\eta}_t$ is a sequence of zero mean, independent, Gaussian vectors with covariance $\text{Diag}(\boldsymbol{\Sigma}, \boldsymbol{\Sigma}_{slope})$ and \mathbf{T} is a $2*dim$ -dimensional block matrix $\mathbf{T} = (\mathbf{I}_{dim} \ \mathbf{I}_{dim}, \ \mathbf{0} \ \mathbf{I}_{dim})$. The initial condition is fully diffuse ($\mathbf{Q}_1 = 0$ and $\mathbf{A}_1 = \mathbf{I}_{2*dim}$). This is a multivariate generalization of the univariate local linear trend.

The multivariate local linear trend is a useful trend model for multivariate time series data. The trend term for the i th response variable is defined by a component that simply picks the i th element ($1 \leq i \leq dim$) of $\boldsymbol{\alpha}_t$. For example, the component `ll_i` defined as follows can be used as a trend term in the MODEL statement of the i th response variable:

```
state localLin(dim) type=ll(slopecov..) ...;
component ll_3 = localLin[3];
```

Multivariate Cycle

The STATE statement option **TYPE=CYCLE** specifies a $(2*dim)$ -dimensional $\boldsymbol{\alpha}_t$, needed for defining a dim -dimensional cycle. As in the LL case, the first dim elements of $\boldsymbol{\alpha}_t$ correspond to the needed dim -dimensional cycle, and the remaining dim elements contain some auxiliary quantities. The cycle model defined in this subsection requires a regular data type—that is, the CT option is not included. Let ρ denote the damping factor, and let $\lambda = 2\pi/period$ be the frequency associated with the cycle. The admissible parameter ranges are $0 < \rho \leq 1$ and $period > 2$, which implies that $0 < \lambda < \pi$. Let $\mathbf{C} = \rho(\cos(\lambda) \ \sin(\lambda), \ -\sin(\lambda) \ \cos(\lambda))$, a 2×2 matrix, and let $\mathbf{T} = \mathbf{C} \otimes \mathbf{I}_{dim}$, a $2*dim \times 2*dim$ matrix. With this notation, the transition equation associated with $\boldsymbol{\alpha}_t$ is

$$\boldsymbol{\alpha}_{t+1} = \mathbf{T}\boldsymbol{\alpha}_t + \boldsymbol{\eta}_{t+1}$$

where $\boldsymbol{\eta}_t$ is a sequence of zero mean, independent, $(2 * \dim)$ -dimensional Gaussian vectors with covariance $\text{Diag}(\boldsymbol{\Sigma}, \boldsymbol{\Sigma})$. If $\rho = 1$, the initial condition is fully diffuse ($\mathbf{Q}_1 = 0$ and $\mathbf{A}_1 = \mathbf{I}_{2*\dim}$). Otherwise, it is nondiffuse: $\mathbf{Q}_1 = \frac{1}{(1-\rho^2)} \text{Diag}(\boldsymbol{\Sigma}, \boldsymbol{\Sigma})$ and $\mathbf{A}_1 = 0$.

The multivariate cycle is useful for capturing periodic behavior for multivariate time series data. The cycle term for the i th response variable is defined by a component that simply picks the i th element of $\boldsymbol{\alpha}_t$. For example, the component `cycle_i` defined as follows can be used as a cycle term in the MODEL statement of the i th response variable:

```
state cycleState(dim) type=cycle ...;
component cycle_2 = cycleState[2];
```

Multivariate Season

The STATE statement option `TYPE=SEASON(LENGTH=s)` specifies a $((s-1)*\dim)$ -dimensional $\boldsymbol{\alpha}_t$, needed for defining a \dim -dimensional trigonometric season component with season length s . A (multivariate) trigonometric season component, $\boldsymbol{\gamma}$, is a sum of (multivariate) cycles of different frequencies,

$$\boldsymbol{\gamma} = \sum_{j=1}^{\lfloor s/2 \rfloor} \boldsymbol{\gamma}_j$$

where the constituent cycles $\boldsymbol{\gamma}_j$, called harmonics, have frequencies $\lambda_j = 2\pi j/s$. All the harmonics are assumed to be statistically independent, have the same damping factor $\rho = 1$, and are governed by the disturbances with the same covariance matrix $\boldsymbol{\Sigma}$. The number of harmonics, $\lfloor s/2 \rfloor$, equals $s/2$ if s is even and $(s-1)/2$ if it is odd. This means that specifying `TYPE=SEASON(LENGTH=s)` is equivalent to specifying $\lfloor s/2 \rfloor$ cycle specifications with correct frequencies, damping factor $\rho = 1$, and the `COV` option restricted to the same covariance $\boldsymbol{\Sigma}$. The resulting $\boldsymbol{\alpha}_t$ is necessarily $((s-1)*\dim)$ -dimensional. When the season length s is even, the last harmonic cycle, $\boldsymbol{\gamma}_{s/2}$, has frequency π and requires special attention. It is of dimension \dim rather than $2*\dim$ because its underlying state equation simplifies to a \dim -variate autoregression with autoregression coefficient $-\mathbf{I}_{\dim}$. As a result of this discussion, it is clear that the system matrices \mathbf{T} and \mathbf{Q} associated with the $((s-1)*\dim)$ -dimensional $\boldsymbol{\alpha}_t$ are block-diagonal with the blocks corresponding to the harmonics. The initial condition is fully diffuse.

For all the models discussed so far, the first \dim elements of $\boldsymbol{\alpha}_t$ provided the needed (multivariate) component. This is not the case for the (multivariate) season component. Extracting the i th seasonal component from $\boldsymbol{\alpha}_t$ requires accumulating the contributions from the $\lfloor s/2 \rfloor$ harmonics that are associated with this i th seasonal, which are not organized contiguously in $\boldsymbol{\alpha}_t$. For example, suppose that \dim is 2 and the season length s is 4. In this case $\lfloor s/2 \rfloor$ is 2, and the bivariate seasonal component is a sum of two independent bivariate cycles, $\boldsymbol{\gamma}_1$ and $\boldsymbol{\gamma}_2$. The cycle $\boldsymbol{\gamma}_1$ has frequency $\pi/2$ and its underlying state, say $\boldsymbol{\alpha}_t^a$, has dimension $2*\dim = 4$. The last harmonic, $\boldsymbol{\gamma}_2$, has frequency π , and therefore its underlying state, say $\boldsymbol{\alpha}_t^b$, has dimension 2. The combined state $\boldsymbol{\alpha}_t = (\boldsymbol{\alpha}_t^a, \boldsymbol{\alpha}_t^b)$ has dimension $6 = 4 + 2$. In order to extract the first bivariate seasonal component, you must extract the first components of bivariate cycles $\boldsymbol{\gamma}_1$ and $\boldsymbol{\gamma}_2$, which in turn implies the first elements of $\boldsymbol{\alpha}_t^a$ and $\boldsymbol{\alpha}_t^b$, respectively. Thus, obtaining the first bivariate seasonal component requires extracting the first and the fifth elements of the combined state $\boldsymbol{\alpha}_t$. Similarly, obtaining the second bivariate seasonal component requires extracting the second and the sixth elements of the combined state $\boldsymbol{\alpha}_t$. All this can be summarized by the dot product expressions

$$\begin{aligned} s_{1t} &= (1 \ 0 \ 0 \ 0 \ 1 \ 0) \boldsymbol{\alpha}_t \\ s_{2t} &= (0 \ 1 \ 0 \ 0 \ 0 \ 1) \boldsymbol{\alpha}_t \end{aligned}$$

where s_{1t} and s_{2t} denote the first and second components, respectively, of the bivariate seasonal component. Note that s_{1t} and s_{2t} are univariate seasonal components, each of season length 4, in their own right. They are correlated components; their correlation structure depends on Σ .

Obtaining the desired components of the multivariate seasonal component is made easy by a special syntax convention of the COMPONENT statement. Continuing with the previous example, the following examples illustrate two equivalent ways of obtaining s_{1t} and s_{2t} . The first set of statements explicitly specify the linear combinations needed for defining s_{1t} and s_{2t} :

```
state seasonState(2) type=season(length=4) ...;
component s_1 = ( 1 0 0 0 1 0 ) * seasonState;
component s_2 = ( 0 1 0 0 0 1 ) * seasonState;
```

The following simpler specification achieves the same result:

```
state seasonState(2) type=season(length=4) ...;
component s_1 = seasonState[1];
component s_2 = seasonState[2];
```

In the latter specification, the meaning of the element operator `[]` changes if the state in question is defined by using the `TYPE=` option.

Multivariate ARMA

You can specify a state vector that follows a multivariate autoregressive, moving average (VARMA) model by using the STATE statement option `TYPE=VARMA`. The autoregressive and moving average orders can be either 0 or 1 ($0 \leq p \leq 1$ and $0 \leq q \leq 1$)—that is, only VAR(1), MA(1), and VARMA(1,1) models can be specified. The notation and the state space form of the VARMA model described here is taken from Reinsel (1997), which is a good reference for VARMA modeling.

A dim -dimensional vector process γ_t follows a zero-mean, autoregressive order p , moving average order q (VARMA(p, q)) model if it satisfies the following matrix difference equation:

$$\gamma_t = \sum_{i=1}^p \Phi_i \gamma_{t-i} + \epsilon_t - \sum_{j=1}^q \Theta_j \epsilon_{t-j}$$

Here Φ_i and Θ_j are dim -dimensional square matrices and ϵ_t is a dim -dimensional, Gaussian, white noise sequence with covariance matrix Σ . If autoregressive order p is 0, the term that involves Φ_i is absent; similarly, if the moving average order q is 0, the term that involves Θ_j is absent. Since AR and MA orders can be at most 1, the subscripts of Φ_i and Θ_j can be ignored in this discussion—when applicable, an AR coefficient matrix is denoted by Φ and an MA coefficient matrix is denoted by Θ . The unknown elements of Φ , Θ , and Σ constitute the parameter vector that is associated with a VARMA state. The process γ_t defined by the VARMA difference equation is stationary and invertible (Reinsel 1997) if and only if the eigenvalues of Φ and Θ are strictly less than 1 in magnitude. By default, the SSM procedure imposes these stationarity and invertibility restrictions on Φ and Θ . However, you can specify Φ to be an identity matrix, in which case the resulting process is nonstationary.

A VARMA model can be cast into a state space form. The state space form used by the SSM procedure is described in Reinsel (1997, pp 52–53). The system matrices for the supported VARMA models are as follows:

- The VAR(1) form is the simplest. In this case, the underlying state α_t is the same as the VAR(1) process y_t . Therefore, $T = \Phi$ and $Q_t = \Sigma$.
- Taking Φ equal to the zero matrix if $p = 0$, the VARMA(1,1) and MA(1) cases can be treated together. In this case, the underlying state α_t is $2 \times \dim$ dimensional and the desired VARMA process y_t corresponds to its first \dim elements. Let $\Psi = \Phi - \Theta$. Then, in the blocked form,

$$T = \begin{bmatrix} 0 & I_{\dim} \\ 0 & \Phi \end{bmatrix} \quad \text{and} \quad Q_t = Q = \begin{bmatrix} \Sigma & \Sigma\Psi' \\ \Psi\Sigma & \Psi\Sigma\Psi' \end{bmatrix}$$

Unless Φ is restricted to be identity, the underlying state α_t is stationary and the covariance of the initial condition is computed by

$$\text{vec}(Q_1) = (I - T \otimes T)^{-1} \text{vec}(Q)$$

where \otimes denotes the Kronecker product and the vec operation on a matrix creates a vector formed by vertically stacking the rows of that matrix. If Φ is restricted to be identity, the initial condition is fully diffuse.

Continuous-Time Cycle

The STATE statement option **TYPE=CYCLE(CT)** specifies a two-dimensional α_t , needed for defining a univariate continuous time cycle. In this case the nominal dimension, \dim , must be 1. In particular, Σ becomes one-dimensional, which is denoted by σ^2 . This cycle can be used for any data type. As before, the parameters of the cycle are a damping factor ρ , $0 < \rho \leq 1$, and $\text{period} > 0$. Unlike in the discrete-time cycle described in the section “Multivariate Cycle” on page 1860, the period is not required to be larger than 2. Let $\lambda = 2\pi/\text{period}$, and let $h_t = (\tau_{t+1} - \tau_t)$ denote the difference between successive time points. In this case, the system matrices T and Q that govern α_t depend on h_t . They are:

$$\begin{aligned} T &= \rho^{h_t} (\cos(\lambda h_t) \sin(\lambda h_t), -\sin(\lambda h_t) \cos(\lambda h_t)) \\ Q &= \frac{\sigma^2(1 - \rho^{2h_t})}{-2 \ln(\rho)} * I_2 \quad \text{if } \rho < 1 \\ Q &= \sigma^2 h_t I_2 \quad \text{if } \rho = 1 \end{aligned}$$

If $\rho < 1$, the initial condition is nondiffuse: $Q_1 = \frac{\sigma^2}{-2 \ln(\rho)} I_2$. For $\rho = 1$, the initial condition is fully diffuse.

The first element of α_t corresponds to the needed cycle, and the second element is an auxiliary quantity. You can define a cycle term based on this state as follows:

```
state cycleState(1) type=cycle(CT) ...;
component cycle = cycleState[1];
```

The CT option must be included in the use of **TYPE=CYCLE**.

Covariance Parameterization

The covariance matrices specified by the `COV` and `COV1` options in the `STATE` statement must be positive semidefinite. When these matrices are of general form and are not user-specified, they are internally parameterized by their Cholesky root. Suppose that Σ , an $m \times m$ positive semidefinite matrix of rank r , is such a covariance matrix. Then, Σ can always be written as

$$\Sigma = RR'$$

where the (generalized) Cholesky root, R , is an $m \times r$ lower triangular matrix with nonnegative diagonal elements (that is, $R[i, j] = 0$ if $j > i$ and $R[i, i] \geq 0$, $1 \leq i \leq r$). The SSM procedure parameterizes Σ by the elements of its Cholesky root, which adds $r * (r + 1)/2 + r * (m - r)$ elements to the parameter vector θ .

Missing Values

For a variety of reasons the data might contain missing response and predictor values. Before starting the analysis of a particular BY group, SSM procedure makes an internal copy of the data. The actual analysis is done by using this copy. The data in the copy are first examined for missing values in the response, predictor, and the ID variables. No missing values are permitted in the ID variable (if it is specified). If all the missing values are associated with only the response variables, then the internal copy of the data is not altered. However, if any of the predictors are found to contain missing values, the internal copy of the data is altered as follows: any missing predictor value is replaced by 0, and the response values that are dependent on that predictor in the corresponding row are set to missing. These missing response values are called the *induced missing values*. The reported analysis is based on the (possibly altered) internal copy of the BY group.

Computational Issues

A Well-Behaved Model

The model defined by the state space model equations (see the section “State Space Model and Notation” on page 1843) is very general. This generality is quite useful because it encompasses a wide variety of data generation processes. On the other hand, it also makes it easy to specify overly complex and numerically unstable models. If a suitable model is not already known and you are in the early phases of modeling, it is important to start with models that are relatively simple and well-behaved from the numerical standpoint. From the numerical and statistical considerations, two aspects of model formulation are particularly important: identifiability and numerical stability. A model is identifiable if the observed data has a distinct probability distribution for each admissible parameter vector. Unless proper care is taken, it is easy to specify an unidentifiable state space model. Similarly, predictions according to some types of state space models can display explosive growth or wild oscillations. This behavior is primarily governed by the transition matrix \mathbf{T} (or \mathbf{T}_t in the time-varying case). Unidentifiable models can run into difficulties during parameter estimation, and explosive growth (and wild oscillation) causes numerical problems associated with finite-precision arithmetic. Unfortunately, no simple identifiability check is available for a general state space model, and it is difficult to decide at the outset whether a specified model might suffer from numerical

instability. See Harvey (1989, chap. 4, sec. 4) for a discussion of identifiability issues, and see Harvey (1989, chap. 3, sec. 3) for a discussion of the stability properties of time-invariant state space models. The following guidelines are likely to result in models that are identifiable and numerically stable:

- Build models by composing submodels that are known to be well-behaved. The predefined models provided by the SSM procedure are good submodel candidates (see the sections “[Predefined Trend Models](#)” on page 1855 and “[Predefined Structural Models](#)” on page 1857).
- Pay careful attention to the way the variety of system matrices are defined. The behavior of their elements, as functions of model parameters and other variables, must be well-understood. If these elements are defined by using DATA steps, you can validate their behavior by running these DATA steps outside of the SSM procedure. In particular, note the following:
 - The transition matrix \mathbf{T} (or \mathbf{T}_t in the time-varying case) determines the explosiveness characteristics of the model; it must be well-behaved for all parameters.
 - The disturbance covariances \mathbf{Q}_t must be positive semidefinite for all parameters.
 - If the transition matrix \mathbf{T}_t or the disturbance covariance \mathbf{Q}_t are time-varying and the data contain replicate observations (observations with the same ID value), check that the elements of \mathbf{T}_t and \mathbf{Q}_t do not vary during replicate observations. This follows from the fact that the underlying state does not vary during replications (see the state equation in the section “[State Space Model and Notation](#)” on page 1843 and the section “[Types of Data Organization](#)” on page 1845).

Convergence Problems

As explained in the section “[Likelihood Computation and Model Fitting Phase](#)” on page 1852, the model parameters are estimated by nonlinear optimization of the likelihood. This process is not guaranteed to succeed. For some data sets, the optimization algorithm can fail to converge. Nonconvergence can result from a number of causes, including flat or ridged likelihood surfaces and ill-conditioned data. It is also possible for the algorithm to converge to a point that is not the global optimum of the likelihood.

If you experience convergence problems, consider the following:

- Data that are extremely large or extremely small can adversely affect results because of the internal tolerances used during the filtering steps of the likelihood calculation. Rescaling the data can improve stability.
- Examine your model for redundancies in the included components and regressors. The components or regressors that are nearly collinear to each other can cause the optimization process to become unstable.
- Lack of convergence can indicate model misspecification such as unidentifiable model or a violation of the normality assumption.

Computer Resource Requirements

The computing resources required for the SSM procedure depend on several factors. The memory requirement for the procedure is largely dependent on the number of observations to be processed and the size of the state vector underlying the specified model. If n denotes the sample size and m denotes the size of

the state vector, the memory requirement for the smoothing phase of the Kalman filter is of the order of $6 \times 8 \times n \times m^2$ bytes, ignoring the lower-order terms. If the smoothed component estimates are not needed, then the memory requirement is of the order of $6 \times 8 \times (m^2 + n)$ bytes. Besides m and n , the computing time for the parameter estimation depends on the size of the parameter vector θ and how many likelihood evaluations are needed to reach the optimum.

Displayed Output

The default printed output produced by the SSM procedure contains the following information:

- brief information about the input data set, including the data set name and label
- summary statistics for the response variables in the model, including the names of the variables, the total number of observations and the number of missing observations, the smallest and largest measurements, and the mean and standard deviation
- information about the index variable, including the index value of the first and the last observation, the maximum difference between the successive index values, and the categorization of the data into regular, regular-with-replication, or irregular types
- estimates of the regression parameters if the model contains any predictors, including their standard errors, t statistics, and p -values
- convergence status of the likelihood optimization process if any parameters are estimated
- estimates of the free parameters at the end of the model-fitting phase, including the parameter estimates and their approximate standard errors
- the likelihood-based goodness-of-fit statistics, including the full likelihood, the sum of squares of residuals normalized by their standard errors, and the information criteria: AIC, AICC, HQIC, BIC, and CAIC
- summary of most significant additive outliers

ODS Table Names

The SSM procedure assigns a name to each table it creates. You can use these names to refer to the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 27.9.

Table 27.9 ODS Tables Produced by PROC SSM

ODS Table Name	Description	Statement	Option
Tables That Summarize the Model Information			
ModelSummary	Summary information about the underlying state space model		Default

Table 27.9 *continued*

ODS Table Name	Description	Statement	Option
IdInformation	Summary information about the ID variable		Default
ResponseInfo	Summary information about the response variables		Default
StateSummary	Summary information about the model state vector	PROC SSM	STATEINFO
DiffuseStateSummary	Summary information about the diffuse initial state	PROC SSM	STATEINFO
Tables Related to Model Parameters and the Likelihood			
ConvergenceStatus	Convergence status of the estimation process		Default
RegressionEstimates	Estimates of the regression parameters		Default
FixedStateEstimates	Estimates of the time-invariant deterministic state elements		Default
NamedParameterEstimates	Estimates of the parameters specified in the PARMS statement	PARMS	Default
ParameterEstimates	Estimates of the unknown elements in the model system matrices		Default
DisturbanceCovariance	Estimate of the disturbance covariance	STATE	PRINT=COV
InitialCovariance	Estimate of the initial state covariance	STATE	PRINT=COV1
ARCoefficient	Estimate of the autoregressive coefficient matrix	STATE	PRINT=AR
MACoefficient	Estimate of the moving-average coefficient matrix	STATE	PRINT=MA
TransitionMatrix	Estimate of the state transition matrix	STATE	PRINT=T
FitSummary	Summary of the likelihood-based-fit-statistics		Default
InformationCriteria	Likelihood-based information criteria		Default
Tables Related to Series and Component Forecasts			
Forecasts	Series forecasts	MODEL	PRINT=FILTER
SmoothedResponse	Smoothed series values	MODEL	PRINT=SMOOTH
FilteredComponent	Component forecasts	COMPONENT	PRINT=FILTER
SmoothedComponent	Smoothed component	COMPONENT	PRINT=SMOOTH

PRESS	Prediction error sum of squares	OUTPUT	PRESS

ODS Graph Names

You can refer to every graph produced through ODS Graphics with a name. The names of the graphs that PROC SSM generates are listed in Table 27.10, along with the required statements and options.

Table 27.10 ODS Graphs Produced by PROC SSM

ODS Graph Name	Description	Statement	Option
Graphs for One-Step-Ahead Residual Analysis			
ResidualNormalityPlot	Normality check	PROC SSM	PLOTS=RESIDUAL(NORMAL)
ResidualHistogram	Residual histogram	PROC SSM	PLOTS(UNPACK)=RESIDUAL
ResidualQQPlot	Residual QQ Plot	PROC SSM	PLOTS(UNPACK)=RESIDUAL
StdResidualPlot	Time series plot of standardized residuals	PROC SSM	Default
Graphs Related to Outlier Detection and Structural Break			
PredErrorNormalityPlot	Normality check	PROC SSM	PLOTS=AO(NORMAL)
PredErrorHistogram	Prediction error histogram	PROC SSM	PLOTS(UNPACK)=AO
PredErrorQQPlot	Prediction error QQ plot	PROC SSM	PLOTS(UNPACK)=AO
StdPredErrorPlot	Time series plot of standardized additive-outlier statistics	PROC SSM	PLOTS=AO(STD)
MaximalShockPlot	Time series plot of maximal state shock chi-square statistics	PROC SSM	PLOTS=MAXSHOCK

OUT= Data Set

You can use the OUT= option in the OUTPUT statement to store the series and component forecasts that are produced by PROC SSM. Which columns are included in the data set depends on the model specification. The model can have one or more response variables, a variety of components that appear in the MODEL statement, and components specified by the EVAL statement. The OUT= data set contains the one-step-ahead and full-sample estimates of the response variables, and all these components.

The following list describes the columns of the data set:

- the BY variables
- the ID variable, if specified by the ID statement
- Obs, a variable that contains the observation number
- the response series (more than one in the multivariate case)
- the following columns associated with the response series (the wildcard * is substituted by the name of one of the response variables):
 - FORECAST_* contains the one-step-ahead predicted values. and the multistep forecasts of the response series.
 - RESIDUAL_* contains the difference between the actual and forecast values.
 - StdErr_* contains the standard error of prediction.
 - Lower_* and Upper_* contain the lower and upper forecast confidence limits.
 - Smoothed_* contains the smoothed values of the response variable.
 - StdErr_Smoothed_* contains standard errors of the smoothed values of the response variable.
 - AO_* contains the additive outlier estimate.
 - StdErr_AO_* contains the standard error of the additive outlier estimate.
- the following columns associated with the components (the wildcard * is substituted by the name of one of the components):
 - FORECAST_* contains the one-step-ahead predicted values and the multistep forecasts of the component.
 - StdErr_* contains the standard error of prediction.
 - Smoothed_* contains the smoothed values of the component.
 - StdErr_Smoothed_* contains standard errors of the smoothed values of the component.
 - Smoothed_Lower_* and Smoothed_Upper_* contain the lower and upper confidence limits of the smoothed component.
- the maximal state shock chi-square statistics at distinct time points (this column is present only if the MAXSHOCK option is used in the OUTPUT statement)

Confidence limits are not produced for the smoothed series values or for the component forecasts; they are produced for the smoothed components.

Examples: SSM Procedure

Example 27.1: Bivariate Basic Structural Model

This example illustrates how you can use the SSM procedure to analyze a bivariate time series. The following data set contains two variables, `f_KSI` and `r_KSI`, which are measured quarterly, starting the first quarter of 1969. The variable `f_KSI` represents the quarterly average of the log of the monthly totals of the front-seat passengers killed or seriously injured during the car accidents, and `r_KSI` represents a similar number for the rear-seat passengers. The data set has been extended at the end with eight missing values, which represent four quarters, to cause the SSM procedure to produce model forecasts for this span.

```
data seatBelt;
input f_KSI r_KSI @@;

run;
```

These data have been analyzed in Durbin and Koopman (2001, chap. 9, sec. 3). The analysis presented here is similar. To simplify the illustration, the monthly data have been converted to quarterly data and two predictors (the number of kilometers traveled and the real price of petrol) are excluded from the analysis. You can also use PROC SSM to carry out the more elaborate analysis in Durbin and Koopman (2001).

One of the original reasons for studying these data was to assess the effect on `f_KSI` of the enactment of a seat-belt law in February 1983 that compelled the front seat passengers to wear seat belts. A simple graphical inspection of the data (not shown here) reveals that `f_KSI` and `r_KSI` do not show a pronounced

upward or downward trend but do show seasonal variation, and that these two series seem to move together. Additional inspection also shows that the seasonal effect is relatively stable throughout the data span. These considerations suggest the following model for $y = (f_KSI, r_KSI)$:

$$y_t = \begin{pmatrix} X_t \\ 0 \end{pmatrix} \beta + \mu_t + \gamma_t + \xi_t$$

All the terms on the right-hand side of this equation are assumed to be statistically independent. These terms are as follows:

- The predictor X_t (defined as Q1_83_Shift later in the program) denotes a variable that is 0 before the first quarter of 1983, and 1 thereafter. X_t is supposed to affect only f_KSI (the first element of y); it represents the enactment of the seat-belt law of 1983.
- μ_t denotes a bivariate random walk. It is supposed to capture the slowly changing level of the vector y_t . To capture the fact that f_KSI and r_KSI move together (that is, they are co-integrated), the covariance of the disturbance term of this random walk is assumed to be of lower than full rank.
- γ_t denotes a bivariate trigonometric seasonal term. In this model, it is taken to be fixed (that is, the seasonal effects do not change over time).
- ξ_t denotes a bivariate white noise term, which captures the residual variation that is unexplained by the other terms in the model.

The preceding model is an example of a (bivariate) basic structural model (BSM). The following statements specify and fit this model to f_KSI and r_KSI :

```
proc ssm data=seatBelt stateinfo;
  id date interval=quarter;
  Q1_83_Shift = (date >= '1jan1983'd);
  state error(2) type=WN cov(g) print=cov;
  component wn1 = error[1];
  component wn2 = error[2];
  state level(2) type=RW cov(rank=1) print=cov;
  component rw1 = level[1];
  component rw2 = level[2];
  state season(2) type=season(length=4);
  component s1 = season[1];
  component s2 = season[2];
  model f_KSI = Q1_83_Shift rw1 s1 wn1 / print=(smooth);
  model r_KSI = rw2 s2 wn2;
  eval f_KSI_sa = rw1 + Q1_83_Shift;
  output out=for1;
run;
```

The PROC SSM statement specifies the input data set, `seatBelt`. The use of the `STATEINFO` option in the PROC SSM statement produces additional information about the model state vector and its diffuse initial state. The optional `ID` statement specifies an index variable, `date`. The `INTERVAL=QUARTER` option in the `ID` statement indicates that the measurements were collected on a quarterly basis. Next, a programming statement defines `Q1_83_Shift`, the predictor that represents the enactment of the seat-belt law of 1983. It is used later in the `MODEL` statement for f_KSI . Separate `STATE` statements specify the terms μ_t , γ_t , and

ξ_t because they are statistically independent. Each model that governs them (white noise for ξ_t , random walk for μ_t , and trigonometric seasonal for γ_t) can be specified by using the TYPE= option of the STATE statement. When you use the TYPE= option, you can use the COV option to specify the information about the disturbance covariance in the state transition equation. The other details, such as the transition matrix specification and the specification of A_1 in the initial condition, are inferred from the TYPE= option. The use of PRINT=COV in the STATE statement causes the estimated disturbance covariance to be printed. For ξ_t (a white noise), A_1 is zero and $Q_t = Q$ for all $t \geq 1$, where Q is specified by the COV option. For μ_t and γ_t the initial condition is fully diffuse—that is, A_1 is an identity matrix of appropriate order and $Q_1 = 0$. The total diffuse dimension of this model, $(d + k)$, is $9 = 8 + 1$ as a result of one predictor, Q1_83_Shift, and two fully diffuse state subsections, μ_t and γ_t . The components in the model are defined by suitable linear combinations of these different state subsections. The program statements define the model as follows:

- **state error(2) type=WN cov(g);** defines ξ_t as a two-dimensional white noise, named error, with the covariance of general form. Then two COMPONENT statements define wn1 and wn2 as the first and second elements of error, respectively.
- **state level(2) type=RW cov(rank=1);** defines μ_t as a two-dimensional random walk, named level, with covariance of general form whose rank is restricted to 1. Then two COMPONENT statements define rw1 and rw2 as the first and second elements of level, respectively.
- **state season(2) type=season(length=4);** defines γ_t as a two-dimensional trigonometric seasonal of season length 4, named season, with zero covariance—signified by the absence of the COV option. Then two COMPONENT statements define s1 and s2 as appropriate linear combinations of season so that s1 represents the seasonal for f_KSI and s2 represents the seasonal for r_KSI. Because TYPE=SEASON in the STATE statement, the COMPONENT statement appropriately interprets **component s1 = season[1];** as s1 being a dot product: $(1 \ 0 \ 0 \ 0 \ 1 \ 0) * \text{season}$. See the section “Multivariate Season” on page 1861 for more information.
- **model f_KSI = Q1_83_Shift rw1 s1 wn1;** defines the model for f_KSI, and **model r_KSI = rw2 s2 wn2;** defines the model for r_KSI.

The SSM procedure fits the model and reports the parameter estimates, their approximate standard errors, and the likelihood-based goodness-of-fit measures by default. In order to output the one-step-ahead and full-sample estimates of the components in the model, you can either use the PRINT= options in the MODEL statement and the respective COMPONENT statements or you can specify an output data set in the OUTPUT statement. In addition, you can use the EVAL statement to define specific linear combinations of the underlying state that should also be estimated. The statement **eval f_KSI_sa = rw1 + Q1_83_Shift;** is an example of one such linear combination. It defines f_KSI_sa, a linear combination that represents the seasonal adjustment of f_KSI. The output data set, for1 (named in the OUTPUT statement) contains estimates of all the model components in addition to the estimate of f_KSI_sa.

The model summary table, shown in [Output 27.1.1](#), provides basic model information, such as the dimension of the underlying state equation ($m = 10$), the diffuse dimension of the model ($(d + k) = 9$), and the number of parameters (5) in the model parameter vector θ .

Output 27.1.1 Bivariate Basic Structural Model

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	2
State Dimension	10
Dimension of the Diffuse Initial Condition	9
Number of Parameters	5

Additional details about the role of different components in forming the model state and its diffuse initial condition are shown in [Output 27.1.2](#) and [Output 27.1.3](#). They show that the 10-dimensional model state vector is made up of subsections that are associated with error and level (each of dimension 2) and season (of dimension 6). Similarly, the nine-dimensional diffuse vector in the initial condition is made up of subsections that correspond to level, season, and the regression variable, Q1_83_Shift. Note that error does not contribute to the diffuse initial vector because it has a fully nondiffuse initial state.

Output 27.1.2 Bivariate Basic Structural Model State Vector Summary

State Vector Composition	
Subsection	Dimension
error	2
level	2
season	6

Output 27.1.3 Bivariate Basic Structural Model Initial Diffuse State Vector Summary

Diffuse Initial State Composition (Including Regressors)	
Subsection	Dimension
level	2
season	6
Q1_83_Shift	1

The index variable information is shown in [Output 27.1.4](#).

Output 27.1.4 Index Variable Information

ID Variable Information				
Name	Start	End	Max Delta	Type
date	1969:1	1985:4	1	Regular

Output 27.1.5 provides simple summary information about the response variables. It shows that `f_KSI` and `r_KSI` have four missing values each and no induced missing values because the predictor in the model, `Q1_83_Shift`, has no missing values.

Output 27.1.5 Response Variable Summary

Response Variable Information							
Name	---Number of Observations---			Minimum	Maximum	Mean	Std Deviation
	Total	Missing	Induced Missing				
f_KSI	68	4	0	6.16	7.09	6.71	0.206
r_KSI	68	4	0	5.56	6.41	5.97	0.186

The regression coefficient of `Q1_83_Shift`, shown in Output 27.1.6, is negative and is statistically significant. This is consistent with the expected drop in `f_KSI` after the enactment of the seat-belt law.

Output 27.1.6 Regression Coefficient of `Q1_83_Shift`

Regression Parameter Estimates					
Response Variable	Regression Variable	Estimate	Standard Error	t Value	Pr > t
f_KSI	Q1_83_Shift	-0.408	0.0259	-15.74	<.0001

Output 27.1.7 shows the estimates of the elements of θ . The five parameters in θ correspond to unknown elements that are associated with the covariance matrices in the specifications of error and level. Whenever a covariance specification is of a general form and is not defined by a user-specified variable list, it is internally parameterized as a product of its Cholesky root: $\text{Cov} = \text{Root} \text{Root}'$. This ensures that the resulting covariance is positive semidefinite. The Cholesky root is constrained to be lower triangular, with positive diagonal elements. If rank constraints (such as the rank-one constraint on the covariance in the specification of level) are imposed, the number of free parameters in the Cholesky factor is reduced appropriately. See the section “Covariance Parameterization” on page 1864 for more information. In view of these considerations, the five parameters in θ are a result of three parameters from the Cholesky root of error and two parameters that are associated with the Cholesky root of level.

Output 27.1.7 Parameter Estimates

Model Parameter Estimates					
Component	Type		Parameter	Estimate	Standard Error
error	Disturbance	Covariance	RootCov[1, 1]	0.0361	0.00736
error	Disturbance	Covariance	RootCov[2, 1]	0.0338	0.01131
error	Disturbance	Covariance	RootCov[2, 2]	0.0462	0.00470
level	Disturbance	Covariance	RootCov[1, 1]	0.0375	0.00843
level	Disturbance	Covariance	RootCov[2, 1]	0.0223	0.00569

Output 27.1.8 shows the resulting covariance estimate of error after multiplying the Cholesky factors.

Output 27.1.8 White Noise Covariance Estimate

Disturbance Covariance for error			
	Col1	Col2	
Row1	0.001307	0.001222	
Row2	0.001222	0.003277	

Similarly, Output 27.1.9 shows the covariance estimate of level disturbance. Note that because of the rank-one constraint, the determinant of this matrix is 0.

Output 27.1.9 Covariance Estimate of the Random Walk Disturbance

Disturbance Covariance for level			
	Col1	Col2	
Row1	0.001408	0.000837	
Row2	0.000837	0.000497	

Output 27.1.10 shows the likelihood computation summary. This table is produced by using the fitted model to carry out the filtering operation on the data. See the section “[Likelihood Computation and Model Fitting Phase](#)” on page 1852 for more information.

Output 27.1.10 Likelihood Computation Summary of the Fitted Model

Likelihood Computation Summary	
Statistic	Value
Nonmissing Response Values Used	128
Estimated Parameters	5
Initialized Diffuse State Elements	9
Normalized Residual Sum of Squares	119
Full Log Likelihood	166.158

The output data set, `for1`, specified in the `OUTPUT` statement contains one-step-ahead and full-sample estimates of all the model components and the user-specified components (defined by the `EVAL` statement). Their standard errors and the upper and lower confidence limits (by default, 95%) are also produced.

The following statements use the `for1` data set to produce a time series plot of the seasonally adjusted `f_KSI`:

```
proc sgplot data=for1;
  title "Seasonally Adjusted f_KSI with 95% Confidence Band";
  band x=date lower=smoothed_lower_f_KSI_sa
      upper=smoothed_upper_f_KSI_sa ;
  series x=date y=smoothed_f_KSI_sa;
  refline '1jan1985'd / axis=x lineattrs=(pattern=shortdash)
      LEGENDLABEL= "Start of Multi-Step Forecasts"
      name="Forecast Reference Line";
  scatter x=date y=f_KSI ;
run;
```

The generated plot is shown in [Output 27.1.11](#).

Output 27.1.11 Plot of Seasonally Adjusted f_KSI 

Example 27.2: Two-Way Random-Effects and Autoregressive Model for Panel Data

This example shows how you can use the SSM procedure to specify and fit the two-way random-effects model and the autoregressive model to analyze a panel of time series. These (and a few other) model types can also be fitted by the PANEL procedure, a SAS/ETS procedure that is specially designed to efficiently handle the cross-sectional time series data. However, because of the differences in their model fitting algorithms, generally the parameter estimates and other fit statistics produced by the SSM and PANEL procedures do not match. The SSM procedure always uses the (restricted) maximum likelihood for parameter estimation. The estimation method used by the PANEL procedure depends on the model type and the particular estimation options.

The cross-sectional data, Cigar, that are used in the section “[Getting Started: SSM Procedure](#)” on page 1815 are reused in this example. The output shown here is less extensive than the output shown in that section. The main emphasis of this example is how you can specify the two-way random effects model and the autoregressive model in the SSM procedure.

According to the two-way random effects model, the cigarette sales, `lsales`, can be described by the following equation:

$$\text{lsales}_{i,t} = \mu + \text{lprice} \beta_1 + \text{lndi} \beta_2 + \text{lpimin} \beta_3 + \gamma_i + \eta_t + \epsilon_{i,t}$$

This model represents `lsales` in region i and in year t as a sum of an overall intercept μ , the regression effects due to `lprice`, `lndi`, and `lpimin`, a zero-mean, random effect γ_i associated with region i , a zero-mean, random effect η_t associated with year t , and the observation noise $\epsilon_{i,t}$. The region-specific random effects γ_i and the year-specific random effects η_t are assumed to be independent, Gaussian sequences with variances σ_γ^2 and σ_η^2 , respectively. In addition, they are assumed to be independent of the observation noise, which is also assumed to be a sequence of independent, zero-mean, Gaussian variables with variance σ_ϵ^2 .

You can specify and fit this model by using the following statements:

```
proc ssm data=cigar;
  id year interval=year;
  parms s2g/ lower=(1.e-6);
  array RegionArray{46} region1-region46;
  do i=1 to 46;
    RegionArray[i] = (region=i);
  end;
  /* region-specific random effects */
  state gamma(46) T(I) cov1(I)=(s2g);
  component regionEffect = gamma * (RegionArray);
  /* year-specific random effect */
  state eta(1) type=wn cov(D);
  component timeEffect = eta[1];
  irregular wn;
  intercept = 1.0;
  model lsales = intercept lprice lndi lpimin
    timeEffect regionEffect wn;
run;
```

The `PARMS` statement defines `s2g`, a parameter that is restricted to be positive and is used later as the variance parameter for the region effect. Similarly the 46-dimensional array, `RegionArray`, of region-specific dummy variables is defined to be used later. The state subsection `gamma` corresponds to γ , which is the 46-dimensional vector of region-specific, zero-mean, random effects. The component `regionEffect` extracts the proper element of γ by using the array `RegionArray`. A constant column, `intercept`, is defined to be used later as an intercept term. The component `timeEffect` corresponds to η_t , and `wn` specifies the observation noise $\epsilon_{i,t}$. Finally the `MODEL` statement defines the model. Some of the tables that are produced by running these statements are shown in [Output 27.2.1](#) through [Output 27.2.5](#).

The model summary, shown in [Output 27.2.1](#), shows that the model is defined by one `MODEL` statement, the dimension of the underlying state vector is 47 (because γ is 46-dimensional and η_t is one-dimensional), the diffuse dimension is 4 (because of the four predictors in the model), and there are three parameters to be estimated.

Output 27.2.1 Two-Way Random-Effects Model: Model Summary

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	47
Dimension of the Diffuse Initial Condition	4
Number of Parameters	3

Output 27.2.2 provides the likelihood information about the fitted model.

Output 27.2.2 Two-Way Random-Effects Model: Likelihood Summary

Likelihood Computation Summary	
Statistic	Value
Nonmissing Response Values Used	1380
Estimated Parameters	3
Initialized Diffuse State Elements	4
Normalized Residual Sum of Squares	1376
Full Log Likelihood	1459.03

Output 27.2.3 shows the regression estimates.

Output 27.2.3 Two-Way Random-Effects Model: Regression Estimates

Regression Parameter Estimates					
Response Variable	Regression Variable	Estimate	Standard Error	t Value	Pr > t
lsales	intercept	2.798	0.1136	24.62	<.0001
lsales	lprice	-0.903	0.0365	-24.73	<.0001
lsales	lndi	0.592	0.0246	24.08	<.0001
lsales	lpimin	0.127	0.0398	3.18	0.0015

The ML estimate of s2g, a parameter specified in the PARMS statement, is shown in [Output 27.2.4](#). It corresponds to σ_γ^2 , the variance of the region effect.

Output 27.2.4 Two-Way Random-Effects Model: Estimate of σ_γ^2

Estimates of Named Parameters		
Parameter	Estimate	Standard Error
s2g	0.0241	0.00512

Output 27.2.5 Variance Estimates of η_t and ϵ_{it}

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
eta	Disturbance Covariance	Cov[1, 1]	0.000681	0.000264
wn	Irregular	Variance	0.005698	0.000224

The estimates of the other unknown parameters in the model are shown in [Output 27.2.5](#). It shows the estimate of the variance of the irregular component wn and the estimate of the variance of the time effect η_t .

The remainder of this example describes how you can specify and fit the following first-order vector autoregressive model to the cigarette data:

$$\begin{aligned} \text{lsales}_{i,t} &= \mu + \text{lprice} \beta_1 + \text{lndi} \beta_2 + \text{lpimin} \beta_3 + \gamma_t[i] \\ \gamma_t &= \Phi \gamma_{t-1} + \eta_t \end{aligned}$$

This model represents lsales in region i and in year t as a sum of an overall intercept μ , the regression effects due to lprice, lndi, and lpimin, and the i th element of a vector error term $\gamma_t[i]$. The multidimensional error sequence γ_t is assumed to follow a first-order autoregression with a diagonal autoregressive coefficient matrix Φ and with a multivariate, white noise sequence η_t as its disturbance sequence. The covariance matrix of η_t , Σ , is assumed to be dense. Note that the dimension of the vectors γ_t is the same as the number of cross-sections in the study (the number of regions in this example). Therefore, even for a relatively modest panel study, the total number of parameters to be estimated can get quite large. Therefore, in this example only the first three regions are considered in the analysis. The following statements specify and fit this model to the Cigar data set:

```
proc ssm data=cigar;
  where region <= 3;
  id year interval=year;
  array RegionArray{3} region1-region3;
  do i=1 to 3;
    RegionArray[i] = (region=i);
  end;
  state gamma(3) type=varma(p(d)=1) cov(g) print=(ar cov);
  component eta = gamma*(RegionArray);
  intercept = 1.0;
  model lsales = intercept lprice lndi lpimin eta;
run;
```

The vectors \boldsymbol{y}_t are specified in the STATE statement. The TYPE= specification signifies that the three-dimensional state subsection, gamma, follows a vector AR(1) model with a diagonal transition matrix and a disturbance covariance of a general form. The PRINT=(AR COV) option causes the SSM procedure to print the estimated AR coefficient matrix, Φ , and the disturbance error covariance Σ , respectively. The COMPONENT statement defines the appropriate error contribution (named eta), $\boldsymbol{y}_t[i]$. [Output 27.2.6](#) shows the estimated regression coefficients, [Output 27.2.7](#) shows the estimate of Φ , and [Output 27.2.8](#) shows the estimate of Σ :

Output 27.2.6 Autoregressive Model: Regression Estimates

Example 27.3: Backcasting, Forecasting, and Interpolation

This example illustrates how you can do model-based extrapolation—backcasting, forecasting, or interpolation—of a response variable. All you need is to appropriately augment the input data set with the relevant ID and predictor information and assign missing values to the response variable in these places. The following DATA step creates one such augmented data set by using a well-known data set that contains recordings of the Nile River water level measured between the years 1871 and 1970. Suppose you want to backcast the Nile water level for two years before 1871, forecast it for two years after 1970, and interpolate its value for the year 1921—for illustration purposes, this value is assumed to be missing in the available data set.

```
data nile;
  input level @@;
  year = intnx( 'year', '1jan1869'd, _n_-1 );
  format year year4.;
  if year = '1jan1921'd then level=.;
datalines;
. .
1120 1160 963 1210 1160 1160 813 1230 1370 1140
995 935 1110 994 1020 960 1180 799 958 1140
1100 1210 1150 1250 1260 1220 1030 1100 774 840
874 694 940 833 701 916 692 1020 1050 969
831 726 456 824 702 1120 1100 832 764 821
768 845 864 862 698 845 744 796 1040 759
781 865 845 944 984 897 822 1010 771 676
649 846 812 742 801 1040 860 874 848 890
744 749 838 1050 918 986 797 923 975 815
1020 906 901 1170 912 746 919 718 714 740
. .
;
```

It is also known that for this time span the Nile water level can be reasonably modeled as a sum of a random walk trend, a level shift in the year 1899, and the observation error. The following statements fit this model to the data:

```
proc ssm data=nile;
  id year interval=year;
  shift1899 = ( year >= '1jan1899'd );
  trend rw(rw);
  irregular wn;
  model level = shift1899 RW wn / print=smooth;
  output out=nileOut;
quit;
```

The model-based interpolated and extrapolated values of the Nile water level are shown in [Output 27.3.1](#), which is produced by using the PRINT=SMOOTH option in the MODEL statement.

Output 27.3.1 Interpolated and Extrapolated Nile Water Level

The SSM Procedure					
Full-Sample Prediction of Missing Values for level					
Obs	ID	Estimate	Standard Error	95% Confidence Limits	
1	1869	1098	130	843	1353

104	1972	851	129	599	1104

Example 27.4: Smoothing of Repeated Measures Data

This example of a repeated measures study is taken from Diggle, Liang, and Zeger (1994, p. 100). The data consist of body weights of 27 cows, measured at 23 unequally spaced time points over a period of approximately 22 months. Following Diggle, Liang, and Zeger (1994), one animal is removed from the analysis, one observation is removed according to their Figure 5.7, and the time is shifted to start at 0 and is measured in 10-day increments. The design is a 2×2 factorial, and the factors are the infection of an animal with *M. paratuberculosis* and whether the animal is receiving iron dosing. The data set contains five variables: *cow* assigns a unique identification number—from 1 to 26—to each cow in the study, *tpoint* denotes the time of the growth measurement, *weight* denotes the growth measurement, *iron* is a dummy variable that indicates whether the animal is receiving iron or not, and *infection* is a dummy variable that indicates whether the animal is infected or not. The goal of the study is to assess the effect of iron and infection—and their possible interaction—on weight. The following DATA steps create this data set:

```
data times;
  input time1-time23;
  datalines;
122 150 166 179 219 247 276 296 324 354 380 445
478 508 536 569 599 627 655 668 723 751 781
;

data cows;
  if _n_ = 1 then merge times;
  array t{23} time1 - time23;
  array w{23} weight1 - weight23;
  input cow iron infection weight1-weight23 @@;
  do i=1 to 23;
    weight = w{i};
    tpoint = (t{i}-t{1})/10;
    output;
  end;
  keep cow iron infection tpoint weight;
```

```

datalines;
1 0 0 4.7      4.905  5.011  5.075  5.136  5.165  5.298  5.323
      5.416  5.438  5.541  5.652  5.687  5.737  5.814  5.799

... more lines ...

```

The following DATA step adds `ironInf`, a grouping variable that is used later during the plotting of the results. In the next step, the data are sorted by the index variable, `tpoint`.

```

data cows;
  set cows;
  ironInf = "No Iron and No Infection";
  if iron=1 and infection=1 then ironInf = "Iron and Infection";
  else if iron=1 and infection=0 then ironInf = "No Iron and Infection";
  else if iron=0 and infection=1 then ironInf = "Iron and No Infection";
  else ironInf = "No Iron and No Infection";
  run;

proc sort data=cows;
  by tpoint ;
run;

```

To assess the effect of iron and infection on weight, the natural growth profile of the animals must also be accounted for. Here two alternate models for this problem are considered. The first model assumes that the observed weight of an animal is the sum of a common growth profile, which is modeled by a polynomial spline trend of order 2, the regression effects of iron and infection, and the observation error—modeled as white noise. An interaction term, for interaction between iron and infection, was found to be insignificant and is not included. In the second model, the common growth profile and the regression variables of the first model are replaced by four environment specific growth profiles.

The following statements fit the first model:

```

proc ssm data=cows;
  id tpoint;
  trend growth(ps(2));
  irregular wn;
  model weight = iron infection growth wn;
  eval pattern = iron + infection + growth;
  output out=for;
quit;

```

Output 27.4.1 shows that the state dimension of this model is 2 (corresponding to the polynomial trend specification of order 2), the number of diffuse elements in the initial condition is 4 (corresponding to the trend and the two regressors iron and infection), and the number of unknown parameters is 2 (corresponding to the variance parameters of trend and irregular).

Output 27.4.1 Model1: Model Summary Information

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	2
Dimension of the Diffuse Initial Condition	4
Number of Parameters	2

Output 27.4.2 shows that the ID variable is irregularly spaced with replication.

Output 27.4.2 ID Variable Information

ID Variable Information				
Name	Start	End	Max Delta	Type
tpoint	0	65.9000	6.5	Irregular with Replication

The estimated regression coefficients of iron and infection, shown in [Output 27.4.3](#), are significant and negative. This implies that both iron and infection adversely affect the response variable, weight.

Output 27.4.3 Model 1: Regression Estimates

Regression Parameter Estimates					
Response Variable	Regression Variable	Estimate	Standard Error	t Value	Pr > t
weight	iron	-0.0748	0.00761	-9.82	<.0001
weight	infection	-0.1292	0.00859	-15.04	<.0001

The variance estimates of the trend component and the irregular component are shown in [Output 27.4.4](#).

Output 27.4.4 Model 1: Estimates of Unnamed Parameters

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
growth	PS(2) Trend	Level Variance	0.0000162	9.01E-06
wn	Irregular	Variance	0.0085849	5.03E-04

After examining the model fit, it is useful to study how well the patterns implied by the model follow the data. `pattern`, defined by the `EVAL` statement, is a sum of the trend component and the regression effects. A graphical examination of the smoothed estimate of `pattern` is done next. The following `DATA` step merges the output data set specified in the `OUTPUT` statement, `for`, with the input data set, `cows`. In particular, this adds `ironInf` (a grouping variable from `cows`) to `for`.

```
data for;
    merge for cows;
    by tpoint;
run;
```

The following statements produce the graphs of `smoothed_pattern`, grouped according to the environment condition (see [Output 27.4.5](#)). The plot clearly shows that the control group “No Iron and No Infection” has the best growth profile, while the worst growth profile is for the group “Iron and Infection.”

```
proc sgplot data=for noautolegend;
    title 'Common Growth Profile Adjusted by Iron and Infection Status';
    band x=tpoint lower=smoothed_lower_pattern
        upper=smoothed_upper_pattern / group=ironInf name="band";
    series x=tpoint y=smoothed_pattern / group=ironInf name="series";
    keylegend "series";
run;
```

Output 27.4.5 Model 1: Growth Profile Comparison with 95% Confidence Bands

The following statements produce a panel of plots that show how well `smoothed_pattern` follows the observed data:

```
proc sgpanel data=for noautolegend;
  title 'Growth Plots Grouped by Iron and Infection';
  label tpoint='Time' ;
  panelby iron infection / columns=2;
  band x=tpoint lower=smoothed_lower_pattern
        upper=smoothed_upper_pattern ;
  scatter x=tpoint y=weight;
  series x=tpoint y=smoothed_pattern ;
run;
```

Output 27.4.6 shows that the model fits the data reasonably well.

Output 27.4.6 Model 1: Smoothed Model Fit Lines

The following statements fit the second model. In this model separate polynomial trends are fit according to different settings of iron and infection by specifying an appropriate list of (dummy) variables in the **CROSS=** option of the trend specification.

```
proc ssm data=cows;
  id tpoint;
  a1 = (iron=1 and infection=1);
  a2 = (iron=1 and infection=0);
  a3 = (iron=0 and infection=1);
  a4 = (iron=0 and infection=0);
```

```

trend growth(ps(2)) cross=(a1-a4);
irregular wn;
model weight = growth wn;
output out=for1;
quit;

```

As a result of the **CROSS=** option, the trend component **growth** is actually a sum of four separate trends that correspond to the different iron-infection settings. Denoting **growth** by μ_t and the four independent trends by $\mu_{1,t}$, $\mu_{2,t}$, $\mu_{3,t}$, and $\mu_{4,t}$,

$$\mu_t = a1 * \mu_{1,t} + a2 * \mu_{2,t} + a3 * \mu_{3,t} + a4 * \mu_{4,t}$$

where **a1**, **a2**, **a3**, and **a4** are the dummy variables specified in the **CROSS=** option. This shows that, for any given setting (say, the one for **a4**) μ_t is simply the corresponding trend $\mu_{4,t}$. The model summary, shown in [Output 27.4.7](#), reflects the increased state dimension and the increased number of parameters.

Output 27.4.7 Model2: Model Summary Information

The SSM Procedure	
Model Summary	
Model Property	Value
Number of Model Equations	1
State Dimension	8
Dimension of the Diffuse Initial Condition	8
Number of Parameters	5

[Output 27.4.8](#) shows the parameter estimates for this model.

Output 27.4.8 Model2: Estimates of Unnamed Parameters (Partial Output)

Component	Parameter	Estimate	StdErr
growth(Cross = a1)	Level Variance	1.28E-05	6.83E-06
growth(Cross = a2)	Level Variance	8.72E-06	3.81E-06
growth(Cross = a3)	Level Variance	9.07E-06	4.23E-06
growth(Cross = a4)	Level Variance	8.45E-06	3.40E-06
wn	Variance	8.39E-03	4.98E-04

Next, the smoothed estimate of trend (**growth**) is graphically studied. The following **DATA** step prepares the data for the grouped plots of **smoothed_growth** by merging **for1** with the input data set **cows**. As before, the reason is merely to include **ironInf** (the grouping variable).

```

data for1;
  merge for1 cows;
  by tpoint;
run;

```

The following statements produce the graphs of smoothed μ_t for the desired settings (since the grouping variable `ironInf` exactly corresponds to these settings). Once again, the plot in [Output 27.4.9](#) clearly shows that the control group “No Iron and No Infection” has the best growth profile, while the worst growth profile is for the group “Iron and Infection.” However, unlike the first model, the profile curves are not merely shifted versions of a common profile.

```
proc sgplot data=for1 noautolegend;
  title 'Iron and Infection Status-Specific Growth Profiles';
  band x=tpoint lower=smoothed_lower_growth
      upper=smoothed_upper_growth / group=ironInf name="band";
  series x=tpoint y=smoothed_growth / group=ironInf name="series";
  keylegend "series";
run;
```

Output 27.4.9 Model 2: Growth Profile Comparison with 95% Confidence Bands

Example 27.5: A User-Defined Trend Model

This example shows how to specify a continuous-time trend model discussed in Harvey (1989, chap. 9, sec. 9.2.1). This model is not one of the predefined trend models in the SSM procedure. The system matrices that govern the two-dimensional state of this model are

$$\mathbf{T} = \begin{bmatrix} 1 & h \\ 0 & 1 \end{bmatrix}$$

$$\mathbf{Q} = \begin{bmatrix} h\sigma_1^2 + \frac{h^3\sigma_2^2}{3} & \frac{h^2\sigma_2^2}{2} \\ \frac{h^2\sigma_2^2}{2} & h\sigma_2^2 \end{bmatrix}$$

where $h = h_t = (\tau_{t+1} - \tau_t)$ denotes the difference between the successive time points, and the parameters σ_1^2 and σ_2^2 are called the level variance and the slope variance, respectively. The initial condition is fully diffuse. The trend component corresponds to the first element of this state vector. The second element of the state vector corresponds to the slope of this trend component. This model reduces to the polynomial spline model of order 2 if the level variance $\sigma_1^2 = 0$. See the section “[Polynomial Spline Trend](#)” on page 1856.

The following statements specify a trend-plus-noise model to model the growth of cows in the previous example ([Example 27.4](#)). The only cows that are considered are the ones that received iron and are infected.

```
proc ssm data=cows;
  where iron=1 and infection=1;
  id tpoint;
  parms var1 var2 / lower=(1.e-8 1.e-8);
  array tMat{2,2};
  tMat[1,1] = 1;
  tMat[2,2] = 1;
  tMat[1,2] = _ID_DELTA_;
  array covMat{2,2};
  covMat[1,1] = var1*_ID_DELTA_ + var2*_ID_DELTA_**3/3;
  covMat[1,2] = var2*_ID_DELTA_**2/2;
  covMat[2,1] = covMat[1,2];
  covMat[2,2] = var2*_ID_DELTA_;
  state harveyLL(2) T(g)=(tMat) cov(g)=(covMat) a1(2);
  component trend = harveyLL[1];
  component slope = harveyLL[2];
  irregular wn;
  model weight = trend wn;
  output out=for;
run;
```

The program is easy to follow. The PARMS statement declares var1 and var2 as positive parameters, which correspond to σ_1^2 and σ_2^2 , respectively. The programming statements define arrays tMat and covMat, which later become the matrices \mathbf{T} and \mathbf{Q} , respectively. Note that the element tMat[2,1] is left unassigned, since it is a structural zero of \mathbf{T} (see the section “[Sparse Transition Matrix Specification](#)” on page 1848 for more information). Recall that the predefined variable _ID_DELTA_ contains the value of h_t , which is needed for defining the elements of \mathbf{T} and \mathbf{Q} (see the section “[ID Statement](#)” on page 1832). The STATE statement defines the trend state vector, harveyLL, and the COMPONENT statement defines the trend component, trend, by selecting the first element of harveyLL. An additional COMPONENT statement defines the slope component, slope, as the second element of harveyLL. The slope component (which represents the cow’s

growth rate) is not part of the observation equation; it is specified so that its estimate is output to for (the OUT= data set specified in the OUTPUT statement). The IRREGULAR statement defines the observation noise, and the MODEL statement defines the trend-plus-noise model.

The estimates of var1 and var2 are shown in [Output 27.5.1](#). It shows that the estimate of the level variance is nearly 0, implying that the fitted trend model is identical to the polynomial spline trend of order 2.

Output 27.5.1 Estimates of the Named Parameters

The SSM Procedure		
Estimates of Named Parameters		
Parameter	Estimate	Standard Error
var1	1.00E-08	0.000849
var2	1.24E-05	.

The estimate of the noise variance is shown in [Output 27.5.2](#).

Output 27.5.2 Estimates of the Unnamed Parameters

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
wn	Irregular	Variance	0.00954	0.000909

The following statements produce the plot of the fit of this trend model (shown in [Output 27.5.3](#)).

```
proc sgplot data=for;
  title "Model Fit: Two-Parameter Polynomial Spline of Order 2";
  series x=tpoint y=smoothed_trend;
  scatter x=tpoint y=weight;
run;
```

Output 27.5.3 A User-Defined Trend Model

The following statements produce the plot of the estimate of the slope component (shown in [Output 27.5.4](#)). This plot complements the preceding plot of trend; it shows the pattern of decline in the growth rate as the animals age.

```
proc sgplot data=for;
  title "Smoothed Estimate of Growth-Rate";
  series x=tpoint y=smoothed_slope;
run;
```

Output 27.5.4 Estimate of the slope Component

Example 27.6: Model with Multiple ARIMA Components

This example shows how you can fit the REGCOMPONENT models in Bell (2011) by using the SSM procedure. The following DATA step generates the data used in the last example of this article (Example 6: “Modeling a time series with a sampling error component”). The variable *y* in this data set contains monthly values of the VIP series (value of construction put in place), a U.S. Census Bureau publication that measures the value of construction installed or erected at construction sites during a given month. The values of *y* are known to be contaminated with heterogeneous sampling errors; the variable *hwt* in the data set is a proxy for this sampling error in the log scale. The variable *hwt* is treated as a weight variable for the noise component in the model.

```
data test;
  input y hwt;
  date = intnx('month', '01jan1997'd, _n_-1 );
  format date date.;
  logy = log(y);
  label logy = 'Log value of construction put in place';
  datalines;
```

```

115.2    0.042
110.4    0.042
111.5    0.067
127.9    0.122
150.0    0.129
149.5    0.135
139.5    0.152
144.6    0.168
176.0    0.173

```

```
... more lines ...
```

The article proposes the following model for the log VIP series:

$$\log(y) = \mu_t + hwt * \eta_t$$

where μ_t follows an $\text{ARIMA}(0,1,1) \times (0,1,1)_{12}$ model and η_t is a zero-mean, $\text{AR}(2)$ error process. The following statements specify this model for logy:

```

proc ssm data=test;
  id date interval=month;
  trend airlineTrend(arma(d=1 sd=1 q=1 sq=1 s=12));
  trend ar2Noise(arma(p=2)) cross=(hwt);
  model logy = airlineTrend ar2Noise;
  output outfor=for;
run;

```

Output 27.6.1 Estimates of the ARIMA Components Model

The SSM Procedure				
Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
airlineTrend	ARMA Trend	Error Variance	0.000768	0.00717
airlineTrend	ARMA Trend	MA_1	0.342128	0.38575
airlineTrend	ARMA Trend	SMA_1	-0.999000	9.30218
ar2Noise	ARMA Trend	Error Variance	0.410905	0.09947
ar2Noise	ARMA Trend	AR_1	0.484630	0.06758
ar2Noise	ARMA Trend	AR_2	0.439580	0.23570

The $\text{ARIMA}(0,1,1) \times (0,1,1)_{12}$ trend μ_t is named `airlineTrend` and the zero-mean, $\text{AR}(2)$ error process η_t is named `ar2Noise`. See the **TREND** statement for more information about the ARIMA notation. The estimates of model parameters are shown in [Output 27.6.1](#). These estimates are different from the estimates given in the article; however, the estimated trend and noise series are qualitatively similar. The article uses an estimation procedure that consists of a sequence of alternating steps in which one subset of parameters is held fixed and the remaining parameters are estimated by MLE in each step. This process continues until all the estimates stabilize. The SSM procedure estimates all the parameters simultaneously by MLE.

The following statements produce the plot of the estimate of the `airlineTrend` component (shown in [Output 27.6.2](#)). This plot is very similar to the trend plot shown in the article (the article plots are in the antilog scale).

```
proc sgplot data=for;
  title "Smoothed Estimate of the ARIMA(0,1,1)(0,1,1)12 Trend";
  series x= date y=smoothed_airlineTrend;
  scatter x= date y=logy;
run;
```

Output 27.6.2 Estimate of the `airlineTrend` Component

The following statements produce the plot of the estimate of the `ar2Noise` component (shown in [Output 27.6.3](#)). This plot is also very similar to the noise plot shown in the article (once again, the article plots are in the antilog scale).

```
proc sgplot data=for;
  title "Smoothed Estimate of the AR(2) Noise";
  series x= date y=smoothed_ar2Noise;
  refline 0;
run;
```

Output 27.6.3 Estimate of the ar2Noise Component

Example 27.7: Dynamic Factor Modeling

This example shows how you can fit the dynamic Nelson-Siegel (DNS) factor model discussed in Koopman, Mallee, and Van der Wel (2010). The following DATA step creates the yield-curve data set, `dns`, that is used in this article. The data are monthly bond yields that were recorded between the start of 1970 to the end of 2000 for 17 bonds of different maturities; the maturities range from three months to 10 years (120 months). The variable `date` contains the observation date, `yield` contains the bond yield, `maturity` contains the associated bond maturity, and `mtype` contains an index (ranging from 1 to 17) that sequentially labels bonds of increasing maturity. The data have been extended for two more years by adding missing yields for the years 2001 and 2002, which causes the SSM procedure to produce model forecasts for this span.

```
data dns;
input date : date. yield maturity mtype;
format date date.;
datalines;
1-Jan-70      8.019      3      1
1-Jan-70      8.091      6      2
1-Jan-70      8.108      9      3
```

1-Jan-70	8.01	12	4
1-Jan-70	7.836	15	5
1-Jan-70	7.888	18	6
1-Jan-70	7.896	21	7
1-Jan-70	7.989	24	8
1-Jan-70	8.058	30	9
1-Jan-70	8.065	36	10
1-Jan-70	8.088	48	11
1-Jan-70	8.067	60	12

... more lines ...

Suppose that $\theta_t(\tau)$ denotes the (idealized) yield at time t that is associated with a bond of maturity τ (in months). Even if time is not measured continuously and the bonds of only certain maturities are traded, $\theta_t(\tau)$ is treated as a smooth function of two continuous variables, time t and maturity τ . Koopman, Mallee, and Van der Wel (2010) discuss a variety of models for $\theta_t(\tau)$, which is called the yield surface. One of these models depends on a positive, time-varying, scalar parameter λ_t and a time-varying three-dimensional vector parameter β_t . This model can be described as follows:

$$\begin{aligned}\theta_t(\tau) &= \theta(\tau; \lambda_t, \beta_t) \\ &= \beta_{1t} + \beta_{2t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} \right) + \beta_{3t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} - \exp(-\lambda_t \tau) \right)\end{aligned}$$

This model is a dynamic version of a static model discussed in Nelson and Siegel (1987), where λ_t and β_t are time invariant. For fixed time period t , the three terms in this model have relatively simple interpretation. The first term β_{1t} can be thought of as the overall yield level because it does not depend on τ , the bond maturity. It can also be thought of as the long term yield because as $\tau \uparrow \infty$ the other two terms vanish; the coefficients of both β_{2t} and β_{3t} converge to 0 as $\tau \uparrow \infty$ (recall that λ_t is positive). Next, note that as $\tau \downarrow 0$ the coefficient of β_{2t} in the second term converges to 1 while that of β_{3t} in the third term converges to 0; therefore the second term can be thought of as a correction to the overall yield that is associated with the short term bonds. Finally, note that the coefficient of β_{3t} in the third term is a unimodal function of τ that decays monotonically to 0 as $\tau \downarrow 0$ and as $\tau \uparrow \infty$; therefore the third term is associated with the medium term bond yields. It is postulated that the observed yield, denoted by $y_t(\tau)$, is a noisy version of this unobserved (true) yield $\theta_t(\tau)$. The observed yield can be modeled as

$$\begin{aligned}y_t(\tau) &= \theta(\tau; \lambda_t, \beta_t) + \epsilon_{t,\tau} \\ &= \beta_{1t} + \beta_{2t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} \right) + \beta_{3t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} - \exp(-\lambda_t \tau) \right) + \epsilon_{t,\tau} \\ (\beta_t - \mu) &= \Phi(\beta_{t-1} - \mu) + \eta_t\end{aligned}$$

where $\epsilon_{t,\tau}$ are zero-mean, independent, Gaussian variables with variance σ_τ^2 , and η_t is a three-dimensional, Gaussian white noise. That is, β_t is a VAR(1) process with mean vector μ . The remainder of this example explains how to use the SSM procedure to fit this model to the yield data in the dns data set.

Suppose that variables Z1, Z2, and Z3 are defined as the coefficients of β_{1t} , β_{2t} , and β_{3t} , respectively. That is,

$$\begin{aligned} Z1 &= 1 \\ Z2 &= \frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} \\ Z3 &= \frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} - \exp(-\lambda_t \tau) \end{aligned}$$

In this case,

$$\theta_t(\tau) = Z1 * \beta_{1t} + Z2 * \beta_{2t} + Z3 * \beta_{3t}$$

Let $\gamma_t = \beta_t - \mu$. Then γ_t is a zero-mean VAR(1) process and $\beta_t = \gamma_t + \mu$. In particular,

$$\begin{aligned} \theta_t(\tau) &= Z1 * \beta_{1t} + Z2 * \beta_{2t} + Z3 * \beta_{3t} \\ &= Z1 * \gamma_{1t} + Z2 * \gamma_{2t} + Z3 * \gamma_{3t} + Z1 * \mu_1 + Z2 * \mu_2 + Z3 * \mu_3 \end{aligned}$$

This shows that the model for $y_t(\tau)$ can be cast into a state space form with the following observation equation:

$$y_t(\tau) = \mathbf{Z}\gamma_t + \mathbf{Z}\mu + \epsilon_{t,\tau}$$

The underlying six-dimensional state vector α_t is formed by joining the two independent subvectors, γ_t (which is a zero-mean, VAR(1) process) and the constant mean vector μ . That is, $\alpha_t = (\gamma_{1t} \gamma_{2t} \gamma_{3t} \mu_1 \mu_2 \mu_3)'$.

Note that the variables Z2 and Z3 depend on the time varying parameter λ_t , which is unknown. λ_t is assumed to be a smooth and positive function of time t . In what follows λ_t is represented as an exponential of a cubic spline—a B-spline—in time with four evenly spaced interior knots between January 1970 and December 2002. A cubic spline with four interior knots can be represented as a sum of seven (number of knots + spline degree + 1) B-spline basis functions, $c_{1t}, c_{2t}, \dots, c_{7t}$, for example. More specifically, λ_t can be expressed as

$$\lambda_t = \exp(v1 * c_{1t} + \dots + v7 * c_{7t})$$

for some parameters $v1, v2, \dots, v7$ and the B-spline basis functions (of time) $c_{1t}, c_{2t}, \dots, c_{7t}$. Thus, the variables Z2 and Z3 become known functions of time, except for the parameters $v1, v2, \dots, v7$, which are estimated from the data. The following statements augment the dns data set with the B-spline basis columns in two steps. First a data set that contains the basis columns, c1–c7, is created by using the BSPLINE function in the IML procedure. This data set is then merged with the dns data set.

```
proc iml;
  use dns;
  read all var {date} into x;
  bsp = bspline(x, 2, ., 4);
  create spline var{c1 c2 c3 c4 c5 c6 c7};
  append from bsp;
quit;
data dns;
  merge dns spline;
run;
```

The following statements use the SSM procedure to carry out the model fitting and forecasting calculations:

```
proc ssm data=dns optimizer(technique=dbldog maxiter=400);
  id date interval=month;

  /* Time varying parameter lambda */
  parms v1-v7;
  lambda = exp(v1*c1 + v2*c2 + v3*c3 + v4*c4
    + v5*c5 + v6*c6 + v7*c7);

  /* Observation equation white noise -- separate variance for each maturity */
  parms signal-signal17 / lower=1.e-4;
  array s_array(17) signal-signal17;
  do i=1 to 17;
    if (mtype=i) then sigma = s_array[i];
  end;
  irregular wn variance=sigma;

  /* Variables Z1, Z2, Z3 needed in the observation equation */
  Z1= 1.0;
  tmp = lambda*maturity;
  Z2 = (1-exp(-tmp))/tmp;
  Z3 = ( 1-exp(-tmp)-tmp*exp(-tmp) )/tmp;

  /* Zero-mean VAR(1) factor gamma and the associated component */
  state gamma(3) type=VARMA(p(d)=1) cov(g) print=(cov ar);
  comp gammaComp = (Z1-Z3)*gamma;

  /* Constant mean vector mu and the associated component */
  state mu(3) type=rw;
  comp muComp = (Z1-Z3)*mu;

  /* Observation equation */
  model yield = muComp gammaComp wn;

  /* Various components defined only for the output purposes */
  eval yieldSurface = muComp + gammaComp;

  comp gamma1 = gamma[1];
  comp gamma2 = gamma[2];
  comp gamma3 = gamma[3];
  comp mu1 = mu[1];
  comp mu2 = mu[2];
  comp mu3 = mu[3];

  comp z2Gamma = (Z2)*gamma[2];
  comp z3Gamma = (Z3)*gamma[3];
  comp z2Mu = (Z2)*mu[2];
  comp z3Mu = (Z3)*mu[3];

  eval beta1 = mu1 + gamma1;
  eval beta2 = mu2 + gamma2;
  eval beta3 = mu3 + gamma3;
```

```

eval shortTem = z2Gamma + z2Mu;
eval medTerm = z3Gamma + z3Mu;

/* output the component estimates and the forecasts */
output out=dnsFor pdv;
run;

```

The DBLDOG optimization technique is used for parameter estimation since it is computationally more efficient in this example. The transition matrix, Φ , in the VAR(1) specification of **gamma** is taken to be diagonal (TYPE=VARMA(P(D)=1)) because the use of more general square matrix did not improve the model fit significantly. The mean vector **mu** (recall that $\mathbf{beta}_t = \mathbf{gamma}_t + \mathbf{mu}$) is specified as a three-dimensional random walk with zero disturbance covariance (signified by the absence of COV= option). The model specification part of the program ends with the MODEL statement; the subsequent COMP and EVAL statements define some useful linear combinations of the underlying state. Their estimates are computed after the model fit is completed and are output to the output data set dnsFor. The dnsFor data set also contains all the program variables and the parameters defined in the PARMS statement because the OUTPUT statement contains the PDV option.

Output 27.7.1 shows the estimated mean vector (μ). It shows that the mean long-term yield is 7.63864. Output 27.7.2 shows the estimates of v1–v7 (used for defining time-varying λ_t) and the maturity specific observation variances. Output 27.7.3 shows the estimate of the VAR(1) transition matrix Φ , and Output 27.7.4 shows the associated disturbance covariance matrix Σ . The model fit summary is shown in Output 27.7.5.

The following statements produce the time series plots of the smoothed estimate of the idealized bond yield ($\theta_t(\tau)$) for bonds with maturities 30, 60, and 120 months (shown in [Output 27.7.6](#)). To simplify the display, the plots exclude the time span prior to 1991.

```
proc sgplot data= dnsFor;
  title "The Estimated Yield Surface and the Observed Yields ";
  where maturity in (3 60 120) and date >= '31dec1990'd;
  series x=date y=smoothed_yieldSurface / group=maturity;
  scatter x=date y=yield / group=maturity;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multi-step forecasts";
run;
```

Output 27.7.6 Smoothed Estimate of $\theta_t(\tau)$ for $\tau = 3, 60, 120$ 

The plots indicate that the DNS model is a reasonable description of the yield data. Similar plots (not shown here) for other maturities also indicate the adequacy of the DNS model. The following statements produce the time series plot of the smoothed estimate of β_{1t} , the long-term bond yield (shown in [Output 27.7.7](#)) :

```
proc sgplot data=dnsFor;
  title "Long-Term Bond Yields Over Time ";
  series x=date y=smoothed_beta1 ;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multi-step forecasts";
run;
```

Output 27.7.7 Smoothed Estimate of β_{1t} , the Long-Term Yield

Similarly, [Output 27.7.8](#), which is produced by the following statements, shows the smoothed estimate of the correction to the overall yield that is provided by the second term ($Z_2 * \beta_{2t}$) for maturities of 3 months and 120 months. As expected, the correction for the (long-term) maturity of 120 months is negligible compared to the (short-term) maturity of 3 months.

```
proc sgplot data=dnsFor;
  title "The Correction Term for the Short-Term Yields ";
  where maturity in (3 120);
  series x=date y=smoothed_shortTem / group=maturity;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multi-step forecasts";
run;
```

Output 27.7.8 Smoothed Estimate of $Z_2 * \beta_{2t}$, the Correction Term for the Short-Term Yields

Example 27.8: Diagnostic Plots

This example provides information about the diagnostic plots that are produced by the SSM procedure. The following plots are available:

- A panel of two plots—a histogram and a Q-Q plot—for the normality check of the one-step-ahead residuals $v_{t,i}$. A separate panel is produced for each response variable.
- A time series plot of standardized residuals, one per response variable.
- A panel of two plots—a histogram and a Q-Q plot—for the normality check of the prediction errors $AO_{t,i}$. A separate panel is produced for each response variable.
- A time series plot of standardized prediction errors, one per response variable.
- A time series plot of maximal state shock chi-square statistics.

All these plots are used primarily for model diagnostics. In this example the seat-belt data discussed in [Example 27.1](#) are revisited. In [Example 27.1](#) the question under consideration was whether the data showed

evidence for the effectiveness of seat-belt law that was introduced in the first quarter of 1983. An intervention variable, `Q1_83_Shift`, was used in the model to measure the effect of this law on the front-seat passengers who were killed or seriously injured in the car accidents (`f_KSI`). Here the analysis of these data begins without the knowledge of this seat-belt law. In effect, the same model is fitted without the use of the intervention variable `Q1_83_Shift`.

```
proc ssm data=seatBelt optimizer(tech=interiorpoint) plots=all;
  id date interval=quarter;
  state error(2) type=WN cov(g);
  component wn1 = error[1];
  component wn2 = error[2];
  state level(2) type=RW cov(rank=1) ;
  component rw1 = level[1];
  component rw2 = level[2];
  state season(2) type=season(length=4);
  component s1 = season[1];
  component s2 = season[2];
  model f_KSI = rw1 s1 wn1;
  model r_KSI = rw2 s2 wn2;
run;
```

The `PLOTS=ALL` option in the `PROC SSM` statement turns on all the plotting options. Since there are two response variables, nine plots in total are produced: a separate set of four plots—two residual and two prediction error—is produced for `f_KSI` and `r_KSI`, and one maximal shock plot is produced. Only three of these plots are shown here. [Output 27.8.1](#) shows the normality check for the one-step-ahead residuals for `f_KSI`. It shows some evidence of lack of normality.

Output 27.8.1 Normality Check of One-Step-Ahead Residuals for `f_KSI`

Output 27.8.2 shows the time series plot of standardized prediction errors for f_KSI . It identifies some extreme observations (additive outliers): two near 1983 and one near 1970.

Output 27.8.2 Time Series Plot of Standardized Prediction Errors for f_KSI

Output 27.8.3 shows the time series plot of maximal shock statistics. This plot can be very informative about the temporal locations of the structural changes in the overall observation-generation process (treating the fitted model as the reference). It can indicate locations of shifts in the process level or shifts in other characteristics such as its slope. The precise nature of the shift (whether the shift is in the level or in some other aspects) must be determined by additional modeling steps such as adding appropriate intervention variables to the model. In this example, the maximal shock statistics plot indicates two locations—the last quarter of 1973 and the first quarter of 1983—as likely locations for the structural breaks that are associated with the traffic accident process. These are indeed reasonable findings since the last quarter of 1973 (October 1973) is associated with the start of the oil shock that severely affected worldwide automobile traffic and the first quarter of 1983 is associated with the introduction of the seat-belt law that might have improved the safety of front-seat passengers.

Output 27.8.3 Time Series Plot of Maximal Shock Statistics

The following statements fit a revised model that includes the intervention variable Q1_83_Shift:

```
proc ssm data=seatBelt optimizer(tech=interiorpoint) plots=all;
  id date interval=quarter;
  Q1_83_Shift = (date >= '1jan1983'd);
  state error(2) type=WN cov(g);
  component wn1 = error[1];
  component wn2 = error[2];
  state level(2) type=RW cov(rank=1) ;
  component rw1 = level[1];
  component rw2 = level[2];
  state season(2) type=season(length=4);
  component s1 = season[1];
  component s2 = season[2];
  model f_KSI = Q1_83_Shift rw1 s1 wn1;
  model r_KSI = rw2 s2 wn2;
run;
```

Output 27.8.4 shows the time series plot of maximal shock statistics for this revised model. As expected, the plot no longer shows the first quarter of 1983 as a structural break location. It continues to show the last

quarter of 1973 as a structural break location because the fitted model does not try to explicitly account for this shift.

Output 27.8.4 Time Series Plot of Maximal Shock Statistics for the Model with Q1_83_Shift

Note that the reference line in [Output 27.8.3](#) is drawn at 99.9th percentile while the reference line in [Output 27.8.4](#) is drawn at 99th percentile. The reference line location in the maximal state shock chi-square statistics plot is decided based on the points in the plot. A reference line is drawn at percentiles 80, 90, 99, or 99.9 based on the largest maximal shock statistic being shown.

Example 27.9: Variable Bandwidth Smoothing

The data for this example, taken from Givens and Hoeting (2005, chap. 11, Example 11.8), contain two variables, x and y . The variable y represents noisy evaluation of an unknown smooth function at x . The data are sorted by x .

```
data difficult;
input x y;
datalines;
0.002 0.040
```

```
0.011 0.009
0.013 0.719
0.016 0.199
0.017 -0.409

... more lines ...
```

Output 27.9.1 shows the scatter plot of y against x that is generated by the following statements:

```
proc sgplot data=difficult;
  title "Scatter Plot of Y versus X";
  scatter x=x y=y ;
run;
```

Output 27.9.1 Scatter Plot of Y versus X

The plot clearly shows that the variance of y values varies considerably over the range of x values—the variance is larger for x values around 0.2 and gets increasingly smaller as the x values get closer to 1.0. Givens and Hoeting (2005) discuss the difficulties of extracting a smooth pattern from such data.

Consider the following model for y :

$$y(x) = \mu_x + \epsilon_x$$

where μ_x is a smooth trend component and ϵ_x is the observation noise with variance, $h(x)$, which changes with x : $\epsilon_x \sim N(0, h(x))$. It is known (Durbin and Koopman 2001, chap. 3, sect. 10 and sect. 11) that modeling the trend μ_x as a polynomial smoothing spline (for example, the way the growth curves are modeled in Example 27.4) and taking the variance function of the observation noise ϵ_x a constant results in a trend estimate that can be termed a fixed-bandwidth-smoother. The optimal bandwidth turns out to be a function of the signal-to-noise ratio: the ratio of the observation noise variance and the disturbance variance of the trend component. On the other hand, allowing the variance function of the observation noise to change with the x values results in a trend estimate that can be termed a variable-bandwidth-smoother. The rest of this example shows how to use the SSM procedure to create a data-dependent variance function $h(x)$ and to extract the associated (variable-bandwidth) smooth trend from such data. Suppose that the (unknown) variance function $h(x)$ can be approximated as

$$h(x) = \exp\left(\sum_{i=1}^7 v_i \text{SplineBasis}_i(x)\right)$$

where $v_i, i = 1, 2, \dots, 7$ are unknown parameters and $\text{SplineBasis}_i(x), i = 1, 2, \dots, 7$, are the full set of cubic spline basis functions (B-splines) with four evenly spaced internal knots between the range of x values—essentially, four equispaced points between 0.0 and 1.0. Note that the number of basis functions in the full set, 7, is the sum of the number of internal knots, 4, and the degree of the polynomial, 3. The following statements create a data set, combined, that contains the variables x and y , along with the desired spline basis functions (col1–col7) that are created by using the BSPLINE function in PROC IML:

```
proc iml;
  use difficult;
  /* read x and y from difficult into temp */
  read all var _num_ into temp;
  x = temp[,1];
  /* generate B-spline basis for a cubic spline
     with 4 evenly spaced internal knots in the x-range */
  bsp = bspline(x, 2, ., 4);
  combined = temp || bsp;
  /* create a merged data set with x, y, and
     spline basis columns */
  create combined var {x y col1 col2 col3 col4 col5 col6 col7};
  append from combined;
quit;
```

The following statements specify and fit the desired model to the data:

```
proc ssm data=combined opt (tech=dbldog);
  id x;
  /* parameters needed to define h(x) */
  parms v1-v7;
  /* defining h(x) */
  var = exp(v1*col1 + v2*col2 + v3*col3 + v4*col4
            + v5*col5 + v6*col6 + v7*col7);
  /* defining the polynomial spline trend */
  trend trend(ps(2));
  /* defining the observation noise with variance h(x) */
  irregular wn variance=var;
  model y = trend wn;
  output out=for pdv;
run;
```

Output 27.9.2 shows the estimates of $v_i, i = 1, 2, \dots, 7$, and Output 27.9.3 shows the estimate of the disturbance variance associated with the polynomial spline trend that is specified in the TREND statement.

Output 27.9.2 Estimates of v1–v7

The SSM Procedure			
Estimates of Named Parameters			
Parameter	Estimate	Standard Error	
v1	-3.302	1.501	
v2	-0.826	0.619	
v3	-2.234	0.453	
v4	-3.130	0.412	
v5	-4.306	0.415	
v6	-6.901	0.588	
v7	-19.514	2.306	

Output 27.9.3 Estimate of the Disturbance Variance Associated with the Trend

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error
trend	PS(2) Trend	Level Variance	339	110

The following statements produce a plot, shown in Output 27.9.4, of the fitted trend with 95% confidence band:

```
proc sgplot data=for;
  title "Variable Bandwidth Smoothing Spline";
  band x=x lower=smoothed_lower_trend
      upper=smoothed_upper_trend ;
  series x=x y=smoothed_trend;
  scatter x=x y=y;
run;
```

Output 27.9.4 Fitted Trend with 95% Confidence Band

Clearly the fitted curve tracks the data quite well. Lastly, [Output 27.9.5](#) (produced by using the following statements) shows the estimated variance function $h(x)$.

```
proc sgplot data=for;
  title "Estimated Variance Function";
  series x=x y=var;
run;
```

As expected, the curve attains its peak at an x value around 0.18 and decays to nearly 0 as x values reach 1.0.

Output 27.9.5 Estimated Variance Function $h(x) = \exp(\sum_{i=1}^7 v_i \text{SplineBasis}_i(x))$

Overview: STATESPACE Procedure

The STATESPACE procedure uses the state space model to analyze and forecast multivariate time series. The STATESPACE procedure is appropriate for jointly forecasting several related time series that have dynamic interactions. By taking into account the autocorrelations among all the variables in a set, the STATESPACE procedure can give better forecasts than methods that model each series separately.

By default, the STATESPACE procedure automatically selects a state space model appropriate for the time series, making the procedure a good tool for automatic forecasting of multivariate time series. Alternatively, you can specify the state space model by giving the form of the state vector and the state transition and innovation matrices.

The methods used by the STATESPACE procedure assume that the time series are jointly stationary. Non-stationary series must be made stationary by some preliminary transformation, usually by differencing. The STATESPACE procedure enables you to specify differencing of the input data. When differencing is specified, the STATESPACE procedure automatically integrates forecasts of the differenced series to produce forecasts of the original series.

The State Space Model

The *state space model* represents a multivariate time series through auxiliary variables, some of which might not be directly observable. These auxiliary variables are called the *state vector*. The state vector summarizes all the information from the present and past values of the time series that is relevant to the prediction of future values of the series. The observed time series are expressed as linear combinations of the state variables. The state space model is also called a Markovian representation, or a canonical representation, of a multivariate time series process. The state space approach to modeling a multivariate stationary time series is summarized in Akaike (1976).

The state space form encompasses a very rich class of models. Any Gaussian multivariate stationary time series can be written in a state space form, provided that the dimension of the predictor space is finite. In particular, any autoregressive moving average (ARMA) process has a state space representation and, conversely, any state space process can be expressed in an ARMA form (Akaike 1974). More details on the relation of the state space and ARMA forms are given in the section “[Relation of ARMA and State Space Forms](#)” on page 1950.

Let \mathbf{x}_t be the $r \times 1$ vector of observed variables, after differencing (if differencing is specified) and subtracting the sample mean. Let \mathbf{z}_t be the state vector of dimension s , $s \geq r$, where the first r components of \mathbf{z}_t consist of \mathbf{x}_t . Let the notation $\mathbf{x}_{t+k|t}$ represent the conditional expectation (or prediction) of \mathbf{x}_{t+k} based on the information available at time t . Then the last $s - r$ elements of \mathbf{z}_t consist of elements of $\mathbf{x}_{t+k|t}$, where $k > 0$ is specified or determined automatically by the procedure.

There are various forms of the state space model in use. The form of the state space model used by the STATESPACE procedure is based on Akaike (1976). The model is defined by the following *state transition equation* :

$$\mathbf{z}_{t+1} = \mathbf{F}\mathbf{z}_t + \mathbf{G}\mathbf{e}_{t+1}$$

In the state transition equation, the $s \times s$ coefficient matrix \mathbf{F} is called the *transition matrix*; it determines the dynamic properties of the model.

The $s \times r$ coefficient matrix \mathbf{G} is called the *input matrix*; it determines the variance structure of the transition equation. For model identification, the first r rows and columns of \mathbf{G} are set to an $r \times r$ identity matrix.

The input vector \mathbf{e}_t is a sequence of independent normally distributed random vectors of dimension r with mean $\mathbf{0}$ and covariance matrix Σ_{ee} . The random error \mathbf{e}_t is sometimes called the innovation vector or shock vector.

In addition to the state transition equation, state space models usually include a *measurement equation* or *observation equation* that gives the observed values \mathbf{x}_t as a function of the state vector \mathbf{z}_t . However, since PROC STATESPACE always includes the observed values \mathbf{x}_t in the state vector \mathbf{z}_t , the measurement equation in this case merely represents the extraction of the first r components of the state vector.

The measurement equation used by the STATESPACE procedure is

$$\mathbf{x}_t = [\mathbf{I}_r \mathbf{0}] \mathbf{z}_t$$

where \mathbf{I}_r is an $r \times r$ identity matrix. In practice, PROC STATESPACE performs the extraction of \mathbf{x}_t from \mathbf{z}_t without reference to an explicit measurement equation.

In summary:

\mathbf{x}_t	is an observation vector of dimension r .
\mathbf{z}_t	is a state vector of dimension s , whose first r elements are \mathbf{x}_t and whose last $s - r$ elements are conditional prediction of future \mathbf{x}_t .
\mathbf{F}	is an $s \times s$ transition matrix.
\mathbf{G}	is an $s \times r$ input matrix, with the identity matrix \mathbf{I}_r forming the first r rows and columns.
\mathbf{e}_t	is a sequence of independent normally distributed random vectors of dimension r with mean $\mathbf{0}$ and covariance matrix Σ_{ee} .

How PROC STATESPACE Works

The design of the STATESPACE procedure closely follows the modeling strategy proposed by Akaike (1976). This strategy employs canonical correlation analysis for the automatic identification of the state space model.

Following Akaike (1976), the procedure first fits a sequence of unrestricted vector autoregressive (VAR) models and computes Akaike's information criterion (AIC) for each model. The vector autoregressive models are estimated using the sample autocovariance matrices and the Yule-Walker equations. The order of the VAR model that produces the smallest Akaike information criterion is chosen as the order (number of lags into the past) to use in the canonical correlation analysis.

The elements of the state vector are then determined via a sequence of canonical correlation analyses of the sample autocovariance matrices through the selected order. This analysis computes the sample canonical correlations of the past with an increasing number of steps into the future. Variables that yield significant correlations are added to the state vector; those that yield insignificant correlations are excluded from further consideration. The importance of the correlation is judged on the basis of another information criterion

proposed by Akaike. See the section “[Canonical Correlation Analysis Options](#)” on page 1935 for details. If you specify the state vector explicitly, these model identification steps are omitted.

After the state vector is determined, the state space model is fit to the data. The free parameters in the F , G , and Σ_{ee} matrices are estimated by approximate maximum likelihood. By default, the F and G matrices are unrestricted, except for identifiability requirements. Optionally, conditional least squares estimates can be computed. You can impose restrictions on elements of the F and G matrices.

After the parameters are estimated, the Kalman filtering technique is used to produce forecasts from the fitted state space model. If differencing was specified, the forecasts are integrated to produce forecasts of the original input variables.

Getting Started: STATESPACE Procedure

The following introductory example uses simulated data for two variables X and Y . The following statements generate the X and Y series.

```
data in;
  x=10;  y=40;
  x1=0;  y1=0;
  a1=0;  b1=0;
  iseed=123;
  do t=-100 to 200;
    a=rannor(iseed);
    b=rannor(iseed);
    dx = 0.5*x1 + 0.3*y1 + a - 0.2*a1 - 0.1*b1;
    dy = 0.3*x1 + 0.5*y1 + b;
    x = x + dx + .25;
    y = y + dy + .25;
    if t >= 0 then output;
    x1 = dx; y1 = dy;
    a1 = a; b1 = b;
  end;
  keep t x y;
run;
```

The simulated series X and Y are shown in [Figure 28.1](#).

Figure 28.1 Example Series

Automatic State Space Model Selection

The STATESPACE procedure is designed to automatically select the best state space model for forecasting the series. You can specify your own model if you want, and you can use the output from PROC STATESPACE to help you identify a state space model. However, the easiest way to use PROC STATESPACE is to let it choose the model.

Stationarity and Differencing

Although PROC STATESPACE selects the state space model automatically, it does assume that the input series are stationary. If the series are nonstationary, then the process might fail. Therefore the first step is to examine your data and test to see if differencing is required. (See the section “[Stationarity and Differencing](#)” on page 1940 for further discussion of this issue.)

The series shown in [Figure 28.1](#) are nonstationary. In order to forecast X and Y with a state space model, you must difference them (or use some other detrending method). If you fail to difference when needed and try to use PROC STATESPACE with nonstationary data, an inappropriate state space model might be selected, and the model estimation might fail to converge.

The following statements identify and fit a state space model for the first differences of X and Y, and forecast X and Y 10 periods ahead:

```
proc statespace data=in out=out lead=10;
  var x(1) y(1);
  id t;
run;
```

The DATA= option specifies the input data set and the OUT= option specifies the output data set for the forecasts. The LEAD= option specifies forecasting 10 observations past the end of the input data. The VAR statement specifies the variables to forecast and specifies differencing. The notation X(1) Y(1) specifies that the state space model analyzes the first differences of X and Y.

Descriptive Statistics and Preliminary Autoregressions

The first page of the printed output produced by the preceding statements is shown in [Figure 28.2](#).

Figure 28.2 Descriptive Statistics and VAR Order Selection

The STATESPACE Procedure			
Number of Observations		200	
Variable	Mean	Standard Error	
x	0.144316	1.233457	Has been differenced. With period(s) = 1.
y	0.164871	1.304358	Has been differenced. With period(s) = 1.

The STATESPACE Procedure								
Information Criterion for Autoregressive Models								
Lag=0	Lag=1	Lag=2	Lag=3	Lag=4	Lag=5	Lag=6	Lag=7	Lag=8
149.697	8.387786	5.517099	12.05986	15.36952	21.79538	24.00638	29.88874	33.55708

Information Criterion for Autoregressive Models		
Lag=9	Lag=10	
41.17606	47.70222	

Figure 28.2 continued

Schematic Representation of Correlations											
Name/Lag	0	1	2	3	4	5	6	7	8	9	10
x	++	++	++	++	++	++	+	..	+	+	..
y	++	++	++	++	++	+	+	+	+

+ is > 2*std error, - is < -2*std error, . is between

Descriptive statistics are printed first, giving the number of nonmissing observations after differencing and the sample means and standard deviations of the differenced series. The sample means are subtracted before the series are modeled (unless the NOCENTER option is specified), and the sample means are added back when the forecasts are produced.

Let X_t and Y_t be the observed values of X and Y, and let x_t and y_t be the values of X and Y after differencing and subtracting the mean difference. The series x_t modeled by the STATESPACE procedure is

$$\mathbf{x}_t = \begin{bmatrix} x_t \\ y_t \end{bmatrix} = \begin{bmatrix} (1 - B)X_t - 0.144316 \\ (1 - B)Y_t - 0.164871 \end{bmatrix}$$

where B represents the backshift operator.

After the descriptive statistics, PROC STATESPACE prints the Akaike information criterion (AIC) values for the autoregressive models fit to the series. The smallest AIC value, in this case 5.517 at lag 2, determines the number of autocovariance matrices analyzed in the canonical correlation phase.

A schematic representation of the autocorrelations is printed next. This indicates which elements of the autocorrelation matrices at different lags are significantly greater than or less than 0.

The second page of the STATESPACE printed output is shown in Figure 28.3.

Figure 28.3 Partial Autocorrelations and VAR Model

Schematic Representation of Partial Autocorrelations											
Name/Lag	1	2	3	4	5	6	7	8	9	10	
x	++	+	
y	++	

+ is > 2*std error, - is < -2*std error, . is between

Yule-Walker Estimates for Minimum AIC											
-----Lag=1-----				-----Lag=2-----							
		x		y		x		y			
x		0.257438		0.202237		0.170812		0.133554			
y		0.292177		0.469297		-0.00537		-0.00048			

Figure 28.3 shows a schematic representation of the partial autocorrelations, similar to the autocorrelations shown in Figure 28.2. The selection of a second order autoregressive model by the AIC statistic looks reasonable in this case because the partial autocorrelations for lags greater than 2 are not significant.

Next, the Yule-Walker estimates for the selected autoregressive model are printed. This output shows the coefficient matrices of the vector autoregressive model at each lag.

Selected State Space Model Form and Preliminary Estimates

After the autoregressive order selection process has determined the number of lags to consider, the canonical correlation analysis phase selects the state vector. By default, output for this process is not printed. You can use the CANCELL option to print details of the canonical correlation analysis. See the section “[Canonical Correlation Analysis Options](#)” on page 1935 for an explanation of this process.

After the state vector is selected, the state space model is estimated by approximate maximum likelihood. Information from the canonical correlation analysis and from the preliminary autoregression is used to form preliminary estimates of the state space model parameters. These preliminary estimates are used as starting values for the iterative estimation process.

The form of the state vector and the preliminary estimates are printed next, as shown in Figure 28.4.

Figure 28.4 Preliminary Estimates of State Space Model

The STATESPACE Procedure		
Selected Statespace Form and Preliminary Estimates		
State Vector		
$\mathbf{x}(T;T)$	$\mathbf{y}(T;T)$	$\mathbf{x}(T+1;T)$
Estimate of Transition Matrix		
0	0	1
0.291536	0.468762	-0.00411
0.24869	0.24484	0.204257
Input Matrix for Innovation		
1	0	
0	1	
0.257438	0.202237	
Variance Matrix for Innovation		
0.945196	0.100786	
0.100786	1.014703	

Figure 28.4 first prints the state vector as $X[T;T] \ Y[T;T] \ X[T+1;T]$. This notation indicates that the state vector is

$$\mathbf{z}_t = \begin{bmatrix} x_{t|t} \\ y_{t|t} \\ x_{t+1|t} \end{bmatrix}$$

The notation $x_{t+1|t}$ indicates the conditional expectation or prediction of x_{t+1} based on the information available at time t , and $x_{t|t}$ and $y_{t|t}$ are x_t and y_t , respectively.

The remainder of Figure 28.4 shows the preliminary estimates of the transition matrix F , the input matrix G , and the covariance matrix Σ_{ee} .

Estimated State Space Model

The next page of the STATESPACE output prints the final estimates of the fitted model, as shown in Figure 28.5. This output has the same form as in Figure 28.4, but it shows the maximum likelihood estimates instead of the preliminary estimates.

Figure 28.5 Fitted State Space Model

The STATESPACE Procedure		
Selected Statespace Form and Fitted Model		
State Vector		
$\mathbf{x}(T;T)$	$\mathbf{y}(T;T)$	$\mathbf{x}(T+1;T)$
Estimate of Transition Matrix		
0	0	1
0.297273	0.47376	-0.01998
0.2301	0.228425	0.256031
Input Matrix for Innovation		
1	0	
0	1	
0.257284	0.202273	
Variance Matrix for Innovation		
0.945188	0.100752	
0.100752	1.014712	

The estimated state space model shown in Figure 28.5 is

$$\begin{bmatrix} x_{t+1|t+1} \\ y_{t+1|t+1} \\ x_{t+2|t+1} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 \\ 0.297 & 0.474 & -0.020 \\ 0.230 & 0.228 & 0.256 \end{bmatrix} \begin{bmatrix} x_t \\ y_t \\ x_{t+1|t} \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0.257 & 0.202 \end{bmatrix} \begin{bmatrix} e_{t+1} \\ n_{t+1} \end{bmatrix}$$

$$\text{var} \begin{bmatrix} e_{t+1} \\ n_{t+1} \end{bmatrix} = \begin{bmatrix} 0.945 & 0.101 \\ 0.101 & 1.015 \end{bmatrix}$$

The next page of the STATESPACE output lists the estimates of the free parameters in the **F** and **G** matrices with standard errors and *t* statistics, as shown in Figure 28.6.

Figure 28.6 Final Parameter Estimates

Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	
F(2,1)	0.297273	0.129995	2.29

G(3,2)	0.202273	0.068593	2.95	

Convergence Failures

The maximum likelihood estimates are computed by an iterative nonlinear maximization algorithm, which might not converge. If the estimates fail to converge, warning messages are printed in the output.

If you encounter convergence problems, you should recheck the stationarity of the data and ensure that the specified differencing orders are correct. Attempting to fit state space models to nonstationary data is a common cause of convergence failure. You can also use the MAXIT= option to increase the number of iterations allowed, or experiment with the convergence tolerance options DETTOL= and PARMTOL=.

Forecast Data Set

The following statements print the output data set. The WHERE statement excludes the first 190 observations from the output, so that only the forecasts and the last 10 actual observations are printed.

```
proc print data=out;
  id t;
  where t > 190;
run;
```

The PROC PRINT output is shown in Figure 28.7.

Figure 28.7 OUT= Data Set Produced by PROC STATESPACE

The OUT= data set produced by PROC STATESPACE contains the VAR and ID statement variables. In addition, for each VAR statement variable, the OUT= data set contains the variables FOR_i , RES_i , and STD_i . These variables contain the predicted values, residuals, and forecast standard errors for the i th variable in the VAR statement list. In this case, X is listed first in the VAR statement, so FOR1 contains the forecasts of X, while FOR2 contains the forecasts of Y.

The following statements plot the forecasts and actuals for the series.

```
proc sgplot data=out noautolegend;
  where t > 150;
  series x=t y=for1 / markers
    markerattrs=(symbol=circle color=blue)
    lineattrs=(pattern=solid color=blue);
  series x=t y=for2 / markers
    markerattrs=(symbol=circle color=blue)
    lineattrs=(pattern=solid color=blue);
  series x=t y=x / markers
    markerattrs=(symbol=circle color=red)
    lineattrs=(pattern=solid color=red);
  series x=t y=y / markers
    markerattrs=(symbol=circle color=red)
    lineattrs=(pattern=solid color=red);
  refline 200.5 / axis=x;
run;
```

The forecast plot is shown in Figure 28.8. The last 50 observations are also plotted to provide context, and a reference line is drawn between the historical and forecast periods.

Figure 28.8 Plot of Forecasts

Controlling Printed Output

By default, the STATESPACE procedure produces a large amount of printed output. The NOPRINT option suppresses all printed output. You can suppress the printed output for the autoregressive model selection process with the PRINTOUT=NONE option. The descriptive statistics and state space model estimation output are still printed when PRINTOUT=NONE is specified. You can produce more detailed output with the PRINTOUT=LONG option and by specifying the printing control options CANCELL, COVB, and PRINT.

Specifying the State Space Model

Instead of allowing the STATESPACE procedure to select the model automatically, you can use FORM and RESTRICT statements to specify a state space model.

Specifying the State Vector

Use the FORM statement to control the form of the state vector. You can use this feature to force PROC STATESPACE to estimate and forecast a model different from the model it would select automatically. You can also use this feature to reestimate the automatically selected model (possibly with restrictions) without repeating the canonical correlation analysis.

The FORM statement specifies the number of lags of each variable to include in the state vector. For example, the statement FORM X 3; forces the state vector to include $x_{t|t}$, $x_{t+1|t}$, and $x_{t+2|t}$. The following statement specifies the state vector $(x_{t|t}, y_{t|t}, x_{t+1|t})$, which is the same state vector selected in the preceding example:

```
form x 2 y 1;
```

You can specify the form for only some of the variables and allow PROC STATESPACE to select the form for the other variables. If only some of the variables are specified in the FORM statement, canonical correlation analysis is used to determine the number of lags included in the state vector for the remaining variables not specified by the FORM statement. If the FORM statement includes specifications for all the variables listed in the VAR statement, the state vector is completely defined and the canonical correlation analysis is not performed.

Restricting the F and G matrices

After you know the form of the state vector, you can use the RESTRICT statement to fix some parameters in the F and G matrices to specified values. One use of this feature is to remove insignificant parameters by restricting them to 0.

In the introductory example shown in the preceding section, the F[2,3] parameter is not significant. (The parameters estimation output shown in Figure 28.6 gives the t statistic for F[2,3] as -0.06 . F[3,3] and F[3,1] also have low significance with $t < 2$.)

The following statements reestimate this model with F[2,3] restricted to 0. The FORM statement is used to specify the state vector and thus bypass the canonical correlation analysis.

```
proc statespace data=in out=out lead=10;
  var x(1) y(1);
  id t;
  form x 2 y 1;
  restrict f(2,3)=0;
run;
```

The final estimates produced by these statements are shown in Figure 28.10.

Syntax: STATESPACE Procedure

The STATESPACE procedure uses the following statements:

```

PROC STATESPACE options ;
  BY variable ... ;
  FORM variable value ... ;
  ID variable ;
  INITIAL F (row,column)=value ... G(row,column)=value ... ;
  RESTRICT F (row,column)=value ... G (row,column)=value ... ;
  VAR variable (difference, difference, ...) ... ;

```

Functional Summary

Table 28.1 summarizes the statements and options used by PROC STATESPACE.

Table 28.1 STATESPACE Functional Summary

Description	Statement	Option
Input Data Set Options		
specify the input data set	PROC STATESPACE	DATA=
prevent subtraction of sample mean	PROC STATESPACE	NOCENTER
specify the ID variable	ID	
specify the observed series and differencing	VAR	
Options for Autoregressive Estimates		
specify the maximum order	PROC STATESPACE	ARMAX=
specify maximum lag for autocovariances	PROC STATESPACE	LAGMAX=
output only minimum AIC model	PROC STATESPACE	MINIC
specify the amount of detail printed	PROC STATESPACE	PRINTOUT=
write preliminary AR models to a data set	PROC STATESPACE	OUTAR=
Options for Canonical Correlation Analysis		
print the sequence of canonical correlations	PROC STATESPACE	CANCORR
specify upper limit of dimension of state vector	PROC STATESPACE	DIMMAX=
specify the minimum number of lags	PROC STATESPACE	PASTMIN=
specify the multiplier of the degrees of freedom	PROC STATESPACE	SIGCORR=
Options for State Space Model Estimation		
specify starting values	INITIAL	
print covariance matrix of parameter estimates	PROC STATESPACE	COVB
specify the convergence criterion	PROC STATESPACE	DETTOL=
specify the convergence criterion	PROC STATESPACE	PARMTOL=
print the details of the iterations	PROC STATESPACE	ITPRINT
specify an upper limit of the number of lags	PROC STATESPACE	KLAGE=
specify maximum number of iterations allowed	PROC STATESPACE	MAXIT=
suppress the final estimation	PROC STATESPACE	NOEST
write the state space model parameter estimates to an output data set	PROC STATESPACE	OUTMODEL=
use conditional least squares for final estimates	PROC STATESPACE	RESIDEST
specify criterion for testing for singularity	PROC STATESPACE	SINGULAR=
Options for Forecasting		
start forecasting before end of the input data	PROC STATESPACE	BACK=
specify the time interval between observations	PROC STATESPACE	INTERVAL=

Description	Statement	Option
specify multiple periods in the time series	PROC STATESPACE	INTPER=
specify how many periods to forecast	PROC STATESPACE	LEAD=
specify the output data set for forecasts	PROC STATESPACE	OUT=

specify the state vector	FORM	
specify the parameter values	RESTRICT	
BY Groups		
specify BY-group processing	BY	
Printing		
suppresses all printed output	NOPRINT	

PROC STATESPACE Statement

PROC STATESPACE *options* ;

The following options can be specified in the PROC STATESPACE statement.

Printing Options

NOPRINT

suppresses all printed output.

Input Data Options

DATA=SAS-data-set

specifies the name of the SAS data set to be used by the procedure. If the DATA= option is omitted, the most recently created SAS data set is used.

LAGMAX=k

specifies the number of lags for which the sample autocovariance matrix is computed. The LAGMAX= option controls the number of lags printed in the schematic representation of the autocorrelations.

The sample autocovariance matrix of lag i , denoted as C_i , is computed as

$$C_i = \frac{1}{N-1} \sum_{t=1+i}^N \mathbf{x}_t \mathbf{x}'_{t-i}$$

where \mathbf{x}_t is the differenced and centered data and N is the number of observations. (If the NOCENTER option is specified, 1 is not subtracted from N .) LAGMAX= k specifies that C_0 through C_k are computed. The default is LAGMAX=10.

NOCENTER

prevents subtraction of the sample mean from the input series (after any specified differencing) before the analysis.

Options for Preliminary Autoregressive Models**ARMAX=*n***

specifies the maximum order of the preliminary autoregressive models. The ARMAX= option controls the autoregressive orders for which information criteria are printed, and controls the number of lags printed in the schematic representation of partial autocorrelations. The default is ARMAX=10. See the section “[Preliminary Autoregressive Models](#)” on page 1941 for details.

MINIC

writes to the OUTAR= data set only the preliminary Yule-Walker estimates for the VAR model that produces the minimum AIC. See the section “[OUTAR= Data Set](#)” on page 1952 for details.

OUTAR=*SAS-data-set*

writes the Yule-Walker estimates of the preliminary autoregressive models to a SAS data set. See the section “[OUTAR= Data Set](#)” on page 1952 for details.

PRINTOUT=SHORT | LONG | NONE

determines the amount of detail printed. PRINTOUT=LONG prints the lagged covariance matrices, the partial autoregressive matrices, and estimates of the residual covariance matrices from the sequence of autoregressive models. PRINTOUT=NONE suppresses the output for the preliminary autoregressive models. The descriptive statistics and state space model estimation output are still printed when PRINTOUT=NONE is specified. PRINTOUT=SHORT is the default.

Canonical Correlation Analysis Options**CANCORR**

prints the canonical correlations and information criterion for each candidate state vector considered. See the section “[Canonical Correlation Analysis Options](#)” on page 1935 for details.

DIMMAX=*n*

specifies the upper limit to the dimension of the state vector. The DIMMAX= option can be used to limit the size of the model selected. The default is DIMMAX=10.

PASTMIN=*n*

specifies the minimum number of lags to include in the canonical correlation analysis. The default is PASTMIN=0. See the section “[Canonical Correlation Analysis Options](#)” on page 1935 for details.

SIGCORR=*value*

specifies the multiplier of the degrees of freedom for the penalty term in the information criterion used to select the state space form. The default is SIGCORR=2. The larger the value of the SIGCORR= option, the smaller the state vector tends to be. Hence, a large value causes a simpler model to be fit. See the section “[Canonical Correlation Analysis Options](#)” on page 1935 for details.

State Space Model Estimation Options

COVB

prints the inverse of the observed information matrix for the parameter estimates. This matrix is an estimate of the covariance matrix for the parameter estimates.

DETTOL=*value*

specifies the convergence criterion. The DETTOL= and PARMTOL= option values are used together to test for convergence of the estimation process. If, during an iteration, the relative change of the parameter estimates is less than the PARMTOL= value and the relative change of the determinant of the innovation variance matrix is less than the DETTOL= value, then iteration ceases and the current estimates are accepted. The default is DETTOL=1E-5.

ITPRINT

prints the iterations during the estimation process.

KLAG=*n*

sets an upper limit for the number of lags of the sample autocovariance matrix used in computing the approximate likelihood function. If the data have a strong moving average character, a larger KLAG= value might be necessary to obtain good estimates. The default is KLAG=15. See the section “[Parameter Estimation](#)” on page 1947 for details.

MAXIT=*n*

sets an upper limit to the number of iterations in the maximum likelihood or conditional least squares estimation. The default is MAXIT=50.

NOEST

suppresses the final maximum likelihood estimation of the selected model.

OUTMODEL=*SAS-data-set*

writes the parameter estimates and their standard errors to a SAS data set. See the section “[OUTMODEL= Data Set](#)” on page 1953 for details.

PARMTOL=*value*

specifies the convergence criterion. The DETTOL= and PARMTOL= option values are used together to test for convergence of the estimation process. If, during an iteration, the relative change of the parameter estimates is less than the PARMTOL= value and the relative change of the determinant of the innovation variance matrix is less than the DETTOL= value, then iteration ceases and the current estimates are accepted. The default is PARMTOL=0.001.

RESIDEST

computes the final estimates by using conditional least squares on the raw data. This type of estimation might be more stable than the default maximum likelihood method but is usually more computationally expensive. See the section “[Parameter Estimation](#)” on page 1947 for details about the conditional least squares method.

SINGULAR=*value*

specifies the criterion for testing for singularity of a matrix. A matrix is declared singular if a scaled pivot is less than the SINGULAR= value when sweeping the matrix. The default is SINGULAR=1E-7.

Forecasting Options

BACK=*n*

starts forecasting *n* periods before the end of the input data. The BACK= option value must not be greater than the number of observations. The default is BACK=0.

INTERVAL=*interval*

specifies the time interval between observations. The INTERVAL= value is used in conjunction with the ID variable to check that the input data are in order and have no missing periods. The INTERVAL= option is also used to extrapolate the ID values past the end of the input data. See Chapter 4, “[Date Intervals, Formats, and Functions](#),” for details about the INTERVAL= values allowed.

INTPER=*n*

specifies that each input observation corresponds to *n* time periods. For example, the options INTERVAL=MONTH and INTPER=2 specify bimonthly data and are equivalent to specifying INTERVAL=MONTH2. If the INTERVAL= option is not specified, the INTPER= option controls the increment used to generate ID values for the forecast observations. The default is INTPER=1.

LEAD=*n*

specifies how many forecast observations are produced. The forecasts start at the point set by the BACK= option. The default is LEAD=0, which produces no forecasts.

OUT=*SAS-data-set*

writes the residuals, actual values, forecasts, and forecast standard errors to a SAS data set. See the section “[OUT= Data Set](#)” on page 1952 for details.

PRINT

prints the forecasts.

BY Statement

BY *variable ...* ;

A BY statement can be used with the STATESPACE procedure to obtain separate analyses on observations in groups defined by the BY variables.

FORM Statement

FORM *variable value ...* ;

The FORM statement specifies the number of times a variable is included in the state vector. Values can be specified for any variable listed in the VAR statement. If a value is specified for each variable in the VAR statement, the state vector for the state space model is entirely specified, and automatic selection of the state space model is not performed.

The FORM statement forces the state vector, \mathbf{z}_t , to contain a specific variable a given number of times. For example, if Y is one of the variables in \mathbf{x}_t , then the statement

```
form y 3;
```

forces the state vector to contain Y_t , $Y_{t+1|t}$, and $Y_{t+2|t}$, possibly along with other variables.

The following statements illustrate the use of the FORM statement:

```
proc statespace data=in;
  var x y;
  form x 3 y 2;
run;
```

These statements fit a state space model with the following state vector:

$$\mathbf{z}_t = \begin{bmatrix} x_{t|t} \\ y_{t|t} \\ x_{t+1|t} \\ y_{t+1|t} \\ x_{t+2|t} \end{bmatrix}$$

ID Statement

ID *variable* ;

The ID statement specifies a variable that identifies observations in the input data set. The variable specified in the ID statement is included in the OUT= data set. The values of the ID variable are extrapolated for the forecast observations based on the values of the INTERVAL= and INTPER= options.

INITIAL Statement

INITIAL *F (row,column)= value ... G(row, column)= value ... ;*

The INITIAL statement gives initial values to the specified elements of the **F** and **G** matrices. These initial values are used as starting values for the iterative estimation.

Parts of the **F** and **G** matrices represent fixed structural identities. If an element specified is a fixed structural element instead of a free parameter, the corresponding initialization is ignored.

The following is an example of an INITIAL statement:

```
initial f(3,2)=0 g(4,1)=0 g(5,1)=0;
```

RESTRICT Statement

RESTRICT *F(row,column)= value ... G(row,column)= value ... ;*

The RESTRICT statement restricts the specified elements of the **F** and **G** matrices to the specified values.

To use the restrict statement, you need to know the form of the model. Either specify the form of the model with the FORM statement, or do a preliminary run (perhaps with the NOEST option) to find the form of the model that PROC STATESPACE selects for the data.

The following is an example of a RESTRICT statement:

```
restrict f(3,2)=0 g(4,1)=0 g(5,1)=0 ;
```

Parts of the **F** and **G** matrices represent fixed structural identities. If a restriction is specified for an element that is a fixed structural element instead of a free parameter, the restriction is ignored.

VAR Statement

VAR *variable (difference, difference, ...) ... ;*

The VAR statement specifies the variables in the input data set to model and forecast. The VAR statement also specifies differencing of the input variables. The VAR statement is required.

Differencing is specified by following the variable name with a list of difference periods separated by commas. See the section “[Stationarity and Differencing](#)” on page 1940 for more information about differencing of input variables.

The order in which variables are listed in the VAR statement controls the order in which variables are included in the state vector. Usually, potential inputs should be listed before potential outputs.

For example, assuming the input data are monthly, the following VAR statement specifies modeling and forecasting of the one period and seasonal second difference of X and Y:

```
var x(1,12) y(1,12);
```

In this example, the vector time series analyzed is

$$\mathbf{x}_t = \begin{bmatrix} (1 - B)(1 - B^{12})X_t - \bar{x} \\ (1 - B)(1 - B^{12})Y_t - \bar{y} \end{bmatrix}$$

where B represents the back shift operator and \bar{x} and \bar{y} represent the means of the differenced series. If the NOCENTER option is specified, the mean differences are not subtracted.

Details: STATESPACE Procedure

Missing Values

The STATESPACE procedure does not support missing values. The procedure uses the first contiguous group of observations with no missing values for any of the VAR statement variables. Observations at the beginning of the data set with missing values for any VAR statement variable are not used or included in the output data set.

Stationarity and Differencing

The state space model used by the STATESPACE procedure assumes that the time series are stationary. Hence, the data should be checked for stationarity. One way to check for stationarity is to plot the series. A graph of series over time can show a time trend or variability changes.

You can also check stationarity by using the sample autocorrelation functions displayed by the ARIMA procedure. The autocorrelation functions of nonstationary series tend to decay slowly. See Chapter 7, “[The ARIMA Procedure](#),” for more information.

Another alternative is to use the STATIONARITY= option in the IDENTIFY statement in PROC ARIMA to apply Dickey-Fuller tests for unit roots in the time series. See Chapter 7, “[The ARIMA Procedure](#),” for more information about Dickey-Fuller unit root tests.

The most popular way to transform a nonstationary series to stationarity is by differencing. Differencing of the time series is specified in the VAR statement. For example, to take a simple first difference of the series X, use this statement:

```
var x(1);
```

In this example, the change in X from one period to the next is analyzed. When the series has a seasonal pattern, differencing at a period equal to the length of the seasonal cycle can be desirable. For example, suppose the variable X is measured quarterly and shows a seasonal cycle over the year. You can use the following statement to analyze the series of changes from the same quarter in the previous year:

```
var x(4);
```

To difference twice, add another differencing period to the list. For example, the following statement analyzes the series of second differences $(X_t - X_{t-1}) - (X_{t-1} - X_{t-2}) = X_t - 2X_{t-1} + X_{t-2}$:

```
var x(1,1);
```

The following statement analyzes the seasonal second difference series:

```
var x(1,4);
```

The series that is being modeled is the 1-period difference of the 4-period difference:

$$(X_t - X_{t-4}) - (X_{t-1} - X_{t-5}) = X_t - X_{t-1} - X_{t-4} + X_{t-5}.$$

Another way to obtain stationary series is to use a regression on time to detrend the data. If the time series has a deterministic linear trend, regressing the series on time produces residuals that should be stationary. The following statements write residuals of X and Y to the variable RX and RY in the output data set DETREND.

```

data a;
  set a;
  t=_n_;
run;

proc reg data=a;
  model x y = t;
  output out=detrend r=rx ry;
run;

```

You then use PROC STATESPACE to forecast the detrended series RX and RY. A disadvantage of this method is that you need to add the trend back to the forecast series in an additional step. A more serious disadvantage of the detrending method is that it assumes a deterministic trend. In practice, most time series appear to have a stochastic rather than a deterministic trend. Differencing is a more flexible and often more appropriate method.

There are several other methods to handle nonstationary time series. For more information and examples, see Brockwell and Davis (1991).

Preliminary Autoregressive Models

After computing the sample autocovariance matrices, PROC STATESPACE fits a sequence of vector autoregressive models. These preliminary autoregressive models are used to estimate the autoregressive order of the process and limit the order of the autocovariances considered in the state vector selection process.

Yule-Walker Equations for Forward and Backward Models

Unlike a univariate autoregressive model, a multivariate autoregressive model has different forms, depending on whether the present observation is being predicted from the past observations or from the future observations.

Let \mathbf{x}_t be the r -component stationary time series given by the VAR statement after differencing and subtracting the vector of sample means. (If the NOCENTER option is specified, the mean is not subtracted.) Let n be the number of observations of \mathbf{x}_t from the input data set.

Let \mathbf{e}_t be a vector white noise sequence with mean vector $\mathbf{0}$ and variance matrix Σ_p , and let \mathbf{n}_t be a vector white noise sequence with mean vector $\mathbf{0}$ and variance matrix Ω_p . Let p be the order of the vector autoregressive model for \mathbf{x}_t .

The forward autoregressive form based on the past observations is written as follows:

$$\mathbf{x}_t = \sum_{i=1}^p \Phi_i^p \mathbf{x}_{t-i} + \mathbf{e}_t$$

The backward autoregressive form based on the future observations is written as follows:

$$\mathbf{x}_t = \sum_{i=1}^p \Psi_i^p \mathbf{x}_{t+i} + \mathbf{n}_t$$

Letting E denote the expected value operator, the autocovariance sequence for the \mathbf{x}_t series, $\mathbf{\Gamma}_i$, is

$$\mathbf{\Gamma}_i = E\mathbf{x}_t\mathbf{x}'_{t-i}$$

The Yule-Walker equations for the autoregressive model that matches the first p elements of the autocovariance sequence are

$$\begin{bmatrix} \mathbf{\Gamma}_0 & \mathbf{\Gamma}_1 & \cdots & \mathbf{\Gamma}_{p-1} \\ \mathbf{\Gamma}'_1 & \mathbf{\Gamma}_0 & \cdots & \mathbf{\Gamma}_{p-2} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{\Gamma}'_{p-1} & \mathbf{\Gamma}'_{p-2} & \cdots & \mathbf{\Gamma}_0 \end{bmatrix} \begin{bmatrix} \mathbf{\Phi}_1^p \\ \mathbf{\Phi}_2^p \\ \vdots \\ \mathbf{\Phi}_p^p \end{bmatrix} = \begin{bmatrix} \mathbf{\Gamma}_1 \\ \mathbf{\Gamma}_2 \\ \vdots \\ \mathbf{\Gamma}_p \end{bmatrix}$$

and

$$\begin{bmatrix} \mathbf{\Gamma}_0 & \mathbf{\Gamma}'_1 & \cdots & \mathbf{\Gamma}'_{p-1} \\ \mathbf{\Gamma}_1 & \mathbf{\Gamma}_0 & \cdots & \mathbf{\Gamma}'_{p-2} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{\Gamma}_{p-1} & \mathbf{\Gamma}_{p-2} & \cdots & \mathbf{\Gamma}_0 \end{bmatrix} \begin{bmatrix} \mathbf{\Psi}_1^p \\ \mathbf{\Psi}_2^p \\ \vdots \\ \mathbf{\Psi}_p^p \end{bmatrix} = \begin{bmatrix} \mathbf{\Gamma}'_1 \\ \mathbf{\Gamma}'_2 \\ \vdots \\ \mathbf{\Gamma}'_p \end{bmatrix}$$

Here $\mathbf{\Phi}_i^p$ are the coefficient matrices for the past observation form of the vector autoregressive model, and $\mathbf{\Psi}_i^p$ are the coefficient matrices for the future observation form. More information about the Yule-Walker equations in the multivariate setting can be found in Whittle (1963) and Ansley and Newbold (1979).

The innovation variance matrices for the two forms can be written as follows:

$$\mathbf{\Sigma}_p = \mathbf{\Gamma}_0 - \sum_{i=1}^p \mathbf{\Phi}_i^p \mathbf{\Gamma}'_i$$

$$\mathbf{\Omega}_p = \mathbf{\Gamma}_0 - \sum_{i=1}^p \mathbf{\Psi}_i^p \mathbf{\Gamma}_i$$

The autoregressive models are fit to the data by using the preceding Yule-Walker equations with $\mathbf{\Gamma}_i$ replaced by the sample covariance sequence \mathbf{C}_i . The covariance matrices are calculated as

$$\mathbf{C}_i = \frac{1}{N-1} \sum_{t=i+1}^N \mathbf{x}_t \mathbf{x}'_{t-i}$$

Let $\hat{\mathbf{\Phi}}_p$, $\hat{\mathbf{\Psi}}_p$, $\hat{\mathbf{\Sigma}}_p$, and $\hat{\mathbf{\Omega}}_p$ represent the Yule-Walker estimates of $\mathbf{\Phi}_p$, $\mathbf{\Psi}_p$, $\mathbf{\Sigma}_p$, and $\mathbf{\Omega}_p$, respectively. These matrices are written to an output data set when the OUTAR= option is specified.

When the PRINTOUT=LONG option is specified, the sequence of matrices $\hat{\mathbf{\Sigma}}_p$ and the corresponding correlation matrices are printed. The sequence of matrices $\hat{\mathbf{\Sigma}}_p$ is used to compute Akaike information criteria for selection of the autoregressive order of the process.

Akaike Information Criterion

The Akaike information criterion (AIC) is defined as $-2(\text{maximum of log likelihood}) + 2(\text{number of parameters})$. Since the vector autoregressive models are estimates from the Yule-Walker equations, not by maximum likelihood, the exact likelihood values are not available for computing the AIC. However, for the vector autoregressive model the maximum of the log likelihood can be approximated as

$$\ln(L) \approx -\frac{n}{2} \ln(|\hat{\Sigma}_p|)$$

Thus, the AIC for the order p model is computed as

$$AIC_p = n \ln(|\hat{\Sigma}_p|) + 2pr^2$$

You can use the printed AIC array to compute a likelihood ratio test of the autoregressive order. The log-likelihood ratio test statistic for testing the order p model against the order $p - 1$ model is

$$-n \ln(|\hat{\Sigma}_p|) + n \ln(|\hat{\Sigma}_{p-1}|)$$

This quantity is asymptotically distributed as a χ^2 with r^2 degrees of freedom if the series is autoregressive of order $p - 1$. It can be computed from the AIC array as

$$AIC_{p-1} - AIC_p + 2r^2$$

You can evaluate the significance of these test statistics with the PROBCHI function in a SAS DATA step or with a χ^2 table.

Determining the Autoregressive Order

Although the autoregressive models can be used for prediction, their primary value is to aid in the selection of a suitable portion of the sample covariance matrix for use in computing canonical correlations. If the multivariate time series \mathbf{x}_t is of autoregressive order p , then the vector of past values to lag p is considered to contain essentially all the information relevant for prediction of future values of the time series.

By default, PROC STATESPACE selects the order p that produces the autoregressive model with the smallest AIC_p . If the value p for the minimum AIC_p is less than the value of the PASTMIN= option, then p is set to the PASTMIN= value. Alternatively, you can use the ARMAX= and PASTMIN= options to force PROC STATESPACE to use an order you select.

Significance Limits for Partial Autocorrelations

The STATESPACE procedure prints a schematic representation of the partial autocorrelation matrices that indicates which partial autocorrelations are significantly greater than or significantly less than 0. Figure 28.11 shows an example of this table.

Figure 28.11 Significant Partial Autocorrelations

Schematic Representation of Partial Autocorrelations										
Name/Lag	1	2	3	4	5	6	7	8	9	10
x	++	+.
y	++
+ is > 2*std error, - is < -2*std error, . is between										

The partial autocorrelations are from the sample partial autoregressive matrices $\hat{\Phi}_p^p$. The standard errors used for the significance limits of the partial autocorrelations are computed from the sequence of matrices Σ_p and Ω_p .

Under the assumption that the observed series arises from an autoregressive process of order $p - 1$, the p th sample partial autoregressive matrix $\hat{\Phi}_p^p$ has an asymptotic variance matrix $\frac{1}{n}\Omega_p^{-1} \otimes \Sigma_p$.

The significance limits for $\hat{\Phi}_p^p$ used in the schematic plot of the sample partial autoregressive sequence are derived by replacing Ω_p and Σ_p with their sample estimators to produce the variance estimate, as follows:

$$\widehat{Var}(\hat{\Phi}_p^p) = \left(\frac{1}{n - rp} \right) \hat{\Omega}_p^{-1} \otimes \hat{\Sigma}_p$$

Canonical Correlation Analysis

Given the order p , let \mathbf{p}_t be the vector of current and past values relevant to prediction of \mathbf{x}_{t+1} :

$$\mathbf{p}_t = (\mathbf{x}'_t, \mathbf{x}'_{t-1}, \dots, \mathbf{x}'_{t-p})'$$

Let \mathbf{f}_t be the vector of current and future values:

$$\mathbf{f}_t = (\mathbf{x}'_t, \mathbf{x}'_{t+1}, \dots, \mathbf{x}'_{t+p})'$$

In the canonical correlation analysis, consider submatrices of the sample covariance matrix of \mathbf{p}_t and \mathbf{f}_t . This covariance matrix, \mathbf{V} , has a block Hankel form:

$$\mathbf{V} = \begin{bmatrix} \mathbf{C}_0 & \mathbf{C}'_1 & \mathbf{C}'_2 & \cdots & \mathbf{C}'_p \\ \mathbf{C}'_1 & \mathbf{C}'_2 & \mathbf{C}'_3 & \cdots & \mathbf{C}'_{p+1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{C}'_p & \mathbf{C}'_{p+1} & \mathbf{C}'_{p+2} & \cdots & \mathbf{C}'_{2p} \end{bmatrix}$$

State Vector Selection Process

The canonical correlation analysis forms a sequence of potential state vectors \mathbf{z}_t^j . Examine a sequence \mathbf{f}_t^j of subvectors of \mathbf{f}_t , form the submatrix \mathbf{V}^j that consists of the rows and columns of \mathbf{V} that correspond to the components of \mathbf{f}_t^j , and compute its canonical correlations.

The smallest canonical correlation of \mathbf{V}^j is then used in the selection of the components of the state vector. The selection process is described in the following discussion. For more details about this process, see Akaike (1976).

In the following discussion, the notation $\mathbf{x}_{t+k|t}$ denotes the wide sense conditional expectation (best linear predictor) of \mathbf{x}_{t+k} , given all \mathbf{x}_s with s less than or equal to t . In the notation $x_{i,t+1}$, the first subscript denotes the i th component of \mathbf{x}_{t+1} .

The initial state vector \mathbf{z}_t^1 is set to \mathbf{x}_t . The sequence \mathbf{f}_t^j is initialized by setting

$$\mathbf{f}_t^1 = (\mathbf{z}_t^{1'}, x_{1,t+1|t})' = (\mathbf{x}_t', x_{1,t+1|t})'$$

That is, start by considering whether to add $x_{1,t+1|t}$ to the initial state vector \mathbf{z}_t^1 .

The procedure forms the submatrix \mathbf{V}^1 that corresponds to \mathbf{f}_t^1 and computes its canonical correlations. Denote the smallest canonical correlation of \mathbf{V}^1 as ρ_{min} . If ρ_{min} is significantly greater than 0, $x_{1,t+1|t}$ is added to the state vector.

If the smallest canonical correlation of \mathbf{V}^1 is not significantly greater than 0, then a linear combination of \mathbf{f}_t^1 is uncorrelated with the past, \mathbf{p}_t . Assuming that the determinant of \mathbf{C}_0 is not 0, (that is, no input series is a constant), you can take the coefficient of $x_{1,t+1|t}$ in this linear combination to be 1. Denote the coefficients of \mathbf{z}_t^1 in this linear combination as ℓ . This gives the relationship:

$$x_{1,t+1|t} = \ell' \mathbf{x}_t$$

Therefore, the current state vector already contains all the past information useful for predicting $x_{1,t+1}$ and any greater leads of $x_{1,t}$. The variable $x_{1,t+1|t}$ is not added to the state vector, nor are any terms $x_{1,t+k|t}$ considered as possible components of the state vector. The variable x_1 is no longer active for state vector selection.

The process described for $x_{1,t+1|t}$ is repeated for the remaining elements of \mathbf{f}_t . The next candidate for inclusion in the state vector is the next component of \mathbf{f}_t that corresponds to an active variable. Components of \mathbf{f}_t that correspond to inactive variables that produced a zero ρ_{min} in a previous step are skipped.

Denote the next candidate as $x_{l,t+k|t}$. The vector \mathbf{f}_t^j is formed from the current state vector and $x_{l,t+k|t}$ as follows:

$$\mathbf{f}_t^j = (\mathbf{z}_t^{j'}, x_{l,t+k|t})'$$

The matrix \mathbf{V}^j is formed from \mathbf{f}_t^j and its canonical correlations are computed. The smallest canonical correlation of \mathbf{V}^j is judged to be either greater than or equal to 0. If it is judged to be greater than 0, $x_{l,t+k|t}$ is added to the state vector. If it is judged to be 0, then a linear combination of \mathbf{f}_t^j is uncorrelated with the \mathbf{p}_t , and the variable x_l is now inactive.

The state vector selection process continues until no active variables remain.

Testing Significance of Canonical Correlations

For each step in the canonical correlation sequence, the significance of the smallest canonical correlation ρ_{min} is judged by an information criterion from Akaike (1976). This information criterion is

$$-n \ln(1 - \rho_{min}^2) - \lambda(r(p + 1) - q + 1)$$

where q is the dimension of \mathbf{f}_t^j at the current step, r is the order of the state vector, p is the order of the vector autoregressive process, and λ is the value of the SIGCORR= option. The default is SIGCORR=2. If this information criterion is less than or equal to 0, ρ_{min} is taken to be 0; otherwise, it is taken to be significantly greater than 0. (Do not confuse this information criterion with the AIC.)

Variables in $\mathbf{x}_{t+p|t}$ are not added in the model, even with positive information criterion, because of the singularity of \mathbf{V} . You can force the consideration of more candidate state variables by increasing the size of the \mathbf{V} matrix by specifying a PASTMIN= option value larger than p .

Printing the Canonical Correlations

To print the details of the canonical correlation analysis process, specify the CANCELL option in the PROC STATESPACE statement. The CANCELL option prints the candidate state vectors, the canonical correlations, and the information criteria for testing the significance of the smallest canonical correlation.

Bartlett's χ^2 and its degrees of freedom are also printed when the CANCELL option is specified. The formula used for Bartlett's χ^2 is

$$\chi^2 = -(n - .5(r(p + 1) - q + 1)) \ln(1 - \rho_{min}^2)$$

with $r(p + 1) - q + 1$ degrees of freedom.

Figure 28.12 shows the output of the CANCELL option for the introductory example shown in the “Getting Started: STATESPACE Procedure” on page 1922.

```
proc statespace data=in out=out lead=10 cancell;
  var x(1) y(1);
  id t;
run;
```

Figure 28.12 Canonical Correlations Analysis

The STATESPACE Procedure Canonical Correlations Analysis					
$\mathbf{x}(T;T)$	$\mathbf{y}(T;T)$	$\mathbf{x}(T+1;T)$	Information Criterion	Chi Square	DF
1	1	0.237045	3.566167	11.4505	4

New variables are added to the state vector if the information criteria are positive. In this example, $\mathbf{y}_{t+1|t}$ and $\mathbf{x}_{t+2|t}$ are not added to the state space vector because the information criteria for these models are negative.

If the information criterion is nearly 0, then you might want to investigate models that arise if the opposite

decision is made regarding ρ_{min} . This investigation can be accomplished by using a FORM statement to specify part or all of the state vector.

Preliminary Estimates of F

When a candidate variable $x_{l,t+k|t}$ yields a zero ρ_{min} and is not added to the state vector, a linear combination of \mathbf{f}_t^j is uncorrelated with the \mathbf{p}_t . Because of the method used to construct the \mathbf{f}_t^j sequence, the coefficient of $x_{l,t+k|t}$ in \mathbf{l} can be taken as 1. Denote the coefficients of \mathbf{z}_t^j in this linear combination as \mathbf{l} .

This gives the relationship:

$$x_{l,t+k|t} = \mathbf{l}' \mathbf{z}_t^j$$

The vector \mathbf{l} is used as a preliminary estimate of the first r columns of the row of the transition matrix \mathbf{F} corresponding to $x_{l,t+k-1|t}$.

Parameter Estimation

The model is $\mathbf{z}_{t+1} = \mathbf{F}\mathbf{z}_t + \mathbf{G}\mathbf{e}_{t+1}$, where \mathbf{e}_t is a sequence of independent multivariate normal innovations with mean vector $\mathbf{0}$ and variance Σ_{ee} . The observed sequence \mathbf{x}_t composes the first r components of \mathbf{z}_t , and thus $\mathbf{x}_t = \mathbf{H}\mathbf{z}_t$, where \mathbf{H} is the $r \times s$ matrix $[\mathbf{I}_r \ \mathbf{0}]$.

Let \mathbf{E} be the $r \times n$ matrix of innovations:

$$\mathbf{E} = [\mathbf{e}_1 \ \cdots \ \mathbf{e}_n]$$

If the number of observations n is reasonably large, the log likelihood L can be approximated up to an additive constant as follows:

$$L = -\frac{n}{2} \ln(|\Sigma_{ee}|) - \frac{1}{2} \text{trace}(\Sigma_{ee}^{-1} \mathbf{E}\mathbf{E}')$$

The elements of Σ_{ee} are taken as free parameters and are estimated as follows:

$$\mathbf{S}_0 = \frac{1}{n} \mathbf{E}\mathbf{E}'$$

Replacing Σ_{ee} by \mathbf{S}_0 in the likelihood equation, the log likelihood, up to an additive constant, is

$$L = -\frac{n}{2} \ln(|\mathbf{S}_0|)$$

Letting B be the backshift operator, the formal relation between \mathbf{x}_t and \mathbf{e}_t is

$$\mathbf{x}_t = \mathbf{H}(\mathbf{I} - B\mathbf{F})^{-1} \mathbf{G}\mathbf{e}_t$$

$$\mathbf{e}_t = (\mathbf{H}(\mathbf{I} - B\mathbf{F})^{-1} \mathbf{G})^{-1} \mathbf{x}_t = \sum_{i=0}^{\infty} \mathbf{\Xi}_i \mathbf{x}_{t-i}$$

Letting C_i be the i th lagged sample covariance of \mathbf{x}_t and neglecting end effects, the matrix \mathbf{S}_0 is

$$\mathbf{S}_0 = \sum_{i,j=0}^{\infty} \mathbf{\Xi}_i \mathbf{C}_{-i+j} \mathbf{\Xi}_j'$$

For the computation of \mathbf{S}_0 , the infinite sum is truncated at the value of the KLAG= option. The value of the KLAG= option should be large enough that the sequence $\mathbf{\Xi}_i$ is approximately 0 beyond that point.

Let $\boldsymbol{\theta}$ be the vector of free parameters in the \mathbf{F} and \mathbf{G} matrices. The derivative of the log likelihood with respect to the parameter $\boldsymbol{\theta}$ is

$$\frac{\partial L}{\partial \boldsymbol{\theta}} = -\frac{n}{2} \text{trace} \left(\mathbf{S}_0^{-1} \frac{\partial \mathbf{S}_0}{\partial \boldsymbol{\theta}} \right)$$

The second derivative is

$$\frac{\partial^2 L}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} = \frac{n}{2} \left(\text{trace} \left(\mathbf{S}_0^{-1} \frac{\partial \mathbf{S}_0}{\partial \boldsymbol{\theta}'} \mathbf{S}_0^{-1} \frac{\partial \mathbf{S}_0}{\partial \boldsymbol{\theta}} \right) - \text{trace} \left(\mathbf{S}_0^{-1} \frac{\partial^2 \mathbf{S}_0}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} \right) \right)$$

Near the maximum, the first term is unimportant and the second term can be approximated to give the following second derivative approximation:

$$\frac{\partial^2 L}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} \cong -n \text{trace} \left(\mathbf{S}_0^{-1} \frac{\partial \mathbf{E}}{\partial \boldsymbol{\theta}} \frac{\partial \mathbf{E}'}{\partial \boldsymbol{\theta}'} \right)$$

The first derivative matrix and this second derivative matrix approximation are computed from the sample covariance matrix \mathbf{C}_0 and the truncated sequence $\mathbf{\Xi}_i$. The approximate likelihood function is maximized by a modified Newton-Raphson algorithm that employs these derivative matrices.

The matrix \mathbf{S}_0 is used as the estimate of the innovation covariance matrix, $\boldsymbol{\Sigma}_{ee}$. The negative of the inverse of the second derivative matrix at the maximum is used as an approximate covariance matrix for the parameter estimates. The standard errors of the parameter estimates printed in the parameter estimates tables are taken from the diagonal of this covariance matrix. The parameter covariance matrix is printed when the COVB option is specified.

If the data are nearly nonstationary, a better estimate of $\boldsymbol{\Sigma}_{ee}$ and the other parameters can sometimes be obtained by specifying the RESIDEST option. The RESIDEST option estimates the parameters by using conditional least squares instead of maximum likelihood.

The residuals are computed using the state space equation and the sample mean values of the variables in the model as start-up values. The estimate of \mathbf{S}_0 is then computed using the residuals from the i th observation on, where i is the maximum number of times any variable occurs in the state vector. A multivariate Gauss-Marquardt algorithm is used to minimize $|\mathbf{S}_0|$. See Harvey (1981a) for a further description of this method.

Forecasting

Given estimates of \mathbf{F} , \mathbf{G} , and Σ_{ee} , forecasts of \mathbf{x}_t are computed from the conditional expectation of \mathbf{z}_t .

In forecasting, the parameters \mathbf{F} , \mathbf{G} , and Σ_{ee} are replaced with the estimates or by values specified in the RESTRICT statement. One-step-ahead forecasting is performed for the observation \mathbf{x}_t , where $t \leq n - b$. Here n is the number of observations and b is the value of the BACK= option. For the observation \mathbf{x}_t , where $t > n - b$, m -step-ahead forecasting is performed for $m = t - n + b$. The forecasts are generated recursively with the initial condition $\mathbf{z}_0 = \mathbf{0}$.

The m -step-ahead forecast of \mathbf{z}_{t+m} is $\mathbf{z}_{t+m|t}$, where $\mathbf{z}_{t+m|t}$ denotes the conditional expectation of \mathbf{z}_{t+m} given the information available at time t . The m -step-ahead forecast of \mathbf{x}_{t+m} is $\mathbf{x}_{t+m|t} = \mathbf{H}\mathbf{z}_{t+m|t}$, where the matrix $\mathbf{H} = [\mathbf{I}_r \mathbf{0}]$.

Let $\Psi_i = \mathbf{F}^i \mathbf{G}$. Note that the last $s - r$ elements of \mathbf{z}_t consist of the elements of $\mathbf{x}_{u|t}$ for $u > t$.

The state vector \mathbf{z}_{t+m} can be represented as

$$\mathbf{z}_{t+m} = \mathbf{F}^m \mathbf{z}_t + \sum_{i=0}^{m-1} \Psi_i \mathbf{e}_{t+m-i}$$

Since $\mathbf{e}_{t+i|t} = \mathbf{0}$ for $i > 0$, the m -step-ahead forecast $\mathbf{z}_{t+m|t}$ is

$$\mathbf{z}_{t+m|t} = \mathbf{F}^m \mathbf{z}_t = \mathbf{F} \mathbf{z}_{t+m-1|t}$$

Therefore, the m -step-ahead forecast of \mathbf{x}_{t+m} is

$$\mathbf{x}_{t+m|t} = \mathbf{H} \mathbf{z}_{t+m|t}$$

The m -step-ahead forecast error is

$$\mathbf{z}_{t+m} - \mathbf{z}_{t+m|t} = \sum_{i=0}^{m-1} \Psi_i \mathbf{e}_{t+m-i}$$

The variance of the m -step-ahead forecast error is

$$\mathbf{V}_{z,m} = \sum_{i=0}^{m-1} \Psi_i \Sigma_{ee} \Psi_i'$$

Letting $\mathbf{V}_{z,0} = \mathbf{0}$, the variance of the m -step-ahead forecast error of \mathbf{z}_{t+m} , $\mathbf{V}_{z,m}$, can be computed recursively as follows:

$$\mathbf{V}_{z,m} = \mathbf{V}_{z,m-1} + \Psi_{m-1} \Sigma_{ee} \Psi_{m-1}'$$

The variance of the m -step-ahead forecast error of \mathbf{x}_{t+m} is the $r \times r$ left upper submatrix of $\mathbf{V}_{z,m}$; that is,

$$\mathbf{V}_{x,m} = \mathbf{H} \mathbf{V}_{z,m} \mathbf{H}'$$

Unless the NOCENTER option is specified, the sample mean vector is added to the forecast. When differencing is specified, the forecasts $\mathbf{x}_{t+m|t}$ plus the sample mean vector are integrated back to produce forecasts for the original series.

Let \mathbf{y}_t be the original series specified by the VAR statement, with some 0 values appended that correspond to the unobserved past observations. Let B be the backshift operator, and let $\Delta(B)$ be the $s \times s$ matrix polynomial in the backshift operator that corresponds to the differencing specified by the VAR statement. The off-diagonal elements of Δ_i are 0. Note that $\Delta_0 = \mathbf{I}_s$, where \mathbf{I}_s is the $s \times s$ identity matrix. Then $\mathbf{z}_t = \Delta(B)\mathbf{y}_t$.

This gives the relationship

$$\mathbf{y}_t = \Delta^{-1}(B)\mathbf{z}_t = \sum_{i=0}^{\infty} \Lambda_i \mathbf{z}_{t-i}$$

where $\Delta^{-1}(B) = \sum_{i=0}^{\infty} \Lambda_i B^i$ and $\Lambda_0 = \mathbf{I}_s$.

The m -step-ahead forecast of \mathbf{y}_{t+m} is

$$\mathbf{y}_{t+m|t} = \sum_{i=0}^{m-1} \Lambda_i \mathbf{z}_{t+m-i|t} + \sum_{i=m}^{\infty} \Lambda_i \mathbf{z}_{t+m-i}$$

The m -step-ahead forecast error of \mathbf{y}_{t+m} is

$$\sum_{i=0}^{m-1} \Lambda_i (\mathbf{z}_{t+m-i} - \mathbf{z}_{t+m-i|t}) = \sum_{i=0}^{m-1} \left(\sum_{u=0}^i \Lambda_u \Psi_{i-u} \right) \mathbf{e}_{t+m-i}$$

Letting $\mathbf{V}_{y,0} = \mathbf{0}$, the variance of the m -step-ahead forecast error of \mathbf{y}_{t+m} , $\mathbf{V}_{y,m}$, is

$$\begin{aligned} \mathbf{V}_{y,m} &= \sum_{i=0}^{m-1} \left(\sum_{u=0}^i \Lambda_u \Psi_{i-u} \right) \Sigma_{ee} \left(\sum_{u=0}^i \Lambda_u \Psi_{i-u} \right)' \\ &= \mathbf{V}_{y,m-1} + \left(\sum_{u=0}^{m-1} \Lambda_u \Psi_{m-1-u} \right) \Sigma_{ee} \left(\sum_{u=0}^{m-1} \Lambda_u \Psi_{m-1-u} \right)' \end{aligned}$$

Relation of ARMA and State Space Forms

Every state space model has an ARMA representation, and conversely every ARMA model has a state space representation. This section discusses this equivalence. The following material is adapted from Akaike (1974), where there is a more complete discussion. Pham-Dinh-Tuan (1978) also contains a discussion of this material.

Suppose you are given the following ARMA model:

$$\Phi(B)\mathbf{x}_t = \Theta(B)\mathbf{e}_t$$

or, in more detail,

$$\mathbf{x}_t - \Phi_1 \mathbf{x}_{t-1} - \cdots - \Phi_p \mathbf{x}_{t-p} = \mathbf{e}_t + \Theta_1 \mathbf{e}_{t-1} + \cdots + \Theta_q \mathbf{e}_{t-q} \quad (1)$$

where \mathbf{e}_t is a sequence of independent multivariate normal random vectors with mean $\mathbf{0}$ and variance matrix Σ_{ee} , B is the backshift operator ($B\mathbf{x}_t = \mathbf{x}_{t-1}$), $\Phi(B)$ and $\Theta(B)$ are matrix polynomials in B , and \mathbf{x}_t is the observed process.

If the roots of the determinantal equation $|\Phi(B)| = 0$ are outside the unit circle in the complex plane, the model can also be written as

$$\mathbf{x}_t = \Phi^{-1}(B)\Theta(B)\mathbf{e}_t = \sum_{i=0}^{\infty} \Psi_i \mathbf{e}_{t-i}$$

The Ψ_i matrices are known as the impulse response matrices and can be computed as $\Phi^{-1}(B)\Theta(B)$.

You can assume $p > q$ since, if this is not initially true, you can add more terms Φ_i that are identically 0 without changing the model.

To write this set of equations in a state space form, proceed as follows. Let $\mathbf{x}_{t+i|t}$ be the conditional expectation of \mathbf{x}_{t+i} given \mathbf{x}_w for $w \leq t$. The following relations hold:

$$\mathbf{x}_{t+i|t} = \sum_{j=i}^{\infty} \Psi_j \mathbf{e}_{t+i-j}$$

$$\mathbf{x}_{t+i|t+1} = \mathbf{x}_{t+i|t} + \Psi_{i-1} \mathbf{e}_{t+1}$$

However, from equation (1) you can derive the following relationship:

$$\mathbf{x}_{t+p|t} = \Phi_1 \mathbf{x}_{t+p-1|t} + \cdots + \Phi_p \mathbf{x}_t \quad (2)$$

Hence, when $i = p$, you can substitute for $\mathbf{x}_{t+p|t}$ in the right-hand side of equation (2) and close the system of equations.

This substitution results in the following model in the state space form $\mathbf{z}_{t+1} = \mathbf{F}\mathbf{z}_t + \mathbf{G}\mathbf{e}_{t+1}$:

$$\begin{bmatrix} \mathbf{x}_{t+1} \\ \mathbf{x}_{t+2|t+1} \\ \vdots \\ \mathbf{x}_{t+p|t+1} \end{bmatrix} = \begin{bmatrix} 0 & \mathbf{I} & 0 & \cdots & 0 \\ 0 & 0 & \mathbf{I} & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \Phi_p & \Phi_{p-1} & \cdots & \Phi_1 & 0 \end{bmatrix} \begin{bmatrix} \mathbf{x}_t \\ \mathbf{x}_{t+1|t} \\ \vdots \\ \mathbf{x}_{t+p-1|t} \end{bmatrix} + \begin{bmatrix} \mathbf{I} \\ \Psi_1 \\ \vdots \\ \Psi_{p-1} \end{bmatrix} \mathbf{e}_{t+1}$$

Note that the state vector \mathbf{z}_t is composed of conditional expectations of \mathbf{x}_t and the first r components of \mathbf{z}_t are equal to \mathbf{x}_t .

The state space form can be cast into an ARMA form by solving the system of difference equations for the first r components.

When converting from an ARMA form to a state space form, you can generate a state vector larger than needed; that is, the state space model might not be a minimal representation. When going from a state space form to an ARMA form, you can have nontrivial common factors in the autoregressive and moving average operators that yield an ARMA model larger than necessary.

If the state space form used is not a minimal representation, some but not all components of $\mathbf{x}_{t+i|t}$ might be linearly dependent. This situation corresponds to $[\Phi_p \Theta_{p-1}]$ being of less than full rank when $\Phi(B)$ and

$\Theta(B)$ have no common nontrivial left factors. In this case, \mathbf{z}_t consists of a subset of the possible components of $[\mathbf{x}_{t+i|t}]$ $i = 1, 2, \dots, p - 1$. However, once a component of $\mathbf{x}_{t+i|t}$ (for example, the j th one) is linearly dependent on the previous conditional expectations, then all subsequent j th components of $\mathbf{x}_{t+k|t}$ for $k > i$ must also be linearly dependent. Note that in this case, equivalent but seemingly different structures can arise if the order of the components within \mathbf{x}_t is changed.

OUT= Data Set

The forecasts are contained in the output data set specified by the OUT= option in the PROC STATESPACE statement. The OUT= data set contains the following variables:

- the BY variables
- the ID variable
- the VAR statement variables. These variables contain the actual values from the input data set.
- FOR_i , numeric variables that contain the forecasts. The variable FOR_i contains the forecasts for the i th variable in the VAR statement list. Forecasts are one-step-ahead predictions until the end of the data or until the observation specified by the BACK= option.
- RES_i , numeric variables that contain the residual for the forecast of the i th variable in the VAR statement list. For forecast observations, the actual values are missing and the RES_i variables contain missing values.
- STD_i , numeric variables that contain the standard deviation for the forecast of the i th variable in the VAR statement list. The values of the STD_i variables can be used to construct univariate confidence limits for the corresponding forecasts. However, such confidence limits do not take into account the covariance of the forecasts.

OUTAR= Data Set

The OUTAR= data set contains the estimates of the preliminary autoregressive models. The OUTAR= data set contains the following variables:

- ORDER, a numeric variable that contains the order p of the autoregressive model that the observation represents
- AIC, a numeric variable that contains the value of the information criterion AIC_p
- $SIGF_l$, numeric variables that contain the estimate of the innovation covariance matrices for the forward autoregressive models. The variable $SIGF_l$ contains the l th column of $\hat{\Sigma}_p$ in the observations with ORDER= p .
- $SIGB_l$, numeric variables that contain the estimate of the innovation covariance matrices for the backward autoregressive models. The variable $SIGB_l$ contains the l th column of $\hat{\Omega}_p$ in the observations with ORDER= p .

- **FOR*k*_l**, numeric variables that contain the estimates of the autoregressive parameter matrices for the forward models. The variable **FOR*k*_l** contains the *l*th column of the lag *k* autoregressive parameter matrix $\hat{\Phi}_k^p$ in the observations with **ORDER**=*p*.
- **BACK*k*_l**, numeric variables that contain the estimates of the autoregressive parameter matrices for the backward models. The variable **BACK*k*_l** contains the *l*th column of the lag *k* autoregressive parameter matrix $\hat{\Psi}_k^p$ in the observations with **ORDER**=*p*.

The estimates for the order *p* autoregressive model can be selected as those observations with **ORDER**=*p*. Within these observations, the *k*,*l*th element of Φ_i^p is given by the value of the **FOR*i*_l** variable in the *k*th observation. The *k*,*l*th element of Ψ_i^p is given by the value of **BAC*i*_l** variable in the *k*th observation. The *k*,*l*th element of Σ_p is given by **SIGF*l*** in the *k*th observation. The *k*,*l*th element of Ω_p is given by **SIGB*l*** in the *k*th observation.

Table 28.2 shows an example of the OUTAR= data set, with **ARMAX**=3 and \mathbf{x}_t of dimension 2. In Table 28.2, (*i*, *j*) indicate the *i*,*j*th element of the matrix.

7	$\Phi_{3,3}^3(1,2)$	$\Psi_3^3(1,1)$	$\Psi_3^3(1,2)$	$\Psi_3^3(1,1)$	$\Psi_3^3(1,2)$	$\Psi_{3,3}^3(1,1)$	$\Psi_{3,3}^3(1,2)$
8	$\Phi_{3,3}^3(2,2)$	$\Psi_3^3(2,1)$	$\Psi_3^3(2,2)$	$\Psi_3^3(2,1)$	$\Psi_3^3(2,2)$	$\Psi_{3,3}^3(2,1)$	$\Psi_{3,3}^3(2,2)$

The estimated autoregressive parameters can be used in the IML procedure to obtain autoregressive estimates of the spectral density function or forecasts based on the autoregressive models.

OUTMODEL= Data Set

The OUTMODEL= data set contains the estimates of the **F** and **G** matrices and their standard errors, the names of the components of the state vector, and the estimates of the innovation covariance matrix. The variables contained in the OUTMODEL= data set are as follows:

- the **BY** variables
- **STATEVEC**, a character variable that contains the name of the component of the state vector corresponding to the observation. The **STATEVEC** variable has the value **STD** for standard deviations observations, which contain the standard errors for the estimates given in the preceding observation.

- F_j , numeric variables that contain the columns of the \mathbf{F} matrix. The variable F_j contains the j th column of \mathbf{F} . The number of F_j variables is equal to the value of the DIMMAX= option. If the model is of smaller dimension, the extraneous variables are set to missing.
- G_j , numeric variables that contain the columns of the \mathbf{G} matrix. The variable G_j contains the j th column of \mathbf{G} . The number of G_j variables is equal to r , the dimension of \mathbf{x}_t given by the number of variables in the VAR statement.
- SIG_j , numeric variables that contain the columns of the innovation covariance matrix. The variable SIG_j contains the j th column of Σ_{ee} . There are r variables SIG_j .

Table 28.3 shows an example of the OUTMODEL= data set, with $\mathbf{x}_t = (x_t, y_t)'$, $\mathbf{z}_t = (x_t, y_t, x_{t+1}|t)'$, and DIMMAX=4. In Table 28.3, $F_{i,j}$ and $G_{i,j}$ are the i,j th elements of \mathbf{F} and \mathbf{G} respectively. Note that all elements for F_4 are missing because \mathbf{F} is a 3×3 matrix.

Printed Output

The printed output produced by the STATESPACE procedure includes the following:

1. descriptive statistics, which include the number of observations used, the names of the variables, their means and standard deviations (Std), and the differencing operations used
2. the Akaike information criteria for the sequence of preliminary autoregressive models
3. if the PRINTOUT=LONG option is specified, the sample autocovariance matrices of the input series at various lags
4. if the PRINTOUT=LONG option is specified, the sample autocorrelation matrices of the input series
5. a schematic representation of the autocorrelation matrices, showing the significant autocorrelations
6. if the PRINTOUT=LONG option is specified, the partial autoregressive matrices. (These are Φ_p^p as described in the section “Preliminary Autoregressive Models” on page 1941.)
7. a schematic representation of the partial autocorrelation matrices, showing the significant partial autocorrelations
8. the Yule-Walker estimates of the autoregressive parameters for the autoregressive model with the minimum AIC

9. if the PRINTOUT=LONG option is specified, the autocovariance matrices of the residuals of the minimum AIC model. This is the sequence of estimated innovation variance matrices for the solutions of the Yule-Walker equations.
10. if the PRINTOUT=LONG option is specified, the autocorrelation matrices of the residuals of the minimum AIC model
11. If the CANCORR option is specified, the canonical correlations analysis for each potential state vector considered in the state vector selection process. This includes the potential state vector, the canonical correlations, the information criterion for the smallest canonical correlation, Bartlett's χ^2 statistic ("Chi Square") for the smallest canonical correlation, and the degrees of freedom of Bartlett's χ^2 .
12. the components of the chosen state vector
13. the preliminary estimate of the transition matrix, **F**, the input matrix, **G**, and the variance matrix for the innovations, Σ_{ee}
14. if the ITPRINT option is specified, the iteration history of the likelihood maximization. For each iteration, this shows the iteration number, the number of step halvings, the determinant of the innovation variance matrix, the damping factor Lambda, and the values of the parameters.
15. the state vector, printed again to aid interpretation of the following listing of **F** and **G**
16. the final estimate of the transition matrix **F**
17. the final estimate of the input matrix **G**
18. the final estimate of the variance matrix for the innovations Σ_{ee}
19. a table that lists the estimates of the free parameters in **F** and **G** and their standard errors and *t* statistics
20. if the COVB option is specified, the covariance matrix of the parameter estimates
21. if the COVB option is specified, the correlation matrix of the parameter estimates
22. if the PRINT option is specified, the forecasts and their standard errors

ODS Table Names

PROC STATESPACE assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

Table 28.4 ODS Tables Produced in PROC STATESPACE

ODS Table Name	Description	Option
NObs	number of observations	default
Summary	simple summary statistics table	default
InfoCriterion	information criterion table	default

Table 28.4 *continued*

ODS Table Name	Description	Option
CovLags	covariance matrices of input series	PRINTOUT=LONG
CorrLags	correlation matrices of input series	PRINTOUT=LONG
PartialAR	partial autoregressive matrices	PRINTOUT=LONG
YWEstimates	Yule-Walker estimates for minimum AIC	default
CovResiduals	covariance of residuals	PRINTOUT=LONG
CorrResiduals	residual correlations from AR models	PRINTOUT=LONG
StateVector	state vector table	default
CorrGraph	schematic representation of correlations	default
TransitionMatrix	transition matrix	default
InputMatrix	input matrix	default
VarInnov	variance matrix for the innovation	default
CovB	covariance of parameter estimates	COVB
CorrB	correlation of parameter estimates	COVB
CanCorr	canonical correlation analysis	CANCORR
IterHistory	iterative fitting table	ITPRINT
ParameterEstimates	parameter estimates table	default
Forecasts	forecasts table	PRINT
ConvergenceStatus	convergence status table	default

Examples: STATESPACE Procedure

Example 28.1: Series J from Box and Jenkins

This example analyzes the gas furnace data (series J) from Box and Jenkins. (The data are not shown; see Box and Jenkins (1976) for the data.)

First, a model is selected and fit automatically using the following statements.

```

title1 'Gas Furnace Data';
title2 'Box & Jenkins Series J';
title3 'Automatically Selected Model';

proc statespace data=seriesj cancorr;
  var x y;
run;
```

The results for the automatically selected model are shown in [Output 28.1.1](#).

The two series are believed to have a transfer function relation with the gas rate (variable X) as the input and the CO₂ concentration (variable Y) as the output. Since the parameter estimates shown in [Output 28.1.1](#) support this kind of model, the model is reestimated with the feedback parameters restricted to 0. The following statements fit the transfer function (no feedback) model.

```

title3 'Transfer Function Model';
proc statespace data=seriesj printout=none;
  var x y;
  restrict f(3,2)=0 f(3,4)=0
           g(3,2)=0 g(4,1)=0 g(5,1)=0;
run;

```

The last two pages of the output are shown in [Output 28.1.8](#).

Overview: SYSLIN Procedure

The SYSLIN procedure estimates parameters in an interdependent system of linear regression equations.

Ordinary least squares (OLS) estimates are biased and inconsistent when current period endogenous variables appear as regressors in other equations in the system. The errors of a set of related regression equations are often correlated, and the efficiency of the estimates can be improved by taking these correlations into account. The SYSLIN procedure provides several techniques that produce consistent and asymptotically efficient estimates for systems of regression equations.

The SYSLIN procedure provides the following estimation methods:

- ordinary least squares (OLS)
- two-stage least squares (2SLS)
- limited information maximum likelihood (LIML)
- K-class
- seemingly unrelated regressions (SUR)
- iterated seemingly unrelated regressions (ITSUR)
- three-stage least squares (3SLS)
- iterated three-stage least squares (IT3SLS)
- full information maximum likelihood (FIML)
- minimum expected loss (MELO)

Other features of the SYSLIN procedure enable you to:

- impose linear restrictions on the parameter estimates

- test linear hypotheses about the parameters
- write predicted and residual values to an output SAS data set
- write parameter estimates to an output SAS data set
- write the crossproducts matrix (SSCP) to an output SAS data set
- use raw data, correlations, covariances, or cross products as input

Getting Started: SYSLIN Procedure

This section introduces the use of the SYSLIN procedure. The problem of dependent regressors is introduced using a supply and demand example. This section explains the terminology used for variables in a system of regression equations and introduces the SYSLIN procedure statements for declaring the roles the variables play. The syntax used for the different estimation methods and the output produced is shown.

An Example Model

In simultaneous systems of equations, endogenous variables are determined jointly rather than sequentially. Consider the following supply and demand functions for some product:

$$Q_D = a_1 + b_1 P + c_1 Y + d_1 S + \epsilon_1 \text{ (demand)}$$

$$Q_S = a_2 + b_2 P + c_2 U + \epsilon_2 \text{ (supply)}$$

$$Q = Q_D = Q_S \text{ (market equilibrium)}$$

The variables in this system are as follows:

Q_D	quantity demanded
Q_S	quantity supplied
Q	the observed quantity sold, which equates quantity supplied and quantity demanded in equilibrium
P	price per unit
Y	income
S	price of substitutes
U	unit cost
ϵ_1	the random error term for the demand equation
ϵ_2	the random error term for the supply equation

In this system, quantity demanded depends on price, income, and the price of substitutes. Consumers normally purchase more of a product when prices are lower and when income and the price of substitute goods are higher. Quantity supplied depends on price and the unit cost of production. Producers supply more when price is high and when unit cost is low. The actual price and quantity sold are determined jointly by the values that equate demand and supply.

Since price and quantity are jointly endogenous variables, both structural equations are necessary to adequately describe the observed values. A critical assumption of OLS is that the regressors are uncorrelated with the residual. When current endogenous variables appear as regressors in other equations (endogenous variables depend on each other), this assumption is violated and the OLS parameter estimates are biased and inconsistent. The bias caused by the violated assumptions is called *simultaneous equation bias*. Neither the demand nor supply equation can be estimated consistently by OLS.

Variables in a System of Equations

Before explaining how to use the SYSLIN procedure, it is useful to define some terms. The variables in a system of equations can be classified as follows:

- *Endogenous variables*, which are also called *jointly dependent* or *response variables*, are the variables determined by the system. Endogenous variables can also appear on the right-hand side of equations.
- *Exogenous variables* are independent variables that do not depend on any of the endogenous variables in the system.
- *Predetermined variables* include both the exogenous variables and *lagged endogenous variables*, which are past values of endogenous variables determined at previous time periods. PROC SYSLIN does not compute lagged values; any lagged endogenous variables must be computed in a preceding DATA step.
- *Instrumental variables* are predetermined variables used in obtaining predicted values for the current period endogenous variables by a first-stage regression. The use of instrumental variables characterizes estimation methods such as two-stage least squares and three-stage least squares. Instrumental variables estimation methods substitute these first-stage predicted values for endogenous variables when they appear as regressors in model equations.

Using PROC SYSLIN

First specify the input data set and estimation method in the PROC SYSLIN statement. If any model uses dependent regressors, and you are using an instrumental variables regression method, declare the dependent regressors with an ENDOGENOUS statement and declare the instruments with an INSTRUMENTS statement. Next, use MODEL statements to specify the structural equations of the system.

The use of different estimation methods is shown by the following examples. These examples use the simulated dataset WORK.IN given below.

```

data in;
  label q = "Quantity"
        p = "Price"
        s = "Price of Substitutes"
        y = "Income"
        u = "Unit Cost";
  drop i e1 e2;
  p = 0; q = 0;
  do i = 1 to 60;
    y = 1 + .05*i + .15*rannor(123);
    u = 2          + .05*rannor(123) + .05*rannor(123);
    s = 4 - .001*(i-10)*(i-110) + .5*rannor(123);
    e1 = .15 * rannor(123);
    e2 = .15 * rannor(123);
    demandx = 1 + .3 * y + .35 * s + e1;
    supplyx = -1 - 1 * u + e2 - .4*e1;
    q = 1.4/2.15 * demandx + .75/2.15 * supplyx;
    p = ( - q + supplyx ) / -1.4;
    output;
  end;
run;

```

OLS Estimation

PROC SYSLIN performs OLS regression if you do not specify a method of estimation in the PROC SYSLIN statement. OLS does not use instruments, so the ENDOGENOUS and INSTRUMENTS statements can be omitted.

The following statements estimate the supply and demand model shown previously:

```

proc syslin data=in;
  demand: model q = p y s;
  supply: model q = p u;
run;

```

The PROC SYSLIN output for the demand equation is shown in [Figure 29.1](#), and the output for the supply equation is shown in [Figure 29.2](#).

u	1	-1.07757	0.234150	-4.60	<.0001	Unit Cost

For each MODEL statement, the output first shows the model label and dependent variable name and label. This is followed by an analysis-of-variance table for the model, which shows the model, error, and total mean squares, and an F test for the no-regression hypothesis. Next, the procedure prints the root mean squared error, dependent variable mean and coefficient of variation, and the R^2 and adjusted R^2 statistics.

Finally, the table of parameter estimates shows the estimated regression coefficients, standard errors, and t tests. You would expect the price coefficient in a demand equation to be negative. However, note that the OLS estimate of the price coefficient P in the demand equation (0.1233) has a positive sign. This could be caused by simultaneous equation bias.

Two-Stage Least Squares Estimation

In the supply and demand model, P is an endogenous variable, and consequently the OLS estimates are biased. The following example estimates this model using two-stage least squares.

```
proc syslin data=in 2sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

The 2SLS option in the PROC SYSLIN statement specifies the two-stage least squares method. The ENDOGENOUS statement specifies that P is an endogenous regressor for which first-stage predicted values are substituted. You need to declare an endogenous variable in the ENDOGENOUS statement only if it is used as a regressor; thus although Q is endogenous in this model, it is not necessary to list it in the ENDOGENOUS statement.

Usually, all predetermined variables that appear in the system are used as instruments. The INSTRUMENTS statement specifies that the exogenous variables Y, U, and S are used as instruments for the first-stage regression to predict P.

The 2SLS results are shown in Figure 29.3 and Figure 29.4. The first-stage regressions are not shown. To see the first-stage regression results, use the FIRST option in the PROC SYSLIN statement.

Corrected Total	59	10.03724			

Figure 29.4 *continued*

Root MSE	0.13781	R-Square	0.89910			
Dependent Mean	1.30095	Adj R-Sq	0.89556			
Coeff Var	10.59291					
Parameter Estimates						
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t	Variable Label
Intercept	1	-0.51878	0.490999	-1.06	0.2952	Intercept
p	1	1.333080	0.059271	22.49	<.0001	Price
u	1	-1.14623	0.243491	-4.71	<.0001	Unit Cost

The 2SLS output is similar in form to the OLS output. However, the 2SLS results are based on predicted values for the endogenous regressors from the first stage instrumental regressions. This makes the analysis-of-variance table and the R^2 statistics difficult to interpret. See the sections “[ANOVA Table for Instrumental Variables Methods](#)” on page 1999 and “[The R-Square Statistics](#)” on page 1999 for details.

Note that, unlike the OLS results, the 2SLS estimate for the P coefficient in the demand equation (−1.115) is negative.

LIML, K-Class, and MELO Estimation

To obtain limited information maximum likelihood, general K-class, or minimum expected loss estimates, use the ENDOGENOUS, INSTRUMENTS, and MODEL statements as in the 2SLS case but specify the LIML, K=, or MELO option instead of 2SLS in the PROC SYSLIN statement. The following statements show this for K-class estimation.

```
proc syslin data=in k=.5;
    endogenous p;
    instruments y u s;
    demand: model q = p y s;
    supply: model q = p u;
run;
```

For more information about these estimation methods, see the section “[Estimation Methods](#)” on page 1996 and consult econometrics textbooks.

SUR, 3SLS, and FIML Estimation

In a multivariate regression model, the errors in different equations might be correlated. In this case, the efficiency of the estimation might be improved by taking these cross-equation correlations into account.

Seemingly Unrelated Regression

Seemingly unrelated regression (SUR), also called joint generalized least squares (JGLS) or Zellner estimation, is a generalization of OLS for multi-equation systems. Like OLS, the SUR method assumes that all the regressors are independent variables, but SUR uses the correlations among the errors in different equations to improve the regression estimates. The SUR method requires an initial OLS regression to compute residuals. The OLS residuals are used to estimate the cross-equation covariance matrix.

The SUR option in the PROC SYSLIN statement specifies seemingly unrelated regression, as shown in the following statements:

```
proc syslin data=in sur;
    demand: model q = p y s;
    supply: model q = p u;
run;
```

INSTRUMENTS and ENDOGENOUS statements are not needed for SUR, because the SUR method assumes there are no endogenous regressors. For SUR to be effective, the models must use different regressors. SUR produces the same results as OLS unless the model contains at least one regressor not used in the other equations.

Three-Stage Least Squares

The three-stage least squares method generalizes the two-stage least squares method to take into account the correlations between equations in the same way that SUR generalizes OLS. Three-stage least squares requires three steps: first-stage regressions to get predicted values for the endogenous regressors; a two-stage least squares step to get residuals to estimate the cross-equation correlation matrix; and the final 3SLS estimation step.

The 3SLS option in the PROC SYSLIN statement specifies the three-stage least squares method, as shown in the following statements.

```
proc syslin data=in 3sls;
    endogenous p;
    instruments y u s;
    demand: model q = p y s;
    supply: model q = p u;
run;
```

The 3SLS output begins with a two-stage least squares regression to estimate the cross-model correlation matrix. This output is the same as the 2SLS results shown in [Figure 29.3](#) and [Figure 29.4](#), and is not repeated here. The next part of the 3SLS output prints the cross-model correlation matrix computed from the 2SLS residuals. This output is shown in [Figure 29.5](#) and includes the cross-model covariances, correlations, the inverse of the correlation matrix, and the inverse covariance matrix.

Figure 29.5 Estimated Cross-Model Covariances Used for 3SLS Estimates

The SYSLIN Procedure

Parameter Estimates						
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t	Variable Label
Intercept	1	1.980269	1.169176	1.69	0.0959	Intercept
p	1	-1.17654	0.605015	-1.94	0.0568	Price
y	1	0.404117	0.117179	3.45	0.0011	Income
s	1	0.359204	0.085077	4.22	<.0001	Price of Substitutes

Model			SUPPLY	
Dependent Variable			q	
Label			Quantity	

Parameter Estimates						
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t	Variable Label
Intercept	1	-0.51878	0.490999	-1.06	0.2952	Intercept
p	1	1.333080	0.059271	22.49	<.0001	Price
u	1	-1.14623	0.243491	-4.71	<.0001	Unit Cost

This output first prints the system weighted mean squared error and system weighted R^2 statistics. The system weighted MSE and system weighted R^2 measure the fit of the joint model obtained by stacking all the models together and performing a single regression with the stacked observations weighted by the inverse of the model error variances. See the section “[The R-Square Statistics](#)” on page 1999 for details.

Next, the table of 3SLS parameter estimates for each model is printed. This output has the same form as for the other estimation methods.

Note that, in some cases, the 3SLS and 2SLS results can be the same. Such a case could arise because of the same principle that causes OLS and SUR results to be identical, unless an equation includes a regressor not used in the other equations of the system. However, the application of this principle is more complex when instrumental variables are used. When all the exogenous variables are used as instruments, linear combinations of all the exogenous variables appear in the third-stage regressions through substitution of first-stage predicted values.

In this example, 3SLS produces different (and, it is hoped, more efficient) estimates for the demand equation. However, the 3SLS and 2SLS results for the supply equation are the same. This is because the supply equation has one endogenous regressor and one exogenous regressor not used in other equations. In contrast, the demand equation has fewer endogenous regressors than exogenous regressors not used in other equations in the system.

Full Information Maximum Likelihood

The FIML option in the PROC SYSLIN statement specifies the full information maximum likelihood method, as shown in the following statements.

```

proc syslin data=in fiml;
  endogenous p q;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;

```

The FIML results are shown in Figure 29.7.

Computing Reduced Form Estimates

A system of structural equations with endogenous regressors can be represented as functions of only the predetermined variables. For this to be possible, there must be as many equations as endogenous variables. If

there are more endogenous variables than regression models, you can use IDENTITY statements to complete the system. See the section “[Reduced Form Estimates](#)” on page 2001 for details.

The REDUCED option in the PROC SYSLIN statement prints reduced form estimates. The following statements show this by using the 3SLS estimates of the structural parameters.

```
proc syslin data=in 3sls reduced;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
run;
```

The first four pages of this output were as shown previously and are not repeated here. (See [Figure 29.3](#), [Figure 29.4](#), [Figure 29.5](#), and [Figure 29.6](#).) The final page of the output from this example contains the reduced form coefficients from the 3SLS structural estimates, as shown in [Figure 29.8](#).

Restricting Parameter Estimates

You can impose restrictions on the parameter estimates with RESTRICT and SRESTRICT statements. The RESTRICT statement imposes linear restrictions on parameters in the equation specified by the preceding MODEL statement. The SRESTRICT statement imposes linear restrictions that relate parameters in different models.

To impose restrictions involving parameters in different equations, use the SRESTRICT statement. Specify the parameters in the linear hypothesis as *model-label.regressor-name*. (If the MODEL statement does not have a label, you can use the dependent variable name as the label for the model, provided the dependent variable uniquely labels the model.)

Tests for the significance of the restrictions are printed when RESTRICT or SRESTRICT statements are used. You can label RESTRICT and SRESTRICT statements to identify the restrictions in the output.

The RESTRICT statement in the following example restricts the price coefficient in the demand equation to equal 0.015. The SRESTRICT statement restricts the estimate of the income coefficient in the demand equation to be 0.01 times the estimate of the unit cost coefficient in the supply equation.

```
proc syslin data=in 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  peq015: restrict p = .015;
  supply: model q = p u;
  yeq01u: srestrict demand.y = .01 * supply.u;
run;
```

The restricted estimation results are shown in [Figure 29.9](#).

Parameter Estimates						
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t	Variable Label
Intercept	1	-1.31894	0.477633	-2.76	0.0077	Intercept
p	1	1.291718	0.059101	21.86	<.0001	Price
u	1	-0.67887	0.235679	-2.88	0.0056	Unit Cost

Parameter Estimates						
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t	Variable Label
RESTRICT	-1	342.3605	38.12094	8.98	<.0001	YEQ01U

The standard error for P in the demand equation is 0, since the value of the P coefficient was specified by the RESTRICT statement and not estimated from the data. The “Parameter Estimates” table for the demand equation contains an additional row for the restriction specified by the RESTRICT statement. The parameter estimate for the restriction is the value of the Lagrange multiplier used to impose the restriction. The restriction is highly significant ($t = 6.777$), which means that the data are not consistent with the restriction, and the model does not fit as well with the restriction imposed. See the section “[RESTRICT Statement](#)” on page 1990 for details.

Following the “Parameter Estimates” table for the supply equation, the results for the cross model restrictions are printed. This shows that the restriction specified by the SRESTRICT statement is not consistent with the data ($t = 8.98$). See the section “[SRESTRICT Statement](#)” on page 1991 for details.

Testing Parameters

You can test linear hypotheses about the model parameters with TEST and STEST statements. The TEST statement tests hypotheses about parameters in the equation specified by the preceding MODEL statement. The STEST statement tests hypotheses that relate parameters in different models.

For example, the following statements test the hypothesis that the price coefficient in the demand equation is equal to 0.015.

```
proc syslin data=in 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  test_1: test p = .015;
  supply: model q = p u;
run;
```

The TEST statement results are shown in [Figure 29.10](#). This reports an F test for the hypothesis specified by the TEST statement. In this case, the F statistic is 6.79 (3.879/.571) with 1 and 113 degrees of freedom.

The p value for this F statistic is 0.0104, which indicates that the hypothesis tested is almost but not quite rejected at the 0.01 level. See the section “[TEST Statement](#)” on page 1994 for details.

Figure 29.10 TEST Statement Results

The SYSLIN Procedure						
Three-Stage Least Squares Estimation						
System Weighted MSE		0.5711

Intercept	1	1.980269	1.169176	1.69	0.0959	Intercept
p	1	-1.17654	0.605015	-1.94	0.0568	Price
y	1	0.404117	0.117179	3.45	0.0011	Income
s	1	0.359204	0.085077	4.22	<.0001	Price of Substitutes
Test Results						
Num DF	Den DF	F Value	Pr > F	Label		
1	113	6.79	0.0104	TEST_1		

To test hypotheses that involve parameters in different equations, use the `STEST` statement. Specify the parameters in the linear hypothesis as *model-label.regressor-name*. (If the `MODEL` statement does not have a label, you can use the dependent variable name as the label for the model, provided the dependent variable uniquely labels the model.)

For example, the following statements test the hypothesis that the income coefficient in the demand equation is 0.01 times the unit cost coefficient in the supply equation:

```
proc syslin data=in 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  supply: model q = p u;
  stest1: stest demand.y = .01 * supply.u;
run;
```

The `STEST` statement results are shown in [Figure 29.11](#). The form and interpretation of the `STEST` statement results are like the `TEST` statement results. In this case, the F test produces a p value less than 0.0001, and strongly rejects the hypothesis tested. See the section “[STEST Statement](#)” on page 1993 for details.

Figure 29.11 STEST Statement Results

The SYSLIN Procedure						
Three-Stage Least Squares Estimation

1	113	22.46	0.0001	STEST1		

You can combine TEST and STEST statements with RESTRICT and SRESTRICT statements to perform hypothesis tests for restricted models. Of course, the validity of the TEST and STEST statement results depends on the correctness of any restrictions you impose on the estimates.

Saving Residuals and Predicted Values

You can store predicted values and residuals from the estimated models in a SAS data set. Specify the OUT= option in the PROC SYSLIN statement and use the OUTPUT statement to specify names for new variables to contain the predicted and residual values.

For example, the following statements store the predicted quantity from the supply and demand equations in a data set PRED:

```
proc syslin data=in out=pred 3sls;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  output predicted=q_demand;
  supply: model q = p u;
  output predicted=q_supply;
run;
```

Plotting Residuals

You can plot the residuals against the regressors by using the PROC SGPLOT. For example, the following statements plot the 2SLS residuals for the demand model against price, income, and price of substitutes.

```
proc syslin data=in 2sls out=out;
  endogenous p;
  instruments y u s;
  demand: model q = p y s;
  output residual=residual_q;
run;

proc sgplot data=out;
  scatter x=p y=residual_q;
  refline 0 / axis=y;
run;

proc sgplot data=out;
  scatter x=y y=residual_q;
  refline 0 / axis=y;
run;

proc sgplot data=out;
  scatter x=s y=residual_q;
  refline 0 / axis=y;
run;
```

The plot for income is shown in [Figure 29.12](#). The other plots are not shown.

Figure 29.12 Plot of Residuals against Income

Syntax: SYSLIN Procedure

The SYSLIN procedure uses the following statements:

```
PROC SYSLIN options ;
  BY variables ;
  ENDOGENOUS variables ;
  IDENTITY identities ;
  INSTRUMENTS variables ;
  MODEL response = regressors / options ;
  OUTPUT PREDICTED= variable RESIDUAL= variable ;
  RESTRICT restrictions ;
  SRESTRICT restrictions ;
  STEST equations ;
  TEST equations ;
  VAR variables ;
  WEIGHT variable ;
```

Functional Summary

The SYSLIN procedure statements and options are summarized in the following table.

Description	Statement	Option
Data Set Options		
specify the input data set	PROC SYSLIN	DATA=
specify the output data set	PROC SYSLIN	OUT=
write parameter estimates to an output data set	PROC SYSLIN	OUTEST=
write covariances to the OUTEST= data set	PROC SYSLIN	OUTCOV OUTCOV3
write the SSCP matrix to an output data set	PROC SYSLIN	OUTSSCP=
Estimation Method Options		
specify full information maximum likelihood estimation	PROC SYSLIN	FIML
specify iterative SUR estimation	PROC SYSLIN	ITSUR
specify iterative 3SLS estimation	PROC SYSLIN	IT3SLS
specify K-class estimation	PROC SYSLIN	K=
specify limited information maximum likelihood estimation	PROC SYSLIN	LIML
specify minimum expected loss estimation	PROC SYSLIN	MELO
specify ordinary least squares estimation	PROC SYSLIN	OLS
specify seemingly unrelated estimation	PROC SYSLIN	SUR
specify two-stage least squares estimation	PROC SYSLIN	2SLS
specify three-stage least squares estimation	PROC SYSLIN	3SLS
specify Fuller's modification to LIML	PROC SYSLIN	ALPHA=
specify convergence criterion	PROC SYSLIN	CONVERGE=
specify maximum number of iterations	PROC SYSLIN	MAXIT=
use diagonal of S instead of S	PROC SYSLIN	SDIAG
exclude RESTRICT statements in final stage	PROC SYSLIN	NOINCLUDE
specify criterion for testing for singularity	PROC SYSLIN	SINGULAR=
specify denominator for variance estimates	PROC SYSLIN	VARDEF=
Printing Control Options		
print all results	PROC SYSLIN	ALL
print first-stage regression statistics	PROC SYSLIN	FIRST
print estimates and SSE at each iteration	PROC SYSLIN	ITPRINT
print the reduced form estimates	PROC SYSLIN	REDUCED
print descriptive statistics	PROC SYSLIN	SIMPLE
print uncorrected SSCP matrix	PROC SYSLIN	USSCP
print correlations of the parameter estimates	MODEL	CORRB

Description	Statement	Option
print covariances of the parameter estimates	MODEL	COVB
print Durbin-Watson statistics	MODEL	DW
print Basmann's test	MODEL	OVERID
plot residual values against regressors	MODEL	PLOT
print standardized parameter estimates	MODEL	STB
print unrestricted parameter estimates	MODEL	UNREST
print the model crossproducts matrix	MODEL	XPX
print the inverse of the crossproducts matrix	MODEL	I
suppress printed output	MODEL	NOPRINT
suppress all printed output	PROC SYSLIN	NOPRINT
Model Specification		
specify structural equations	MODEL	
suppress the intercept parameter	MODEL	NOINT
specify linear relationship among variables	IDENTITY	
perform weighted regression	WEIGHT	
Tests and Restrictions on Parameters		
place restrictions on parameter estimates	RESTRICT	
place restrictions on parameter estimates	SRESTRICT	
test linear hypothesis	STEST	
test linear hypothesis	TEST	
Other Statements		
specify BY-group processing	BY	
specify the endogenous variables	ENDOGENOUS	
specify instrumental variables	INSTRUMENTS	
write predicted and residual values to a data set	OUTPUT	
name variable for predicted values	OUTPUT	PREDICTED=
name variable for residual values	OUTPUT	RESIDUAL=
include additional variables in $X'X$ matrix	VAR	

PROC SYSLIN Statement

PROC SYSLIN *options* ;

The following options can be used with the PROC SYSLIN statement.

Data Set Options

DATA=SAS-data-set

specifies the input data set. If the DATA= option is omitted, the most recently created SAS data set is used. In addition to ordinary SAS data sets, PROC SYSLIN can analyze data sets of TYPE=CORR, TYPE=COV, TYPE=UCORR, TYPE=UCOV, and TYPE=SSCP. See the section “[Special TYPE= Input Data Sets](#)” on page 1996 for details.

OUT=SAS-data-set

specifies an output SAS data set for residuals and predicted values. The OUT= option is used in conjunction with the OUTPUT statement. See the section “[OUT= Data Set](#)” on page 2002 for details.

OUTEST=SAS-data-set

writes the parameter estimates to an output data set. See the section “[OUTEST= Data Set](#)” on page 2003 for details.

OUTCOV

COVOUT

writes the covariance matrix of the parameter estimates to the OUTEST= data set in addition to the parameter estimates.

OUTCOV3

COV3OUT

writes covariance matrices for each model in a system to the OUTEST= data set when the 3SLS, SUR, or FIML option is used.

OUTSSCP=SAS-data-set

writes the sum-of-squares-and-crossproducts matrix to an output data set. See the section “[OUT-SSCP= Data Set](#)” on page 2004 for details.

Estimation Method Options

2SLS

specifies the two-stage least squares estimation method.

3SLS

specifies the three-stage least squares estimation method.

ALPHA=value

specifies Fuller’s modification to the LIML estimation method. See the section “[Fuller’s Modification to LIML](#)” on page 2002 for details.

CONVERGE=value

specifies the convergence criterion for the iterative estimation methods IT3SLS, ITSUR, and FIML. The default is CONVERGE=0.0001.

FIML

specifies the full information maximum likelihood estimation method.

ITSUR

specifies the iterative seemingly unrelated estimation method.

IT3SLS

specifies the iterative three-stage least squares estimation method.

K=value

specifies the K-class estimation method.

LIML

specifies the limited information maximum likelihood estimation method.

MAXITER=n

specifies the maximum number of iterations allowed for the IT3SLS, ITSUR, and FIML estimation methods. The MAXITER= option can be abbreviated as MAXIT=. The default is MAXITER=30.

MELO

specifies the minimum expected loss estimation method.

NOINCLUDE

excludes the RESTRICT statements from the final stage for the 3SLS, IT3SLS, SUR, and ITSUR estimation methods.

OLS

specifies the ordinary least squares estimation method. This is the default.

SDIAG

uses the diagonal of **S** instead of **S** to do the estimation, where **S** is the covariance matrix of equation errors. See the section “[Uncorrelated Errors across Equations](#)” on page 2002 for details.

SINGULAR=value

specifies a criterion for testing singularity of the crossproducts matrix. This is a tuning parameter used to make PROC SYSLIN more or less sensitive to singularities. The value must be between 0 and 1. The default is SINGULAR=1E-8.

SUR

specifies the seemingly unrelated estimation method.

Printing Control Options**ALL**

specifies the CORRB, COVB, DW, I, OVERID, PLOT, STB, and XPX options for every MODEL statement.

FIRST

prints first-stage regression statistics for the endogenous variables regressed on the instruments. This output includes sums of squares, estimates, variances, and standard deviations.

ITPRINT

prints parameter estimates, system-weighted residual sum of squares, and R^2 at each iteration for the IT3SLS and ITSUR estimation methods. For the FIML method, the ITPRINT option prints parameter estimates, negative of log-likelihood function, and norm of gradient vector at each iteration.

NOPRINT

suppresses all printed output. Specifying NOPRINT in the PROC SYSLIN statement is equivalent to specifying NOPRINT in every MODEL statement.

REDUCED

prints the reduced form estimates. If the REDUCED option is specified, you should specify any IDENTITY statements needed to make the system square. See the section “[Reduced Form Estimates](#)” on page 2001 for details.

SIMPLE

prints descriptive statistics for the dependent variables. The statistics printed include the sum, mean, uncorrected sum of squares, variance, and standard deviation.

USSCP

prints the uncorrected sum-of-squares-and-crossproducts matrix.

USSCP2

prints the uncorrected sum-of-squares-and-crossproducts matrix for all variables used in the analysis, including predicted values of variables generated by the procedure.

VARDEF=DF | N | WEIGHT | WGT

specifies the denominator to use in calculating cross-equation error covariances and parameter standard errors and covariances. The default is VARDEF=DF, which corrects for model degrees of freedom. VARDEF=N specifies no degrees-of-freedom correction. VARDEF=WEIGHT specifies the sum of the observation weights. VARDEF=WGT specifies the sum of the observation weights minus the model degrees of freedom. See the section “[Computation of Standard Errors](#)” on page 2001 for details.

BY Statement

BY *variables* ;

A BY statement can be used with PROC SYSLIN to obtain separate analyses on observations in groups defined by the BY variables.

ENDOGENOUS Statement

ENDOGENOUS *variables* ;

The ENDOGENOUS statement declares the jointly dependent variables that are projected in the first-stage regression through the instrument variables. The ENDOGENOUS statement is not needed for the SUR, ITSUR, or OLS estimation methods. The default ENDOGENOUS list consists of all the dependent variables in the MODEL and IDENTITY statements that do not appear in the INSTRUMENTS statement.

IDENTITY Statement

IDENTITY *equation* ;

The IDENTITY statement specifies linear relationships among variables to write to the OUTEST= data set. It provides extra information in the OUTEST= data set but does not create or compute variables. The OUTEST= data set can be processed by the SIMLIN procedure in a later step.

The IDENTITY statement is also used to compute reduced form coefficients when the REDUCED option in the PROC SYSLIN statement is specified. See the section “[Reduced Form Estimates](#)” on page 2001 for details.

The *equation* given by the IDENTITY statement has the same form as equations in the MODEL statement. A label can be specified for an IDENTITY statement as follows:

label : **IDENTITY** ... ;

INSTRUMENTS Statement

INSTRUMENTS *variables* ;

The INSTRUMENTS statement declares the variables used in obtaining first-stage predicted values. All the instruments specified are used in each first-stage regression. The INSTRUMENTS statement is required for the 2SLS, 3SLS, IT3SLS, LIML, MELO, and K-class estimation methods. The INSTRUMENTS statement is not needed for the SUR, ITSUR, OLS, or FIML estimation methods.

MODEL Statement

MODEL *response = regressors / options* ;

The MODEL statement regresses the response variable on the left side of the equal sign against the regressors listed on the right side.

Models can be given labels. Model labels are used in the printed output to identify the results for different models. Model labels are also used in SRESTRICT and STEST statements to refer to parameters in different models. If no label is specified, the response variable name is used as the label for the model. The model label is specified as follows:

label : **MODEL** ... ;

The following options can be used in the MODEL statement after a slash (/).

ALL

specifies the CORRB, COVB, DW, I, OVERID, PLOT, STB, and XPX options.

ALPHA=*value*

specifies the α parameter for Fuller’s modification to the LIML estimation method. See the section “[Fuller’s Modification to LIML](#)” on page 2002 for details.

CORRB

prints the matrix of estimated correlations between the parameter estimates.

COVB

prints the matrix of estimated covariances between the parameter estimates.

DW

prints Durbin-Watson statistics and autocorrelation coefficients for the residuals. If there are missing values, d' is calculated according to Savin and White (1978). Use the DW option only if the data set to be analyzed is an ordinary SAS data set with time series observations sorted in time order. The Durbin-Watson test is not valid for models with lagged dependent regressors.

I

prints the inverse of the crossproducts matrix for the model, $(X'X)^{-1}$. If restrictions are specified, the crossproducts matrix printed is adjusted for the restrictions. See the section “[Computational Details](#)” on page 2000 for details.

K=value

specifies K-class estimation.

NOINT

suppresses the intercept parameter from the model.

NOPRINT

suppresses the normal printed output.

OVERID

prints Basmann’s (1960) test for over identifying restrictions. See the section “[Overidentification Restrictions](#)” on page 2002 for details.

PLOT

plots residual values against regressors. A plot of the residuals for each regressor is printed.

STB

prints standardized parameter estimates. Sometimes known as a standard partial regression coefficient, a standardized parameter estimate is a parameter estimate multiplied by the standard deviation of the associated regressor and divided by the standard deviation of the response variable.

UNREST

prints parameter estimates computed before restrictions are applied. The UNREST option is valid only if a RESTRICT statement is specified.

XPX

prints the model crossproducts matrix, $X'X$. See the section “[Computational Details](#)” on page 2000 for details.

OUTPUT Statement

OUTPUT < *PREDICTED=variable* > < *RESIDUAL=variable* > ;

The OUTPUT statement writes predicted values and residuals from the preceding model to the data set specified by the OUT= option in the PROC SYSLIN statement. An OUTPUT statement must come after the MODEL statement to which it applies. The OUT= option must be specified in the PROC SYSLIN statement.

The following options can be specified in the OUTPUT statement:

PREDICTED=*variable*

names a new variable to contain the predicted values for the response variable. The PREDICTED= option can be abbreviated as PREDICT=, PRED=, or P=.

RESIDUAL=*variable*

names a new variable to contain the residual values for the response variable. The RESIDUAL= option can be abbreviated as RESID= or R=.

For example, the following statements create an output data set named B. In addition to the variables in the input data set, the data set B contains the variable YHAT, with values that are predicted values of the response variable Y, and YRESID, with values that are the residual values of Y.

```
proc syslin data=a out=b;
  model y = x1 x2;
  output p=yhat r=yresid;
run;
```

For example, the following statements create an output data set named PRED. In addition to the variables in the input data set, the data set PRED contains the variables Q_DEMAND and Q_SUPPLY, with values that are predicted values of the response variable Q for the demand and supply equations respectively, and R_DEMAND and R_SUPPLY, with values that are the residual values of the demand and supply equations respectively.

```
proc syslin data=in out=pred;
  demand: model q = p y s;
  output p=q_demand r=r_demand;
  supply: model q = p u;
  output p=q_supply r=r_supply;
run;
```

See the section “OUT= Data Set” on page 2002 for details.

RESTRICT Statement

RESTRICT *equation* , . . . , *equation* ;

The RESTRICT statement places restrictions on the parameter estimates for the preceding MODEL statement. Any number of RESTRICT statements can follow a MODEL statement. Each restriction is written as a linear equation. If more than one restriction is specified in a single RESTRICT statement, the restrictions are separated by commas.

Parameters are referred to by the name of the corresponding regressor variable. Each name used in the equation must be a regressor in the preceding MODEL statement. The keyword INTERCEPT is used to refer to the intercept parameter in the model.

RESTRICT statements can be given labels. The labels are used in the printed output to distinguish results for different restrictions. Labels are specified as follows:

label : **RESTRICT** ...;

The following is an example of the use of the RESTRICT statement, in which the coefficients of the regressors X1 and X2 are required to sum to 1.

```
proc syslin data=a;
  model y = x1 x2;
  restrict x1 + x2 = 1;
run;
```

Variable names can be multiplied by constants. When no equal sign appears, the linear combination is set equal to 0. Note that the parameters associated with the variables are restricted, not the variables themselves. Here are some examples of valid RESTRICT statements:

```
restrict x1 + x2 = 1;
restrict x1 + x2 - 1;
restrict 2 * x1 = x2 + x3 , intercept + x4 = 0;
restrict x1 = x2 = x3 = 1;
restrict 2 * x1 - x2;
```

Restricted parameter estimates are computed by introducing a Lagrangian parameter λ for each restriction (Pringle and Rayner 1971). The estimates of these Lagrangian parameters are printed in the “Parameter Estimates” table. If a restriction cannot be applied, its parameter value and degrees of freedom are listed as 0.

The Lagrangian parameter λ measures the sensitivity of the sum of squared errors (SSE) to the restriction. If the restriction is changed by a small amount ϵ , the SSE is changed by $2\lambda\epsilon$.

The t ratio tests the significance of the restrictions. If λ is zero, the restricted estimates are the same as the unrestricted.

Any number of restrictions can be specified on a RESTRICT statement, and any number of RESTRICT statements can be used. The estimates are computed subject to all restrictions specified. However, restrictions should be consistent and not redundant.

NOTE: The RESTRICT statement is not supported for the FIML estimation method.

SRESTRICT Statement

SRESTRICT *equation* , . . . , *equation* ;

The SRESTRICT statement imposes linear restrictions that involve parameters in two or more MODEL statements. The SRESTRICT statement is like the RESTRICT statement but is used to impose restrictions across equations, whereas the RESTRICT statement applies only to parameters in the immediately preceding MODEL statement.

Each restriction is written as a linear equation. Parameters are referred to as *label.variable*, where *label* is the model label and *variable* is the name of the regressor to which the parameter is attached. (If the

MODEL statement does not have a label, you can use the dependent variable name as the label for the model, provided the dependent variable uniquely labels the model.) Each variable name used must be a regressor in the indicated MODEL statement. The keyword INTERCEPT is used to refer to intercept parameters.

SRESTRICT statements can be given labels. The labels are used in the printed output to distinguish results for different restrictions. Labels are specified as follows:

label : **SRESTRICT** ...;

The following is an example of the use of the SRESTRICT statement, in which the coefficient for the regressor X2 is constrained to be the same in both models.

```
proc syslin data=a 3sls;
  endogenous y1 y2;
  instruments x1 x2;
  model y1 = y2 x1 x2;
  model y2 = y1 x2;
  srestrict y1.x2 = y2.x2;
run;
```

When no equal sign is used, the linear combination is set equal to 0. Thus, the restriction in the preceding example can also be specified as

```
srestrict y1.x2 - y2.x2;
```

Any number of restrictions can be specified on an SRESTRICT statement, and any number of SRESTRICT statements can be used. The estimates are computed subject to all restrictions specified. However, restrictions should be consistent and not redundant.

When a system restriction is requested for a single equation estimation method (such as OLS or 2SLS), PROC SYSLIN produces the restricted estimates by actually using a corresponding system method. For example, when SRESTRICT is specified along with OLS, PROC SYSLIN produces the restricted OLS estimates via a two-step process equivalent to using SUR estimation with the SDIAG option. First, the unrestricted OLS results are produced. Then, the GLS (SUR) estimation with the system restriction is performed, using the diagonal of the covariance matrix of the residuals. When SRESTRICT is specified along with 2SLS, PROC SYSLIN produces the restricted 2SLS estimates via a multistep process equivalent to using 3SLS estimation with the SDIAG option. First, the unrestricted 2SLS results are produced. Then, the GLS (3SLS) estimation with the system restriction is performed, using the diagonal of the covariance matrix of the residuals.

The results of the SRESTRICT statements are printed after the parameter estimates for all the models in the system. The format of the SRESTRICT statement output is the same as the “Parameter Estimates” table. In this output the parameter estimate is the Lagrangian parameter λ used to impose the restriction.

The Lagrangian parameter λ measures the sensitivity of the system sum of square errors to the restriction. The system SSE is the system MSE shown in the printed output multiplied by the degrees of freedom. If the restriction is changed by a small amount ϵ , the system SSE is changed by $2\lambda\epsilon$.

The t ratio tests the significance of the restriction. If λ is zero, the restricted estimates are the same as the unrestricted estimates.

The model degrees of freedom are not adjusted for the cross-model restrictions imposed by SRESTRICT statements.

NOTE: The SRESTRICT statement is not supported for the LIML and the FIML estimation methods.

STEST Statement

STEST *equation* , . . . , *equation* / *options* ;

The STEST statement performs an F test for the joint hypotheses specified in the statement.

The hypothesis is represented in matrix notation as

$$\mathbf{L}\beta = \mathbf{c}$$

and the F test is computed as

$$\frac{(\mathbf{L}b - \mathbf{c})'(\mathbf{L}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{L}')^{-1}(\mathbf{L}b - \mathbf{c})}{m\hat{\sigma}^2}$$

where b is the estimate of β , m is the number of restrictions, and $\hat{\sigma}^2$ is the system weighted mean squared error. See the section “[Computational Details](#)” on page 2000 for information about the matrix $\mathbf{X}'\mathbf{X}$.

Each hypothesis to be tested is written as a linear equation. Parameters are referred to as *label.variable*, where *label* is the model label and *variable* is the name of the regressor to which the parameter is attached. (If the MODEL statement does not have a label, you can use the dependent variable name as the label for the model, provided the dependent variable uniquely labels the model.) Each variable name used must be a regressor in the indicated MODEL statement. The keyword INTERCEPT is used to refer to intercept parameters.

STEST statements can be given labels. The label is used in the printed output to distinguish different tests. Any number of STEST statements can be specified. Labels are specified as follows:

label : **STEST** ...;

The following is an example of the STEST statement:

```
proc syslin data=a 3sls;
  endogenous y1 y2;
  instruments x1 x2;
  model y1 = y2 x1 x2;
  model y2 = y1 x2;
  stest y1.x2 = y2.x2;
run;
```

The test performed is exact only for ordinary least squares, given the OLS assumptions of the linear model. For other estimation methods, the F test is based on large sample theory and is only approximate in finite samples.

If RESTRICT or SRESTRICT statements are used, the tests computed by the STEST statement are conditional on the restrictions specified. The validity of the tests can be compromised if incorrect restrictions are imposed on the estimates.

The following are examples of STEST statements:

```

stest a.x1 + b.x2 = 1;
stest 2 * b.x2 = c.x3 + c.x4 ,
      a.intercept + b.x2 = 0;
stest a.x1 = c.x2 = b.x3 = 1;
stest 2 * a.x1 - b.x2 = 0;

```

The PRINT option can be specified in the STEST statement after a slash (/):

PRINT

prints intermediate calculations for the hypothesis tests.

NOTE: The STEST statement is not supported for the FIML estimation method.

TEST Statement

TEST *equation* , ... , *equation* / *options* ;

The TEST statement performs F tests of linear hypotheses about the parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. If more than one equation is specified, the equations are separated by commas.

Variable names must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The keyword INTERCEPT is used to refer to the model intercept.

TEST statements can be given labels. The label is used in the printed output to distinguish different tests. Any number of TEST statements can be specified. Labels are specified as follows:

label : **TEST** ...;

The following is an example of the use of TEST statement, which tests the hypothesis that the coefficients of X1 and X2 are the same:

```

proc syslin data=a;
  model y = x1 x2;
  test x1 = x2;
run;

```

The following statements perform F tests for the hypothesis that the coefficients of X1 and X2 are equal, for the hypothesis that the sum of the X1 and X2 coefficients is twice the intercept, and for the joint hypothesis.

```

proc syslin data=a;
  model y = x1 x2;
  x1eqx2: test x1 = x2;
  sumeq2i: test x1 + x2 = 2 * intercept;
  joint: test x1 = x2, x1 + x2 = 2 * intercept;
run;

```

The following are additional examples of TEST statements:

```
test x1 + x2 = 1;
test x1 = x2 = x3 = 1;
test 2 * x1 = x2 + x3, intercept + x4 = 0;
test 2 * x1 - x2;
```

The TEST statement performs an F test for the joint hypotheses specified. The hypothesis is represented in matrix notation as follows:

$$\mathbf{L}\beta = \mathbf{c}$$

The F test is computed as

$$\frac{(\mathbf{L}b - \mathbf{c})'(\mathbf{L}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{L}')^{-1}(\mathbf{L}b - \mathbf{c})}{m\hat{\sigma}^2}$$

where b is the estimate of β , m is the number of restrictions, and $\hat{\sigma}^2$ is the model mean squared error. See the section “[Computational Details](#)” on page 2000 for information about the matrix $\mathbf{X}'\mathbf{X}$.

The test performed is exact only for ordinary least squares, given the OLS assumptions of the linear model. For other estimation methods, the F test is based on large sample theory and is only approximate in finite samples.

If RESTRICT or SRESTRICT statements are used, the tests computed by the TEST statement are conditional on the restrictions specified. The validity of the tests can be compromised if incorrect restrictions are imposed on the estimates.

The PRINT option can be specified in the TEST statement after a slash (/):

PRINT

prints intermediate calculations for the hypothesis tests.

NOTE: The TEST statement is not supported for the FIML estimation method.

VAR Statement

VAR *variables* ;

The VAR statement is used to include variables in the crossproducts matrix that are not specified in any MODEL statement. This statement is rarely used with PROC SYSLIN and is used only with the OUTSSCP= option in the PROC SYSLIN statement.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement is used to perform weighted regression. The WEIGHT statement names a variable in the input data set whose values are relative weights for a weighted least squares fit. If the weight value is proportional to the reciprocal of the variance for each observation, the weighted estimates are the best linear unbiased estimates (BLUE).

Details: SYSLIN Procedure

Input Data Set

PROC SYSLIN does not compute new values for regressors. For example, if you need a lagged variable, you must create it with a DATA step. No values are computed by IDENTITY statements; all values must be in the input data set.

Special TYPE= Input Data Sets

The input data set for most applications of the SYSLIN procedure contains standard rectangular data. However, PROC SYSLIN can also process input data in the form of a crossproducts, covariance, or correlation matrix. Data sets that contain such matrices are identified by values of the TYPE= data set option.

These special kinds of input data sets can be used to save computer time. It takes nk^2 operations, where n is the number of observations and k is the number of variables, to calculate cross products; the regressions are of the order k^3 . When n is in the thousands and k is much smaller, you can save most of the computer time in later runs of PROC SYSLIN by reusing the SSCP matrix rather than recomputing it.

The SYSLIN procedure can process TYPE=CORR, COV, UCORR, UCOV, or SSCP data sets. TYPE=CORR and TYPE=COV data sets, usually created by the CORR procedure, contain means and standard deviations, and correlations or covariances. TYPE=SSCP data sets, usually created in previous runs of PROC SYSLIN, contain sums of squares and cross products. See the *SAS/STAT User's Guide* for more information about special SAS data sets.

When special SAS data sets are read, you must specify the TYPE= data set option. PROC CORR and PROC SYSLIN automatically set the type for output data sets; however, if you create the data set by some other means, you must specify its type with the TYPE= data set option.

When the special data sets are used, the DW (Durbin-Watson test) and PLOT options in the MODEL statement cannot be performed, and the OUTPUT statements are not valid.

Estimation Methods

A brief description of the methods used by the SYSLIN procedure follows. For more information about these methods, see the references at the end of this chapter.

There are two fundamental methods of estimation for simultaneous equations: least squares and maximum likelihood. There are two approaches within each of these categories: single equation methods (also referred to as limited information methods) and system methods (also referred to as full information methods). System methods take into account cross-equation correlations of the disturbances in estimating parameters, while single equation methods do not.

OLS, 2SLS, MELO, K-class, SUR, ITSUR, 3SLS, and IT3SLS use the least squares method; LIML and FIML use the maximum likelihood method.

OLS, 2SLS, MELO, K-class, and LIML are single equation methods. The system methods are SUR, ITSUR, 3SLS, IT3SLS, and FIML.

Single Equation Estimation Methods

Single equation methods do not take into account correlations of errors across equations. As a result, these estimators are not asymptotically efficient compared to full information methods; however, there are instances in which they may be preferred. (See the section “[Choosing a Method for Simultaneous Equations](#)” on page 1998 for details.)

Let y_i be the dependent endogenous variable in equation i , and X_i and Y_i be the matrices of exogenous and endogenous variables appearing as regressors in the same equation.

The 2SLS method owes its name to the fact that, in a first stage, the instrumental variables are used as regressors to obtain a projected value \hat{Y}_i that is uncorrelated with the residual in equation i . In a second stage, \hat{Y}_i replaces Y_i on the right-hand side to obtain consistent least squares estimators.

Normally, the predetermined variables of the system are used as the instruments. It is possible to use variables other than predetermined variables from your system as instruments; however, the estimation might not be as efficient. For consistent estimates, the instruments must be uncorrelated with the residual and correlated with the endogenous variables.

The LIML method results in consistent estimates that are equal to the 2SLS estimates when an equation is exactly identified. LIML can be viewed as a least-variance ratio estimation or as a maximum likelihood estimation. LIML involves minimizing the ratio $\lambda = (rvar_eq)/(rvar_sys)$, where $rvar_eq$ is the residual variance associated with regressing the weighted endogenous variables on all predetermined variables that appear in that equation, and $rvar_sys$ is the residual variance associated with regressing weighted endogenous variables on all predetermined variables in the system.

The MELO method computes the minimum expected loss estimator. MELO estimators “minimize the posterior expectation of generalized quadratic loss functions for structural coefficients of linear structural models” (Judge et al. 1985, p. 635).

K-class estimators are a class of estimators that depends on a user-specified parameter k . A k value less than 1 is recommended but not required. The parameter k can be deterministic or stochastic, but its probability limit must equal 1 for consistent parameter estimates. When all the predetermined variables are listed as instruments, they include all the other single equation estimators supported by PROC SYSLIN. The instance when some of the predetermined variables are not listed among the instruments is not supported by PROC SYSLIN for the general K-class estimation. However, it is supported for the other methods.

For $k = 1$, the K-class estimator is the 2SLS estimator, while for $k = 0$, the K-class estimator is the OLS estimator. The K-class interpretation of LIML is that $k = \lambda$. Note that k is stochastic in the LIML method, unlike for OLS and 2SLS.

MELO is a Bayesian K-class estimator. It yields estimates that can be expressed as a matrix-weighted average of the OLS and 2SLS estimates. MELO estimators have finite second moments and hence finite risk. Other frequently used K-class estimators might not have finite moments under some commonly encountered circumstances, and hence there can be infinite risk relative to quadratic and other loss functions.

One way of comparing K-class estimators is to note that when $k=1$, the correlation between regressor and the residual is completely corrected for. In all other cases, it is only partially corrected for.

See “[Computational Details](#)” on page 2000 for more details about K-class estimators.

SUR and 3SLS Estimation Methods

SUR might improve the efficiency of parameter estimates when there is contemporaneous correlation of errors across equations. In practice, the contemporaneous correlation matrix is estimated using OLS residuals. Under two sets of circumstances, SUR parameter estimates are the same as those produced by OLS: when there is no contemporaneous correlation of errors across equations (the estimate of the contemporaneous correlation matrix is diagonal) and when the independent variables are the same across equations.

Theoretically, SUR parameter estimates are always at least as efficient as OLS in large samples, provided that your equations are correctly specified. However, in small samples the need to estimate the covariance matrix from the OLS residuals increases the sampling variability of the SUR estimates. This effect can cause SUR to be less efficient than OLS. If the sample size is small and the cross-equation correlations are small, then OLS is preferred to SUR. The consequences of specification error are also more serious with SUR than with OLS.

The 3SLS method combines the ideas of the 2SLS and SUR methods. Like 2SLS, the 3SLS method uses \hat{Y} instead of Y for endogenous regressors, which results in consistent estimates. Like SUR, the 3SLS method takes the cross-equation error correlations into account to improve large sample efficiency. For 3SLS, the 2SLS residuals are used to estimate the cross-equation error covariance matrix.

The SUR and 3SLS methods can be iterated by recomputing the estimate of the cross-equation covariance matrix from the SUR or 3SLS residuals and then computing new SUR or 3SLS estimates based on this updated covariance matrix estimate. Continuing this iteration until convergence produces ITSUR or IT3SLS estimates.

FIML Estimation Method

The FIML estimator is a system generalization of the LIML estimator. The FIML method involves minimizing the determinant of the covariance matrix associated with residuals of the reduced form of the equation system. From a maximum likelihood standpoint, the LIML method involves assuming that the errors are normally distributed and then maximizing the likelihood function subject to restrictions on a particular equation. FIML is similar, except that the likelihood function is maximized subject to restrictions on all of the parameters in the model, not just those in the equation being estimated.

NOTE: The RESTRICT, SRESTRICT, TEST, and STEST statements are not supported when the FIML method is used.

Choosing a Method for Simultaneous Equations

A number of factors should be taken into account in choosing an estimation method. Although system methods are asymptotically most efficient in the absence of specification error, system methods are more sensitive to specification error than single equation methods.

In practice, models are never perfectly specified. It is a matter of judgment whether the misspecification is serious enough to warrant avoidance of system methods.

Another factor to consider is sample size. With small samples, 2SLS might be preferred to 3SLS. In general, it is difficult to say much about the small sample properties of K-class estimators because the results depend on the regressors used.

LIML and FIML are invariant to the normalization rule imposed but are computationally more expensive than 2SLS or 3SLS.

If the reason for contemporaneous correlation among errors across equations is a common, omitted variable, it is not necessarily best to apply SUR. SUR parameter estimates are more sensitive to specification error than OLS. OLS might produce better parameter estimates under these circumstances. SUR estimates are also affected by the sampling variation of the error covariance matrix. There is some evidence from Monte Carlo studies that SUR is less efficient than OLS in small samples.

ANOVA Table for Instrumental Variables Methods

In the instrumental variables methods (2SLS, LIML, K-class, MELO), first-stage predicted values are substituted for the endogenous regressors. As a result, the regression sum of squares (RSS) and the error sum of squares (ESS) do not sum to the total corrected sum of squares for the dependent variable (TSS). The analysis-of-variance table included in the second-stage results gives these sums of squares and the mean squares that are used for the F test, but this table is not a variance decomposition in the usual sense.

The F test shown in the instrumental variables case is a valid test of the no-regression hypothesis that the true coefficients of all regressors are 0. However, because of the first-stage projection of the regression mean square, this is a Wald-type test statistic, which is asymptotically F but not exactly F -distributed in finite samples. Thus, for small samples the F test is only approximate when instrumental variables are used.

The R-Square Statistics

As explained in the section “ANOVA Table for Instrumental Variables Methods” on page 1999, when instrumental variables are used, the regression sum of squares (RSS) and the error sum of squares (ESS) do not sum to the total corrected sum of squares. In this case, there are several ways that the R^2 statistic can be defined.

The definition of R^2 used by the SYSLIN procedure is

$$R^2 = \frac{RSS}{RSS + ESS}$$

This definition is consistent with the F test of the null hypothesis that the true coefficients of all regressors are zero. However, this R^2 might not be a good measure of the goodness of fit of the model.

System Weighted R-Square and System Weighted Mean Squared Error

The system weighted R^2 , printed for the 3SLS, IT3SLS, SUR, ITSUR, and FIML methods, is computed as follows.

$$R^2 = \mathbf{Y}'\mathbf{W}\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}'\mathbf{W}\mathbf{Y}/\mathbf{Y}'\mathbf{W}\mathbf{Y}$$

In this equation, the matrix $\mathbf{X}'\mathbf{X}$ is $\mathbf{R}'\mathbf{W}\mathbf{R}$ and \mathbf{W} is the projection matrix of the instruments:

$$\mathbf{W} = \mathbf{S}^{-1} \otimes \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$$

The matrix \mathbf{Z} is the instrument set, \mathbf{R} is the regressor set, and \mathbf{S} is the estimated cross-model covariance matrix.

The system weighted MSE, printed for the 3SLS, IT3SLS, SUR, ITSUR, and FIML methods, is computed as follows:

$$MSE = \frac{1}{tdf} (Y'WY - Y'WR(X'X)^{-1}R'WY)$$

In this equation, tdf is the sum of the error degrees of freedom for the equations in the system.

Computational Details

This section discusses various computational details.

Computation of Least Squares-Based Estimators

Let the system be composed of G equations and let the i th equation be expressed in this form:

$$y_i = Y_i\beta_i + X_i\gamma_i + \mathbf{u}$$

where

- y_i is the vector of observations on the dependent variable
- Y_i is the matrix of observations on the endogenous variables included in the equation
- β_i is the vector of parameters associated with Y_i
- X_i is the matrix of observations on the predetermined variables included in the equation
- γ_i is the vector of parameters associated with X_i
- \mathbf{u} is a vector of errors

Let $\hat{V}_i = Y_i - \hat{Y}_i$, where \hat{Y}_i is the projection of Y_i onto the space spanned by the instruments matrix \mathbf{Z} .

Let

$$\delta_i = \begin{bmatrix} \beta_i \\ \gamma_i \end{bmatrix}$$

be the vector of parameters associated with both the endogenous and exogenous variables.

The K-class of estimators (Theil 1971) is defined by

$$\hat{\delta}_{i,k} = \begin{bmatrix} Y_i'Y_i - k\hat{V}_i'\hat{V}_i & Y_i'X_i \\ X_i'Y_i & X_i'X_i \end{bmatrix}^{-1} \begin{bmatrix} (Y_i - k\hat{V}_i)'y_i \\ X_i'y_i \end{bmatrix}$$

where k is a user-defined value.

Let

$$\mathbf{R} = [Y_i X_i]$$

and

$$\hat{\mathbf{R}} = [\hat{Y}_i X_i]$$

The 2SLS estimator is defined as

$$\hat{\delta}_{i,2SLS} = [\hat{R}_i' \hat{R}_i]^{-1} \hat{R}_i' y_i$$

Let y and δ be the vectors obtained by stacking the vectors of dependent variables and parameters for all G equations, and let \mathbf{R} and $\hat{\mathbf{R}}$ be the block diagonal matrices formed by R_i and \hat{R}_i , respectively.

The SUR and ITSUR estimators are defined as

$$\hat{\delta}_{(IT)SUR} = [\mathbf{R}' (\hat{\Sigma}^{-1} \otimes \mathbf{I}) \mathbf{R}]^{-1} \mathbf{R}' (\hat{\Sigma}^{-1} \otimes \mathbf{I}) y$$

while the 3SLS and IT3SLS estimators are defined as

$$\hat{\delta}_{(IT)3SLS} = [\hat{\mathbf{R}}' (\hat{\Sigma}^{-1} \otimes \mathbf{I}) \hat{\mathbf{R}}]^{-1} \hat{\mathbf{R}}' (\hat{\Sigma}^{-1} \otimes \mathbf{I}) y$$

where \mathbf{I} is the identity matrix, and $\hat{\Sigma}$ is an estimator of the cross-equation correlation matrix. For 3SLS, $\hat{\Sigma}$ is obtained from the 2SLS estimation, while for SUR it is derived from the OLS estimation. For IT3SLS and ITSUR, it is obtained iteratively from the previous estimation step, until convergence.

Computation of Standard Errors

The VARDEF= option in the PROC SYSLIN statement controls the denominator used in calculating the cross-equation covariance estimates and the parameter standard errors and covariances. The values of the VARDEF= option and the resulting denominator are as follows:

N	uses the number of nonmissing observations.
DF	uses the number of nonmissing observations less the degrees of freedom in the model.
WEIGHT	uses the sum of the observation weights given by the WEIGHTS statement.
WDF	uses the sum of the observation weights given by the WEIGHTS statement less the degrees of freedom in the model.

The VARDEF= option does not affect the model mean squared error, root mean squared error, or R^2 statistics. These statistics are always based on the error degrees of freedom, regardless of the VARDEF= option. The VARDEF= option also does not affect the dependent variable coefficient of variation (CV).

Reduced Form Estimates

The REDUCED option in the PROC SYSLIN statement computes estimates of the reduced form coefficients. The REDUCED option requires that the equation system be square. If there are fewer models than endogenous variables, IDENTITY statements can be used to complete the equation system.

The reduced form coefficients are computed as follows. Represent the equation system, with all endogenous variables moved to the left-hand side of the equations and identities, as

$$\mathbf{B}\mathbf{Y} = \mathbf{\Gamma}\mathbf{X}$$

Here \mathbf{B} is the estimated coefficient matrix for the endogenous variables \mathbf{Y} , and $\mathbf{\Gamma}$ is the estimated coefficient matrix for the exogenous (or predetermined) variables \mathbf{X} .

The system can be solved for \mathbf{Y} as follows, provided \mathbf{B} is square and nonsingular:

$$\mathbf{Y} = \mathbf{B}^{-1}\mathbf{\Gamma}\mathbf{X}$$

The reduced form coefficients are the matrix $\mathbf{B}^{-1}\mathbf{\Gamma}$.

Uncorrelated Errors across Equations

The SDIAG option in the PROC SYSLIN statement computes estimates by assuming uncorrelated errors across equations. As a result, when the SDIAG option is used, the 3SLS estimates are identical to 2SLS estimates, and the SUR estimates are the same as the OLS estimates.

Overidentification Restrictions

The OVERID option in the MODEL statement can be used to test for overidentifying restrictions on parameters of each equation. The null hypothesis is that the predetermined variables that do not appear in any equation have zero coefficients. The alternative hypothesis is that at least one of the assumed zero coefficients is nonzero. The test is approximate and rejects the null hypothesis too frequently for small sample sizes.

The formula for the test is given as follows. Let $y_i = \beta_i Y_i + \gamma_i Z_i + e_i$ be the i th equation. Y_i are the endogenous variables that appear as regressors in the i th equation, and Z_i are the instrumental variables that appear as regressors in the i th equation. Let N_i be the number of variables in Y_i and Z_i .

Let $v_i = y_i - Y_i \hat{\beta}_i$. Let Z represent all instrumental variables, T be the total number of observations, and K be the total number of instrumental variables. Define \hat{l} as follows:

$$\hat{l} = \frac{v_i' (\mathbf{I} - Z_i (Z_i' Z_i)^{-1} Z_i') v_i}{v_i' (\mathbf{I} - Z (Z' Z)^{-1} Z') v_i}$$

Then the test statistic

$$\frac{T - K}{K - N_i} (\hat{l} - 1)$$

is distributed approximately as an F with $K - N_i$ and $T - K$ degrees of freedom. See Basmann (1960) for more information.

Fuller's Modification to LIML

The ALPHA= option in the PROC SYSLIN and MODEL statements parameterizes Fuller's modification to LIML. This modification is $k = \gamma - (\alpha/(n - g))$, where α is the value of the ALPHA= option, γ is the LIML k value, n is the number of observations, and g is the number of predetermined variables. Fuller's modification is not used unless the ALPHA= option is specified. See Fuller (1977) for more information.

Missing Values

Observations that have a missing value for any variable in the analysis are excluded from the computations.

OUT= Data Set

The output SAS data set produced by the OUT= option in the PROC SYSLIN statement contains all the variables in the input data set and the variables that contain predicted values and residuals specified by OUTPUT statements.

The residuals are computed as actual values minus predicted values. Predicted values never use lags of other predicted values, as would be desirable for dynamic simulation. For these applications, PROC SIMLIN is available to predict or simulate values from the estimated equations.

OUTEST= Data Set

The OUTEST= option produces a TYPE=EST output SAS data set that contains estimates from the regressions. The variables in the OUTEST= data set are as follows:

BY variables	identifies the BY statement variables that are included in the OUTEST= data set.
TYPE	identifies the estimation type for the observations. The _TYPE_ value INST indicates first-stage regression estimates. Other values indicate the estimation method used: 2SLS indicates two-stage least squares results, 3SLS indicates three-stage least squares results, LIML indicates limited information maximum likelihood results, and so forth. Observations added by IDENTITY statements have the _TYPE_ value IDENTITY.
STATUS	identifies the convergence status of the estimation. _STATUS_ equals 0 when convergence criteria are met. Otherwise, _STATUS_ equals 1 when the estimation converges with a note, 2 when it converges with a warning, or 3 when it fails to converge.
MODEL	identifies the model label. The model label is the label specified in the MODEL statement or the dependent variable name if no label is specified. For first-stage regression estimates, _MODEL_ has the value FIRST.
DEPVAR	identifies the name of the dependent variable for the model.
NAME	identifies the names of the regressors for the rows of the covariance matrix, if the COVOUT option is specified. _NAME_ has a blank value for the parameter estimates observations. The _NAME_ variable is not included in the OUTEST= data set unless the COVOUT option is used to output the covariance of parameter estimates matrix.
SIGMA	contains the root mean squared error for the model, which is an estimate of the standard deviation of the error term. The _SIGMA_ variable contains the same values reported as Root MSE in the printed output.
INTERCEPT	identifies the intercept parameter estimates.
regressors	identifies the regressor variables from all the MODEL statements that are included in the OUTEST= data set. Variables used in IDENTIFY statements are also included in the OUTEST= data set.

The parameter estimates are stored under the names of the regressor variables. The intercept parameters are stored in the variable INTERCEPT. The dependent variable of the model is given a coefficient of -1 . Variables that are not in a model have missing values for the OUTEST= observations for that model.

Some estimation methods require computation of preliminary estimates. All estimates computed are output to the OUTEST= data set. For each BY group and each estimation, the OUTEST= data set contains one observation for each MODEL or IDENTITY statement. Results for different estimations are identified by the _TYPE_ variable.

For example, consider the following statements:

```
proc syslin data=a outest=est 3sls;
  by b;
  endogenous y1 y2;
  instruments x1-x4;
  model y1 = y2 x1 x2;
  model y2 = y1 x3 x4;
  identity x1 = x3 + x4;
run;
```

The 3SLS method requires both a preliminary 2SLS stage and preliminary first-stage regressions for the endogenous variable. The OUTEST= data set thus contains three different kinds of estimates. The observations for the first-stage regression estimates have the `_TYPE_` value INST. The observations for the 2SLS estimates have the `_TYPE_` value 2SLS. The observations for the final 3SLS estimates have the `_TYPE_` value 3SLS.

Since there are two endogenous variables in this example, there are two first-stage regressions and two `_TYPE_=INST` observations in the OUTEST= data set. Since there are two model statements, there are two OUTEST= observations with `_TYPE_=2SLS` and two observations with `_TYPE_=3SLS`. In addition, the OUTEST= data set contains an observation with the `_TYPE_` value IDENTITY that contains the coefficients specified by the IDENTITY statement. All these observations are repeated for each BY group in the input data set defined by the values of the BY variable B.

When the COVOUT option is specified, the estimated covariance matrix for the parameter estimates is included in the OUTEST= data set. Each observation for parameter estimates is followed by observations that contain the rows of the parameter covariance matrix for that model. The row of the covariance matrix is identified by the variable `_NAME_`. For observations that contain parameter estimates, `_NAME_` is blank. For covariance observations, `_NAME_` contains the regressor name for the row of the covariance matrix and the regressor variables contain the covariances.

See [Example 29.1](#) for an example of the OUTEST= data set.

OUTSSCP= Data Set

The OUTSSCP= option produces a TYPE=SSCP output SAS data set that contains sums of squares and cross products. The data set contains all variables used in the MODEL, IDENTITY, and VAR statements. Observations are identified by the variable `_NAME_`.

The OUTSSCP= data set can be useful when a large number of observations are to be explored in many different SYSLIN runs. The sum-of-squares-and-crossproducts matrix can be saved with the OUTSSCP= option and used as the DATA= data set on subsequent SYSLIN runs. This is much less expensive computationally because PROC SYSLIN never reads the original data again. In the step that creates the OUTSSCP= data set, include in the VAR statement all the variables you expect to use.

Printed Output

The printed output produced by the SYSLIN procedure is as follows:

1. If the SIMPLE option is used, a table of descriptive statistics is printed that shows the sum, mean, sum of squares, variance, and standard deviation for all the variables used in the models.
2. If the FIRST option is specified and an instrumental variables method is used, first-stage regression results are printed. The results show the regression of each endogenous variable on the variables in the INSTRUMENTS list.
3. The results of the second-stage regression are printed for each model. (See the following section “Printed Output for Each Model” on page 2005 for details.)
4. If a systems method like 3SLS, SUR, or FIML is used, the cross-equation error covariance matrix is printed. This matrix is shown four ways: the covariance matrix itself, the correlation matrix form, the inverse of the correlation matrix, and the inverse of the covariance matrix.
5. If a systems method like 3SLS, SUR, or FIML is used, the system weighted mean squared error and system weighted R^2 statistics are printed. The system weighted MSE and R^2 measure the fit of the joint model obtained by stacking all the models together and performing a single regression with the stacked observations weighted by the inverse of the model error variances.
6. If a systems method like 3SLS, SUR, or FIML is used, the final results are printed for each model.
7. If the REDUCED option is used, the reduced form coefficients are printed. These consist of the structural coefficient matrix for the endogenous variables, the structural coefficient matrix for the exogenous variables, the inverse of the endogenous coefficient matrix, and the reduced form coefficient matrix. The reduced form coefficient matrix is the product of the inverse of the endogenous coefficient matrix and the exogenous structural coefficient matrix.

Printed Output for Each Model

The results printed for each model include the analysis-of-variance table, the “Parameter Estimates” table, and optional items requested by TEST statements or by options in the MODEL statement.

The printed output produced for each model is described in the following.

The analysis-of-variance table includes the following:

- the model degrees of freedom, sum of squares, and mean square
- the error degrees of freedom, sum of squares, and mean square. The error mean square is computed by dividing the error sum of squares by the error degrees of freedom and is not affected by the VARDEF= option.
- the corrected total degrees of freedom and total sum of squares. Note that for instrumental variables methods, the model and error sums of squares do not add to the total sum of squares.

- the F ratio, labeled “F Value,” and its significance, labeled “PROB>F,” for the test of the hypothesis that all the nonintercept parameters are 0
- the root mean squared error. This is the square root of the error mean square.
- the dependent variable mean
- the coefficient of variation (CV) of the dependent variable
- the R^2 statistic. This R^2 is computed consistently with the calculation of the F statistic. It is valid for hypothesis tests but might not be a good measure of fit for models estimated by instrumental variables methods.
- the R^2 statistic adjusted for model degrees of freedom, labeled “Adj R-SQ”

The “Parameter Estimates” table includes the following:

- estimates of parameters for regressors in the model and the Lagrangian parameter for each restriction specified
- a degrees of freedom column labeled DF. Estimated model parameters have 1 degree of freedom. Restrictions have a DF of –1. Regressors or restrictions dropped from the model due to collinearity have a DF of 0.
- the standard errors of the parameter estimates
- the t statistics, which are the parameter estimates divided by the standard errors
- the significance of the t tests for the hypothesis that the true parameter is 0, labeled “Pr > |t|.” As previously noted, the significance tests are strictly valid in finite samples only for OLS estimates but are asymptotically valid for the other methods.
- the standardized regression coefficients, if the STB option is specified. This is the parameter estimate multiplied by the ratio of the standard deviation of the regressor to the standard deviation of the dependent variable.
- the labels of the regressor variables or restriction labels

In addition to the analysis-of-variance table and the “Parameter Estimates” table, the results printed for each model can include the following:

- If TEST statements are specified, the test results are printed.
- If the DW option is specified, the Durbin-Watson statistic and first-order autocorrelation coefficient are printed.
- If the OVERID option is specified, the results of Basmann’s test for overidentifying restrictions are printed.
- If the PLOT option is used, plots of residual against each regressor are printed.

- If the COVB or CORRB options are specified, the results for each model also include the covariance or correlation matrix of the parameter estimates. For systems methods like 3SLS and FIML, the COVB and CORB output is printed for the whole system after the output for the last model, instead of separately for each model.

The third-stage output for 3SLS, SUR, IT3SLS, ITSUR, and FIML does not include the analysis-of-variance table. When a systems method is used, the second-stage output does not include the optional output, except for the COVB and CORRB matrices.

ODS Table Names

PROC SYSLIN assigns a name to each table it creates. You can use these names to reference the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. If the estimation method used is 3SLS, IT3SLS, ITSUR or SUR, you can obtain tables by specifying ODS OUTPUT CorrResiduals, InvCorrResiduals, InvCovResiduals.

Table 29.2 ODS Tables Produced in PROC SYSLIN

ODS Table Name	Description	Option
ANOVA	Summary of the SSE, MSE for the equations	default
AugXPXMat	Model crossproducts	XPX or USSCP
AutoCorrStat	Autocorrelation statistics	DW
ConvergenceStatus	Convergence status	default
CorrB	Correlations of parameters	CORRB
CorrResiduals	Correlations of residuals	
CovB	Covariance of parameters	COVB
CovResiduals	Covariance of residuals	
EndoMat	Endogenous variables	REDUCED
ExogMat	Exogenous variables	REDUCED
FitStatistics	Statistics of fit	default
InvCorrResiduals	Inverse correlations of residuals	
InvCovResiduals	Inverse covariance of residuals	
InvEndoMat	Inverse endogenous variables	REDUCED
InvXPX	$X'X$ inverse for system	I
IterHistory	Iteration printing	ITPRINT
MissingValues	Missing values generated by the program	default
ModelVars	Name and label for the model	default
ParameterEstimates	Parameter estimates	default
RedMat	Reduced form	REDUCED
SimpleStatistics	Descriptive statistics	SIMPLE
SSCP	Model crossproducts	XPX or USSCP
TestResults	Test for overidentifying restrictions	
Weight	Weighted model statistics	

ODS Graphics

This section describes the use of ODS for creating graphics with the SYSLIN procedure.

ODS Graph Names

PROC SYSLIN assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when you use ODS. The names are listed in [Table 29.3](#).

To request these graphs, you must specify the ODS GRAPHICS statement.

Table 29.3 ODS Graphics Produced by PROC SYSLIN

ODS Graph Name	Plot Description

Examples: SYSLIN Procedure

Example 29.1: Klein's Model I Estimated with LIML and 3SLS

This example uses PROC SYSLIN to estimate the classic Klein Model I. For a discussion of this model, see Theil (1971). The following statements read the data.

```
*-----Klein's Model I-----*
| By L.R. Klein, Economic Fluctuations in the United States, 1921-1941 |
| (1950), NY: John Wiley.  A macro-economic model of the U.S. with   |
| three behavioral equations, and several identities. See Theil, p.456. |
*-----*
data klein;

```

The following statements estimate the Klein model using the limited information maximum likelihood method. In addition, the parameter estimates are written to a SAS data set with the OUTEST= option.

```

proc syslin data=klein outest=b liml;
  endogenous c p w i x wsum k y;
  instruments klag plag xlag wp g t yr;
  consume: model c = p plag wsum;
  invest:  model i = p plag klag;
  labor:   model w = x xlag yr;
run;

proc print data=b;
run;

```

The PROC SYSLIN estimates are shown in [Output 29.1.1](#) through [Output 29.1.3](#).

Example 29.2: Grunfeld's Model Estimated with SUR

The following example was used by Zellner in his classic 1962 paper on seemingly unrelated regressions. Different stock prices often move in the same direction at a given point in time. The SUR technique might provide more efficient estimates than OLS in this situation.

The following statements read the data. (The prefix GE stands for General Electric and WH stands for Westinghouse.)

```
*-----Zellner's Seemingly Unrelated Technique-----*
| A. Zellner, "An Efficient Method of Estimating Seemingly |
| Unrelated Regressions and Tests for Aggregation Bias," |
| JASA 57(1962) pp.348-364 |
| |
| J.C.G. Boot, "Investment Demand: an Empirical Contribution |
| to the Aggregation Problem," IER 1(1960) pp.3-30. |
| |
| Y. Grunfeld, "The Determinants of Corporate Investment," |
| Unpublished thesis, Chicago, 1958 |

Example 29.3: Illustration of ODS Graphics

This example illustrates the use of ODS graphics. This is a continuation of the section “[Example 29.1: Klein’s Model I Estimated with LIML and 3SLS](#)” on page 2008. These graphical displays are requested by specifying the ODS GRAPHICS statement before running PROC SYSLIN. For information about the graphics available in the SYSLIN procedure, see the section “[ODS Graphics](#)” on page 2008.

The following statements show how to generate ODS graphics plots with the SYSLIN procedure. The plots of residuals for each one of the equations in the model are displayed in [Figure 29.3.1](#) through [Figure 29.3.3](#).

```

Overview: TCOUNTREG Procedure

The TCOUNTREG procedure is an experimental version of the COUNTREG procedure. The main difference of the new procedure is the addition of panel estimation and variable selection capabilities.

The TCOUNTREG (count regression) procedure analyzes regression models in which the dependent variable takes nonnegative integer or count values. The dependent variable is usually an *event count*, which refers to the number of times an event occurs. For example, an event count might represent the number of ship accidents per year for a given fleet. In count regression, the conditional mean $E(y_i | x_i)$ of the dependent variable y_i is assumed to be a function of a vector of covariates x_i .

The Poisson (log-linear) regression model is the most basic model that explicitly takes into account the nonnegative integer-valued aspect of the outcome. With this model, the probability of an event count is determined by a Poisson distribution, where the conditional mean of the distribution is a function of a vector of covariates. However, the basic Poisson regression model is limited because it forces the conditional mean of the outcome to equal the conditional variance. This assumption is often violated in real-life data. Negative binomial regression is an extension of Poisson regression in which the conditional variance can exceed the conditional mean. Also, an often encountered characteristic of count data is that the number of zeros in the sample exceeds the number of zeros predicted by either the Poisson or negative binomial model. Zero-inflated Poisson (ZIP) and zero-inflated negative binomial (ZINB) models explicitly model the production of zero counts to account for excess zeros and also enable the conditional variance of the outcome to differ from the conditional mean.

Under zero-inflated models, additional zeros occur with probability φ_i , which is determined by a separate model, $\varphi_i = F(z_i' \gamma)$, where F is the normal or logistic distribution function that results in a probit or logistic model and z_i is a set of covariates.

PROC TCOUNTREG supports the following models for count data:

- Poisson regression
- negative binomial regression with quadratic (NEGBIN2) and linear (NEGBIN1) variance functions (Cameron and Trivedi 1986)
- zero-inflated Poisson (ZIP) model (Lambert 1992)
- zero-inflated negative binomial (ZINB) model
- fixed effects and random effects Poisson models for panel data
- fixed effects and random effects negative binomial models for panel data

In recent years, count data models have been used extensively in economics, political science, and sociology. For example, Hausman, Hall, and Griliches (1984) examine the effects of research and development expenditures on the number of patents received by U.S. companies. Cameron and Trivedi (1986) study factors that affect the number of doctor visits. Greene (1994) studies the number of derogatory reports to a credit reporting agency for a group of credit card applicants. As a final example, Long (1997) analyzes the number of doctoral publications in the final three years of Ph.D. studies.

The TCOUNTREG procedure uses maximum likelihood estimation. When a model with a dependent count variable is estimated using linear ordinary least squares (OLS) regression, the count nature of the dependent variable is ignored. This can lead to negative predicted counts and to parameter estimates with undesirable properties in terms of statistical efficiency, consistency, and unbiasedness unless the mean of the counts is high, in which case the Gaussian approximation and linear regression might be satisfactory.

Getting Started: TCOUNTREG Procedure

The TCOUNTREG procedure is similar in use to other regression model procedures in the SAS System. For example, the following statements are used to estimate a Poisson regression model:

```
proc tcountreg data=one ;
    model y = x / dist=poisson ;
run;
```

The response variable *y* is numeric and has nonnegative integer values. To allow for variance greater than the mean, specify the DIST=NEGBIN option to fit the negative binomial model instead of the Poisson.

The following example illustrates the use of PROC TCOUNTREG. The data are taken from Long (1997) and can be found in the SAS/ETS Sample Library. This study examines how factors such as gender (*fem*), marital status (*mar*), number of young children (*kid5*), prestige of the graduate program (*phd*), and number of articles published by a scientist's mentor (*ment*) affect the number of articles (*art*) published by the scientist.

The first 10 observations are shown in [Figure 30.1](#).

Figure 30.1 Article Count Data

Obs	art	fem	mar	kid5	phd	ment
1	3	0	1	2	1.38000	8.0000
2	0	0	0	0	4.29000	7.0000
3	4	0	0	0	3.85000	47.0000
4	1	0	1	1	3.59000	19.0000
5	1	0	1	0	1.81000	0.0000
6	1	0	1	1	3.59000	6.0000
7	0	0	1	1	2.12000	10.0000
8	0	0	1	0	4.29000	2.0000
9	3	0	1	2	2.58000	2.0000
10	3	0	1	1	1.80000	4.0000

The following SAS statements estimate the Poisson regression model:

```
proc tcountreg data=long97data;
  model art = fem mar kid5 phd ment / dist=poisson;
run;
```

The “Model Fit Summary” table, shown in [Figure 30.2](#), lists several details about the model. By default, the TCOUNTREG procedure uses the Newton-Raphson optimization technique. The maximum log-likelihood value is shown, in addition to two information measures, Akaike’s information criterion (AIC) and Schwarz’s Bayesian information criterion (SBC), which can be used to compare competing Poisson models. Smaller values of these criteria indicate better models.

Figure 30.2 Estimation Summary Table for a Poisson Regression

The TCOUNTREG Procedure	
Model Fit Summary	
Dependent Variable	art
Number of Observations	915
Data Set	WORK.LONG97DATA
Model	Poisson
Optimization Method	Newton-Raphson
Log Likelihood	-1651
Maximum Absolute Gradient	3.5741E-9
Number of Iterations	5
AIC	3314
SBC	3343

The parameter estimates of the model and their standard errors are shown in [Figure 30.3](#). All covariates are significant predictors of the number of articles, except for the prestige of the program (phd), which has a *p*-value of 0.6271.

Figure 30.3 Parameter Estimates of Poisson Regression

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.304617	0.102982	2.96	0.0031
fem	1	-0.224594	0.054614	-4.11	<.0001
mar	1	0.155243	0.061375	2.53	0.0114
kid5	1	-0.184883	0.040127	-4.61	<.0001
phd	1	0.012823	0.026397	0.49	0.6271
ment	1	0.025543	0.002006	12.73	<.0001

The following statements fit the negative binomial model. Although the Poisson model requires that the conditional mean and conditional variance be equal, the negative binomial model allows for overdispersion; that is, the conditional variance can exceed the conditional mean.

```
proc tcountreg data=long97data;
  model art = fem mar kid5 phd ment / dist=negbin(p=2) method=qn;
run;
```

The fit summary is shown in Figure 30.4, and parameter estimates are listed in Figure 30.5.

Figure 30.4 Estimation Summary Table for a Negative Binomial Regression

The TCOUNTREG Procedure	
Model Fit Summary	
Dependent Variable	art
Number of Observations	915
Data Set	WORK.LONG97DATA
Model	NegBin
Optimization Method	Quasi-Newton
Log Likelihood	-1561
Maximum Absolute Gradient	1.75584E-6
Number of Iterations	16
AIC	3136
SBC	3170

Figure 30.5 Parameter Estimates of Negative Binomial Regression

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.256144	0.138560	1.85	0.0645
fem	1	-0.216418	0.072672	-2.98	0.0029
mar	1	0.150489	0.082106	1.83	0.0668
kid5	1	-0.176415	0.053060	-3.32	0.0009
phd	1	0.015271	0.036040	0.42	0.6718
ment	1	0.029082	0.003470	8.38	<.0001
_Alpha	1	0.441620	0.052967	8.34	<.0001

The parameter estimate for _Alpha of 0.4416 is an estimate of the dispersion parameter in the negative binomial distribution. A t test for the hypothesis $H_0 : \alpha = 0$ is provided. It is highly significant, indicating overdispersion ($p < 0.0001$).

The null hypothesis $H_0 : \alpha = 0$ can be also tested against the alternative $\alpha > 0$ by using the likelihood ratio test, as described by Cameron and Trivedi (1998, pp. 45, 77–78). The likelihood ratio test statistic is equal to $-2(\mathcal{L}_P - \mathcal{L}_{NB}) = -2(-1651 + 1561) = 180$, where \mathcal{L}_P and \mathcal{L}_{NB} are the log likelihoods for the Poisson and negative binomial models, respectively. The likelihood ratio test is highly significant, providing strong evidence of overdispersion.

Syntax: TCOUNTREG Procedure

The following statements are available in the TCOUNTREG procedure:

```

PROC TCOUNTREG < options > ;
  BOUNDS bound1 < , bound2 ... > ;
  BY variables ;
  CLASS variables ;
  FREQ variable ;
  ID variable ;
  INIT initvalue1 < , initvalue2 ... > ;
  MODEL dependent = < regressors > < / options > ;
  NLOPTIONS < options > ;
  OUTPUT < OUT=SAS-data-set > < output-options > ;
  RESTRICT restriction1 < , restriction2 ... > ;
  WEIGHT variable < / options > ;
  ZEROMODEL dependent variable ~ < zero-inflated regressors > < / options > ;

```

You can specify only one MODEL statement. The CLASS statement must precede the MODEL statement. If you include the ZEROMODEL statement, it must appear after the MODEL statement. If you specify more than one FREQ or WEIGHT statement, the variable specified in the first instance is used.

Functional Summary

Table 30.1 summarizes statements and options used with the TCOUNTREG procedure.

Table 30.1 TCOUNTREG Functional Summary

Description	Statement	Option
Data Set Options		
Specifies the input data set	TCOUNTREG	DATA=
Writes parameter estimates to an output data set	TCOUNTREG	OUTEST=
Requests that the procedure produce graphics via the Output Delivery System	TCOUNTREG	PLOTS=
Writes estimates of $\mathbf{x}_i' \boldsymbol{\beta}$ and $\mathbf{z}_i' \boldsymbol{\gamma}$ to an output data set	OUTPUT	OUT=
Declaring the Role of Variables		
Specifies BY-group processing	BY	
Specifies classification variables	CLASS	
Specifies a frequency variable	FREQ	
Specifies a weight variable	WEIGHT	
Specifies the ID variable for panel data analysis	ID	
Printing Control Options		
Prints the correlation matrix of the estimates	MODEL	CORRB

Description	Statement	Option
Prints the covariance matrix of the estimates	MODEL	COVB
Prints a summary iteration listing	MODEL	ITPRINT
Suppresses the normal printed output	TCOUNTREG	NOPRINT
Requests all printing options	MODEL	PRINTALL
Options to Control the Optimization Process		
Specifies maximum number of iterations allowed	MODEL	MAXITER=
Selects the iterative minimization method to use	TCOUNTREG	METHOD=
Sets boundary restrictions on parameters	BOUNDS	
Sets initial values for parameters	INIT	
Sets linear restrictions on parameters	RESTRICT	
Specifies the optimization options	NLOPTIONS	See Chapter 6, “Non-linear Optimization Methods”
Model Estimation Options		
Specifies the type of model	MODEL	DIST=
Specifies the type of model	TCOUNTREG	DIST=
Specifies the type of covariance matrix	MODEL	COVEST=
Specifies the type of error components model for panel data	MODEL	ERRORCOMP=
Suppresses the intercept parameter	MODEL	NOINT
Specifies the offset variable	MODEL	OFFSET=
Specifies the zero-inflated offset variable	ZEROMODEL	OFFSET=
Specifies the zero-inflated link function	ZEROMODEL	LINK=
Specifies variable selection	MODEL	SELECT=()
Output Control Options		
Includes covariances in the OUTEST= data set	TCOUNTREG	COVOUT
Outputs the probability of response variable taking the current value	OUTPUT	PROB=
Outputs probabilities for particular response values	OUTPUT	PROBCOUNT()
Outputs expected value of response variable	OUTPUT	PRED=
Outputs estimates of $\mathbf{XBeta} = \mathbf{x}_i' \boldsymbol{\beta}$	OUTPUT	XBETA=
Outputs estimates of $\mathbf{ZGamma} = \mathbf{z}_i' \boldsymbol{\gamma}$	OUTPUT	ZGAMMA=
Outputs the probability of the response variable taking a zero value as a result of the zero-generating process	OUTPUT	PROBZERO=

PROC TCOUNTREG Statement

PROC TCOUNTREG < options > ;

The following options can be used in the PROC TCOUNTREG statement:

Data Set Options

DATA=SAS-data-set

specifies the input SAS data set. If the DATA= option is not specified, PROC TCOUNTREG uses the most recently created SAS data set.

Output Data Set Options

OUTEST=SAS-data-set

writes the parameter estimates to the specified output data set.

COVOUT

writes the covariance matrix for the parameter estimates to the OUTEST= data set. This option is valid only if the OUTEST= option is specified.

Printing Options

NOPRINT

suppresses all printed output.

CORRB

prints the correlation matrix of the parameter estimates. This option can also be specified in the MODEL statement.

COVB

prints the covariance matrix of the parameter estimates. This option can also be specified in the MODEL statement.

Estimation Control Options

COVEST=value

specifies the type of covariance matrix of the parameter estimates. The quasi-maximum-likelihood estimates are computed with COVEST=QML. The default is COVEST=HESSIAN. The supported covariance types are as follows:

OP	specifies the covariance from the outer product matrix.
HESSIAN	specifies the covariance from the Hessian matrix.
QML	specifies the covariance from the outer product and Hessian matrices.

Plot Control Options

PLOTS<(global-plot-options)> < = specific-plot-options>

requests that the TCOUNTREG procedure produce statistical graphics via the Output Delivery System, provided that the ODS GRAPHICS statement has been specified. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*). The *global-plot-options* apply to all relevant plots that are generated by the TCOUNTREG procedure.

You can specify the following *global-plot-options*:

ONLY

suppresses the default plots. Only the plots specifically requested are produced.

UNPACKPANEL

UNPACK

displays each graph separately. (By default, some graphs can appear together in a single panel.)

COUNTS(value1 <value2...>)

supplies the plots PREDPROB and PREDPROFILE with particular values of the response variable. Each value should be a nonnegative integer. Nonintegers are rounded to the nearest integer. The *value* can also be a list of the form X TO Y BY Z. For example, CNTLVLS(0 1 2 TO 10 BY 2 15) specifies plotting for counts 0, 1, 2, 4, 6, 8, 10, and 15.

You can specify the following *specific-plot-options*:

ALL

requests that all plots appropriate for the particular analysis be produced.

DISPERSION

produces the overdispersion diagnostic plot.

PREDPROB

produces the overall predictive probabilities of the specified count levels. You must also specify CNTLVLS in *global-plot-options*.

PREDPROFILE | PREDPRO

produces the predictive probability profiles of specified count levels against model regressors. The regressor on the X axis is varied whereas all other regressors are fixed at the mean of the observed data set.

PROFILELIKE

produces the profile likelihood functions of the model parameters, the model parameter on the X axis is varied whereas all other parameters are fixed at their estimated maximum likelihood estimates.

ZEROPROFILE | ZPPRO

produces the probability profiles of zero-inflation process selection and zero count prediction against model regressors. The regressor on the X axis is varied whereas all other regressors are fixed at the mean of the observed data set.

NONE

suppresses all plots.

Optimization Process Control Options

PROC TCOUNTREG uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. All the NLO options are available in the NLOPTIONS statement. For details, see the “[NLOPTIONS Statement](#)” on page 2038. In addition, the following option is supported in the PROC TCOUNTREG statement:

METHOD=*value*

specifies the iterative minimization method to use. The default is METHOD=NRA.

CONGRA	specifies the conjugate-gradient method.
DBLDOG	specifies the double-dogleg method.
NMSIMP	specifies Nelder-Mead simplex method.
NRA	specifies the Newton-Raphson method.
NRRIDG	specifies the Newton-Raphson ridge method.
QN	specifies the quasi-Newton method.
TR	specifies the trust region method.

BOUNDS Statement

BOUNDS *bound1* <, *bound2* ... > ;

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. BOUNDS statement constraints refer to the parameters estimated by the TCOUNTREG procedure. You can specify any number of BOUNDS statements as follows.

Each *bound* is composed of parameter names, constants, and inequality operators as follows:

item operator item < *operator item operator item* ... >

Each *item* is a constant, a parameter name, or a list of parameter names. Each *operator* is <, >, <=, or >=. Parameter names are as shown in the ESTIMATE column of the “Parameter Estimates” table or can be seen in the OUTEST= data set.

You can use both the BOUNDS statement and the RESTRICT statement to impose boundary constraints; however, the BOUNDS statement provides a simpler syntax for specifying these kinds of constraints. See also the section “[RESTRICT Statement](#)” on page 2039.

The following BOUNDS statement constrains the estimates of the parameter for *z* to be negative, the parameters for *x1* through *x10* to be between zero and one, and the parameter for *x1* in the zero-inflation model to be less than one:

```
bounds z < 0,
       0 < x1-x10 < 1,
       Inf_x1 < 1;
```

BY Statement

BY *variables* ;

A BY statement can be used with PROC TCOUNTREG to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the input data set should be sorted in the order of the BY variables.

CLASS Statement

CLASS *variables* ;

The CLASS statement names the classification variables that are used to group (classify) data in the analysis. Classification variables can be either character or numeric.

Class levels are determined from the formatted values of the CLASS *variables*. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the *SAS Language Reference: Dictionary* for details. The CLASS statement must precede the MODEL statement.

FREQ Statement

FREQ *variable* ;

The FREQ statement specifies a variable whose values represent the frequency of occurrence of each observation. PROC TCOUNTREG treats each observation as if it appears n times, where n is the value of the FREQ variable for the observation. If the frequency value is not an integer, it is truncated to an integer; if it is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1. If you specify more than one FREQ statement, then the first statement is used.

ID Statement

ID *variable* ;

The ID statement must be used with PROC TCOUNTREG to specify an identification variable when a panel data model is estimated. The identification variable is a cross section ID variable.

INIT Statement

INIT *initvalue1* < , *initvalue2* ... > ;

The INIT statement sets initial values for parameters in the optimization.

Each *initvalue* is written as a parameter or parameter list, followed by an optional equal sign (=), followed by a number:

parameter <=> number

For continuous regressors, the names of the parameters are the same as the corresponding variables. For a regressor that is a CLASS variable, the parameter name combines the corresponding CLASS variable name with the variable level. For interaction and nested regressors, the parameter names combine the names of each regressor. The names of the parameters can be seen in the OUTEST= data set. By default, initial values are determined by OLS regression. Initial values can be displayed with the ITPRINT option in the PROC statement.

MODEL Statement

MODEL *dependent* = <regressors> </ options> ;

The MODEL statement specifies the dependent variable and independent covariates (regressors) for the regression model. If you specify no regressors, PROC TCOUNTREG fits a model that contains only an intercept. The dependent count variable should take on only nonnegative integer values in the input data set. PROC TCOUNTREG rounds any positive noninteger count values to the nearest integer. PROC TCOUNTREG ignores any observations with a negative count.

Only one MODEL statement can be specified. The following options can be used in the MODEL statement after a slash (/).

DIST=*value*

specifies a type of model to be analyzed. If you specify this option in both the MODEL statement and the PROC TCOUNTREG statement, then only the value in the MODEL statement is used. The following model types are supported:

POISSON | P specifies a Poisson regression model.

NEGBIN(P=1) specifies a negative binomial regression model with a linear variance function.

NEGBIN(P=2) | NEGBIN specifies a negative binomial regression model with a quadratic variance function.

ZIPOISSON | ZIP specifies a zero-inflated Poisson regression. The ZEROMODEL statement must be specified when this model type is specified.

ZINEGBIN | ZINB specifies a zero-inflated negative binomial regression. The ZEROMODEL statement must be specified when this model type is specified.

ERRORCOMP=*value*

specifies a type of conditional panel model to be analyzed. The following model types are supported:

FIXED specifies a fixed-effect error component regression model.

RANDOM specifies a random-effect error component regression model.

NOINT

suppresses the intercept parameter.

OFFSET=*variable*

specifies a variable in the input data set to be used as an offset variable. The offset variable appears as a covariate in the model with its parameter restricted to 1. The offset variable cannot be the response variable, the zero-inflation offset variable (if any), or one of the explanatory variables. The “Model Fit Summary” table gives the name of the data set variable used as the offset variable; it is labeled as “Offset.”

SELECT=(INFO(option) | PEN(option))

specifies variable selection.

SELECT= INFO specifies that the variable selection method is based on an information criterion. For more information, see the section “[Variable Selection Using an Information Criterion](#)” on page 2053. The following *options* are available for SELECT=INFO:

DIRECTION=FORWARD | BACKWARD

specifies the searching algorithm used in the variable selection method. The default is FORWARD.

CRITER=AIC | SBC

specifies the information criterion used for the variable selection. The default is SBC.

MAXSTEPS=*value*

specifies the maximum number of steps allowed in the search algorithm. The default is infinite; that is, the algorithm does not stop until the stopping criterion is satisfied.

LSTOP=*value*

specifies the stopping criterion. *value* represents the percentage of decrease or increase in the AIC or SBC that is required for the algorithm to proceed; it must be a positive number less than 1. The default is zero.

SELECT=PEN specifies that the variable selection method is penalized likelihood. For more information, see the section “[Variable Selection Using Penalized Likelihood](#)” on page 2053. The following *options* are available for SELECT=PEN:

LLASTEPS=*value*

specifies the maximum number of iterations in the algorithm of local linear approximations. The default is 5.

GCVLENGTH=*value*

specifies the number of different values that is used for the generalized cross-validation (GCV) tuning parameter. The value corresponds to λ in the computations described in the section “[Variable Selection Using Penalized Likelihood](#)” on page 2053. The default value is 20.

GCV

specifies that the generalized cross-validation (GCV) approach be used. For more information, see the section “[The GCV Approach](#)” on page 2055.

GCV1

specifies that the GCV1 approach be used. For more information, see the section “[The GCV1 Approach](#)” on page 2056. GCV1 is the default.

Printing Options

CORRB

prints the correlation matrix of the parameter estimates. The CORRB option can also be specified in the PROC TCOUNTREG statement.

COVB

prints the covariance matrix of the parameter estimates. The COVB can also be specified in the PROC TCOUNTREG statement.

ITPRINT

prints the objective function and parameter estimates at each iteration. The objective function is the negative log-likelihood function. The ITPRINT option can also be specified in the PROC TCOUNTREG statement.

PRINTALL

requests all printing options. The PRINTALL option can also be specified in the PROC TCOUNTREG statement.

NLOPTIONS Statement

NLOPTIONS < options > ;

The NLOPTIONS statement provides the options to control the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. For a list of all the options of the NLOPTIONS statement, see Chapter 6, “Nonlinear Optimization Methods.”

OUTPUT Statement

OUTPUT < OUT=SAS-data-set > < output-options > ;

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimates of $\mathbf{x}_i' \boldsymbol{\beta}$, the expected value of the response variable, and the probability of the response variable taking on the current value or other values that you specify. In a zero-inflated model, you can additionally request that the output data set contain the estimates of $\mathbf{z}_i' \boldsymbol{\gamma}$ and the probability that the response is zero as a result of the zero-generating process. Except for the probability of the current value, these statistics can be computed for all observations in which the regressors are not missing, even if the response is missing. By adding observations with missing response values to the input data set, you can compute these statistics for new observations or for settings of the regressors that are not present in the data without affecting the model fit.

You can specify only one OUTPUT statement. You can specify the following *output-options*:

OUT=SAS-data-set

names the output data set.

XBETA=name

names the variable that contains estimates of $\mathbf{x}_i' \boldsymbol{\beta}$.

PRED=name

names the variable that contains the predicted value of the response variable.

PROB=name

names the variable that contains the probability of the response variable taking the current value, $\Pr(Y = y_i)$.

PROBCOUNT(value1 <value2...>)

outputs the probability of the response variable taking particular values. Each value should be a nonnegative integer. Nonintegers are rounded to the nearest integer. *value* can also be a list of the form X TO Y BY Z. For example, PROBCOUNT(0 1 2 TO 10 BY 2 15) requests predicted probabilities for counts 0, 1, 2, 4, 5, 6, 8, 10, and 15. This option is not available for the fixed and random effect panel models.

ZGAMMA=name

names the variable that contains estimates of $\mathbf{z}_i' \boldsymbol{\gamma}$.

PROBZERO=name

names the variable that contains the value of φ_i , the probability of the response variable taking on the value of zero as a result of the zero-generating process. It is written to the output file only if the model is zero-inflated. This is not the overall probability of a zero response; that is provided by the PROBCOUNT(0) option.

RESTRICT Statement

RESTRICT *restriction1* <, *restriction2* ... > ;

The RESTRICT statement imposes linear restrictions on the parameter estimates. You can specify any number of RESTRICT statements.

Each *restriction* is written as an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

expression operator expression

The *operator* can be =, <, >, <=, or >=.

Restriction expressions can be composed of parameter names, constants, and the operators times (*), plus (+), and minus (−). The restriction expressions must be a linear function of the parameters. For continuous regressors, the names of the parameters are the same as the corresponding variables. For a regressor that is a CLASS variable, the parameter name combines the corresponding CLASS variable name with the variable level. For interaction and nested regressors, the parameter names combine the names of each regressor. The names of the parameters can be seen in the OUTEST= data set.

Lagrange multipliers are reported in the “Parameter Estimates” table for all the active linear constraints. They are identified with the names Restrict1, Restrict2, and so on. The probabilities of these Lagrange multipliers are computed using a beta distribution (LaMotte 1994). Nonactive (nonbinding) restrictions have no effect on the estimation results and are not noted in the output.

The following RESTRICT statement constrains the negative binomial dispersion parameter α to 1, which restricts the conditional variance to be $\mu + \mu^2$:

```
restrict _Alpha = 1;
```

WEIGHT Statement

WEIGHT *variable* </option> ;

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters. The log likelihood for each observation is multiplied by the corresponding weight variable value.

If the weight of an observation is nonpositive, that observation is not used in the estimation.

The following option can be added to the WEIGHT statement after a slash (/).

NONNORMALIZE

does not normalize the weights. By default, the weights are normalized so that they add up to the actual sample size. Weights w_i are normalized by multiplying them by $\frac{n}{\sum_{i=1}^n w_i}$, where n is the sample size. If the weights are required to be used as is, then specify the NONNORMALIZE option.

ZEROMODEL Statement

ZEROMODEL *dependent variable* ~ <zero-inflated regressors> </options> ;

The ZEROMODEL statement is required if either ZIP or ZINB is specified in the DIST= option in the MODEL statement. If ZIP or ZINB is specified, then the ZEROMODEL statement must follow immediately after the MODEL statement. The dependent variable in the ZEROMODEL statement must be the same as the dependent variable in the MODEL statement.

The zero-inflated (ZI) regressors appear in the equation that determines the probability (φ_i) of a zero count. Each of these q variables has a parameter to be estimated in the regression. For example, let \mathbf{z}_i' be the i th observation's $1 \times (q + 1)$ vector of values of the q ZI explanatory variables (w_0 is set to 1 for the intercept term). Then φ_i is a function of $\mathbf{z}_i' \boldsymbol{\gamma}$, where $\boldsymbol{\gamma}$ is the $(q + 1) \times 1$ vector of parameters to be estimated. (The ZI intercept is γ_0 ; the coefficients for the q ZI covariates are $\gamma_1, \dots, \gamma_q$.) If this option is omitted, then only the intercept term γ_0 is estimated. The “Parameter Estimates” table in the displayed output gives the estimates for the ZI intercept and ZI explanatory variables; they are labeled with the prefix “Inf_”. For example, the ZI intercept is labeled “Inf_intercept”. If you specify Age (a variable in your data set) as a ZI explanatory variable, then the “Parameter Estimates” table labels the corresponding parameter estimate “Inf_Age”.

The following options can be specified in the ZEROMODEL statement following a slash (/):

LINK=value

specifies the distribution function used to compute probability of zeros. The following distribution functions are supported:

LOGISTIC	specifies the logistic distribution.
NORMAL	specifies the standard normal distribution.

If this option is omitted, then the default ZI link function is logistic.

OFFSET=variable

specifies a variable in the input data set to be used as a zero-inflated (ZI) offset variable. The ZI offset variable is included as a term, with coefficient restricted to 1, in the equation that determines the probability (ϕ_i) of a zero count. The ZI offset variable cannot be the response variable, the offset variable (if any), or one of the explanatory variables. The name of the data set variable used as the ZI offset variable is displayed in the “Model Fit Summary” output, where it is labeled as “Inf_offset”.

Details: TCOUNTREG Procedure

Specification of Regressors

Each term in a model, called *regressor*, is a variable or combination of variables. Regressors are specified with a special notation that uses variable names and operators. There are two kinds of variables: *classification (CLASS) variables* and *continuous variables*. There are two primary operators: *crossing* and *nesting*. A third operator, the *bar operator*, is used to simplify effect specification.

In the SAS System, *classification (CLASS) variables* are declared in the **CLASS** statement. (They can also be called *categorical*, *qualitative*, *discrete*, or *nominal variables*.) Classification variables can be either *numeric* or *character*. The values of a classification variable are called *levels*. For example, the classification variable Sex has the levels “male” and “female.”

In a model, an independent variable that is not declared in the **CLASS** statement is assumed to be continuous. *Continuous variables*, which must be numeric, are used for covariates. For example, the heights and weights of subjects are continuous variables. A response variable is a *discrete count variable* and must also be numeric.

Types of Regressors

Seven different types of regressors are used in the TCOUNTREG procedure. In the following list, assume that A, B, C, D, and E are **CLASS** variables and that X1 and X2 are continuous variables:

- Regressors are specified by writing continuous variables by themselves: X1 X2.
- Polynomial regressors are specified by joining (crossing) two or more continuous variables with asterisks: X1*X1 X1*X2.
- Dummy regressors are specified by writing CLASS variables by themselves: A B C.
- Dummy interactions are specified by joining classification variables with asterisks: A*B B*C A*B*C.

- Nested regressors are specified by following a dummy variable or dummy interaction with a classification variable or list of classification variables enclosed in parentheses. The dummy variable or dummy interaction is nested within the regressor listed in parentheses: B(A) C(B*A) D*E(C*B*A). In this example, B(A) is read “B nested within A.”
- Continuous-by-class regressors are written by joining continuous variables and classification variables with asterisks: X1*A.
- Continuous-nesting-class regressors consist of continuous variables followed by a classification variable interaction enclosed in parentheses: X1(A) X1*X2(A*B).

One example of the general form of an effect that involves several variables is

$$X1*X2*A*B*C(D*E)$$

This example contains an interaction of continuous terms with classification terms that are nested within more than one classification variable. The continuous list comes first, followed by the dummy list, followed by the nesting list in parentheses. Note that asterisks can appear within the nested list but not immediately before the left parenthesis.

The **MODEL** statement and several other statements use these effects. Some examples of **MODEL** statements that use various kinds of effects are shown in the following table, where a, b, and c represent classification variables. Variables x and z are continuous.

Specification	Type of Model
<code>model y=x;</code>	Simple regression
<code>model y=x z;</code>	Multiple regression
<code>model y=x x*x;</code>	Polynomial regression
<code>model y=a;</code>	Regression with one classification variable
<code>model y=a b c;</code>	Regression with multiple classification variables
<code>model y=a b a*b;</code>	Regression with classification variables and their interactions
<code>model y=a b(a) c(b a);</code>	Regression with classification variables and their interactions
<code>model y=a x;</code>	Regression with both countibuous and classification variables
<code>model y=a x(a);</code>	Separate-slopes regression
<code>model y=a x x*a;</code>	Homogeneity-of-slopes regression

The Bar Operator

You can shorten the specification of a large factorial model by using the bar operator. For example, two ways of writing the model for a full three-way factorial model follow:

```
model Y = A B C A*B A*C B*C A*B*C;

model Y = A|B|C;
```

When the bar (|) is used, the right and left sides become effects, and the cross of them becomes an effect. Multiple bars are permitted. The expressions are expanded from left to right, using rules 2–4 given in Searle (1971, p. 390).

- Multiple bars are evaluated from left to right. For instance, $A|B|C$ is evaluated as follows:

$$\begin{aligned} A|B|C &\rightarrow \{A|B\}|C \\ &\rightarrow \{A\ B\ A*B\}|C \\ &\rightarrow A\ B\ A*B\ C\ A*C\ B*C\ A*B*C \end{aligned}$$

- Crossed and nested groups of variables are combined. For example, $A(B)|C(D)$ generates $A*C(B\ D)$, among other terms.
- Duplicate variables are removed. For example, $A(C)|B(C)$ generates $A*B(C\ C)$, among other terms, and the extra C is removed.
- Effects are discarded if a variable occurs on both the crossed and nested parts of an effect. For instance, $A(B)|B(D\ E)$ generates $A*B(B\ D\ E)$, but this effect is eliminated immediately.

You can also specify the maximum number of variables involved in any effect that results from bar evaluation by specifying that maximum number, preceded by an @ sign, at the end of the bar effect. For example, the specification $A|B|C@2$ would result in only those effects that contain two or fewer variables: in this case, $A\ B\ A*B\ C\ A*C$ and $B*C$.

More examples of using the | and @ operators follow:

$A C(B)$	is equivalent to	$A\ C(B)\ A*C(B)$
$A(B) C(B)$	is equivalent to	$A(B)\ C(B)\ A*C(B)$
$A(B) B(D\ E)$	is equivalent to	$A(B)\ B(D\ E)$
$A B(A) C$	is equivalent to	$A\ B(A)\ C\ A*C\ B*C(A)$
$A B(A) C@2$	is equivalent to	$A\ B(A)\ C\ A*C$
$A B C D@2$	is equivalent to	$A\ B\ A*B\ C\ A*C\ B*C\ D\ A*D\ B*D\ C*D$
$A*B(C*D)$	is equivalent to	$A*B(C\ D)$

Missing Values

Any observation in the input data set with a missing value for one or more of the regressors is ignored by PROC TCOUNTREG and not used in the model fit. PROC TCOUNTREG rounds any positive noninteger count values to the nearest integer. PROC TCOUNTREG ignores any observations with a negative count, a zero or negative weight, or a frequency less than 1.

If there are observations in the input data set with missing response values but with nonmissing regressors, PROC TCOUNTREG can compute several statistics and store them in an output data set by using the OUTPUT statement. For example, you can request that the output data set contain the estimates of $\mathbf{x}'_i\boldsymbol{\beta}$, the expected value of the response variable, and the probability of the response variable taking on values

that you specify. In a zero-inflated model, you can additionally request that the output data set contain the estimates of $\mathbf{z}'_i \boldsymbol{\gamma}$, and the probability that the response is zero as a result of the zero-generating process. The presence of such observations (with missing response values) does not affect the model fit.

Poisson Regression

The most widely used model for count data analysis is Poisson regression. This assumes that y_i , given the vector of covariates \mathbf{x}_i , is independently Poisson-distributed with

$$P(Y_i = y_i | \mathbf{x}_i) = \frac{e^{-\mu_i} \mu_i^{y_i}}{y_i!}, \quad y_i = 0, 1, 2, \dots$$

and the mean parameter (that is, the mean number of events per period) is given by

$$\mu_i = \exp(\mathbf{x}'_i \boldsymbol{\beta})$$

where $\boldsymbol{\beta}$ is a $(k + 1) \times 1$ parameter vector. (The intercept is β_0 ; the coefficients for the k regressors are β_1, \dots, β_k .) Taking the exponential of $\mathbf{x}'_i \boldsymbol{\beta}$ ensures that the mean parameter μ_i is nonnegative. It can be shown that the conditional mean is given by

$$E(y_i | \mathbf{x}_i) = \mu_i = \exp(\mathbf{x}'_i \boldsymbol{\beta})$$

The name *log-linear model* is also used for the Poisson regression model since the logarithm of the conditional mean is linear in the parameters:

$$\ln[E(y_i | \mathbf{x}_i)] = \ln(\mu_i) = \mathbf{x}'_i \boldsymbol{\beta}$$

Note that the conditional variance of the count random variable is equal to the conditional mean in the Poisson regression model:

$$V(y_i | \mathbf{x}_i) = E(y_i | \mathbf{x}_i) = \mu_i$$

The equality of the conditional mean and variance of y_i is known as *equidispersion*.

The marginal effect of a regressor is given by

$$\frac{\partial E(y_i | \mathbf{x}_i)}{\partial x_{ji}} = \exp(\mathbf{x}'_i \boldsymbol{\beta}) \beta_j = E(y_i | \mathbf{x}_i) \beta_j$$

Thus, a one-unit change in the j th regressor leads to a *proportional* change in the conditional mean $E(y_i | \mathbf{x}_i)$ of β_j .

The standard estimator for the Poisson model is the maximum likelihood estimator (MLE). Since the observations are independent, the log-likelihood function is written as

$$\mathcal{L} = \sum_{i=1}^N w_i (-\mu_i + y_i \ln \mu_i - \ln y_i!) = \sum_{i=1}^N w_i (-e^{\mathbf{x}'_i \boldsymbol{\beta}} + y_i \mathbf{x}'_i \boldsymbol{\beta} - \ln y_i!)$$

where w_i is defined as follows:

1	if neither the WEIGHT nor the FREQ statement is used.
W_i	where W_i are the nonnormalized values of the variable specified in the WEIGHT statement in which the NONNORMALIZE option is specified.
$\frac{n}{\sum_{i=1}^n W_i} W_i$	where W_i are the nonnormalized values of the variable specified in the WEIGHT statement.
F_i	where F_i are the values of the variable specified in the FREQ statement.
$W_i F_i$	if both the WEIGHT statement, without the NONNORMALIZE option, and the FREQ statement are specified.
$\frac{\sum_{i=1}^n F_i}{\sum_{i=1}^n F_i W_i} W_i F_i$	if both the FREQ and the WEIGHT statements are specified.

The gradient and the Hessian are, respectively,

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N w_i (y_i - \mu_i) \mathbf{x}_i = \sum_{i=1}^N w_i (y_i - e^{\mathbf{x}_i' \boldsymbol{\beta}}) \mathbf{x}_i$$

$$\frac{\partial^2 \mathcal{L}}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'} = - \sum_{i=1}^N w_i \mu_i \mathbf{x}_i \mathbf{x}_i' = - \sum_{i=1}^N w_i e^{\mathbf{x}_i' \boldsymbol{\beta}} \mathbf{x}_i \mathbf{x}_i'$$

The Poisson model has been criticized for its restrictive property that the conditional variance equals the conditional mean. Real-life data are often characterized by *overdispersion* (that is, the variance exceeds the mean). Allowing for overdispersion can improve model predictions since the Poisson restriction of equal mean and variance results in the underprediction of zeros when overdispersion exists. The most commonly used model that accounts for overdispersion is the negative binomial model.

Negative Binomial Regression

The Poisson regression model can be generalized by introducing an unobserved heterogeneity term for observation i . Thus, the individuals are assumed to differ randomly in a manner that is not fully accounted for by the observed covariates. This is formulated as

$$E(y_i | \mathbf{x}_i, \tau_i) = \mu_i \tau_i = e^{\mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i}$$

where the unobserved heterogeneity term $\tau_i = e^{\epsilon_i}$ is independent of the vector of regressors \mathbf{x}_i . Then the distribution of y_i conditional on \mathbf{x}_i and τ_i is Poisson with conditional mean and conditional variance $\mu_i \tau_i$:

$$f(y_i | \mathbf{x}_i, \tau_i) = \frac{\exp(-\mu_i \tau_i) (\mu_i \tau_i)^{y_i}}{y_i!}$$

Let $g(\tau_i)$ be the probability density function of τ_i . Then, the distribution $f(y_i | \mathbf{x}_i)$ (no longer conditional on τ_i) is obtained by integrating $f(y_i | \mathbf{x}_i, \tau_i)$ with respect to τ_i :

$$f(y_i | \mathbf{x}_i) = \int_0^\infty f(y_i | \mathbf{x}_i, \tau_i) g(\tau_i) d\tau_i$$

An analytical solution to this integral exists when τ_i is assumed to follow a gamma distribution. This solution is the negative binomial distribution. When the model contains a constant term, it is necessary to

assume that $E(e^{\epsilon_i}) = E(\tau_i) = 1$, in order to identify the mean of the distribution. Thus, it is assumed that τ_i follows a $\text{gamma}(\theta, \theta)$ distribution with $E(\tau_i) = 1$ and $V(\tau_i) = 1/\theta$,

$$g(\tau_i) = \frac{\theta^\theta}{\Gamma(\theta)} \tau_i^{\theta-1} \exp(-\theta \tau_i)$$

where $\Gamma(x) = \int_0^\infty z^{x-1} \exp(-z) dz$ is the gamma function and θ is a positive parameter. Then, the density of y_i given \mathbf{x}_i is derived as

$$\begin{aligned} f(y_i|\mathbf{x}_i) &= \int_0^\infty f(y_i|\mathbf{x}_i, \tau_i) g(\tau_i) d\tau_i \\ &= \frac{\theta^\theta \mu_i^{y_i}}{y_i! \Gamma(\theta)} \int_0^\infty e^{-(\mu_i + \theta)\tau_i} \tau_i^{\theta+y_i-1} d\tau_i \\ &= \frac{\theta^\theta \mu_i^{y_i} \Gamma(y_i + \theta)}{y_i! \Gamma(\theta) (\theta + \mu_i)^{\theta+y_i}} \\ &= \frac{\Gamma(y_i + \theta)}{y_i! \Gamma(\theta)} \left(\frac{\theta}{\theta + \mu_i} \right)^\theta \left(\frac{\mu_i}{\theta + \mu_i} \right)^{y_i} \end{aligned}$$

Making the substitution $\alpha = \frac{1}{\theta}$ ($\alpha > 0$), the negative binomial distribution can then be rewritten as

$$f(y_i|\mathbf{x}_i) = \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left(\frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \left(\frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}, \quad y_i = 0, 1, 2, \dots$$

Thus, the negative binomial distribution is derived as a gamma mixture of Poisson random variables. It has conditional mean

$$E(y_i|\mathbf{x}_i) = \mu_i = e^{\mathbf{x}_i' \boldsymbol{\beta}}$$

and conditional variance

$$V(y_i|\mathbf{x}_i) = \mu_i \left[1 + \frac{1}{\theta} \mu_i \right] = \mu_i [1 + \alpha \mu_i] > E(y_i|\mathbf{x}_i)$$

The conditional variance of the negative binomial distribution exceeds the conditional mean. Overdispersion results from neglected unobserved heterogeneity. The negative binomial model with variance function $V(y_i|\mathbf{x}_i) = \mu_i + \alpha \mu_i^2$, which is quadratic in the mean, is referred to as the NEGBIN2 model (Cameron and Trivedi 1986). To estimate this model, specify `DIST=NEGBIN(p=2)` in the `MODEL` statement. The Poisson distribution is a special case of the negative binomial distribution where $\alpha = 0$. A test of the Poisson distribution can be carried out by testing the hypothesis that $\alpha = \frac{1}{\theta_i} = 0$. A Wald test of this hypothesis is provided (it is the reported t statistic for the estimated α in the negative binomial model).

The log-likelihood function of the negative binomial regression model (NEGBIN2) is given by

$$\begin{aligned} \mathcal{L} &= \sum_{i=1}^N w_i \left\{ \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1}) - \ln(y_i!) \right. \\ &\quad \left. - (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta})) + y_i \ln(\alpha) + y_i \mathbf{x}_i' \boldsymbol{\beta} \right\} \end{aligned}$$

$$\Gamma(y+a)/\Gamma(a) = \prod_{j=0}^{y-1} (j+a)$$

if y is an integer. See “[Poisson Regression](#)” on page 2044 for the definition of w_i .

The gradient is

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N w_i \frac{y_i - \mu_i}{1 + \alpha \mu_i} \mathbf{x}_i$$

and

$$\frac{\partial \mathcal{L}}{\partial \alpha} = \sum_{i=1}^N w_i \left\{ -\alpha^{-2} \sum_{j=0}^{y_i-1} \frac{1}{(j + \alpha^{-1})} + \alpha^{-2} \ln(1 + \alpha \mu_i) + \frac{y_i - \mu_i}{\alpha(1 + \alpha \mu_i)} \right\}$$

Cameron and Trivedi (1986) consider a general class of negative binomial models with mean μ_i and variance function $\mu_i + \alpha \mu_i^p$. The NEGBIN2 model, with $p = 2$, is the standard formulation of the negative binomial model. Models with other values of p , $-\infty < p < \infty$, have the same density $f(y_i | \mathbf{x}_i)$ except that α^{-1} is replaced everywhere by $\alpha^{-1} \mu_i^{2-p}$. The negative binomial model NEGBIN1, which sets $p = 1$, has variance function $V(y_i | \mathbf{x}_i) = \mu_i + \alpha \mu_i$, which is linear in the mean. To estimate this model, specify `DIST=NEGBIN(p=1)` in the `MODEL` statement.

The log-likelihood function of the NEGBIN1 regression model is given by

$$\begin{aligned} \mathcal{L} = & \sum_{i=1}^N w_i \left\{ \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1} \exp(\mathbf{x}_i' \boldsymbol{\beta})) \right. \\ & \left. - \ln(y_i!) - (y_i + \alpha^{-1} \exp(\mathbf{x}_i' \boldsymbol{\beta})) \ln(1 + \alpha) + y_i \ln(\alpha) \right\} \end{aligned}$$

See the section “[Poisson Regression](#)” on page 2044 for the definition of w_i .

The gradient is

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \sum_{i=1}^N w_i \left\{ \left(\sum_{j=0}^{y_i-1} \frac{\mu_i}{(j\alpha + \mu_i)} \right) \mathbf{x}_i - \alpha^{-1} \ln(1 + \alpha) \mu_i \mathbf{x}_i \right\}$$

and

$$\frac{\partial \mathcal{L}}{\partial \alpha} = \sum_{i=1}^N w_i \left\{ - \left(\sum_{j=0}^{y_i-1} \frac{\alpha^{-1} \mu_i}{(j\alpha + \mu_i)} \right) - \alpha^{-2} \mu_i \ln(1 + \alpha) - \frac{(y_i + \alpha^{-1} \mu_i)}{1 + \alpha} + \frac{y_i}{\alpha} \right\}$$

Zero-Inflated Count Regression Overview

The main motivation for zero-inflated count models is that real-life data frequently display overdispersion and excess zeros. Zero-inflated count models provide a way of modeling the excess zeros in addition to allowing for overdispersion. In particular, for each observation, there are two possible data generation

processes. The result of a Bernoulli trial is used to determine which of the two processes is used. For observation i , Process 1 is chosen with probability φ_i and Process 2 with probability $1 - \varphi_i$. Process 1 generates only zero counts. Process 2 generates counts from either a Poisson or a negative binomial model. In general,

$$y_i \sim \begin{cases} 0 & \text{with probability } \varphi_i \\ g(y_i) & \text{with probability } 1 - \varphi_i \end{cases}$$

Therefore, the probability of $\{Y_i = y_i\}$ can be described as

$$\begin{aligned} P(y_i = 0 | \mathbf{x}_i) &= \varphi_i + (1 - \varphi_i)g(0) \\ P(y_i | \mathbf{x}_i) &= (1 - \varphi_i)g(y_i), \quad y_i > 0 \end{aligned}$$

where $g(y_i)$ follows either the Poisson or the negative binomial distribution. You can specify the probability φ with the PROBZERO= option in the OUTPUT statement.

When the probability φ_i depends on the characteristics of observation i , φ_i is written as a function of $\mathbf{z}'_i \boldsymbol{\gamma}$, where \mathbf{z}'_i is the $1 \times (q + 1)$ vector of zero-inflation covariates and $\boldsymbol{\gamma}$ is the $(q + 1) \times 1$ vector of zero-inflation coefficients to be estimated. (The zero-inflation intercept is γ_0 ; the coefficients for the q zero-inflation covariates are $\gamma_1, \dots, \gamma_q$.) The function F that relates the product $\mathbf{z}'_i \boldsymbol{\gamma}$ (which is a scalar) to the probability φ_i is called the zero-inflation link function,

$$\varphi_i = F_i = F(\mathbf{z}'_i \boldsymbol{\gamma})$$

In the TCOUNTREG procedure, the zero-inflation covariates are indicated in the ZEROMODEL statement. Furthermore, the zero-inflation link function F can be specified as either the logistic function,

$$F(\mathbf{z}'_i \boldsymbol{\gamma}) = \Lambda(\mathbf{z}'_i \boldsymbol{\gamma}) = \frac{\exp(\mathbf{z}'_i \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}'_i \boldsymbol{\gamma})}$$

or the standard normal cumulative distribution function (also called the probit function),

$$F(\mathbf{z}'_i \boldsymbol{\gamma}) = \Phi(\mathbf{z}'_i \boldsymbol{\gamma}) = \int_0^{\mathbf{z}'_i \boldsymbol{\gamma}} \frac{1}{\sqrt{2\pi}} \exp(-u^2/2) du$$

The zero-inflation link function is indicated in the LINK option in ZEROMODEL statement. The default ZI link function is the logistic function.

Zero-Inflated Poisson Regression

In the zero-inflated Poisson (ZIP) regression model, the data generation process referred to earlier as Process 2 is

$$g(y_i) = \frac{\exp(-\mu_i) \mu_i^{y_i}}{y_i!}$$

where $\mu_i = e^{\mathbf{x}'_i \boldsymbol{\beta}}$. Thus the ZIP model is defined as

$$\begin{aligned} P(y_i = 0 | \mathbf{x}_i, \mathbf{z}_i) &= F_i + (1 - F_i) \exp(-\mu_i) \\ P(y_i | \mathbf{x}_i, \mathbf{z}_i) &= (1 - F_i) \frac{\exp(-\mu_i) \mu_i^{y_i}}{y_i!}, \quad y_i > 0 \end{aligned}$$

The conditional expectation and conditional variance of y_i are given by

$$E(y_i | \mathbf{x}_i, \mathbf{z}_i) = \mu_i (1 - F_i)$$

$$V(y_i | \mathbf{x}_i, \mathbf{z}_i) = E(y_i | \mathbf{x}_i, \mathbf{z}_i) (1 + \mu_i F_i)$$

Note that the ZIP model (as well as the ZINB model) exhibits overdispersion since $V(y_i | \mathbf{x}_i, \mathbf{z}_i) > E(y_i | \mathbf{x}_i, \mathbf{z}_i)$.

In general, the log-likelihood function of the ZIP model is

$$\mathcal{L} = \sum_{i=1}^N w_i \ln [P(y_i | \mathbf{x}_i, \mathbf{z}_i)]$$

After a specific link function (either logistic or standard normal) for the probability φ_i is chosen, it is possible to write the exact expressions for the log-likelihood function and the gradient.

ZIP Model with Logistic Link Function

First, consider the ZIP model in which the probability φ_i is expressed with a logistic link function—namely,

$$\varphi_i = \frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})}$$

The log-likelihood function is

$$\begin{aligned} \mathcal{L} = & \sum_{\{i: y_i=0\}} w_i \ln [\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))] \\ & + \sum_{\{i: y_i>0\}} w_i \left[y_i \mathbf{x}_i' \boldsymbol{\beta} - \exp(\mathbf{x}_i' \boldsymbol{\beta}) - \sum_{k=2}^{y_i} \ln(k) \right] \\ & - \sum_{i=1}^N w_i \ln [1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})] \end{aligned}$$

See the section “[Poisson Regression](#)” on page 2044 for the definition of w_i .

The gradient for this model is given by

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \boldsymbol{\gamma}} &= \sum_{\{i: y_i=0\}} w_i \left[\frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))} \right] \mathbf{z}_i - \sum_{i=1}^N w_i \left[\frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})} \right] \mathbf{z}_i \\ \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \sum_{\{i: y_i=0\}} w_i \left[\frac{-\exp(\mathbf{x}_i' \boldsymbol{\beta}) \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))}{\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))} \right] \mathbf{x}_i + \sum_{\{i: y_i>0\}} w_i [y_i - \exp(\mathbf{x}_i' \boldsymbol{\beta})] \mathbf{x}_i \end{aligned}$$

ZIP Model with Standard Normal Link Function

Next, consider the ZIP model in which the probability φ_i is expressed with a standard normal link function: $\varphi_i = \Phi(\mathbf{z}'_i \boldsymbol{\gamma})$. The log-likelihood function is

$$\begin{aligned} \mathcal{L} = & \sum_{\{i: y_i=0\}} w_i \ln \{ \Phi(\mathbf{z}'_i \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \exp(-\exp(\mathbf{x}'_i \boldsymbol{\beta})) \} \\ & + \sum_{\{i: y_i>0\}} w_i \left\{ \ln [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] - \exp(\mathbf{x}'_i \boldsymbol{\beta}) + y_i \mathbf{x}'_i \boldsymbol{\beta} - \sum_{k=2}^{y_i} \ln(k) \right\} \end{aligned}$$

See the section “[Poisson Regression](#)” on page 2044 for the definition of w_i .

The gradient for this model is given by

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \boldsymbol{\gamma}} = & \sum_{\{i: y_i=0\}} w_i \frac{\varphi(\mathbf{z}'_i \boldsymbol{\gamma}) [1 - \exp(-\exp(\mathbf{x}'_i \boldsymbol{\beta}))]}{\Phi(\mathbf{z}'_i \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \exp(-\exp(\mathbf{x}'_i \boldsymbol{\beta}))} \mathbf{z}_i \\ & - \sum_{\{i: y_i>0\}} w_i \frac{\varphi(\mathbf{z}'_i \boldsymbol{\gamma})}{[1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})]} \mathbf{z}_i \\ \\ \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = & \sum_{\{i: y_i=0\}} w_i \frac{-[1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \exp(\mathbf{x}'_i \boldsymbol{\beta}) \exp(-\exp(\mathbf{x}'_i \boldsymbol{\beta}))}{\Phi(\mathbf{z}'_i \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \exp(-\exp(\mathbf{x}'_i \boldsymbol{\beta}))} \mathbf{x}_i \\ & + \sum_{\{i: y_i>0\}} w_i [y_i - \exp(\mathbf{x}'_i \boldsymbol{\beta})] \mathbf{x}_i \end{aligned}$$

Zero-Inflated Negative Binomial Regression

The zero-inflated negative binomial (ZINB) model in PROC TCOUNTREG is based on the negative binomial model with quadratic variance function ($p=2$). The ZINB model is obtained by specifying a negative binomial distribution for the data generation process referred to earlier as Process 2:

$$g(y_i) = \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left(\frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \left(\frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}$$

Thus the ZINB model is defined to be

$$\begin{aligned} P(y_i = 0 | \mathbf{x}_i, \mathbf{z}_i) &= F_i + (1 - F_i) (1 + \alpha \mu_i)^{-\alpha^{-1}} \\ P(y_i | \mathbf{x}_i, \mathbf{z}_i) &= (1 - F_i) \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left(\frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \\ &\quad \times \left(\frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}, \quad y_i > 0 \end{aligned}$$

In this case, the conditional expectation and conditional variance of y_i are

$$E(y_i | \mathbf{x}_i, \mathbf{z}_i) = \mu_i(1 - F_i)$$

$$V(y_i | \mathbf{x}_i, \mathbf{z}_i) = E(y_i | \mathbf{x}_i, \mathbf{z}_i) [1 + \mu_i(F_i + \alpha)]$$

As with the ZIP model, the ZINB model exhibits overdispersion because the conditional variance exceeds the conditional mean.

ZINB Model with Logistic Link Function

In this model, the probability φ_i is given by the logistic function—namely,

$$\varphi_i = \frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})}$$

The log-likelihood function is

$$\begin{aligned} \mathcal{L} &= \sum_{\{i: y_i=0\}} w_i \ln \left[\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + (1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta}))^{-\alpha^{-1}} \right] \\ &+ \sum_{\{i: y_i>0\}} w_i \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1}) \\ &+ \sum_{\{i: y_i>0\}} w_i \{ -\ln(y_i!) - (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta})) + y_i \ln(\alpha) + y_i \mathbf{x}_i' \boldsymbol{\beta} \} \\ &- \sum_{i=1}^N w_i \ln [1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})] \end{aligned}$$

See the section “[Poisson Regression](#)” on page 2044 for the definition of w_i .

The gradient for this model is given by

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \boldsymbol{\gamma}} &= \sum_{\{i: y_i=0\}} w_i \left[\frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + (1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta}))^{-\alpha^{-1}}} \right] \mathbf{z}_i \\ &- \sum_{i=1}^N w_i \left[\frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})} \right] \mathbf{z}_i \\ \\ \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \sum_{\{i: y_i=0\}} w_i \left[\frac{-\exp(\mathbf{x}_i' \boldsymbol{\beta})(1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta}))^{-\alpha^{-1}-1}}{\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + (1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta}))^{-\alpha^{-1}}} \right] \mathbf{x}_i \\ &+ \sum_{\{i: y_i>0\}} w_i \left[\frac{y_i - \exp(\mathbf{x}_i' \boldsymbol{\beta})}{1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta})} \right] \mathbf{x}_i \end{aligned}$$

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \alpha} = & \sum_{\{i:y_i=0\}} w_i \frac{\alpha^{-2} [(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) - \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})]}{\exp(\mathbf{z}'_i \boldsymbol{\gamma}) (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{(1+\alpha)/\alpha} + (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))} \\ & + \sum_{\{i:y_i>0\}} w_i \left\{ -\alpha^{-2} \sum_{j=0}^{y_i-1} \frac{1}{(j + \alpha^{-1})} + \alpha^{-2} \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) + \frac{y_i - \exp(\mathbf{x}'_i \boldsymbol{\beta})}{\alpha(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))} \right\} \end{aligned}$$

ZINB Model with Standard Normal Link Function

For this model, the probability φ_i is specified with the standard normal distribution function (probit function): $\varphi_i = \Phi(\mathbf{z}'_i \boldsymbol{\gamma})$. The log-likelihood function is

$$\begin{aligned} \mathcal{L} = & \sum_{\{i:y_i=0\}} w_i \ln \left\{ \Phi(\mathbf{z}'_i \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-\alpha^{-1}} \right\} \\ & + \sum_{\{i:y_i>0\}} w_i \ln [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \\ & + \sum_{\{i:y_i>0\}} w_i \sum_{j=0}^{y_i-1} \{\ln(j + \alpha^{-1})\} \\ & - \sum_{\{i:y_i>0\}} w_i \ln(y_i!) \\ & - \sum_{\{i:y_i>0\}} w_i (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) \\ & + \sum_{\{i:y_i>0\}} w_i y_i \ln(\alpha) \\ & + \sum_{\{i:y_i>0\}} w_i y_i \mathbf{x}'_i \boldsymbol{\beta} \end{aligned}$$

See the section “Poisson Regression” on page 2044 for the definition of w_i .

The gradient for this model is given by

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \boldsymbol{\gamma}} = & \sum_{\{i:y_i=0\}} w_i \left[\frac{\varphi(\mathbf{z}'_i \boldsymbol{\gamma}) [1 - (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-\alpha^{-1}}]}{\Phi(\mathbf{z}'_i \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-\alpha^{-1}}} \right] \mathbf{z}_i \\ & - \sum_{\{i:y_i>0\}} w_i \left[\frac{\varphi(\mathbf{z}'_i \boldsymbol{\gamma})}{1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})} \right] \mathbf{z}_i \end{aligned}$$

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \sum_{\{i:y_i=0\}} w_i \frac{-[1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \exp(\mathbf{x}'_i \boldsymbol{\beta}) (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-(1+\alpha)/\alpha}}{\Phi(\mathbf{z}'_i \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-\alpha^{-1}}} \mathbf{x}_i$$

$$\begin{aligned}
& + \sum_{\{i: y_i > 0\}} w_i \left[\frac{y_i - \exp(\mathbf{x}'_i \boldsymbol{\beta})}{1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})} \right] \mathbf{x}_i \\
\frac{\partial \mathcal{L}}{\partial \alpha} &= \sum_{\{i: y_i = 0\}} w_i \frac{[1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \alpha^{-2} [(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) - \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})]}{\Phi(\mathbf{z}'_i \boldsymbol{\gamma}) (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{(1+\alpha)/\alpha} + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))} \\
& + \sum_{\{i: y_i > 0\}} w_i \left\{ -\alpha^{-2} \sum_{j=0}^{y_i-1} \frac{1}{(j + \alpha^{-1})} + \alpha^{-2} \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) + \frac{y_i - \exp(\mathbf{x}'_i \boldsymbol{\beta})}{\alpha (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))} \right\}
\end{aligned}$$

Variable Selection

Variable Selection Using an Information Criterion

This type of variable selection uses either Akaike's information criterion (AIC) or the Schwartz Bayesian criterion (SBC) and either a forward selection method or a backward elimination method.

Forward selection starts from a small subset of variables. In each step, the variable that gives the largest decrease in the value of the information criterion specified in the CRITER= option (AIC or SBC) is added. The process stops when the next candidate to be added does not reduce the value of the information criterion by more than the amount specified in the LSTOP= option in the MODEL statement.

Backward elimination starts from a larger subset of variables. In each step, one variable is dropped based on the information criterion chosen.

Variable Selection Using Penalized Likelihood

Variable selection in the linear regression context can be achieved by adding some form of penalty on the regression coefficients. One particular such form is L_1 norm penalty, which leads to LASSO:

$$\min_{\boldsymbol{\beta}} \|Y - X\boldsymbol{\beta}\|^2 + \lambda \sum_{j=1}^p |\beta_j|$$

This penalty method is becoming more popular in linear regression, because of the computational development in the recent years. However, how to generalize the penalty method for variable selection to the more general statistical models is not trivial. Some work has been done for the generalized linear models, in the sense that the likelihood depends on the data through a linear combination of the parameters and the data:

$$l(\boldsymbol{\beta} | \mathbf{x}) = l(\mathbf{x}^T \boldsymbol{\beta})$$

In the more general form, the likelihood as a function of the parameters can be denoted by $l(\boldsymbol{\theta}) = \sum_i l_i(\boldsymbol{\theta})$, where $\boldsymbol{\theta}$ is a vector that can include any parameters and $l(\cdot)$ is the likelihood for each observation. For example, in the Poisson model, $\boldsymbol{\theta} = (\beta_0, \beta_1, \dots, \beta_p)$, and in the negative binomial model

$\theta = (\beta_0, \beta_1, \dots, \beta_p, \alpha)$. The following discussion introduces the penalty method using the Poisson model as an example, but it applies similarly to the negative binomial model. The penalized likelihood function takes the form

$$Q(\beta) = \sum_i l_i(\beta) - n \sum_{j=1}^p p_{\lambda_j}(|\beta_j|) \quad (30.1)$$

Some desired properties for the penalty functions are *unbiasedness*, *sparsity*, and *continuity*. Unbiasedness means that the coefficients should be unbiased for significant variables. Sparsity means that the coefficients can be exactly zero when the penalty is large enough. Continuity means that the solution of the penalized problem is continuous in the data, which means that a small perturbation of the data does not change the estimation significantly.

The L_1 norm penalty function used in the calculation is specified as:

$$p_{\lambda}(|\beta|) = \lambda$$

The main challenge for this penalized likelihood method is on the computation side. The penalty function is nondifferentiable at zero, which poses a computational problem for the optimization. To get around this nondifferentiability problem, Fan and Li (2001) suggest a local quadratic approximation for the penalty function. However, it is later found that the numerical performance is not satisfactory in a few aspects. Zou and Li (2008) proposed local linear approximation (LLA) to solve the problem (see page 2053) numerically. The algorithm replaces the penalty function with a linear approximation around a fixed point $\beta^{(0)}$:

$$p_{\lambda}(|\beta_j|) \approx p_{\lambda}(|\beta_j^{(0)}|) + p'_{\lambda}(|\beta_j^{(0)}|) (|\beta_j| - |\beta_j^{(0)}|)$$

Then the problem can be solved iteratively. Start from $\beta^{(0)} = \hat{\beta}_M$, which denotes the usual MLE estimate. For iteration k ,

$$\beta^{(k+1)} = \arg \max_{\beta} \left\{ \sum_i l_i(\beta) - n \sum_{j=1}^p p'_{\lambda}(|\beta_j^{(k)}|) |\beta_j| \right\}$$

The algorithm stops when $\|\beta^{(k+1)} - \beta^{(k)}\|$ is small. To save computing time, you can also choose a maximum number of iterations. This number can be specified by the LLASTEPS= option.

The objective function is nondifferentiable. The optimization problem can be solved using an optimization methods with constraints, by a variable transformation

$$\beta_j = \beta_j^+ - \beta_j^-, \beta_j^+ \geq 0, \beta_j^- \geq 0 \quad (30.2)$$

For each fixed tuning parameter λ , you can solve the preceding optimization problem to obtain an estimate for β . Due to the property of the L_1 norm penalty, some of the coefficients in β can be exactly zero. The remaining question is to choose the best tuning parameter λ . You can use either of the approaches described in the following subsections.

The GCV Approach

In this approach, the generalized cross-validation criteria (GCV) is computed for each value of λ on a predetermined grid $\{\lambda_1, \dots, \lambda_L\}$; the value of λ that achieves the minimum of the GCV is the optimal tuning parameter. The maximum value λ_L can be determined by lemma 1 in Park and Hastie (2007) as follows. Suppose β_0 is free of penalty in the objective function. Let $\hat{\beta}_0$ be the MLE of β_0 by forcing the rest of the parameters to be zero. Then the maximum value of λ is

$$\begin{aligned}\lambda_L &= \arg \max_{\lambda} \left\{ \max_{\lambda} : \left| \frac{\partial l}{\partial \beta_j}(\hat{\beta}_0) \right| \leq n P'_{\lambda}(|\beta_j|), j = 1, \dots, p \right\} \\ &= \arg \max_{\lambda} \left\{ \left| \frac{1}{n} \frac{\partial l}{\partial \beta_j}(\hat{\beta}_0) \right|, j = 1, \dots, p \right\}\end{aligned}$$

You can compute the GCV by using the LASSO framework. In the last step of Newton-Raphson approximation, you have

$$\frac{1}{2} \min_{\beta} \left\| (\nabla^2 l(\beta^{(k)}))^{1/2} (\beta - \beta^{(k)}) + (\nabla^2 l(\beta^{(k)}))^{-1/2} \nabla l(\beta^{(k)}) \right\|^2 + n \sum_{j=1}^p p'_{\lambda}(|\beta_j^{(k)}|) |\beta_j|$$

The solution $\hat{\beta}$ satisfies

$$\hat{\beta} - \beta^{(k)} = -(\nabla^2 l(\beta^{(k)}) - 2W^-)^{-1} (\nabla l(\beta^{(k)}) - 2\mathbf{b})$$

where

$$\begin{aligned}W^- &= n \text{diag}(W_1^-, \dots, W_p^-) \\ W_j^- &= \begin{cases} \frac{p'_{\lambda}(|\beta_j^{(k)}|)}{|\beta_j|}, & \text{if } \beta_j \neq 0 \\ 0, & \text{if } \beta_j = 0 \end{cases} \\ \mathbf{b} &= n \text{diag}(p'_{\lambda}(|\beta_1^{(k)}|) \text{sgn}(\beta_1), \dots, p'_{\lambda}(|\beta_p^{(k)}|) \text{sgn}(\beta_p))\end{aligned}$$

Note that the intercept term has no penalty on its absolute value, and therefore the W_j^- term that corresponds to the intercept is 0. More generally, you can make any parameter (such as the α in the negative binomial model) in the likelihood function free of penalty, and you treat them the same as the intercept.

The effective number of parameters is

$$\begin{aligned}e(\lambda) &= \text{tr} \left\{ \left(\nabla^2 l(\beta^{(k)}) \right)^{1/2} \left(\nabla^2 l(\beta^{(k)}) - 2W^- \right)^{-1} \left(\nabla^2 l(\beta^{(k)}) \right)^{1/2} \right\} \\ &= \text{tr} \left\{ \left(\nabla^2 l(\beta^{(k)}) - 2W^- \right)^{-1} \nabla^2 l(\beta^{(k)}) \right\}\end{aligned}$$

and the generalized cross-validation error is

$$\text{GCV}(\lambda) = \frac{l(\hat{\beta})}{n[1 - e(\lambda)/n]^2}$$

The GCV1 Approach

Another form of GCV uses the number of nonzero coefficients as the degrees-of-freedom:

$$e_1(\lambda) = \sum_{j=0}^p \mathbf{1}_{[\beta_j \neq 0]}$$

$$\text{GCV}_1(\lambda) = \frac{l(\hat{\beta})}{n[1 - e_1(\lambda)/n]^2}$$

The standard errors follow the sandwich formula

$$\begin{aligned} \text{cov}(\hat{\beta}) &= \left\{ \nabla^2 l(\beta^{(k)}) - 2W^- \right\}^{-1} \widehat{\text{cov}} \left(\nabla l(\beta^{(k)}) - 2\mathbf{b} \right) \left\{ \nabla^2 l(\beta^{(k)}) - 2W^- \right\}^{-1} \\ &= \left\{ \nabla^2 l(\beta^{(k)}) - 2W^- \right\}^{-1} \widehat{\text{cov}} \left(\nabla l(\beta^{(k)}) \right) \left\{ \nabla^2 l(\beta^{(k)}) - 2W^- \right\}^{-1} \end{aligned}$$

It is common practice to report only the standard errors of the nonzero parameters.

Panel Data Analysis

Panel Data Poisson Regression with Fixed Effects

The count regression model for panel data can be derived from the Poisson regression model. Consider the multiplicative one-way panel data model,

$$y_{it} \sim \text{Poisson}(\mu_{it})$$

where

$$\mu_{it} = \alpha_i \lambda_{it} = \alpha_i \exp(\mathbf{x}'_{it} \boldsymbol{\beta}), \quad i = 1, \dots, N, \quad t = 1, \dots, T$$

Here, α_i are the individual effects.

In the fixed effects model, the α_i are unknown parameters. The fixed effects model can be estimated by eliminating α_i by conditioning on $\sum_t y_{it}$.

In the random effects model, the α_i are independent and identically distributed (iid) random variables, in contrast to the fixed effects model. The random effects model can then be estimated by assuming a distribution for α_i .

In the Poisson fixed effects model, conditional on λ_{it} and parameter α_i , y_{it} is iid Poisson distributed with parameter $\mu_{it} = \alpha_i \lambda_{it} = \alpha_i \exp(\mathbf{x}'_{it} \boldsymbol{\beta})$, and x_{it} does not include an intercept. Then, the conditional joint density for the outcomes within the i th panel is

$$\begin{aligned} P[y_{i1}, \dots, y_{iT_i} | \sum_{t=1}^{T_i} y_{it}] &= P[y_{i1}, \dots, y_{iT_i}, \sum_{t=1}^{T_i} y_{it}] / P[\sum_{t=1}^{T_i} y_{it}] \\ &= P[y_{i1}, \dots, y_{iT_i}] / P[\sum_{t=1}^{T_i} y_{it}] \end{aligned}$$

Since y_{it} is iid Poisson(μ_{it}), $P[y_{i1}, \dots, y_{iT_i}]$ is the product of T_i Poisson densities. Also, $(\sum_{t=1}^{T_i} y_{it})$ is Poisson($\sum_{t=1}^{T_i} \mu_{it}$). Then,

$$\begin{aligned}
 P[y_{i1}, \dots, y_{iT_i} | \sum_{t=1}^{T_i} y_{it}] &= \frac{\sum_{t=1}^{T_i} (\exp(-\mu_{it}) \mu_{it}^{y_{it}} / y_{it}!)}{\exp(-\sum_{t=1}^{T_i} \mu_{it}) \left(\sum_{t=1}^{T_i} \mu_{it}\right)^{\sum_{t=1}^{T_i} y_{it}} / \left(\sum_{t=1}^{T_i} y_{it}\right)!} \\
 &= \frac{\exp(-\sum_{t=1}^{T_i} \mu_{it}) \left(\prod_{t=1}^{T_i} \mu_{it}^{y_{it}}\right) \left(\prod_{t=1}^{T_i} y_{it}!\right)}{\exp(-\sum_{t=1}^{T_i} \mu_{it}) \prod_{t=1}^{T_i} \left(\sum_{s=1}^{T_i} \mu_{is}\right)^{y_{it}} / \left(\sum_{t=1}^{T_i} y_{it}\right)!} \\
 &= \frac{\left(\sum_{t=1}^{T_i} y_{it}\right)!}{\left(\prod_{t=1}^{T_i} y_{it}!\right)} \prod_{t=1}^{T_i} \left(\frac{\mu_{it}}{\sum_{s=1}^{T_i} \mu_{is}}\right)^{y_{it}} \\
 &= \frac{\left(\sum_{t=1}^{T_i} y_{it}\right)!}{\left(\prod_{t=1}^{T_i} y_{it}!\right)} \prod_{t=1}^{T_i} \left(\frac{\lambda_{it}}{\sum_{s=1}^{T_i} \lambda_{is}}\right)^{y_{it}}
 \end{aligned}$$

Thus, the conditional log-likelihood function of the fixed effects Poisson model is given by

$$\mathcal{L} = \sum_{i=1}^N \left[\ln \left(\left(\sum_{t=1}^{T_i} y_{it} \right)! \right) - \sum_{t=1}^{T_i} \ln(y_{it}!) + \sum_{t=1}^{T_i} y_{it} \ln \left(\frac{\lambda_{it}}{\sum_{s=1}^{T_i} \lambda_{is}} \right) \right]$$

The gradient is

$$\begin{aligned}
 \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \sum_{i=1}^N \sum_{t=1}^{T_i} y_{it} x_{it} - \sum_{i=1}^N \sum_{t=1}^{T_i} \left[\frac{y_{it} \sum_{s=1}^{T_i} (\exp(\mathbf{x}'_{is} \boldsymbol{\beta}) \mathbf{x}_{is})}{\sum_{s=1}^{T_i} \exp(\mathbf{x}'_{is} \boldsymbol{\beta})} \right] \\
 &= \sum_{i=1}^N \sum_{t=1}^{T_i} y_{it} (\mathbf{x}_{it} - \bar{\mathbf{x}}_i)
 \end{aligned}$$

where

$$\bar{\mathbf{x}}_i = \sum_{s=1}^{T_i} \left(\frac{\exp(\mathbf{x}'_{is} \boldsymbol{\beta})}{\sum_{k=1}^{T_i} \exp(\mathbf{x}'_{ik} \boldsymbol{\beta})} \right) \mathbf{x}_{is}$$

Panel Data Poisson Regression with Random Effects

In the Poisson random effects model, conditional on λ_{it} and parameter α_i , y_{it} is iid Poisson distributed with parameter $\mu_{it} = \alpha_i \lambda_{it} = \alpha_i \exp(\mathbf{x}'_{it} \boldsymbol{\beta})$, and the individual effects, α_i , are assumed to be iid random variables. The joint density for observations in all time periods for the i th individual, $P[y_{i1}, \dots, y_{iT} | \lambda_{i1}, \dots, \lambda_{iT_i}]$, can be obtained after the density $g(\alpha)$ of α_i is specified.

Let

$$\alpha_i \sim \text{iid gamma}(\theta, \theta)$$

so that $E(\alpha_i) = 1$ and $V(\alpha_i) = 1/\theta$:

$$g(\alpha_i) = \frac{\theta^\theta}{\Gamma(\theta)} \alpha_i^{\theta-1} \exp(-\theta \alpha_i)$$

Let $\lambda_i = (\lambda_{i1}, \dots, \lambda_{iT_i})$. Since y_{it} is conditional on λ_{it} and parameter α_i is iid Poisson($\mu_{it} = \alpha_i \lambda_{it}$), the conditional joint probability for observations in all time periods for the i th individual, $P[y_{i1}, \dots, y_{iT_i} | \lambda_i, \alpha_i]$, is the product of T_i Poisson densities:

$$\begin{aligned} P[y_{i1}, \dots, y_{iT_i} | \lambda_i, \alpha_i] &= \prod_{t=1}^{T_i} P[y_{it} | \lambda_{it}, \alpha_i] \\ &= \prod_{t=1}^{T_i} \left[\frac{\exp(-\mu_{it}) \mu_{it}^{y_{it}}}{y_{it}!} \right] \\ &= \left[\prod_{t=1}^{T_i} \frac{e^{-\alpha_i \lambda_{it}} (\alpha_i \lambda_{it})^{y_{it}}}{y_{it}!} \right] \\ &= \left[\prod_{t=1}^{T_i} \lambda_{it}^{y_{it}} / y_{it}! \right] \left(e^{-\alpha_i \sum_t \lambda_{it}} \alpha_i^{\sum_t y_{it}} \right) \end{aligned}$$

Then, the joint density for the i th panel conditional on just the λ can be obtained by integrating out α_i :

$$\begin{aligned} P[y_{i1}, \dots, y_{iT_i} | \lambda_i] &= \int_0^\infty P[y_{i1}, \dots, y_{iT_i} | \lambda_i, \alpha_i] g(\alpha_i) d\alpha_i \\ &= \frac{\theta^\theta}{\Gamma(\theta)} \left[\prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it}}}{y_{it}!} \right] \int_0^\infty \exp(-\alpha_i \sum_t \lambda_{it}) \alpha_i^{\sum_t y_{it}} \alpha_i^{\theta-1} \exp(-\theta \alpha_i) d\alpha_i \\ &= \frac{\theta^\theta}{\Gamma(\theta)} \left[\prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it}}}{y_{it}!} \right] \int_0^\infty \exp \left[-\alpha_i \left(\theta + \sum_t \lambda_{it} \right) \right] \alpha_i^{\theta + \sum_t y_{it} - 1} d\alpha_i \\ &= \left[\prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it}}}{y_{it}!} \right] \frac{\Gamma(\theta + \sum_t y_{it})}{\Gamma(\theta)} \\ &\quad \times \left(\frac{\theta}{\theta + \sum_t \lambda_{it}} \right)^\theta \left(\theta + \sum_t \lambda_{it} \right)^{-\sum_t y_{it}} \\ &= \left[\prod_{t=1}^{T_i} \frac{\lambda_{it}^{y_{it}}}{y_{it}!} \right] \frac{\Gamma(\alpha^{-1} + \sum_t y_{it})}{\Gamma(\alpha^{-1})} \\ &\quad \times \left(\frac{\alpha^{-1}}{\alpha^{-1} + \sum_t \lambda_{it}} \right)^{\alpha^{-1}} \left(\alpha^{-1} + \sum_t \lambda_{it} \right)^{-\sum_t y_{it}} \end{aligned}$$

where $\alpha (= 1/\theta)$ is the overdispersion parameter. This is the density of the Poisson random effects model with gamma-distributed random effects. For this distribution, $E(y_{it}) = \lambda_{it}$ and $V(y_{it}) = \lambda_{it} + \alpha \lambda_{it}^2$; that is, there is overdispersion.

Then the log-likelihood function is written as

$$\begin{aligned}\mathcal{L} = & \sum_{i=1}^N \left\{ \sum_{t=1}^{T_i} \ln \left(\frac{\lambda_{it}^{y_{it}}}{y_{it}!} \right) + \alpha^{-1} \ln(\alpha^{-1}) - \alpha^{-1} \ln \left(\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it} \right) \right\} + \\ & \sum_{i=1}^N \left\{ - \left(\sum_{t=1}^{T_i} y_{it} \right) \ln \left(\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it} \right) + \right. \\ & \left. \ln \left[\Gamma \left(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it} \right) \right] - \ln(\Gamma(\alpha^{-1})) \right\}\end{aligned}$$

The gradient is

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \sum_{i=1}^N \left\{ \sum_{t=1}^{T_i} y_{it} \mathbf{x}_{it} - \frac{\alpha^{-1} \sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it}}{\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it}} \right\} - \\ & \sum_{i=1}^N \left\{ \left(\sum_{t=1}^{T_i} y_{it} \right) \frac{\sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it}}{\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it}} \right\} \\ \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \sum_{i=1}^N \left\{ \sum_{t=1}^{T_i} y_{it} \mathbf{x}_{it} - \frac{(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it})(\sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it})}{\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it}} \right\}\end{aligned}$$

and

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial \alpha} &= \sum_{i=1}^N \left\{ -\alpha^{-2} \left[[1 + \ln(\alpha^{-1})] - \frac{(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it})}{(\alpha^{-1}) + \sum_{t=1}^{T_i} \lambda_{it}} - \ln \left(\alpha^{-1} + \sum_{t=1}^{T_i} \lambda_{it} \right) \right] \right\} \\ &+ \sum_{i=1}^N \left\{ -\alpha^{-2} \left[\frac{\Gamma'(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it})}{\Gamma(\alpha^{-1} + \sum_{t=1}^{T_i} y_{it})} - \frac{\Gamma'(\alpha^{-1})}{\Gamma(\alpha^{-1})} \right] \right\}\end{aligned}$$

where $\lambda_{it} = \exp(\mathbf{x}'_{it}\boldsymbol{\beta})$, $\Gamma'(\cdot) = d\Gamma(\cdot)/d(\cdot)$ and $\Gamma'(\cdot)/\Gamma(\cdot)$ is the digamma function.

Panel Data Negative Binomial Regression with Fixed Effects

This section shows the derivation of a negative binomial model with fixed effects. Keep the assumptions of the Poisson-distributed dependent variable

$$y_{it} \sim \text{Poisson}(\mu_{it})$$

But now let the Poisson parameter be random with gamma distribution and parameters (λ_{it}, δ) ,

$$\mu_{it} \sim \Gamma(\lambda_{it}, \delta)$$

where one of the parameters is the exponentially affine function of independent variables $\lambda_{it} = \exp(\mathbf{x}_{it}'\beta)$. Use integration by parts to obtain the distribution of y_{it} ,

$$\begin{aligned} P[y_{it}] &= \int_0^\infty \frac{e^{-\mu_{it}} \mu_{it}^{y_{it}}}{y_{it}!} f(\mu_{it}) d\mu_{it} \\ &= \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)} \left(\frac{\delta}{1 + \delta}\right)^{\lambda_{it}} \left(\frac{1}{1 + \delta}\right)^{y_{it}} \end{aligned}$$

which is a negative binomial distribution with parameters (λ_{it}, δ) . Conditional joint distribution is given as

$$\begin{aligned} P[y_{i1}, \dots, y_{iT_i} | \sum_{t=1}^{T_i} y_{it}] &= \left(\prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)} \right) \\ &\quad \times \left(\frac{\Gamma(\sum_{t=1}^{T_i} \lambda_{it}) \Gamma(\sum_{t=1}^{T_i} y_{it} + 1)}{\Gamma(\sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})} \right). \end{aligned}$$

Hence, the conditional fixed-effects negative binomial log-likelihood is

$$\begin{aligned} \mathcal{L} &= \sum_{i=1}^N \left[\log \Gamma \left(\sum_{t=1}^{T_i} \lambda_{it} \right) + \log \Gamma \left(\sum_{t=1}^{T_i} y_{it} + 1 \right) - \log \Gamma \left(\sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it} \right) \right] \\ &\quad + \sum_{i=1}^N \sum_{t=1}^{T_i} [\log \Gamma(\lambda_{it} + y_{it}) - \log \Gamma(\lambda_{it}) - \log \Gamma(y_{it} + 1)]. \end{aligned}$$

The gradient is

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \beta} &= \sum_{i=1}^N \left[\left(\frac{\Gamma'(\sum_{t=1}^{T_i} \lambda_{it})}{\Gamma(\sum_{t=1}^{T_i} \lambda_{it})} - \frac{\Gamma'(\sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})}{\Gamma(\sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})} \right) \sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it} \right] \\ &\quad + \sum_{i=1}^N \frac{\Gamma'(\sum_{t=1}^{T_i} y_{it} + 1)}{\Gamma(\sum_{t=1}^{T_i} y_{it} + 1)} \\ &\quad + \sum_{i=1}^N \sum_{t=1}^{T_i} \left[\left(\frac{\Gamma'(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it} + y_{it})} - \frac{\Gamma'(\lambda_{it})}{\Gamma(\lambda_{it})} \right) \lambda_{it} \mathbf{x}_{it} - \frac{\Gamma'(y_{it} + 1)}{\Gamma(y_{it} + 1)} \right]. \end{aligned}$$

Panel Data Negative Binomial Regression with Random Effects

This section describes the derivation of negative binomial model with random effects. Suppose

$$y_{it} \sim \text{Poisson}(\mu_{it})$$

with the Poisson parameter distributed as gamma,

$$\mu_{it} \sim \Gamma(v_i \lambda_{it}, \delta)$$

where its parameters are also random:

$$v_i \lambda_{it} = \exp(\mathbf{x}'_{it} \beta + \eta_{it})$$

Assume that the distribution of a function of v_i is beta with parameters (a, b) :

$$\frac{v_i}{1 + v_i} \sim \text{Beta}(a, b).$$

Explicitly, the beta density with $[0, 1]$ domain is

$$f(z) = [B(a, b)]^{-1} z^{a-1} (1 - z)^{b-1}$$

where $B(a, b)$ is the beta function. Then, conditional joint distribution of dependent variables is

$$P[y_{i1}, \dots, y_{iT_i} | \mathbf{x}_{i1}, \dots, \mathbf{x}_{iT_i}, v_i] = \prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)} \left(\frac{1}{1 + v_i} \right)^{\lambda_{it}} \left(\frac{v_i}{1 + v_i} \right)^{y_{it}}$$

Integrating out the variable v_i yields the following conditional distribution function:

$$\begin{aligned} P[y_{i1}, \dots, y_{iT_i} | \mathbf{x}_{i1}, \dots, \mathbf{x}_{iT_i}] &= \int_0^1 \left[\prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)} z_i^{\lambda_{it}} (1 - z_i)^{y_{it}} \right] f(z_i) dz_i \\ &= \frac{\Gamma(a + b) \Gamma\left(a + \sum_{t=1}^{T_i} \lambda_{it}\right) \Gamma\left(b + \sum_{t=1}^{T_i} y_{it}\right)}{\Gamma(a) \Gamma(b) \Gamma\left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it}\right)} \\ &\quad \times \prod_{t=1}^{T_i} \frac{\Gamma(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it}) \Gamma(y_{it} + 1)}. \end{aligned}$$

Consequently, the conditional log-likelihood function for a negative binomial model with random effects is

$$\begin{aligned} \mathcal{L} &= \sum_{i=1}^N \left[\log \Gamma(a + b) + \log \Gamma\left(a + \sum_{t=1}^{T_i} \lambda_{it}\right) + \log \Gamma\left(b + \sum_{t=1}^{T_i} y_{it}\right) \right] \\ &\quad - \sum_{i=1}^N \left[\log \Gamma(a) + \log \Gamma(b) + \log \Gamma\left(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it}\right) \right] \\ &\quad + \sum_{i=1}^N \sum_{t=1}^{T_i} [\log \Gamma(\lambda_{it} + y_{it}) - \log \Gamma(\lambda_{it}) - \log \Gamma(y_{it} + 1)]. \end{aligned}$$

The gradient is

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \beta} &= \sum_{i=1}^N \left[\frac{\Gamma'(a + \sum_{t=1}^{T_i} \lambda_{it})}{\Gamma(a + \sum_{t=1}^{T_i} \lambda_{it})} \sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it} + \frac{\Gamma'(b + \sum_{t=1}^{T_i} y_{it})}{\Gamma(b + \sum_{t=1}^{T_i} y_{it})} \right] \\ &\quad - \sum_{i=1}^N \left[\frac{\Gamma'(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})}{\Gamma(a + b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})} \sum_{t=1}^{T_i} \lambda_{it} \mathbf{x}_{it} \right] \\ &\quad + \sum_{i=1}^N \sum_{t=1}^{T_i} \left[\left(\frac{\Gamma'(\lambda_{it} + y_{it})}{\Gamma(\lambda_{it} + y_{it})} - \frac{\Gamma'(\lambda_{it})}{\Gamma(\lambda_{it})} \right) \lambda_{it} \mathbf{x}_{it} - \frac{\Gamma'(y_{it} + 1)}{\Gamma(y_{it} + 1)} \right], \end{aligned}$$

and

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial a} = & \sum_{i=1}^N \left[\frac{\Gamma'(a+b)}{\Gamma(a+b)} + \frac{\Gamma'(a + \sum_{t=1}^{T_i} \lambda_{it})}{\Gamma(a + \sum_{t=1}^{T_i} \lambda_{it})} \right] \\ & - \sum_{i=1}^N \left[\frac{\Gamma'(a)}{\Gamma(a)} + \frac{\Gamma'(a+b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})}{\Gamma(a+b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})} \right], \end{aligned}$$

and

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial b} = & \sum_{i=1}^N \left[\frac{\Gamma'(a+b)}{\Gamma(a+b)} + \frac{\Gamma'(b + \sum_{t=1}^{T_i} y_{it})}{\Gamma(b + \sum_{t=1}^{T_i} y_{it})} \right] \\ & - \sum_{i=1}^N \left[\frac{\Gamma'(b)}{\Gamma(b)} + \frac{\Gamma'(a+b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})}{\Gamma(a+b + \sum_{t=1}^{T_i} \lambda_{it} + \sum_{t=1}^{T_i} y_{it})} \right]. \end{aligned}$$

Computational Resources

The time and memory required by PROC TCOUNTREG are proportional to the number of parameters in the model and the number of observations in the data set being analyzed. Less time and memory are required for smaller models and fewer observations. Also affecting these resources are the method chosen to calculate the variance-covariance matrix and the optimization method. All optimization methods available through the METHOD= option have similar memory use requirements.

The processing time might differ for each method depending on the number of iterations and functional calls needed. The data set is read into memory to save processing time. If not enough memory is available to hold the data, the TCOUNTREG procedure stores the data in a utility file on disk and rereads the data as needed from this file. When this occurs, the execution time of the procedure increases substantially. The gradient and the variance-covariance matrix must be held in memory. If the model has p parameters including the intercept, then at least $8 * (p + p * (p + 1)/2)$ bytes are needed. If the quasi-maximum likelihood method is used to estimate the variance-covariance matrix (COVEST=QML), an additional $8 * p * (p + 1)/2$ bytes of memory are needed.

Time is also a function of the number of iterations needed to converge to a solution for the model parameters. The number of iterations needed cannot be known in advance. The MAXITER= option can be used to limit the number of iterations that PROC TCOUNTREG does. The convergence criteria can be altered by nonlinear optimization options available in the PROC TCOUNTREG statement. For a list of all the nonlinear optimization options, see Chapter 6, “Nonlinear Optimization Methods.”

Nonlinear Optimization Options

PROC TCOUNTREG uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. In the PROC TCOUNTREG statement, you can specify nonlinear optimization options that are then

passed to the NLO subsystem. For a list of all the nonlinear optimization options, see Chapter 6, “Nonlinear Optimization Methods.”

Covariance Matrix Types

The TCOUNTREG procedure enables you to specify the estimation method for the covariance matrix. The COVEST=HESSIAN option estimates the covariance matrix based on the inverse of the Hessian matrix, COVEST=OP uses the outer product of gradients, and COVEST=QML produces the covariance matrix based on both the Hessian and outer product matrices. The default is COVEST=HESSIAN.

While all three methods produce asymptotically equivalent results, they differ in computational intensity and produce results that might differ in finite samples. The COVEST=OP option provides the covariance matrix that is typically the easiest to compute. In some cases, the OP approximation is considered more efficient than the Hessian or QML approximations because it contains fewer random elements. The QML approximation is computationally the most complex because both the outer product of gradients and the Hessian matrix are required. In most cases, OP or Hessian approximations are preferred to QML. The need to use QML approximation arises in some cases when the model is misspecified and the information matrix equality does not hold.

Displayed Output

PROC TCOUNTREG produces the following displayed output.

Iteration History for Parameter Estimates

If you specify the ITPRINT or PRINTALL options in the PROC TCOUNTREG statement, PROC TCOUNTREG displays a table that contains the following information for each iteration. Some information is specific to the model-fitting procedure chosen (for example, Newton-Raphson, trust region, quasi-Newton).

- iteration number
- number of restarts since the fitting began
- number of function calls
- number of active constraints at the current solution
- value of the objective function (-1 times the log-likelihood value) at the current solution
- change in the objective function from previous iteration
- value of the maximum absolute gradient element
- step size (for Newton-Raphson and quasi-Newton methods)
- slope of the current search direction (for Newton-Raphson and quasi-Newton methods)
- lambda (for trust region method)
- radius value at current iteration (for trust region method)

Model Fit Summary

The “Model Fit Summary” table contains the following information:

- dependent (count) variable name
- number of observations used
- number of missing values in data set, if any
- data set name
- type of model that was fit
- offset variable name, if any
- zero-inflated link function, if any
- zero-inflated offset variable name, if any
- log-likelihood value at solution
- maximum absolute gradient at solution
- number of iterations
- AIC value at solution (a smaller value indicates better fit)
- SBC value at solution (a smaller value indicates better fit)

Under the “Model Fit Summary” is a statement about whether the algorithm successfully converged.

Parameter Estimates

The “Parameter Estimates” table gives the estimates of the model parameters. In zero-inflated (ZI) models, estimates are also given for the ZI intercept and ZI regressor parameters labeled with the prefix “Inf_”. For example, the ZI intercept is labeled “Inf_intercept”. If you specify “Age” as a ZI regressor, then the “Parameter Estimates” table labels the corresponding parameter estimate “Inf_Age”. If you do not list any ZI regressors, then only the ZI intercept term is estimated.

“_Alpha” is the negative binomial dispersion parameter. The t statistic given for “_Alpha” is a test of overdispersion.

Last Evaluation of the Gradient

If you specify the model option ITPRINT, the TCOUNTREG procedure displays the last evaluation of the gradient vector.

Covariance of Parameter Estimates

If you specify the COVB option in the MODEL statement or in the PROC TCOUNTREG statement, the TCOUNTREG procedure displays the estimated covariance matrix, defined as the inverse of the information matrix at the final iteration.

Correlation of Parameter Estimates

If you specify the CORRB option in the MODEL statement or in the PROC TCOUNTREG statement, PROC TCOUNTREG displays the estimated correlation matrix. It is based on the Hessian matrix used at the final iteration.

OUTPUT OUT= Data Set

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimates of $\mathbf{x}_i' \boldsymbol{\beta}$, the expected value of the response variable, and the probability of the response variable taking on the current value or other values that you specify. In a zero-inflated model, you can also request that the output data set contain the estimates of $\mathbf{z}_i' \boldsymbol{\gamma}$, and the probability that the response is zero as a result of the zero-generating process.

Except for the probability of the current value, these statistics can be computed for all observations in which the regressors are not missing, even if the response is missing. By adding observations with missing response values to the input data set, you can compute these statistics for new observations or for settings of the regressors that are not present in the data without affecting the model fit.

OUTEST= Data Set

The OUTEST= data set has two rows: the first row (with `_TYPE_='PARM'`) contains each of the parameter estimates in the model, and the second row (with `_TYPE_='STD'`) contains the standard errors for the parameter estimates in the model.

If you use the COVOUT option in the PROC TCOUNTREG statement, the OUTEST= data set also contains the covariance matrix for the parameter estimates. The covariance matrix appears in the observations with `_TYPE_='COV'`, and the `_NAME_` variable labels the rows with the parameter names.

The names of the parameters are used as variable names. These are the same names as used in the INIT, BOUNDS, and RESTRICT statements.

ODS Table Names

PROC TCOUNTREG assigns a name to each table it creates. You can use these names to denote the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 30.2.

Table 30.2 ODS Tables Produced in PROC TCOUNTREG

ODS Table Name	Description	Option
ODS Tables Created by the MODEL Statement		
ClassLevels	Class levels	Default
FitSummary	Summary of nonlinear estimation	Default
ConvergenceStatus	Convergence status	Default

Table 30.2 *continued*

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Before you create graphs, ODS Graphics must be enabled (for example, with the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

This section describes the use of ODS Graphics to create graphics with the TCOUNTREG procedure.

To request these graphs, you must specify the ODS GRAPHICS ON statement. There is no default plot for the TCOUNTREG procedure. If, in addition to the ODS GRAPHICS statement, you specify the ALL option in the PROC TCOUNTREG statement, then all applicable plots are created.

ODS Graph Names

PROC TCOUNTREG assigns a name to each graph that it creates using ODS. You can use these names to refer to the graphs when using ODS. The names are listed in [Table 30.3](#).

Table 30.3 ODS Graphics Produced in PROC AUTOREG

ODS Table Name	Description	Plots= Option
PredProbPlot	Predictive probability plot	PLOTS(CNTLVLS)=PREDPROB
ProfileLikPlot	Profile likelihood functions	PLOTS(UNPACK)=PROFILELIKE or PROLIK
OverDispersion	Overdispersion diagnostic plot	PLOTS=DISPERSION

Example 30.1: Basic Models

Data Description and Objective

The data set docvisit contains information for approximately 5,000 Australian individuals about the number and possible determinants of doctor visits that were made during a two-week interval. This data set contains a subset of variables taken from the Racd3 data set used by Cameron and Trivedi (1998). The docvisit data set can be found in the SAS/ETS Sample Library.

The variable doctorco represents doctor visits. Additional variables in the data set that you want to evaluate as determinants of doctor visits include sex (coded 0=male, 1=female), age (age in years divided by 100), illness (number of illnesses during the two-week interval, with five or more coded as five), income (annual income in Australian dollars divided by 1,000), and hscore (a general health questionnaire score, where a high score indicates bad health). Summary statistics for these variables are computed in the following statements and presented in [Output 30.1.1](#).

```
proc means data=docvisit;
  var doctorco sex age illness income hscore;
run;
```

Output 30.1.1 Summary Statistics

The MEANS Procedure					
Variable	N	Mean	Std Dev	Minimum	Maximum
doctorco	5190	0.3017341	0.7981338	0	9.0000000
sex	5190	0.5206166	0.4996229	0	1.0000000
age	5190	0.4063854	0.2047818	0.1900000	0.7200000
illness	5190	1.4319846	1.3841524	0	5.0000000
income	5190	0.5831599	0.3689067	0	1.5000000
hscore	5190	1.2175337	2.1242665	0	12.0000000

Poisson Model

The following statements fit a Poisson model to the data by using the covariates SEX, ILLNESS, INCOME, and HSCORE:

```
proc tcountreg data=docvisit plots(only counts(0 to 4 by 1))=(predprob predpro);
  model doctorco=sex illness income hscore / dist=poisson printall;
run;
```

Output 30.1.2 Mean Predicted Count Probabilities

Output 30.1.2 shows the predicted frequencies of count levels 0 to 4 from the Poisson model. Although most of the observed counts would appear to be in the range 0 to 4, in fact observed counts between 0 and 4 account for more than 99% of the entire data set. One thing that would be interesting to explore is how the model-predicted probabilities of those count levels react to different regressor values. Output 30.1.3 shows the predictive profiles of the count levels in question against the first three regressors in the model. In each panel, the regressor in question is varied while all other regressors are fixed at their observed mean and the model parameters are fixed at their MLE.

Output 30.1.3 Profile Function of Predictive Probabilities

In this example, the `DIST=` option in the `MODEL` statement specifies the `POISSON` distribution. In addition, the `PRINTALL` option displays the correlation and covariance matrices for the parameters, log-likelihood values, and convergence information in addition to the parameter estimates. The parameter estimates for this model are shown in [Output 30.1.4](#).

Output 30.1.4 Parameter Estimates of Poisson Model

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	-1.855552	0.074545	-24.89	<.0001
sex	1	0.235583	0.054362	4.33	<.0001
illness	1	0.270326	0.017080	15.83	<.0001
income	1	-0.242095	0.077829	-3.11	0.0019
hscore	1	0.096313	0.009089	10.60	<.0001

Using the CLASS statement

If some regressors are categorical in nature (meaning that these variables can take only a few discrete qualitative values), specify them in the CLASS statement. In this example, SEX is categorical because it takes only two values. A class variable can be numeric or character.

Consider the following extension:

```
proc tcountreg data=docvisit;
  class sex;
  model doctorco=sex illness income hscore / dist=poisson;
run;
```

The partial output is given in [Output 30.1.5](#).

Output 30.1.5 Parameter Estimates of Poisson Model with CLASS statement

The TCOUNTREG Procedure					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	-1.619969	0.063985	-25.32	<.0001
sex 0	1	-0.235583	0.054362	-4.33	<.0001
sex 1	0	0	.	.	.
illness	1	0.270326	0.017080	15.83	<.0001
income	1	-0.242095	0.077829	-3.11	0.0019
hscore	1	0.096313	0.009089	10.60	<.0001

If the CLASS statement is present, the TCOUNTREG procedure creates as many indicator or dummy variables as there are categories in a class variable and uses them as independent variables. In order to avoid collinearity with the intercept, the last-created dummy variable is assigned a zero coefficient by default. This means that only the dummy variable that is associated with the first level of sex (male=0) is used as a regressor. Consequently, the estimated coefficient for this dummy variable is the negative of the one for the original SEX variable in [Output 30.1.4](#) because the reference level has switched from male to female.

Now consider a more practical task. The previous example implicitly assumed that each additional illness during the two-week interval has the same effect. In other words, this variable was thought of as a continuous variable. But this variable has only six values, and it is quite possible that the number of illnesses has a nonlinear effect on doctor visits. In order to check this conjecture, the following statements specify ILLNESS in the CLASS statement so that it is represented in the model by a set of six dummy variables that can account for any type of nonlinearity:

```
proc tcountreg data=docvisit;
  class sex illness;
  model doctorco=sex illness income hscore / dist=poisson;
run;
```

The parameter estimates are displayed in [Output 30.1.6](#).

Output 30.1.6 Parameter Estimates of Poisson Model with CLASS statement

The TCOUNTREG Procedure					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	-0.385930	0.088062	-4.38	<.0001
sex 0	1	-0.219118	0.054190	-4.04	<.0001
sex 1	0	0	.	.	.
illness 0	1	-1.934983	0.121267	-15.96	<.0001
illness 1	1	-0.698307	0.089732	-7.78	<.0001
illness 2	1	-0.471100	0.090742	-5.19	<.0001
illness 3	1	-0.488481	0.099127	-4.93	<.0001
illness 4	1	-0.272372	0.107593	-2.53	0.0114
illness 5	0	0	.	.	.
income	1	-0.253583	0.077441	-3.27	0.0011
hscore	1	0.094590	0.009025	10.48	<.0001

Each ILLNESS parameter in this model represents the difference between each effect of ILLNESS and ILLNESS=5. Note that these estimates for different ILLNESS categories do not increase linearly, but instead show a relatively large jump from zero illnesses to one followed by relatively smaller increases.

Zero-Inflated Poisson model

Suppose that you suspect that the population of individuals can be viewed as two distinct groups: a low-risk group, consisting of individuals who never go to the doctor, and a high-risk group, consisting of individuals who do go to the doctor. You might suspect that the data have this structure both because the sample variance of DOCTORCO (0.64) exceeds its sample mean (0.30), which suggests overdispersion, and also because a large fraction of the DOCTORCO observations (80%) have the value zero. Estimating a zero-inflated model is one way to deal with overdispersion that results from excess zeros.

Suppose also that you suspect that the covariate AGE has an impact on whether an individual belongs to the low-risk group. For example, younger individuals might have illnesses of much lower severity when they do get sick and be less likely to visit a doctor, all else being equal. The following statements estimate a zero-inflated Poisson regression with AGE as a covariate in the zero-generation process:

```
proc tcountreg data=docvisit plots(only)=(dispersion zeroprofile);
  model doctorco=sex illness income hscore / dist=zip;
  zeromodel doctorco ~ age;
run;
```

Output 30.1.7 Profile Function of Zero Process Selection and Zero Prediction

You might be interested in exploring how the zero process selection probability reacts to different regressor values. [Output 30.1.7](#) displays this information in much the same fashion as [Output 30.1.3](#). Since `sex`, `illness`, `income`, and `hscore` do not appear in the `ZEROMODEL` statement, the zero-inflation selection probability does not change for different values of those regressors. However, the plot shows that `age` positively affects the zero process selection probability in a linear fashion.

In this case, the `ZEROMODEL` statement that follows the `MODEL` statement specifies that both an intercept and the variable `AGE` be used to estimate the likelihood of zero doctor visits. [Output 30.1.8](#) shows the resulting parameter estimates.

Output 30.1.8 Parameter Estimates for ZIP Model

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	-1.033387	0.096973	-10.66	<.0001
sex	1	0.122511	0.062566	1.96	0.0502
illness	1	0.237478	0.019997	11.88	<.0001
income	1	-0.143945	0.087810	-1.64	0.1012
hscore	1	0.088386	0.010043	8.80	<.0001
Inf_Intercept	1	0.986557	0.131339	7.51	<.0001
Inf_age	1	-2.090923	0.270580	-7.73	<.0001

The estimates of the zero-inflated intercept (Inf_Intercept) and the zero-inflated regression coefficient for AGE (Inf_age) are approximately 0.99 and -2.09, respectively. Since the zero-inflation model uses a logistic link by default, you can estimate the probabilities for individuals of ages 20, 50, and 70 as follows:

$$\begin{aligned}
 \text{20 years: } & \frac{e^{(0.99-2.09 \cdot .20)}}{1 + e^{(0.99-2.09 \cdot .20)}} = 0.64 \\
 \text{50 years: } & \frac{e^{(0.99-2.09 \cdot .50)}}{1 + e^{(0.99-2.09 \cdot .50)}} = 0.49 \\
 \text{70 years: } & \frac{e^{(0.99-2.09 \cdot .70)}}{1 + e^{(0.99-2.09 \cdot .70)}} = 0.38
 \end{aligned}$$

That is, the estimated probability of belonging to the low-risk group is about 0.64 for a 20-year-old individual, 0.49 for a 50-year-old individual, and only 0.38 for a 70-year-old individual. This supports the suspicion that older individuals are more likely to have a positive number of doctor visits.

Alternative models to account for the overdispersion are the negative binomial and the zero-inflated negative binomial models, which can be fit using the DIST=NEGBIN and DIST=ZINB options, respectively.

Output 30.1.9 Over-dispersion Diagnostic Plot

Output 30.1.9 plots the conditional variance against the conditional mean and can be used as a diagnostic tool to check the level of overdispersion in a model.

Example 30.2: ZIP and ZINB Models for Data Exhibiting Extra Zeros

In the study by Long (1997) of the number of published articles by scientists (see the section “[Getting Started: TCOUNTREG Procedure](#)” on page 2027), the observed proportion of scientists who publish no articles is 0.3005. The following statements use PROC FREQ to compute the proportion of scientists who publish each observed number of articles. [Output 30.2.1](#) shows the results.

```
proc freq data=long97data;
  table art / out=obs;
run;
```

Output 30.2.1 Proportion of Scientists Who Publish a Certain Number of Articles

The FREQ Procedure				
art	Frequency	Percent	Cumulative Frequency	Cumulative Percent
0	275	30.05	275	30.05
1	246	26.89	521	56.94
2	178	19.45	699	76.39
3	84	9.18	783	85.57
4	67	7.32	850	92.90
5	27	2.95	877	95.85
6	17	1.86	894	97.70
7	12	1.31	906	99.02
8	1	0.11	907	99.13
9	2	0.22	909	99.34
10	1	0.11	910	99.45
11	1	0.11	911	99.56
12	2	0.22	913	99.78
16	1	0.11	914	99.89
19	1	0.11	915	100.00

PROC TCOUNTREG is then used to fit Poisson and negative binomial models to the data. For each model, the PROBCOUNT option computes the probability that the number of published articles is m , for $m = 0$ to 10. The following statements compute the estimates for Poisson and negative binomial models. The MEAN procedure is then used to compute the average probability of a zero response.

```
proc tcountreg data=long97data;
  model art=fem mar kid5 phd ment / dist=poisson;
  output out=predpoi probcount(0 to 10);
run;

proc means mean data=predpoi;
  var p_0;
run;
```

The output from the Poisson model for the TCOUNTREG and MEAN procedures is shown in [Output 30.2.2](#).

Output 30.2.2 Poisson Model Estimation

0.3035957					

For each model, the predicted proportion of zero articles can be calculated as the average predicted probability of zero articles across all scientists. Under the Poisson model, the predicted proportion of zero articles is 0.2092, which considerably underestimates the observed proportion. The negative binomial more closely estimates the proportion of zeros (0.3036). Also, the test of the dispersion parameter, $_Alpha$, in the negative binomial model indicates significant overdispersion ($p < 0.0001$). As a result, the negative binomial model is preferred to the Poisson model.

Another way to account for the large number of zeros in this data set is to fit a zero-inflated Poisson (ZIP) or a zero-inflated negative binomial (ZINB) model. In the following statements, `DIST=ZIP` requests the ZIP model. In the `ZEROMODEL` statement, you can specify the predictors, z , for the process that generated the additional zeros. The `ZEROMODEL` statement also specifies the model for the probability φ . By default,

a logistic model is used for φ . The default can be changed using the LINK= option. In this particular ZIP model, all variables used to model the article counts are also used to model φ .

```
proc tcountreg data=long97data;
  model art = fem mar kid5 phd ment / dist=zip;
  zeromodel art ~ fem mar kid5 phd ment;
  output out=predzip probcount(0 to 10);
run;

proc means data=predzip mean;
  var p_0;
run;
```

The parameters of the ZIP model are displayed in [Output 30.2.6](#). The first set of parameters gives the estimates of β in the model for the Poisson process mean. Parameters with the prefix “Inf_” are the estimates of γ in the logistic model for φ .

Output 30.2.6 ZIP Model Estimation

The MEANS Procedure	
Analysis Variable : P_0 Probability of art taking level=0	
	Mean

	0.2985679

The proportion of zeros predicted by the ZIP model is 0.2986, which is much closer to the observed proportion than the Poisson model. But [Output 30.2.8](#) shows that both models deviate from the observed proportions at one, two, and three articles.

The ZINB model is specified by the DIST=ZINB option. All variables are again used to model both the number of articles and φ . The METHOD=QN option specifies that the quasi-Newton method be used to fit the model rather than the default Newton-Raphson method. These options are implemented in the following statements:

```
proc tcountreg data=long97data;
  model art=fem mar kid5 phd ment / dist=zinb method=qn;
  zeromodel art ~ fem mar kid5 phd ment;
  output out=predzinb probcount(0 to 10);
run;

proc means data=predzinb mean;
  var p_0;
run;
```

The estimated parameters of the ZINB model are shown in [Output 30.2.7](#). The test for overdispersion again indicates a preference for the negative binomial version of the zero-inflated model ($p < 0.0001$). The ZINB model also does a good job of estimating the proportion of zeros (0.3119), and it follows the observed proportions well, though possibly not as well as the negative binomial model.

    discretelegend 'poi' 'zip' 'nb' 'zinb' 'obs' / title='Models:'
        location=inside position=ne across=2 down=3;
run;

```

For each of the four fitted models, [Output 30.2.8](#) shows the average predicted count probability for each article count across all scientists. The Poisson model clearly underestimates the proportion of zero articles published, while the other three models are quite accurate at zero. All of the models do well at the larger numbers of articles.

Output 30.2.8 Average Predicted Count Probability

Example 30.3: Variable Selection

This example demonstrates two algorithms of automatic variable selection in the TCOUNTREG procedure. This method is most effective when the number of possible candidates for explaining the variation of some variable is large. For clarity of exposition, this example uses only a small number of variables. The data set ARTICLE published by Long (1997) contains six variables. This data set was already used in “[Example 30.2: ZIP and ZINB Models for Data Exhibiting Extra Zeros](#)” on page 2074. The dependent variable called art records the number of articles published by a graduate student in the last three years of their program. Explanatory factors include sex of a student (fem), his or her marital status (mar), number of children (kid5), prestige of the program (phd), and publishing activity of the academic adviser (ment). All these variables intuitively suggest their affect on students’ primary academic output.

First, for comparison purposes, estimate the simple Poisson model. The choice of model is specified by DIST= option in the MODEL statement.

```
proc tcountreg data = long97data;
  model art = fem mar kid5 phd ment / dist = poisson;
run;
```

The output of these statements is shown in [Figure 30.3.1](#).

Output 30.3.1 Poisson Model for the Number of Published Articles

The TCOUNTREG Procedure					
Model Fit Summary					
Dependent Variable					art
Number of Observations					915
Data Set				WORK.LONG97DATA	
Model				Poisson	
Optimization Method				Newton-Raphson	
Log Likelihood				-1651	
Maximum Absolute Gradient				3.5741E-9	
Number of Iterations				5	
AIC				3314	
SBC				3343	
Algorithm converged.					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.304617	0.102982	2.96	0.0031
fem	1	-0.224594	0.054614	-4.11	<.0001
mar	1	0.155243	0.061375	2.53	0.0114
kid5	1	-0.184883	0.040127	-4.61	<.0001
phd	1	0.012823	0.026397	0.49	0.6271
ment	1	0.025543	0.002006	12.73	<.0001

Note that the Newton-Raphson optimization algorithm took five steps to converge. All parameters, except for one, are significant at a 1% or 5% level, while `phd` is not significant even at the 10% level.

In this case, it might be easy to identify variables with limited explanatory power. However, if the number of variables were large, the manual selection could be time demanding and inaccurate. For a large number of variables, you would be better off by applying one of the automatic algorithms of variable selection. The following statements use the penalized likelihood method, which is indicated by `SELECT=PEN` option in the `MODEL` statement:

```
proc tcountreg data = long97data method = qn;
  model art = fem mar kid5 phd ment / dist = poisson
          select = PEN;
run;
```

The output of these statements is shown in [Output 30.3.2](#).

Output 30.3.2 Poisson Model for the Number of Published Articles with Penalized Likelihood Method

The TCOUNTREG Procedure					
Model Fit Summary					
Dependent Variable					art
Number of Observations					915
Data Set					WORK.LONG97DATA
Model					Poisson
Optimization Method					Quasi-Newton
Log Likelihood					-1651
Maximum Absolute Gradient					4.20414E-6
Number of Iterations					7
AIC					3312
SBC					3336
Algorithm converged.					
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.345174	0.060125	5.74	<.0001
fem	1	-0.225303	0.054615	-4.13	<.0001
mar	1	0.152175	0.061067	2.49	0.0127
kid5	1	-0.184993	0.040139	-4.61	<.0001
ment	1	0.025761	0.001950	13.21	<.0001

The “Parameter Estimates” table shows that the variable *phd* was dropped from the model.

The next statements use the information criterion by specifying the SELECT=INFO option. The direction of search is chosen to be FORWARD, and the information criterion is AIC. In order to achieve the same selection of variables as for the penalized likelihood method, 0.001 is specified for the percentage of decrease in the information criterion necessary for the algorithm to stop.

```
proc tcountreg data = long97data;
  model art = fem mar kid5 phd ment / dist      = poisson
                                     select      = INFO
                                     ( direction = forward
                                     criter      = AIC
                                     lstop      = 0.001 );
run;
```

The output of these statements is shown in [Figure 30.3.3](#).

Output 30.3.3 Poisson Model for the Number of Published Articles with Search Method Using Information Criterion

The TCOUNTREG Procedure					
Variable Selection Information					
Step	Effect Entered	Effect Removed	AIC	SBC	
0	Base Model		3487.146950	3491.965874	
1	ment		3341.286487	3350.924335	
2	fem		3330.744604	3345.201376	
3	kid5		3316.593036	3335.868733	
4	mar		3312.348824	3336.443445	

Model Fit Summary					
Dependent Variable		art			
Number of Observations		915			
Data Set		WORK.LONG97DATA			
Model		Poisson			
Optimization Method		Newton-Raphson			
Log Likelihood		-1651			
Maximum Absolute Gradient		1.28434E-9			
Number of Iterations		0			
AIC		3312			
SBC		3336			

Algorithm converged.

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.345174	0.060125	5.74	<.0001
fem	1	-0.225303	0.054615	-4.13	<.0001
mar	1	0.152175	0.061067	2.49	0.0127
kid5	1	-0.184993	0.040139	-4.61	<.0001
ment	1	0.025761	0.001950	13.21	<.0001

From the output, it is clear that the same set of variables was chosen as the result of information criterion algorithm. Note that the forward optimization algorithm starts with the constant as the only explanatory variable.

Overview: TIMEDATA Procedure

The TIMEDATA procedure analyzes time-stamped transactional data with respect to time and accumulates the data into a time series format.

After the transactional data are accumulated to form a time series and any missing values are interpreted, the accumulated time series can be functionally transformed using log, square root, logistic, or Box-Cox transformations. The time series can be further transformed using simple differencing, seasonal differencing, or both. After functional and difference transformations have been applied, the accumulated and transformed time series can be stored in an output data set. This working time series can then be analyzed further using various time series analysis techniques provided by this procedure or other SAS/ETS procedures.

The TIMEDATA procedure is very similar to the TIMESERIES procedure. However, unlike the TIMESERIES procedure (which enables you to perform a variety of standard time series analysis techniques), the TIMEDATA procedure enables you to define your own analyses using SAS programming statements.

By default, the TIMEDATA procedure provides no further analyses.

The TIMEDATA procedure forms time series vectors and then provides these vectors as SAS data arrays for subsequent processing by your SAS programming statements. Your programming statements are processed independently for each BY group. The TIMEDATA procedure is like the SAS DATA step for time series data. The SAS DATA step processes data by each row; the TIMEDATA procedure processes time series vectors.

As part of your SAS programming statements, you can include user-defined functions and subroutines created by the FCMP procedure. Additionally, you can use the RUN_MACRO subroutine provided by the FCMP procedure to submit SAS statements that use any SAS procedures.

All results of the transactional or time series analysis can be stored in output data sets or printed using the Output Delivery System (ODS).

Getting Started: TIMEDATA Procedure

This section outlines the use of the TIMEDATA procedure and gives a cursory description of some of the analysis techniques that you can perform on time-stamped transactional data.

Given an input data set that contains numerous transaction variables recorded over time at no specific frequency, the TIMEDATA procedure can form time series as follows:

```
PROC TIMEDATA DATA=<input-data-set>
              OUT=<output-data-set>;
  BY <list-of-BY-variables>;
  ID <time-ID-variable> INTERVAL=<frequency>
    ACCUMULATE=<statistic>;
  VAR <time-series-variables>;
  /* programming statements */
RUN;
```

The TIMEDATA procedure forms time series from the input time-stamped transactional data. It can provide results in output data sets or in other output formats by using the Output Delivery System (ODS).

Time-stamped transactional data are recorded at no fixed interval. Analysts often want to use time series analysis techniques that require fixed-time intervals. Therefore, the transactional data must be accumulated to form a fixed-interval time series, such as daily, weekly, or monthly.

Suppose that a bank wants to analyze the transactions that are associated with each of its customers over time. Further, suppose that the data set `Work.Transactions` contains four variables that are related to these transactions: `Customer`, `Date`, `Withdrawals`, and `Deposits`. The following examples illustrate possible ways to analyze these transactions by using the TIMEDATA procedure.

The following TIMEDATA procedure statements accumulate the time-stamped transactional data to form a daily time series based on the accumulated daily totals of each type of transaction (`Withdrawals` and `Deposits`):

```
proc timedata data=transactions
              out=timeseries
              outarray=arrays;
  by customer;
  id date interval=day accumulate=total;
  var withdrawals deposits;
  outarrays balance;

  balance[1] = deposits[1] - withdrawals[1];
  do t = 2 to _LENGTH_;
    balance[t] = balance[t-1] + (deposits[t] - withdrawals[t]);
  end;

run;
```

The `OUT=TIMESERIES` option specifies that the resulting time series data for each customer are to be stored in the data set `Work.Transactions`. The `OUTARRAY=ARRAYS` option specifies that the resulting time series data along with a newly created variable, `Balance`, are to be stored in the data set `Work.Arrays`. The `INTERVAL=DAY` option specifies that the transactions are to be accumulated on a daily basis. The `ACCUMULATE=TOTAL` option specifies that the sum of the transactions is to be calculated. After the transactional data are accumulated into a time series format, many of the procedures provided with SAS/ETS software can be used to analyze the resulting time series data.

For example, the following statements use the ARIMA procedure to model and forecast each customer's balance data by using an $ARIMA(1,0,0)(0,1,0)_s$ model (where the number of seasons is $s=7$ days in a week):

```
proc arima data=arrays;
  by customer;
  identify var=balance(7) noprint;
  estimate p=(1) outest=estimates noprint;
  forecast id=date interval=day out=forecasts;
quit;
```

The `OUTEST=ESTIMATES` data set contains the parameter estimates of the model specified. The `OUT=FORECASTS` data set contains forecasts based on the model specified. See the SAS/ETS ARIMA procedure for more detail.

By default, the TIMEDATA procedure produces no printed output.

Syntax: TIMEDATA Procedure

The following statements are available in the TIMEDATA Procedure:

```
PROC TIMEDATA options ;  
  BY variables ;  
  ID variable INTERVAL= interval-option ;  
  FCMPOPT options ;  
  OUTARRAYS array-name-list ;  
  OUTSCALARS scalar-name-list ;  
  VAR variable-list / options ;  
  Programming Statements ;
```

Functional Summary

Table 31.1 summarizes the statements and options that control the TIMEDATA procedure.

Table 31.1 TIMEDATA Functional Summary

Description	Statement	Option
Statements		
Specifies BY-group processing	BY	
Specifies variables to analyze	VAR	
Specifies the time ID variable	ID	
Specifies the FCMP options	FCMPOPT	
Specifies the arrays to output	OUTARRAYS	
Specifies the scalars to output	OUTSCALARS	
Data Set Options

Specifies seasonal differencing	VAR	SDIF=
Specifies transformation	VAR	TRANSFORM=
Printing Control Options		
Specifies the time ID format	ID	FORMAT=
Specifies which output to print	PROC TIMEDATA	PRINT=
Specifies that detailed output be printed	PROC TIMEDATA	PRINTDETAILS
Miscellaneous Options		
Specifies the forecast horizon or lead used to extend the data set	PROC TIMEDATA	LEAD=
Specifies that analysis variables be processed in sorted order	PROC TIMEDATA	SORTNAMES
Limits error and warning messages	PROC TIMEDATA	MAXERROR=
ODS Graphics Options		
Specifies the variable and array graphical output	PROC TIMEDATA	PLOTS=

PROC TIMEDATA Statement

PROC TIMEDATA *options* ;

The following *options* can be used in the PROC TIMEDATA statement:

CYCLETYPE=*option*

specifies the indexing of each time series with respect to life-cycle. By default, CYCLETYPE=BOL.

The following CYCLETYPE= *options* are available:

BOL	indexes the time series by the beginning of life. The first time value is 1. The following values are incremented by 1.
MOL	indexes the time series by the middle of life. The middle time value is one. The preceding values are decremented by 1. The following values are incremented by 1.
EOL	indexes the time series by the end of life. The last time value is 1. The preceding values are incremented by 1.

The CYCLETYPE= option specifies the indexing of the `_CYCLE_` variable contained in the `OUTARRAY=` data set and the predefined array `_CYCLE_`.

DATA=*SAS-data-set*

names the SAS data set that contains the input data from which the procedure creates the time series. If the DATA= option is not specified, the most recently created SAS data set is used.

LEAD=*n*

specifies the number of periods ahead to forecast (forecast lead or horizon) used to extend the data set. The default is LEAD=0.

The LEAD= value is relative to the last observation in the input data set and not to the last nonmissing observation of a particular series.

MAXERROR=*number*

limits the number of warning and error messages that are produced during the execution of the procedure to the specified *number*. The default is MAXERRORS=50. This option is particularly useful in BY-group processing where it can be used to suppress recurring messages.

OUT=*SAS-data-set*

names the output data set to contain the time series variables specified in the subsequent VAR statements. If BY variables are specified, they are also included in the OUT= data set. If an ID variable is specified, it is also included in the OUT= data set. The values are accumulated based on the INTERVAL= option or the ACCUMULATE= option or both in the ID statement. The OUT= data set is particularly useful when you want to further analyze, model, or forecast the resulting time series with other SAS/ETS procedures.

OUTARRAY=*SAS-data-set*

names the output data set to contain the time series vectors listed in the VAR and OUTARRAYS statements.

The OUTARRAY= data set contains the variables specified in the BY, ID, and VAR statements in addition to the arrays that are specified in the OUTARRAYS statements.

OUTSCALAR=SAS-data-set

names the output data set to contain the scalar names listed in the OUTSCALARS statements.

The OUTSCALAR= data set contains the variables specified in the BY statement and the scalars that are specified in the OUTSCALARS statements.

OUTPROCINFO=SAS-data-set

names the output data set to summarize information in the SAS log, specifically the number of notes, errors, and warnings and the number of series processed, analyses requested, and analyses failed.

OUTSUM=SAS-data-set

names the output data set to contain the descriptive statistics. The descriptive statistics are based on the accumulated time series when the ACCUMULATE= option, the SETMISSING= option, or both are specified in the ID or VAR statements. The OUTSUM= data set is particularly useful when analyzing large numbers of series and a summary of the results is needed.

PLOTS=option | (options)

specifies the univariate graphical output desired. By default, the TIMEDATA procedure produces no graphical output. The PLOTS= option produces results that are similar to the data sets shown in parentheses next to the following *options*:

ARRAYS plots the time series (OUT= data set).

ALL same as PLOTS=(ARRAYS).

For example, PLOTS=ARRAYS plots the time series. The PLOTS= option produces graphical output for these results by using the Output Delivery System (ODS).

PRINT=option | (options)

specifies the printed output desired. By default, the TIMEDATA procedure produces no printed output. The PRINT= option produces results that are similar to the data sets shown in parentheses next to the following *options*:

ARRAYS prints the arrays table (OUTARRAY= data set).

SCALARS prints the scalars table (OUTSCALAR= data set).

SUMMARY prints the descriptive statistics table for all time series (OUTSUM= data set).

ALL same as PRINT=(ARRAYS SCALARS SUMMARY).

For example, PRINT=SCALARS prints the scalars specified in the OUTSCALARS statement. The PRINT= option produces printed output for these results by using the Output Delivery System (ODS).

PRINTDETAILS

specifies that output requested with the PRINT= option be printed in greater detail.

SEASONALITY=number

specifies the length of the seasonal cycle. For example, SEASONALITY=3 means that every group of three time periods forms a seasonal cycle. By default, the length of the seasonal cycle is 1 (no seasonality) or the length implied by the INTERVAL= option specified in the ID statement. For example, INTERVAL=MONTH implies that the length of the seasonal cycle is 12.

SORTNAMES

specifies that the variables specified in the VAR statements be processed in sorted order by the variable names. This option enables the output data sets to be presorted by the variable names.

BY Statement

You can include a BY statement with PROC TIMEDATA to obtain separate dummy variable definitions for groups of observations defined by the BY variables.

When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the option NOTSORTED or DESCENDING in the BY statement for the TIMEDATA procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure.

For more information about the BY statement, see *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FCMPOPT Statement

FCMPOPT *options* ;

The FCMPOPT statement specifies the following *options* that are related to user-defined functions and subroutines:

QUIET=ON | OFF

specifies whether the nonfatal errors and warnings that are generated by the user-defined SAS language functions and subroutines are printed to the log. Nonfatal errors are usually associated with operations with missing values. The default is QUIET=ON.

TRACE=ON | OFF

specifies whether the user-defined SAS language functions and subroutines tracings are printed to the log. Tracings are the results of every operation executed. This option is generally used for debugging. The default is TRACE=OFF.

ID Statement

ID *variable* **INTERVAL=***interval* < *options* > ;

The ID statement names a numeric variable that identifies observations in the input and output data sets. The ID variable's values are assumed to be SAS date or datetime values. In addition, the ID statement specifies the (desired) frequency associated with the time series. The ID statement *options* also specify how the observations are accumulated and how the time ID values are aligned to form the time series. The information specified affects all variables listed in subsequent VAR statements. If the ID statement is specified, the INTERVAL= must also be used. If an ID statement is not specified, the observation number, with respect to the BY group, is used as the time ID.

You can specify following *options* in the ID statement:

ACCUMULATE= *option*

specifies how the data set observations are to be accumulated within each time period. The frequency (width of each time interval) is specified by the INTERVAL= option. The ID variable contains the time ID values. Each time ID variable value corresponds to a specific time period. The accumulated values form the time series, which is used in subsequent analysis.

The ACCUMULATE= option is useful when there are zero or more than one input observations that coincide with a particular time period (for example, time-stamped transactional data). The EXPAND procedure offers additional frequency conversions and transformations that can also be useful in creating a time series.

The following *options* determine how the observations are accumulated within each time period based on the ID variable and the frequency specified by the INTERVAL= option:

NONE	No accumulation occurs; the ID variable values must be equally spaced with respect to the frequency. This is the default. Observations are accumulated based on the:
TOTAL	total sum of their values.
AVERAGE AVG	average of their values.
MINIMUM MIN	minimum of their values.
MEDIAN MED	median of their values.
MAXIMUM MAX	maximum of their values.
N	number of nonmissing observations.
NMISS	number of missing observations.
NOBS	number of observations.
FIRST	first of their values.
LAST	last of their values.
STDDEV STD	standard deviation of their values.
CSS	corrected sum of squares of their values.
USS	uncorrected sum of squares of their values.

If the `ACCUMULATE=` option is specified, the `SETMISSING=` option is useful for specifying how accumulated missing values are to be treated. If missing values should be interpreted as zero, then `SETMISSING=0` should be used. The section “[Details: TIMEDATA Procedure](#)” on page 2102 describes accumulation in greater detail.

ALIGN=option

controls the alignment of SAS dates that are used to identify output observations. The `ALIGN=` option accepts the following values: `BEGINNING | BEG | B`, `MIDDLE | MID | M`, and `ENDING | END | E`. `BEGINNING` is the default.

BOUNDARYALIGN=option

controls how the `ACCUMULATE=` option is processed for the two boundary time intervals, which include the `START=` and `END=` time ID values. Some time ID values might fall inside the first and last accumulation intervals but fall outside the `START=` and `END=` boundaries. In these cases the `BOUNDARYALIGN=` option determines which values to include in the accumulation operation. You can specify the following *options*:

NONE	No values outside the <code>START=</code> and <code>END=</code> boundaries are accumulated. This is the default.
START	All observations in the first time interval are accumulated.
END	All observations in the last time interval are accumulated.
BOTH	All observations in the first and last are accumulated.

If no option is specified, the default value `BOUNDARYALIGN=NONE` is used. The section “[Details: TIMEDATA Procedure](#)” on page 2102 describes the `BOUNDARYALIGN=` accumulation option in greater detail.

END=option

specifies a SAS date or datetime value that represents the end of the data. If the last time ID variable value is less than the `END=` value, the series is extended with missing values. If the last time ID variable value is greater than the `END=` value, the series is truncated. For example, `END=&sysdate` uses the automatic macro variable `SYSDATE` to extend or truncate the series to the current date. You can specify the `START=` and `END=` options to ensure that the data that are associated within each BY group contain the same number of observations.

FORMAT=format

specifies the SAS format for the time ID values. If the `FORMAT=` option is not specified, the default format is inferred from the `INTERVAL=` option.

INTERVAL=interval

specifies the frequency of the accumulated time series. For example, if the input data set consists of quarterly observations, then `INTERVAL=QTR` should be used. If the `SEASONALITY=` option is not specified in the `PROC TIMEDATA` statement, the length of the seasonal cycle is implied from the `INTERVAL=` option. For example, `INTERVAL=QTR` implies a seasonal cycle of length 4. If the `ACCUMULATE=` option is also specified, the `INTERVAL=` option determines the time periods for the accumulation of observations. The `INTERVAL=` option is required and must be specified in the `ID` statement.

NOTSORTED

specifies that the time ID values not be in sorted order. The TIMEDATA procedure sorts the data with respect to the time ID prior to analysis.

SETMISSING=option | number

specifies how missing values (either actual or accumulated) are to be interpreted in the accumulated time series. If a *number* is specified, missing values are set to the *number*. If a missing value indicates an unknown value, specify SETMISSING=MISSING. If a missing value indicates a zero value, specify SETMISSING=0. You would typically use SETMISSING=0 for transactional data because no recorded data usually implies no activity. You can use the following *options* to determine how missing values are assigned. Missing values are set to:

MISSING	a missing value. This is the default.
AVERAGE AVG	the accumulated average value.
MINIMUM MIN	the accumulated minimum value.
MEDIAN MED	the accumulated median value.
MAXIMUM MAX	the accumulated maximum value.
FIRST	the accumulated first nonmissing value.
LAST	the accumulated last nonmissing value.
PREVIOUS PREV	the previous period's accumulated nonmissing value. Missing values at the beginning of the accumulated series remain missing.
NEXT	the next period's accumulated nonmissing value. Missing values at the end of the accumulated series remain missing.

START=option

specifies a SAS date or datetime value that represents the beginning of the data. If the first time ID variable value is greater than the START= value, missing values are added at the beginning of the series. If the first time ID variable value is less than the START= value, the series is truncated. You can specify the START= and END= options to ensure that data associated with each BY group contain the same number of observations.

ZEROMISS=option
