Overview: SCORE Procedure

The SCORE procedure multiplies values from two SAS data sets, one containing coefficients (for example, factor-scoring coefficients or regression coefficients) and the other containing raw data to be scored using the coefficients from the first data set. The result of this multiplication is a SAS data set containing linear combinations of the coefficients and the raw data values.

Many statistical procedures output coefficients that PROC SCORE can apply to raw data to produce scores. The new score variable is formed as a linear combination of raw data and scoring coefficients. For each observation in the raw data set, PROC SCORE multiplies the value of a variable in the raw data set by the matching scoring coefficient from the data set of scoring coefficients. This multiplication process is repeated for each variable in the VAR statement. The resulting products are then summed to produce the value of the new score variable. This entire process is repeated for each observation in the raw data set. In other words, PROC SCORE cross multiplies part of one data set with another.

Raw Data Set

The raw data set can contain the original data used to calculate the scoring coefficients, or it can contain an entirely different data set. The raw data set must contain all the variables needed to produce scores. In addition, the scoring coefficients and the variables in the raw data set that are used in scoring must have the same names. See the section “Getting Started: SCORE Procedure” on page 6947 for more information.

Scoring Coefficients Data Set

The data set containing scoring coefficients must contain two special variables: the `_TYPE_` variable and the `_NAME_` or `_MODEL_` variable.

- The `_TYPE_` variable identifies the observations that contain scoring coefficients.
- The `_NAME_` or `_MODEL_` variable provides a SAS name for the new score variable.

PROC SCORE first looks for a `_NAME_` variable in the `SCORE=` input data set. If there is such a variable, the variable's value is what SCORE uses to name the new score variable. If the `SCORE=` data set does not have a `_NAME_` variable, then PROC SCORE looks for a `_MODEL_` variable.

For example, PROC FACTOR produces an output data set that contains factor-scoring coefficients. In this output data set, the scoring coefficients are identified by `_TYPE_='SCORE'`. For `_TYPE_='SCORE'`, the `_NAME_` variable has values of 'Factor1', 'Factor2', and so forth. PROC SCORE gives the new score variables the names Factor1, Factor2, and so forth.

As another example, the REG procedure produces an output data set that contains parameter estimates. In this output data set, the parameter estimates are identified by `_TYPE_='PARMS'`. The `_MODEL_` variable contains the label used in the MODEL statement in PROC REG, or it uses `MODEL n` if no label is specified. This label is the name PROC SCORE gives to the new score variable.

Standardization of Raw Data

PROC SCORE automatically standardizes or centers the `DATA=` variables for you, based on information from the original variables and analysis from the `SCORE=` data set.

If the `SCORE=` scoring coefficients data set contains observations with `_TYPE_='MEAN'` and `_TYPE_='STD'`, then PROC SCORE standardizes the raw data before scoring. For example, this type of `SCORE=` data set can come from PROC PRINCOMP without the COV option.

If the `SCORE=` scoring coefficients data set contains observations with `_TYPE_='MEAN'` but `_TYPE_='STD'` is absent, then PROC SCORE centers the raw data (the means are subtracted) before scoring. For example, this type of `SCORE=` data set can come from PROC PRINCOMP with the COV option.

If the `SCORE=` scoring coefficients data set does not contain observations with `_TYPE_='MEAN'` and `_TYPE_='STD'`, or if you use the NOSTD option, then PROC SCORE does not center or standardize the raw data.

If the SCORE= scoring coefficients are obtained from observations with `_TYPE_='USCORE'`, then PROC SCORE “standardizes” the raw data by using the uncorrected standard deviations identified by `_TYPE_='USTD'`, and the means are not subtracted from the raw data. For example, this type of SCORE= data set can come from PROC PRINCOMP with the NOINT option. For more information about `_TYPE_='USCORE'` scoring coefficients in TYPE=UCORR or TYPE=UCOV output data sets, see Appendix A, “[Special SAS Data Sets](#).”

You can use PROC SCORE to score the data that were also used to generate the scoring coefficients, although more typically, scoring results are directly obtained from the OUT= data set in a procedure that computes scoring coefficients. When scoring new data, it is important to realize that PROC SCORE assumes that the new data have approximately the same scales as the original data. For example, if you specify the COV option with PROC PRINCOMP for the original analysis, the scoring coefficients in the PROC PRINCOMP OUTSTAT= data set are not appropriate for standardized data. With the COV option, PROC PRINCOMP will not output `_TYPE_='STD'` observations to the OUTSTAT= data set, and PROC SCORE will only subtract the means of the original (not new) variables from the new variables before multiplying. Without the COV option in PROC PRINCOMP, both the original variable means and standard deviations will be in the OUTSTAT= data set, and PROC SCORE will subtract the original variable means from the new variables and divide them by the original variable standard deviations before multiplying.

In general, procedures that output scoring coefficients in their OUTSTAT= data sets provide the necessary information for PROC SCORE to determine the appropriate standardization. However, if you use PROC SCORE with a scoring coefficients data set that you constructed without `_TYPE_='MEAN'` and `_TYPE_='STD'` observations, you might have to do the relevant centering or standardization of the new data first. If you do this, you must use the means and standard deviations of the original variables—that is, the variables that were used to generate the coefficients—not the means and standard deviations of the variables to be scored.

See the section “[Getting Started: SCORE Procedure](#)” on page 6947 for further illustration.

Getting Started: SCORE Procedure

The SCORE procedure multiplies the values from two SAS data sets and creates a new data set to contain the results of the multiplication. The variables in the new data set are linear combinations of the variables in the two input data sets. Typically, one of these data sets contains raw data that you want to score, and the other data set contains scoring coefficients.

The following example demonstrates how to use the SCORE procedure to multiply values from two SAS data sets, one containing factor-scoring coefficients and the other containing raw data to be scored using the scoring coefficients.

Suppose you are interested in the performance of three different types of schools: private schools, state-run urban schools, and state-run rural schools. You want to compare the schools’ performances as measured by student grades on standard tests in English, mathematics, and biology. You administer these tests and record the scores for each of the three types of schools.

The following DATA step creates the SAS data set Schools. The data are provided by Chaseling (1996).

```

data Schools;
    input Type $ English Math Biology @@;
    datalines;
p  52  55  45  p  42  49  40  p  63  64  54
p  47  50  51  p  64  69  47  p  63  67  54
p  59  63  42  p  56  61  41  p  41  44  72
p  39  42  45  p  56  63  44  p  63  73  42

    ... more lines ...

r  50  47  49  r  55  48  46  r  38  36  51
;

```

The data set `Schools` contains the character variable `Type`, which represents the type of school. Valid values are `p` (private schools), `r` (state-run rural schools), and `u` (state-run urban schools).

The three numeric variables in the data set are `English`, `Math`, and `Biology`, which represent the student scores for English, mathematics, and biology, respectively. The double trailing at sign (`@@`) in the `INPUT` statement specifies that observations are input from each line until all values are read.

The following statements invoke the `FACTOR` procedure to compute the data set of factor scoring coefficients. The statements perform a principal components factor analysis that uses all three numeric variables in the SAS data set `Schools`. The `OUTSTAT=` option requests that `PROC FACTOR` output the factor scores to the data set `Scores`. The `NOPRINT` option suppresses display of the output.

```

proc factor data=Schools score outstat=Scores noprint;
    var english math biology;
run;

proc score data=schools score=Scores out=New;
    var english math biology;
    id type;
run;

```

The SCORE procedure is then invoked using Schools as the raw data set to be scored and Scores as the scoring data set. The OUT= option creates the SAS data set New to contain the linear combinations.

The VAR statement specifies that the variables English, Math, and Biology are used in computing scores. The ID statement copies the variable Type from the Schools data set to the output data set New.

The following statements print the SAS output data set Scores, the first two observations from the original data set Schools, and the first two observations of the resulting data set New.

```

title 'OUTSTAT= Data Set from PROC FACTOR';
proc print data=Scores;
run;

title 'First Two Observations of the DATA= Data Set from PROC SCORE';
proc print data=Schools(obs=2);
run;

title 'First Two Observations of the OUT= Data Set from PROC SCORE';
proc print data=New(obs=2);
run;

```

Figure 82.1 displays the output data set Scores produced by the FACTOR procedure. The last observation (number 11) contains the scoring coefficients (_TYPE_='SCORE'). Only one factor has been retained.

Figure 82.1 Listing of the Data Set Created by PROC FACTOR

OUTSTAT= Data Set from PROC FACTOR					
Obs	_TYPE_	_NAME_	English	Math	Biology

11	SCORE	Factor1	0.390	0.378	0.347

Figure 82.2 lists the first two observations of the original SAS data set (Schools).

Figure 82.2 First Two Observations of the Schools Data Set

First Two Observations of the DATA= Data Set from PROC SCORE				
Obs	Type	English	Math	Biology
1	p	52	55	45
2	p	42	49	40

Figure 82.3 lists the first two observations of the output data set New created by PROC SCORE.

Figure 82.3 Listing of the New Data Set

First Two Observations of the OUT= Data Set from PROC SCORE		
Obs	Type	Factor1
1	p	-0.17604
2	p	-0.80294

The score variable Factor1 in the New data set is named according to the value of the `_NAME_` variable in the Scores data set. The values of the variable Factor1 are computed as follows: the DATA= data set variables are standardized using the same means and standard deviations that PROC FACTOR used when extracting the factors because the Scores data set contains observations with `_TYPE_='MEAN'` and `_TYPE_='STD'`.

Note that in order to correctly use standardized scoring coefficients created by other procedures such as PROC FACTOR in this example, the data to be scored must be standardized in the same way that the data were standardized when the scoring coefficients were computed. Otherwise, the resulting scores might be incorrect. PROC SCORE does this automatically if the SCORE= data set is the original OUTSTAT= data set output from the procedure creating the scoring coefficients.

These standardized variables are then multiplied by their respective standardized scoring coefficients from the data set Scores. These products are summed over all three variables, and the sum is the value of the new variable Factor1. The first two values of the scored variable Factor1 are obtained as follows:

$$\left(\frac{(52 - 55.525)}{12.949} \times 0.390 \right) + \left(\frac{(55 - 52.325)}{12.356} \times 0.378 \right) + \left(\frac{(45 - 50.350)}{12.239} \times 0.347 \right) = -0.17604$$

$$\left(\frac{(42 - 55.525)}{12.949} \times 0.390 \right) + \left(\frac{(49 - 52.325)}{12.356} \times 0.378 \right) + \left(\frac{(40 - 50.350)}{12.239} \times 0.347 \right) = -0.80294$$

The following statements request that the SGPLOT procedure produce a horizontal bar chart of the variable *Type*. The length of each bar represents the mean of the variable *Factor1*.

```
title 'Mean Score of Variable Factor1 by Each Type of Schools';
proc sgplot data=New;
  hbar type / stat = mean response=Factor1;
run;
```

Figure 82.4 displays the mean score of the variable *Factor1* for each of the three school types. For private schools (*Type*=p), the average value of the variable *Factor1* is 0.384, while for state-run schools the average values are much lower. The state-run urban schools (*Type*=u) have the lowest mean value of -0.202 , and the state-run rural schools (*Type*=r) have a mean value of -0.183 .

Figure 82.4 Bar Chart of School Type

Syntax: SCORE Procedure

The following statements are available in the SCORE procedure:

```
PROC SCORE DATA=SAS-data-set < options > ;  
  BY variables ;  
  ID variables ;  
  VAR variables ;
```

The only required statement is the PROC SCORE statement. The BY, ID, and VAR statements are described following the PROC SCORE statement.

PROC SCORE Statement

```
PROC SCORE DATA=SAS-data-set < options > ;
```

The PROC SCORE statement invokes the SCORE procedure. Table 82.1 summarizes the options available in the PROC SCORE statement.

Table 82.1 PROC SCORE Statement Options

Option	Description
DATA=	Names the input SAS data set containing the raw data to score
NOSTD	Suppresses centering and scaling of the raw data
OUT=	Specifies the name of the SAS data set
PREDICT	Treats coefficients of -1 as 0
RESIDUAL	Reverses the sign of each score
SCORE=	Names the data set containing the scoring coefficients
TYPE=	Specifies the observations that contain scoring coefficients

You can specify the following options in the PROC SCORE statement.

DATA=SAS-data-set
names the input SAS data set containing the raw data to score. This option is required.

NOSTD
suppresses centering and scaling of the raw data. Ordinarily, if PROC SCORE finds `_TYPE_='MEAN'`, `_TYPE_='USCORE'`, `_TYPE_='USTD'`, or `_TYPE_='STD'` observations in the SCORE= data set, the procedure uses these to standardize the raw data before scoring.

OUT=SAS-data-set
specifies the name of the SAS data set created by PROC SCORE. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*. If the OUT= option is omitted, PROC SCORE still creates an output data set and automatically names it according to the `DATAn` convention, as if you omitted a data set name in a DATA statement.

PREDICT

specifies that PROC SCORE should treat coefficients of -1 in the SCORE= data set as 0. In regression applications, the dependent variable is coded with a coefficient of -1 . Applied directly to regression results, PROC SCORE produces negative residuals (see the description of the RESIDUAL option, which follows); the PREDICT option produces predicted values instead.

RESIDUAL

reverses the sign of each score. Applied directly to regression results, PROC SCORE produces negative residuals (PREDICT–ACTUAL); the RESIDUAL option produces positive residuals (ACTUAL–PREDICT) instead.

SCORE=SAS-data-set

names the data set containing the scoring coefficients. If you omit the SCORE= option, the most recently created SAS data set is used. This data set must have two special variables: `_TYPE_` and either `_NAME_` or `_MODEL_`.

TYPE=name or 'string'

specifies the observations in the SCORE= data set that contain scoring coefficients. The TYPE= procedure option is unrelated to the data set option that has the same name. PROC SCORE examines the values of the special variable `_TYPE_` in the SCORE= data set. When the value of `_TYPE_` matches `TYPE=name`, the observation in the SCORE= data set is used to score the raw data in the DATA= data set.

If you omit the TYPE= option, scoring coefficients are read from observations with either `_TYPE_='SCORE'` or `_TYPE_='USCORE'`. Because the default for PROC SCORE is `TYPE=SCORE`, you need not specify the TYPE= option for factor scoring or for computing scores from OUTSTAT= data sets from the CANCELL, CANDISC, PRINCOMP, or VARCLUS procedure. When you use regression coefficients from PROC REG, specify `TYPE=PARMS`.

The maximum length of the argument specified in the TYPE= option depends on the length defined by the VALIDVARNAME= SAS system option. For additional information, see *SAS System Options: Reference*.

Note that the TYPE= option setting is not case sensitive. For example, the two option settings `TYPE='MyScore'` and `TYPE='myscore'` are equivalent.

BY Statement

BY variables ;

You can specify a BY statement with PROC SCORE to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.

- Specify the NOTSORTED or DESCENDING option in the BY statement for the SCORE procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

You can specify a BY statement to apply separate groups of scoring coefficients to the entire DATA= data set.

If the DATA= data set does not contain any of the BY variables, the entire DATA= data set is scored by each BY group of scoring coefficients in the SCORE= data set.

If the DATA= data set contains some but not all of the BY variables, or if some BY variables do not have the same type or length in the DATA= data set as in the SCORE= data set, then PROC SCORE prints an error message and stops.

If all the BY variables appear in the DATA= data set with the same type and length as in the SCORE= data set, then each BY group in the DATA= data set is scored using scoring coefficients from the corresponding BY group in the SCORE= data set. The BY groups in the DATA= data set must be in the same order as in the SCORE= data set. All BY groups in the DATA= data set must also appear in the SCORE= data set. If you do not specify the NOTSORTED option, some BY groups can appear in the SCORE= data set but not in the DATA= data set; such BY groups are not used in computing scores.

ID Statement

ID *variables* ;

The ID statement identifies variables from the DATA= data set to be included in the OUT= data set. If there is no ID statement, all variables from the DATA= data set are included in the OUT= data set. The ID variables can be character or numeric.

VAR Statement

VAR *variables* ;

The VAR statement specifies the variables to be used in computing scores. These variables must be in both the DATA= and SCORE= input data sets and must be numeric. If you do not specify a VAR statement, the procedure uses all numeric variables in the SCORE= data set. You should almost always specify a VAR statement with PROC SCORE because you would rarely use all the numeric variables in your data set to compute scores.

Details: SCORE Procedure

Missing Values

If one of the scoring variables in the DATA= data set has a missing value for an observation, all the scores have missing values for that observation. The exception to this criterion is that if the PREDICT option is specified, the variable with a coefficient of -1 can tolerate a missing value and still produce a prediction score. Also, a variable with a coefficient of 0 can tolerate a missing value.

If a scoring coefficient in the SCORE= data set has a missing value for an observation, the coefficient is not used in creating the new score variable for the observation. In other words, missing values of scoring coefficients are treated as zeros. This treatment affects only the observation in which the missing value occurs.

Regression Parameter Estimates from PROC REG

If the SCORE= data set is an OUTEST= data set produced by PROC REG and if you specify TYPE=PARMS, the interpretation of the new score variables depends on the PROC SCORE options chosen and the variables listed in the VAR statement. If the VAR statement contains only the independent variables used in a model in PROC REG, the new score variables give the predicted values. If the VAR statement contains the dependent variables and the independent variables used in a model in PROC REG, the interpretation of the new score variables depends on the PROC SCORE options chosen. If you omit both the PREDICT and the RESIDUAL options, the new score variables give negative residuals (PREDICT–ACTUAL). If you specify the RESIDUAL option, the new score variables give positive residuals (ACTUAL–PREDICT). If you specify the PREDICT option, the new score variables give predicted values.

Unless you specify the NOINT option for PROC REG, the OUTEST= data set contains the variable Intercept. The SCORE procedure uses the intercept value in computing the scores.

Output Data Set

PROC SCORE produces an output data set but displays no output. The output OUT= data set contains the following variables:

- the ID variables, if any
- all variables from the DATA= data set, if no ID variables are specified
- the BY variables, if any
- the new score variables, named from the _NAME_ or _MODEL_ values in the SCORE= data set

Computational Resources

Let

- v = number of variables used in computing scores
- s = number of new score variables
- b = maximum number of new score variables in a BY group
- n = original input value

Memory

The array storage required is approximately $8(4v + (3 + v)b + s)$ bytes. When you do not use BY processing, the array storage required is approximately $8(4v + (4 + v)s)$ bytes.

Time

The time required to construct the scoring matrix is roughly proportional to vs , and the time needed to compute the scores is roughly proportional to nvs .

Examples: SCORE Procedure

The following three examples use a subset of the Fitness data set. The complete data set is given in Chapter 79, “The REG Procedure.”

Example 82.1: Factor Scoring Coefficients

This example shows how to use PROC SCORE with factor scoring coefficients. First, the FACTOR procedure produces an output data set containing scoring coefficients in observations identified by `_TYPE_='SCORE'`. These data, together with the original data set Fitness, are supplied to PROC SCORE, resulting in a data set containing scores Factor1 and Factor2. The following statements produce [Output 82.1.1](#) through [Output 82.1.3](#):

```

/* This data set contains only the first 12 observations */
/* from the full data set used in the chapter on PROC REG. */

Since the PROC SCORE statement does not contain the NOSTD option, the data in the Fitness data set are standardized before scoring. For each variable specified in the VAR statement, the mean and standard deviation are obtained from the FactOut data set. For each observation in the Fitness data set, the variables are then standardized. For example, for observation 1 in the Fitness data set, the variable Age is standardized to $0.5569 = [(44 - 42.4167)/2.8431]$.

After the data in the Fitness data set are standardized, the standardized values of the variables in the VAR statement are multiplied by the matching coefficients in the FactOut data set, and the resulting products are summed. This sum is output as a value of the new score variable.

Output 82.1.3 displays the FScore data set produced by PROC SCORE. This data set contains the variables Age, Weight, Oxygen, RunTime, RestPulse, and RunPulse from the Fitness data set. It also contains Factor1 and Factor2, the two new score variables.

Output 82.1.3 OUT= Data Set from PROC SCORE Reproduced with PROC PRINT

Example 82.2: Regression Parameter Estimates

In this example, PROC REG computes regression parameter estimates for the Fitness data. (See [Example 82.1](#) to for more information about how to create the Fitness data set.) The parameter estimates are output to a data set and used as scoring coefficients. For the first part of this example, PROC SCORE is used to score the Fitness data, which are the same data used in the regression.

In the second part of this example, PROC SCORE is used to score a new data set, Fitness2. For PROC SCORE, the TYPE= specification is PARMS, and the names of the score variables are found in the variable `_MODEL_`, which gets its values from the model label. The following code produces [Output 82.2.1](#) through [Output 82.2.3](#):

```
proc reg data=Fitness outest=RegOut;
  OxyHat: model Oxygen=Age Weight RunTime RunPulse RestPulse;
  title 'Regression Scoring Example';
run;

proc print data=RegOut;
  title2 'OUTEST= Data Set from PROC REG';
run;

proc score data=Fitness score=RegOut out=RScoreP type=parms;
  var Age Weight RunTime RunPulse RestPulse;
run;
```

```

proc print data=RScoreP;
    title2 'Predicted Scores for Regression';
run;

proc score data=Fitness score=RegOut out=RScoreR type=parms;
    var Oxygen Age Weight RunTime RunPulse RestPulse;
run;

proc print data=RScoreR;
    title2 'Negative Residual Scores for Regression';
run;

```

Output 82.2.1 shows the PROC REG output. The column labeled “Parameter Estimates” lists the parameter estimates. These estimates are output to the RegOut data set.

Output 82.2.1 Creating an OUTEST= Data Set with PROC REG

Regression Scoring Example					
The REG Procedure					
Model: OxyHat					
Dependent Variable: Oxygen					
Number of Observations Read		12			
Number of Observations Used		12			
Analysis of Variance					
Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	5	509.62201	101.92440	15.80	0.0021
Error	6	38.70060	6.45010		
Corrected Total	11	548.32261			
Root MSE		2.53970	R-Square	0.9294	
Dependent Mean		48.38942	Adj R-Sq	0.8706	
Coeff Var		5.24847			
Parameter Estimates					
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t
Intercept	1	151.91550	31.04738	4.89	0.0027
Age	1	-0.63045	0.42503	-1.48	0.1885
Weight	1	-0.10586	0.11869	-0.89	0.4068
RunTime	1	-1.75698	0.93844	-1.87	0.1103
RunPulse	1	-0.22891	0.12169	-1.88	0.1090
RestPulse	1	-0.17910	0.13005	-1.38	0.2176

Output 82.2.2 lists the RegOut data set. Note that `_TYPE_='PARMS'` and `_MODEL_='OXYHAT'`, which are from the label in the MODEL statement in PROC REG.

Output 82.2.2 OUTEST= Data Set from PROC REG Reproduced with PROC PRINT

Regression Scoring Example OUTEST= Data Set from PROC REG						
Obs	_MODEL_	_TYPE_	_DEPVAR_	_RMSE_	Intercept	Age
1	OxyHat	PARMS	Oxygen	2.53970	151.916	-0.63045
Obs	Weight	RunTime	RunPulse	Rest Pulse	Oxygen	
1	-0.10586	-1.75698	-0.22891	-0.17910	-1	

Output 82.2.3 lists the data sets created by PROC SCORE. Since the SCORE= data set does not contain observations with `_TYPE_='MEAN'` or `_TYPE_='STD'`, the data in the Fitness data set are not standardized before scoring. The SCORE= data set contains the variable Intercept, so this intercept value is used in computing the score. To produce the RScoreP data set, the VAR statement in PROC SCORE includes only the independent variables from the model in PROC REG. As a result, the OxyHat variable contains predicted values. To produce the RScoreR data set, the VAR statement in PROC SCORE includes both the dependent variables and the independent variables from the model in PROC REG. As a result, the OxyHat variable contains negative residuals (PREDICT-ACTUAL) as shown in Output 82.2.4. If the RESIDUAL option is specified, the variable OxyHat contains positive residuals (ACTUAL-PREDICT). If the PREDICT option is specified, the OxyHat variable contains predicted values.

Output 82.2.3 Predicted Scores from the OUT= Data Set Created by PROC SCORE

Regression Scoring Example Predicted Scores for Regression							
Obs	Age	Weight	Oxygen	Run Time	Rest Pulse	Run Pulse	OxyHat
1	44	89.47	44.609	11.37	62	178	42.8771

9	44	81.42	39.442	13.08	63	174	2.01935
10	38	81.87	60.055	8.63	48	170	-3.43787
11	44	73.03	50.541	10.13	45	168	1.58892
12	45	87.66	37.388	14.03	56	186	-0.38002

The second part of this example uses the parameter estimates to score a new data set. The following statements produce [Output 82.2.5](#) and [Output 82.2.6](#):

```

/* The FITNESS2 data set contains observations 13-16 from */
/* the FITNESS data set used in EXAMPLE 2 in the PROC REG */
/* chapter. */
data Fitness2;
  input Age Weight Oxygen RunTime RestPulse RunPulse;
  datalines;
45 66.45 44.754 11.12 51 176
47 79.15 47.273 10.60 47 162
54 83.12 51.855 10.33 50 166
49 81.42 49.156 8.95 44 180
;

proc print data=Fitness2;
  title 'Regression Scoring Example';
  title2 'New Raw Data Set to be Scored';
run;

proc score data=Fitness2 score=RegOut out=NewPred type=parms
  nostd predict;
  var Oxygen Age Weight RunTime RunPulse RestPulse;
run;

proc print data=NewPred;
  title2 'Predicted Scores for Regression';
  title3 'for Additional Data from FITNESS2';
run;

```

Output 82.2.5 lists the Fitness2 data set.

Output 82.2.5 Listing of the Fitness2 Data Set

Regression Scoring Example New Raw Data Set to be Scored							
Obs	Age	Weight	Oxygen	Run Time	Rest Pulse	Run Pulse	
1	45	66.45	44.754	11.12	51	176	
2	47	79.15	47.273	10.60	47	162	
3	54	83.12	51.855	10.33	50	166	
4	49	81.42	49.156	8.95	44	180	

PROC SCORE scores the Fitness2 data set by using the parameter estimates in the RegOut data set. These parameter estimates result from fitting a regression equation to the Fitness data set. The NOSTD option is specified, so the raw data are not standardized before scoring. (However, the NOSTD option is not necessary here. The SCORE= data set does not contain observations with `_TYPE_='MEAN'` or `_TYPE_='STD'`, so standardization is not performed.) The VAR statement contains the dependent variables and the independent variables used in PROC REG. In addition, the PREDICT option is specified. This combination gives predicted values for the new score variable. The name of the new score variable is OxyHat, from the value of the `_MODEL_` variable in the SCORE= data set. [Output 82.2.6](#) shows the data set produced by PROC SCORE.

Output 82.2.6 Predicted Scores from the OUT= Data Set Created by PROC SCORE and Reproduced Using PROC PRINT

Regression Scoring Example Predicted Scores for Regression for Additional Data from FITNESS2							
Obs	Age	Weight	Oxygen	Run Time	Rest Pulse	Run Pulse	OxyHat
1	45	66.45	44.754	11.12	51	176	47.5507
2	47	79.15	47.273	10.60	47	162	49.7802
3	54	83.12	51.855	10.33	50	166	43.9682
4	49	81.42	49.156	8.95	44	180	47.5949

Example 82.3: Custom Scoring Coefficients

This example uses a specially created custom scoring data set and produces [Output 82.3.1](#) and [Output 82.3.2](#). The first scoring coefficient creates a variable that is Age–Weight; the second scoring coefficient evaluates the variable RunPulse–RstPulse; and the third scoring coefficient totals all six variables. Since the scoring coefficients data set (data set A) does not contain any observations with `_TYPE_='MEAN'` or `_TYPE_='STD'`, the data in the Fitness data set (see [Example 82.1](#)) are not standardized before scoring.

The following statements produce [Output 82.3.1](#) and [Output 82.3.2](#):

```
data A;
  input _type_ $ _name_ $
        Age Weight RunTime RunPulse RestPulse;
  datalines;
SCORE AGE_WGT 1 -1 0 0 0
SCORE RUN_RST 0 0 0 1 -1
SCORE TOTAL 1 1 1 1 1
;
proc print data=A;
  title 'Constructed Scoring Example';
  title2 'Scoring Coefficients';
run;

proc score data=Fitness score=A out=B;
  var Age Weight RunTime RunPulse RestPulse;
run;

proc print data=B;
  title2 'Scored Data';
run;
```

Output 82.3.1 Custom Scoring Data Set and Scored Fitness Data: PROC PRINT

Constructed Scoring Example Scoring Coefficients

Overview: SEQDESIGN Procedure

The purpose of the SEQDESIGN procedure is to design interim analyses for clinical trials. Clinical trials are experiments on human subjects to demonstrate the efficacy and safety of new drugs or treatments. A simple example is a trial to test the effectiveness of a new drug in humans by comparing the outcomes in a group of patients who receive the new drug with the outcomes in a comparable group of patients who receive a placebo.

A clinical trial is conducted according to a plan called a *protocol*. A protocol details the objectives of the trial, the data collection process, and the analysis. The protocol specifies the null hypothesis and an alternative hypothesis, a test statistic, the probability α of a Type I error, the probability β of a Type II error, the sample size needed to attain a specified power of $1 - \beta$ at an alternative reference, and critical values that are associated with the test statistic.

In a fixed-sample trial, data about all individuals are first collected and then examined at the end of the study. Most major trials have committees that periodically monitor safety and efficacy data during the trial and recommend that a trial be stopped for safety concerns such as an unacceptable toxicity level. In certain situations, the committee might recommend that a trial be stopped for efficacy. In contrast to a fixed-sample trial, a group sequential trial provides for interim analyses before the completion of the trial while maintaining the specified overall Type I and Type II error probabilities.

A group sequential trial is most useful in situations where it is important to monitor the trial to prevent unnecessary exposure of patients to an unsafe new drug, or alternatively to a placebo treatment if the new drug shows significant improvement. In most cases, if a group sequential trial stops early for safety concerns,

fewer patients are exposed to the new treatment than in the fixed-sample trial. If a trial stops early for efficacy reasons, the new treatment is available sooner than it would be in a fixed-sample trial. Early stopping can also save time and resources.

A group sequential design provides detailed specifications for a group sequential trial. In addition to the usual specification for a fixed-sample design, it provides the total number of stages (the number of interim stages plus a final stage) and a stopping criterion to reject, to accept, or to either reject or accept the null hypothesis at each interim stage. It also provides critical values and the sample size at each stage for the trial.

At each interim stage, the data collected at the current stage in addition to the data collected at previous stages are analyzed, and statistics such as a maximum likelihood test statistic and its associated standard error are computed. The test statistic is then compared with critical values that are generated from the sequential design, and the trial is stopped or continued. If a trial continues to the final stage, the null hypothesis is either rejected or accepted. The critical values for each stage are chosen in such a way that the overall α and β are maintained at the specified levels.

Figure 83.1 shows a two-sided symmetric group sequential trial that stops early to reject the null hypothesis that the parameter Trt is zero.

Figure 83.1 Sequential Plot for Two-Sided Test

The trial has four stages, which are indicated by the vertical lines labeled 1, 2, 3, and 4. With early stopping to reject the null hypothesis, the lower rejection boundary is constructed by connecting the lower critical values for the stages. Similarly, the upper rejection boundary is constructed by connecting the upper critical values for the stages. The horizontal axis indicates the sample size for the group sequential trial, and the vertical axis indicates the values of the test statistic on the standardized Z scale.

At each interim stage, if the test statistic falls into a rejection region (the darker shaded areas in [Figure 83.1](#)), the trial stops and the null hypothesis is rejected. Otherwise, the trial continues to the next stage. At the final stage (stage 4), the null hypothesis is rejected if Z falls into a rejection region. Otherwise, the null hypothesis is not rejected. In [Figure 83.1](#), the test statistic does not fall into the rejection regions for stages 1 and 2, and so the trial continues to stage 3. At stage 3, the test statistic falls into the rejection region, and the null hypothesis is rejected.

A group sequential trial usually involves six steps:

1. You specify the statistical details of the design, including the null and alternative hypotheses, a test statistic for the hypothesis test, the Type I and II error probabilities, a stopping criterion, the total number of stages, and the relative information level at each stage.
2. You compute the boundary values for the trial based on the specifications in Step 1. You also compute the sample size required at each stage for the specified hypothesis test.
3. At each stage, you collect additional data with the required sample sizes. The data available at each stage include the data collected at previous stages in addition to the data collected at the current stage.
4. At each stage, you analyze the available data with a procedure such as the REG procedure, and you compute the test statistic.
5. At each stage, you compare the test statistic with the corresponding boundary values. You stop the trial to reject or accept the hypothesis, or you continue the trial to the next stage. If you continue the trial to the final stage, you either accept or reject the hypothesis.
6. After the trial stops, you compute parameter estimates, confidence limits for the parameter, and a p -value for the hypothesis test.

You use the SEQDESIGN procedure at Step 2 to compute the initial boundary values and required sample sizes for the trial. You use the companion SEQTEST procedure at Step 5 to compare the test statistic with its boundary values. At stage 1, the boundary values are derived by using the boundary information tables created by the SEQDESIGN procedure. These boundary information tables are structured for input to the SEQTEST procedure. At each subsequent stage, the boundary values are derived by using the test information tables created by the SEQTEST procedure at the previous stage. These test information tables are also structured for input to the SEQTEST procedure. You also use the SEQTEST procedure at Step 6 to compute parameter estimates, confidence limits, and p -values after the trial stops.

The flowchart in [Figure 83.2](#) summarizes the steps in a typical group sequential trial and the relevant SAS procedures.

Figure 83.2 Group Sequential Trial

Features of the SEQDESIGN Procedure

The SEQDESIGN procedure assumes that the standardized Z test statistics for the null hypothesis $H_0 : \theta = 0$ at the stages have the joint canonical distribution with the information levels at the stages for the parameter θ . This implies that these test statistics are normally distributed. If the test statistic is not normally distributed, then it is assumed that the test statistic is computed from a large sample such that the statistic has an approximately normal distribution. See the section “[Statistical Assumptions for Group Sequential Designs](#)” on page 7015 for a detailed description of the joint canonical distribution.

You can use the SEQDESIGN procedure to compute required sample sizes for commonly used hypothesis tests. Note that for a fixed-sample design, you should use the POWER and GLMPOWER procedures to compute sample sizes.

The applicable tests include tests for binomial proportions and the log-rank test for two survival distributions. See the section “[Applicable One-Sample Tests and Sample Size Computation](#)” on page 7050, the section “[Applicable Two-Sample Tests and Sample Size Computation](#)” on page 7052, and the section “[Applicable Regression Parameter Tests and Sample Size Computation](#)” on page 7061 for examples of applicable tests in group sequential trials.

At each stage, the data are analyzed with a statistical procedure such as the REG procedure, and a test statistic and its associated information level are computed. The information level is the amount of information available about the unknown parameter. For a maximum likelihood statistic, the information level is the inverse of its variance.

At each stage, you use the SEQTEST procedure to derive the boundary values that correspond to the information level associated with the test statistic. You then use the SEQTEST procedure to compare the test statistic with these boundary values. When a trial is stopped at an interim stage or at the final stage, the SEQTEST procedure also derives parameter estimates, confidence limits for the parameter, and a p -value for hypothesis testing.

Output from the SEQDESIGN Procedure

In addition to computing the boundary values for a group sequential design, the SEQDESIGN procedure computes the following quantities:

- maximum sample size (as a percentage of the corresponding fixed-sample size) if the trial does not stop at an interim stage
- average sample numbers (as percentages of the corresponding fixed-sample sizes for nonsurvival data or fixed-sample numbers of events for survival data) under various hypothetical references, including the null and alternative references
- stopping probabilities at each stage under various hypothetical references to indicate how likely it is that the trial will stop at that stage
- sample sizes required at each stage for the specified hypothesis test
- numbers of events required at each stage for the specified hypothesis test with survival data

You can create more than one design with multiple DESIGN statements in the SEQDESIGN procedure and then choose the design with the most desirable features. The next two subsections introduce some basic aspects of group sequential designs that are useful for getting started with the SEQDESIGN procedure.

Boundaries for Group Sequential Designs

A one-sided test is a test of a hypothesis with either a lower alternative ($H_1 : \theta < 0$) or an upper alternative ($H_1 : \theta > 0$), and a two-sided test is a test with a two-sided alternative ($H_1 : \theta \neq 0$). The number of critical values for a test depends on whether the alternative is one-sided or two-sided, and it also depends on whether the trial is conducted with a fixed-sample design or a group sequential design.

For a fixed-sample trial, a one-sided test has one critical value and a two-sided test has two critical values. These critical values are computed with the specified Type I error probability α . In contrast, at each interim stage of a group sequential trial, a one-sided test has up to two critical values and a two-sided group sequential test has up to four critical values. Thus, there are two or four possible boundaries for a group sequential design, and each boundary is a set of critical values, one from each stage.

Figure 83.3 illustrates the boundaries for a one-sided test with an upper alternative that allows for early stopping to either reject or accept the null hypothesis.

Figure 83.3 Boundary Plot for One-Sided Design

With an upper alternative, as in this example, the design has the following two boundaries: an upper α (rejection) boundary for the rejection region that consists of upper rejection critical values and an upper β (acceptance) boundary for the acceptance region that consists of upper acceptance critical values. The stages are indicated by vertical lines with accompanying stage numbers. In Figure 83.3, the horizontal axis indicates the cumulative sample size for the group sequential trial. The vertical axis indicates the critical values at each stage on the standardized Z scale. Other scales can be used for the vertical axis, including the MLE scale, score statistic scale, and p -value scale.

At each interim stage, if the test statistic is in the rejection region (darker shaded area in Figure 83.3), the trial stops and the null hypothesis is rejected. If the test statistic is in the acceptance region (lightly shaded area in Figure 83.3), the trial stops and the hypothesis is accepted. Otherwise, the trial continues to the next stage. If the trial proceeds to the final stage (stage 4), the upper α and upper β critical values are identical, and the trial stops to either reject or accept the null hypothesis.

If you do not want to stop a trial when a test statistic falls in the acceptance region at an interim stage, you can derive a design with a nonbinding acceptance boundary to allow the trial to continue while maintaining the Type I error level. You need to increase the sample size for a design with this nonbinding feature. See the section “Acceptance (β) Boundary” on page 7035 for a description of the nonbinding acceptance boundary.

Group Sequential Methods

For a group sequential design, there are two possible boundaries for a one-sided test and four possible boundaries for a two-sided test. Each boundary consists of one boundary value (critical value) for each stage. The SEQDESIGN procedure provides various methods for computing the boundary values.

The boundary value for a fixed-sample test cannot be applied to each stage of sequential design because, as shown by Armitage, McPherson, and Rowe (1969), repeated significance tests at a fixed level on accumulating data increase the probability of a Type I error. For example, with a fixed-sample two-sided test, the critical values ± 1.96 for a standardized Z statistic produce a Type I error probability level $\alpha = 0.05$. But for a two-sided group sequential test with two equally spaced stages, if the same critical values ± 1.96 are used to reject the null hypothesis at these two stages, the Type I error probability level is $\alpha = 0.083$, larger than the fixed-sample α .

Numerous methods are available for deriving the critical values for each boundary in a sequential design. Pocock (1977) applies repeated significance tests to group sequential trials with equal-size groups and derives a constant critical value on the standardized normal Z scale across all stages that maintains the specified Type I error probability level. O'Brien and Fleming (1979) propose a sequential procedure that has boundary values (in absolute value) decrease over the stages on the standardized normal Z scale.

The SEQDESIGN procedure provides the following three types of methods:

- fixed boundary shape methods, which derive boundaries with specified boundary shapes
- Whitehead methods, which adjust boundaries derived for continuous monitoring so that they apply to discrete monitoring
- error spending methods

Each type of methods uses a distinct approach to derive the boundary values for a group sequential trial. Whitehead methods require much less computation with resulting Type I error probability and power that are close but differ slightly from the specified values due to the approximations used in deriving the tests (Jennison and Turnbull 2000, p. 106). Fixed boundary shape methods derive boundary values by estimating a fixed number of parameters and require more computation. Error spending methods derive boundary values at each stage sequentially and require much more computation than other types of methods for group sequential trials with a large number of stages.

Within each type of methods, you can choose methods that creating boundary values range from conservative stopping boundary values at early stages to liberal stopping boundary values at very early stages.

You can use the SEQDESIGN procedure to specify methods from the same type for each design. A different method can be specified for each boundary separately, but all methods in a design must be of the same type.

Fixed Boundary Shape Methods

The fixed boundary shape methods include the unified family methods and the Haybittle-Peto method. The unified family methods (Kittelson and Emerson 1999) derive boundaries from specified boundary shapes. These methods include Pocock's method (Pocock 1977) and the O'Brien-Fleming method (O'Brien and Fleming 1979) as special cases.

The Haybittle-Peto method (Haybittle 1971; Peto et al. 1976) uses a value of 3 for the critical values in interim stages, so the critical value at the final stage is close to the critical value for the fixed-sample design. In the SEQDESIGN procedure, the Haybittle-Peto method has been generalized to allow for different boundary values at interim stages.

Whitehead Methods

Whitehead and Stratton (1983) and Whitehead (1997, 2001) develop triangular and straight-line boundaries by adapting tests constructed for continuous monitoring to discrete monitoring of group sequential tests. With continuous monitoring, the values for each boundary fall in a straight line when plotted on the score statistic scale. The discrete boundary is derived by subtracting the expected overshoot from the continuous boundary to obtain the desired Type I and Type II error probabilities. For a design with early stopping to either reject or accept the null hypothesis, the boundaries form a triangle when plotted on the score statistic scale. See the section “[Score Statistic](#)” on page 7005 for a detailed description of the score statistic.

Error Spending Methods

For every sequential design, the α and β errors at each stage can be computed from the boundary values. On the other hand, you can derive the boundary values from specified α and β errors for each stage. The error spending function approach (Lan and DeMets 1983) uses an error spending function to specify the errors at each stage for each boundary and then derives the boundary values.

Getting Started: SEQDESIGN Procedure

This section illustrates a clinical study design that uses a two-sided O’Brien-Fleming design (O’Brien and Fleming 1979) to stop the trial early for ethical concerns about possible harm or for unexpectedly strong efficacy of the new drug.

Suppose that a pharmaceutical company is conducting a clinical trial to test the efficacy of a new cholesterol-lowering drug. The primary focus is low-density lipoprotein (LDL), the so-called bad cholesterol, which is a risk factor for coronary heart disease. LDL is measured in *mg / dL*, milligrams per deciliter of blood.

The trial consists of two groups of equally allocated patients with elevated LDL levels: an experimental group given the new drug and a placebo control group. Suppose the changes in LDL level after the treatment for individuals in the experimental and control groups are normally distributed with means μ_e and μ_c , respectively, and have a common variance σ^2 . Then the null hypothesis of no effect for the new drug is $H_0 : \theta = 0$, where $\theta = \mu_e - \mu_c$.

For a fixed-sample design with a total sample size N , the MLE for θ is computed as $\hat{\theta} = \hat{\mu}_e - \hat{\mu}_c$, where $\hat{\mu}_e$ and $\hat{\mu}_c$ are the sample means of the decreases in LDL level in the experimental and control groups, respectively.

Following the derivation in the section “[Test for the Difference between Two Normal Means](#)” on page 7053, the statistic $\hat{\theta}$ has a normal distribution

$$\hat{\theta} \sim N\left(\theta, \frac{4\sigma^2}{N}\right)$$

Thus, under the null hypothesis $H_0 : \theta = 0$, the standardized statistic

$$Z = \frac{\hat{\theta}}{\sqrt{\frac{4\sigma^2}{N}}} \sim N(0, 1)$$

The Z statistic can be used to test the null hypothesis H_0 . If the variance σ^2 is unknown, the sample variance can be used to compute the test statistic if it is assumed that the sample variance is computed from a large sample such that the Z statistic has an approximately standard normal distribution.

With a Type I error probability $\alpha = 0.05$, the critical values for the Z statistic are given by $\Phi^{-1}(\alpha/2) = -1.96$ and $\Phi^{-1}(1 - \alpha/2) = 1.96$, where Φ is the cumulative standard normal distribution function. At the end of study, if $Z \geq 1.96$, the null hypothesis is rejected for harmful drug effect, and if $Z \leq -1.96$, the null hypothesis is rejected for efficacy of the new drug. Otherwise, the null hypothesis is not rejected and the drug effect is not significant.

Also suppose that for the trial, the alternative reference $\theta = -10$ is the clinically meaningful difference that the trial should detect with a high probability (power). Further suppose that a good estimate of the standard deviation for the changes in LDL level is $\hat{\sigma} = 20$. The following statements invoke the SEQDESIGN procedure and request a four-stage O'Brien-Fleming design for standardized normal test statistics:

```
ods graphics on;
proc seqdesign altref=-10
    plots=boundary(hscale=samplesize)
    ;
    TwoSidedOBrienFleming: design nstages=4
        method=obf
    ;
    samplesize model=twosamplemean(stddev=20);
ods output Boundary=Bnd_LDL;
run;
ods graphics off;
```

The ALTREF= option specifies the alternative reference, and the actual maximum information is derived in the SEQDESIGN procedure. With ODS Graphics enabled, the PLOTS=BOUNDARY option displays a boundary plot with the rejection and acceptance regions.

In the DESIGN statement, the label **TwoSidedOBrienFleming** identifies the design in the output tables. By default (or equivalently if you specify ALT=TWOSIDED and STOP=REJECT in the DESIGN statement), the design has a two-sided alternative hypothesis in which early stopping in the interim stages occurs to reject the null hypothesis. That is, at each interim stage, the trial either is stopped to reject the null hypothesis or continues to the next stage.

The NSTAGES=4 option in the DESIGN statement specifies the total number of stages in the group sequential trial, including three interim stages and a final stage. In the SEQDESIGN procedure, the null hypothesis for the design is $H_0 : \theta = 0$. By default (or equivalently if you specify ALPHA=0.05 and BETA=0.10 in the DESIGN statement), the design has a Type I error probability $\alpha = 0.05$, and a Type II error probability $\beta = 0.10$; the latter corresponds to a power of $1 - \beta = 0.90$ at the alternative reference $H_1 : \theta = -10$.

For a two-sided design with early stopping to reject the null hypothesis, there are two boundaries for the design: an upper α boundary that consists of upper rejection critical values and a lower α boundary that consists of lower rejection critical values. Each boundary is a set of critical values, one from each stage.

With the METHOD=OBF option in the DESIGN statement, the O'Brien-Fleming method is used for the two boundaries for the design; see [Figure 83.7](#).

A property of the boundaries constructed with the O'Brien-Fleming design is that the null hypothesis is more difficult to reject in the early stages than in the later stages. That is, the trial is rejected in the early stages only with overwhelming evidence, because in these stages there might not be a sufficient number of responses for a reliable estimate of the treatment effect.

The SAMPLESIZE statement with the MODEL=TWOSAMPLEMEAN option uses the derived maximum information to compute required sample sizes for a two-sample test for mean difference. The ODS OUTPUT statement with the BOUNDARY=BND_LDL option creates an output data set named BND_LDL which contains the resulting boundary information.

In a clinical trial, the amount of information about an unknown parameter available from the data can be measured by the Fisher information. For a maximum likelihood statistic, the information level is the inverse of its variance. See the section “[Maximum Likelihood Estimator](#)” on page 7004 for a detailed description of Fisher information. At each stage of the trial, data are collected and analyzed with a statistical procedure, and a test statistic and its corresponding information level are computed.

In this example, you can use the REG procedure to compute the maximum likelihood estimate $\hat{\theta}$ for the drug effect and the corresponding standard error for $\hat{\theta}$. At stage 1, you can use the SEQTEST procedure to compare the test statistic with adjusted boundaries derived from the boundary information stored in the BOUND_LDL data set. At each subsequent stage, you can use the SEQTEST procedure to compare the test statistic with adjusted boundaries derived from the boundary information stored in the test information table created by the SEQTEST procedure at the previous stage. The test information tables are structured for input to the SEQTEST procedure.

At each interim stage, the trial will either be stopped to reject the null hypothesis or continue to the next stage. At the final stage, the null hypothesis is either rejected or accepted.

By default (or equivalently if you specify INFO=EQUAL in the DESIGN statement), the SEQDESIGN procedure derives boundary values with equally spaced information levels for all stages—that is, the same information increment between successive stages. The “Design Information,” “Method Information,” and “Boundary Information” tables are displayed by default, as shown in [Figure 83.4](#), [Figure 83.5](#), and [Figure 83.6](#), respectively.

The “Design Information” table in [Figure 83.4](#) displays design specifications and four derived statistics: the actual maximum information, the maximum information, the average sample number under the null hypothesis (Null Ref ASN), and the average sample number under the alternative hypothesis (Alt Ref ASN). Except for the actual maximum information, each statistic is expressed as a percentage of the identical statistic for the corresponding fixed-sample information. The average sample number is the expected sample size (for nonsurvival data) or expected number of events (for survival data). Note that for a symmetric two-sided design, the ALTREF=−10 option implies a lower alternative reference of −10 and an upper alternative reference of 10.

Figure 83.4 O'Brien-Fleming Design Information

The SEQDESIGN Procedure	
Design: TwoSidedOBrienFleming	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	-10
Number of Stages	4
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	102.2163
Max Information	0.107403
Null Ref ASN (Percent of Fixed Sample)	101.5728
Alt Ref ASN (Percent of Fixed Sample)	76.7397

The maximum information is the information level at the final stage of the group sequential trial. The Max Information (Percent Fixed-Sample) is the maximum information for the sequential design expressed as a percentage of the information for the corresponding fixed-sample design. In Figure 83.4, the Max Information (Percent Fixed-Sample) is 102.22%, which means that the information needed for the group sequential trial is 2.22% more than that of the corresponding fixed-sample design if the trial does not stop at any interim stage.

The Null Ref ASN (Percent Fixed-Sample) is the average sample number (expected sample size) required under the null hypothesis for the group sequential design expressed as a percentage of the sample size for the corresponding fixed-sample design. In Figure 83.4, the Null Ref ASN is 101.57%, which means that the expected sample size for the group sequential trial is 1.57% greater than the corresponding fixed-sample size.

Similarly, the Alt Ref ASN (Percent Fixed-Sample) is the average sample number (expected sample size) required under the alternative hypothesis for the group sequential design expressed as a percentage of the sample size for the corresponding fixed-sample design. In Figure 83.4, the Alt Ref ASN is 76.74%, which means that the expected sample size for the group sequential trial is 76.74% of the corresponding fixed-sample size. That is, if the alternative hypothesis is true, then on average, only 76.74% of the fixed-sample size is needed for the group sequential trial.

In this example, the O'Brien-Fleming design requires only a slight increase in sample size if the trial proceeds to the final stage. On the other hand, if the alternative hypothesis is correct, this design provides a substantial saving in sample size on average.

The “Method Information” table in [Figure 83.5](#) displays the computed Type I and Type II error probabilities α and β , and the derived drift parameter for the design. For a two-sided test with early stopping to reject the null hypothesis, both lower and upper α boundaries are created. With the specified ALTREF= option, the alternative references are also included.

With the zero null reference, the drift parameter is the standardized alternative reference at the final stage $\theta_1 \sqrt{I_X}$, where θ_1 is the alternative reference and I_X is the maximum information. See the section “[Specified and Derived Parameters](#)” on page 7039 for a detailed description of the drift parameter. The drift parameters for the design are derived in the SEQDESIGN procedure even if the alternative reference is not specified or derived in the procedure.

Figure 83.5 Method Information

Method Information						
Boundary	Method	Alpha	Beta	-----Unified Family-----		
				Rho	Tau	C

Method Information						
		Alternative Reference		Drift		
Boundary						
Upper Alpha		10		3.277238		
Lower Alpha		-10		-3.27724		

The O'Brien-Fleming method belongs to the unified family of designs, which is parameterized by two parameters, ρ and τ , as implemented in the SEQDESIGN procedure. See [Table 83.3](#) for parameter values of commonly used methods in the unified family. The “Method Information” table in [Figure 83.5](#) displays the values of $\rho = 0.5$ and $\tau = 0$, which are the parameters for the O'Brien-Fleming method. The table also displays the derived parameter $C_\alpha = 2.0243$, which is used in the construction of symmetric lower and upper α boundaries; see the section “[Unified Family Methods](#)” on page 7025.

The “Boundary Information” table in [Figure 83.6](#) displays the information level, including the proportion, actual level, and corresponding sample size (N) at each stage. The table also displays the lower and upper alternative references, and the lower and upper boundary values at each stage.

Figure 83.6 Boundary Information

Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-----Alternative-----	
	Proportion	Actual	N	Lower	Upper
1	0.2500	0.026851	42.96116	-1.63862	1.63862
2	0.5000	0.053701	85.92233	-2.31736	2.31736
3	0.7500	0.080552	128.8835	-2.83817	2.83817
4	1.0000	0.107403	171.8447	-3.27724	3.27724

Boundary Information (Standardized Z Scale)			
Null Reference = 0			
Stage	-----Boundary Values-----		
	---Lower---	---Upper---	
	Alpha	Alpha	
1	-4.04859	4.04859	
2	-2.86278	2.86278	
3	-2.33745	2.33745	
4	-2.02429	2.02429	

The information proportion is the proportion of maximum information available at each stage and N is the corresponding sample size. By default (or equivalently if you specify BOUNDARYSCALE=STDZ), the procedure displays boundary values with the standardized Z scale in the boundary information table and the boundary plot. The alternative reference on the standardized Z scale at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information available at stage k , $k = 1, 2, 3, 4$. These standardized alternative references for the design are derived in the SEQDESIGN procedure even if the alternative reference is not specified or derived in the procedure.

In this example, a standardized Z statistic is computed by standardizing the parameter estimate of the effect in LDL level. A lower Z test statistic indicates a beneficial effect. Consequently, at each interim stage, if the standardized Z test statistic is less than or equal to the corresponding lower α boundary value, the hypothesis $H_0 : \theta = 0$ is rejected for efficacy. If the test statistic is greater than or equal to the corresponding upper α boundary value, the hypothesis H_0 is rejected for harmful effect. Otherwise, the process continues to the next stage. At the final stage (stage 4), the hypothesis H_0 is rejected for efficacy if the Z statistic is less than or equal to the corresponding lower α boundary value -2.0243 , and the hypothesis H_0 is rejected for harmful effect if the Z statistic is greater than or equal to the corresponding upper α boundary value 2.0243 . Otherwise, the hypothesis of no significant difference is accepted.

Note that in a typical trial, the actual information levels do not match the information levels specified in the design. The SEQTEST procedure modifies the boundary values stored in the BOUND_LDL data set to adjust for these new information levels.

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in Figure 83.7. This plot displays the boundary values in the “Boundary Information” table in Figure 83.6. The stages are indicated by vertical lines with accompanying stage numbers. The horizontal axis indicates the sample sizes for the stages. Note that comparing with a fixed-sample design, only a small increase in sample size is needed for the O’Brien-Fleming design, as shown in Figure 83.7.

If a test statistic at an interim stage is in the rejection region (shaded area), the trial stops and the null hypothesis is rejected. If the statistic is not in any rejection region, the trial continues to the next stage.

Figure 83.7 Boundary Plot

The boundary plot also displays critical values for the corresponding fixed-sample design. The symbol “o” identifies the fixed-sample critical values of -1.96 and 1.96 , and the accompanying vertical line indicates the required sample size for the fixed-sample design at the horizontal axis. Note that the boundary values ± 2.0243 at the final stage are close to the fixed-sample critical values ± 1.96 .

When you specify the SAMPLESIZE statement, the maximum information (either explicitly specified or derived in the SEQDESIGN procedure) is used to compute the required sample sizes for the study. The MODEL=TWOSAMPLEMEAN(STDDEV=20) option specifies the test for the difference between two normal means. See the section “[Test for the Difference between Two Normal Means](#)” on page 7053 for a detailed derivation of these required sample sizes.

The “Sample Size Summary” table in Figure 83.8 displays the parameters for the sample size computation and the resulting maximum and expected sample sizes.

Figure 83.8 Sample Size Summary

Sample Size Summary	
Test	Two-Sample Means
Mean Difference	-10
Standard Deviation	20
Max Sample Size	171.8447
Expected Sample Size (Null Ref)	170.7627
Expected Sample Size (Alt Ref)	129.0137

The “Sample Sizes (N)” table in Figure 83.9 displays the required sample sizes at each stage for the trial, in both fractional and integer numbers. The derived fractional sample sizes are displayed under the heading “Fractional N.” These sample sizes are rounded up to integers under the heading “Ceiling N.” By default (or equivalently if you specify WEIGHT=1 in the MODEL=TWOSAMPLEMEAN option), the sample sizes for the two groups are equal for the two-sample test.

Figure 83.9 Derived Sample Sizes

Sample Sizes (N)

Stage	N	N(Grp 1)	N(Grp 2)	Information
1	44	22	22	0.0275
2	86	43	43	0.0538
3	130	65	65	0.0812
4	172	86	86	0.1075

In practice, integer sample sizes are used in the trial, and the resulting information levels increase slightly. Thus, 22, 43, 65, and 86 individuals are needed in each of the two groups for the four stages, respectively.

Syntax: SEQDESIGN Procedure

The following statements are available in the SEQDESIGN procedure:

```
PROC SEQDESIGN < options > ;
    < label: > DESIGN options ;
    SAMPLESIZE < MODEL= option > ;
```

The PROC SEQDESIGN statement and the DESIGN statement are required for the SEQDESIGN procedure. Each DESIGN statement requests a new group sequential design, and multiple DESIGN statements can be used to create more than one design for comparison of features. The label, which must be a valid SAS name, is used to identify the design in the output tables and graphics. The SAMPLESIZE statement computes the required sample sizes for the design specified in each DESIGN statement. With a selected design, the SAMPLESIZE statement computes the required sample sizes for the trial.

PROC SEQDESIGN Statement

```
PROC SEQDESIGN < options > ;
```

The PROC SEQDESIGN statement invokes the SEQDESIGN procedure. [Table 83.1](#) summarizes the options available in the PROC SEQDESIGN statement.

Table 83.1 Summary of PROC SEQDESIGN Options

Option	Description
Design Parameters	
ALTREF=	Specifies the alternative reference
BOUNDARYSCALE=	Specifies the statistic scale for the boundary
MAXINFO=	Specifies the maximum information level
Table Output	
ERRSPEND	Displays the cumulative error spending at each stage
PSS	Displays powers and expected sample sizes
STOPPROB	Displays expected cumulative stopping probabilities
Graphics Output	
PLOTS=ASN	Displays the expected sample numbers plot
PLOTS=BOUNDARY	Displays the detailed boundary plot
PLOTS=COMBINEDBOUNDARY	Displays the combined boundary plot
PLOTS=ERRSPEND	Displays the error spending plot
PLOTS=POWER	Displays the powers plot

By default, the SEQDESIGN procedure displays tables of design information, method information, and boundary information for each specified design. If ODS Graphics is enabled, it also displays a detailed boundary plot.

In addition, you can use output options to display output tables such as expected cumulative stopping probability at each stage under various hypothetical references. If ODS Graphics is enabled, you can also use output options to display plots such as powers and expected sample sizes under various hypothetical references.

The following options can be used in the PROC SEQDESIGN statement to derive boundary values for all sequential designs in the procedure. They are listed in alphabetical order.

ALTREF= θ_1 < (< LOWER= θ_{1l} > < UPPER= θ_{1u} >) >

specifies the alternative reference—that is, the hypothetical reference under the alternative hypothesis at which the power is computed. The LOWER= and UPPER= options are applicable only for a two-sided design with different lower and upper alternative references.

For a one-sided design, $\theta_{1l} = -|\theta_1|$ is the lower alternative reference and $\theta_{1u} = |\theta_1|$ is the upper alternative reference. For a two-sided design, the specified θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. If the LOWER= option is not specified, $\theta_{1l} = -|\theta_1|$, and if the UPPER= option is not specified, $\theta_{1u} = |\theta_1|$.

The specification of the ALTREF= option depends on the hypothesis used in the clinical trial. For example, suppose the null hypothesis $H_0 : \theta = 0$ with an alternative hypothesis $H_1 : \theta = \theta_1$ is used to compare two binomial populations, $p_a = p_b$. Then θ_1 is the proportion difference under H_1 if $\theta = p_a - p_b$, and θ_1 is the log odds ratio under H_1 if $\theta = \log \left(\frac{p_a(1-p_b)}{p_b(1-p_a)} \right)$.

If the ALTREF= option is not specified, the alternative reference θ_1 can also be specified or derived in the SAMPLESIZE statement. If θ_1 is specified or derived in the SAMPLESIZE statement, $\theta_{1l} = -|\theta_1|$ and $\theta_{1u} = |\theta_1|$ are the lower and upper alternative references, respectively.

Note that if the SAMPLESIZE statement is specified with a two-sided design, the sample sizes derived by using the lower and upper alternatives might be different. If θ_1 is specified or derived in the SAMPLESIZE statement, it is used to compute the sample sizes. Otherwise, the θ_1 specified in the ALTREF= option is used.

BOUNDARYSCALE=MLE | SCORE | STDZ | PVALUE

BSCALE=MLE | SCORE | STDZ | PVALUE

specifies the scale for the statistic that is displayed in the boundary table and boundary plots. The keywords MLE, SCORE, STDZ, and PVALUE correspond to the boundary with the maximum likelihood estimate scale, the score statistic scale, the standardized normal Z scale, and the p -value scale, respectively. The default is BOUNDARYSCALE=STDZ.

With the BOUNDARYSCALE=MLE or BOUNDARYSCALE=SCORE option, the maximum information must be either explicitly specified with the MAXINFO= option or derived in the SEQDESIGN procedure to provide the necessary information level at each stage to compute the boundary values. See the section “[Boundary Scales](#)” on page 7017 for a detailed description of the statistic scale for the boundary values.

Note that for a two-sided design, the p -value scale displays the one-sided fixed-sample p -value under the null hypothesis with a lower alternative hypothesis.

MAXINFO=number

specifies the maximum information level for the design. If the MAXINFO=option is specified and the alternative reference is either specified explicitly with the ALTREF= option or derived from the SAMPLESIZE statement, then the Type I and Type II error probability levels cannot be met simultaneously. In this case, the ALPHA= option in the DESIGN statement is applicable only with the BOUNDARYKEY=ALPHA option (which is the default) in the DESIGN statement, and the Type II error probability β is derived. The BETA= option in the DESIGN statement is applicable only with the BOUNDARYKEY=BETA option in the DESIGN statement, and the Type I error probability α is derived.

Table Output Options

The following options can be used in the PROC SEQDESIGN statement to display addition table output. They are listed in alphabetical order.

ERRSPEND

displays the error spending at each stage for each boundary in the design.

PSS <(CREF= $c_1 < c_2 \dots >$)>

displays powers and expected sample sizes under various hypothetical references, where the numbers $c_i \geq 0$.

For a one-sided design, the power and expected sample sizes under hypotheses $\theta = c_i \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, the power and expected sample sizes under hypotheses $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The default is CREF= 0 0.5 1.0 1.5.

Note that for a symmetric two-sided design, only the power and expected sample sizes under hypotheses $\theta = c_i \theta_{1u}$ are derived. See the section “[Type I and Type II Errors](#)” on page 7022 for a detailed description of the power computation. See the section “[Powers and Expected Sample Sizes](#)” on page 7069 for a detailed description of the expected sample size computation.

STOPPROB <(CREF= $c_1 < c_2 \dots >$)>

displays expected cumulative stopping probabilities under various hypothetical references, where the numbers $c_i \geq 0$.

For a one-sided design, expected cumulative stopping probabilities at each stage under hypotheses $\theta = c_i \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, expected cumulative stopping probabilities at each stage under hypotheses $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only expected cumulative stopping probabilities under hypotheses $\theta = c_i \theta_{1u}$ are derived. The default is CREF= 0 0.5 1.0 1.5.

Graphics Output Options

This section describes the options for using ODS Graphics with the SEQDESIGN procedure to create plots.

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc seqdesign altref=-10 plots=boundary(hscale=samplesize);
    TwoSidedOBrienFleming: design nstages=4 method=obf;
    samplesize model=twosamplemean(stddev=20);
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” on page 600 in Chapter 21, “Statistical Graphics Using ODS.”

The following options can be used in the PROC SEQDESIGN statement to display graphs with ODS Graphics. They are listed in alphabetical order.

PLOTS < (ONLY) > <= plot-request >

PLOTS < (ONLY) > <= (plot-request < ... plot-request >) >

specifies options that control the details of the plots. The default is PLOTS=BOUNDARY. The global plot option ONLY suppresses the default plots and displays only plots specifically requested.

The plot request options are as follows.

ALL

produces all appropriate plots.

ASN < (CREF= $c_1 < c_2 \dots$) >

displays a plot of the average sample numbers (expected sample sizes for nonsurvival data or expected numbers of events for survival data) under various hypothetical references, where the numbers $c_i \geq 0$. These average sample numbers are displayed as percentages of the average sample numbers for the corresponding fixed-sample design.

For a one-sided design, expected sample numbers under hypotheses $\theta = c_i \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, expected sample numbers under hypotheses $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only the average sample numbers under hypotheses $\theta = c_i \theta_{1u}$ are derived. The default is CREF= 0 to 1.5 by 0.01.

BOUNDARY < (HSCALE=INFO | SAMPLESIZE) >

displays a plot of the resulting sequential boundaries with the acceptance and rejection regions for each design. Either the information level (HSCALE=INFO) or the sample size (HSCALE=SAMPLESIZE) is displayed on the horizontal axis. If the maximum information is not available for the design, the information in percentage of its corresponding fixed-sample design are used in the plot. The stage number for each stage is displayed inside the plot. The default is HSCALE=INFO.

If the HSCALE=SAMPLESIZE option is specified, the SAMPLESIZE statement must also be specified. The options MODEL=INPUTNEVENTS, MODEL=TWOSAMPLESURVIVAL, and MODEL=PHREG in the SAMPLESIZE statement indicate survival data. For a sample that

does not contain survival data, the sample size at each stage is displayed on the horizontal axis. For survival data, the number of events is displayed on the horizontal axis at each stage. The critical values for the corresponding fixed-sample design are also displayed in the plot.

COMBINEDBOUNDARY < (HSCALE=INFO | SAMPLESIZE | STAGE) >

displays a plot of the resulting sequential boundaries for all designs simultaneously. You can display the information level (HSCALE=INFO), the sample size (HSCALE=SAMPLESIZE), or the stage number (HSCALE=STAGE) on the horizontal axis. The default is HSCALE=INFO. With HSCALE=INFO, if the maximum information is not available for the design, then the information in percentage of its corresponding fixed-sample design is used in the plot.

If the HSCALE=SAMPLESIZE option is specified, the SAMPLESIZE statement must also be specified. The options MODEL=INPUTNEVENTS, MODEL=TWOSAMPLESURVIVAL, and MODEL=PHREG in the SAMPLESIZE statement indicate survival data. For a sample that does not contain survival data, the sample size at each stage is displayed on the horizontal axis. For survival data, the number of events is displayed on the horizontal axis at each stage.

ERRSPEND < (HSCALE=INFO | STAGE) >

displays a plot of the error spending for all sequential boundaries in the designs simultaneously. You can display the information level (HSCALE=INFO) or the stage number (HSCALE=STAGE) on the horizontal axis. With HSCALE=INFO, the information fractions are used in the plot. The default is HSCALE=STAGE.

NONE

suppresses all plots.

POWER < (CREF= $c_1 < c_2 \dots$) >

displays a plot of the power curves under various hypothetical references, where the numbers $c_i \geq 0$.

For a one-sided design, powers under hypotheses $\theta = c_i \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, powers under hypotheses $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only powers under hypotheses $\theta = c_i \theta_{1u}$ are derived. The default is CREF= 0 to 1.5 by 0.01.

DESIGN Statement

< label:> **DESIGN** < options> ;

The DESIGN statement requests a new group sequential design. You can use multiple DESIGN statements, and each DESIGN statement corresponds to a separate group sequential design.

Table 83.2 summarizes the options available in the DESIGN statement.

Table 83.2 Design Statement Options

Option	Description
Design Parameters	
ALPHA=	Specifies the Type I error probability level α
ALT=	Specifies the type of alternative hypothesis
BETA=	Specifies the Type II error probability level β
BETAOVERLAP=	Checks for overlapping of the lower and upper β boundaries in a two-sided design with error spending methods
BOUNDARYKEY=	Specifies the type of error probability to maintain
INFO=	Specifies the information levels
NSTAGES=	Specifies the number of stages
STOP=	Specifies the condition for early stopping
Boundary Methods	
METHOD=	Specifies methods for boundary values

The required NSTAGES= option specifies the number of stages. The METHOD= option is required if the number of stages specified in the NSTAGES= option is greater than one. The following options can be used in the DESIGN statement. They are listed in alphabetical order.

ALPHA= α < (< LOWER= α_l > < UPPER= α_u >) >

specifies the Type I error probability α . The default is $\alpha = 0.05$. The LOWER= and UPPER= options are applicable only for the two-sided design. The LOWER= option specifies the lower Type I error probability α_l , and the upper Type I error probability is computed as $\alpha_u = \alpha - \alpha_l$. The UPPER= option specifies the upper Type I error probability α_u , and the lower Type I error probability is computed as $\alpha_l = \alpha - \alpha_u$. If both LOWER= and UPPER= options are not specified, $\alpha_l = \alpha_u = \alpha/2$.

If both the MAXINFO= and ALTREF= options are specified, then the Type I and Type II error probability levels cannot be met simultaneously. In this case, the ALPHA= option is applicable only with the BOUNDARYKEY=ALPHA option (which is the default), and the Type II error probability β is derived.

ALT=LOWER | UPPER | TWOSIDED

specifies the type of alternative hypothesis in the design. For a test of $H_0 : \theta = 0$, the keywords LOWER, UPPER, and TWOSIDED correspond to the alternatives of $\theta < 0$, $\theta > 0$, and $\theta \neq 0$, respectively. The default is ALT=TWOSIDED.

BETA= β < (< LOWER= β_l > < UPPER= β_u >) >

specifies the Type II error probability level β . The default is $\beta = 0.10$. The LOWER= and UPPER= options are applicable only for the two-sided design. The LOWER= option specifies the lower Type II error probability level β_l , and the UPPER= option specifies the upper Type II error probability level β_u . If the LOWER= or UPPER= option is not specified, β is used.

If both the MAXINFO= and ALTREF= options are specified, then the Type I and Type II error probability levels cannot be met simultaneously. In this case, the BETA= option is applicable only with the BOUNDARYKEY=BETA option, and the Type I error probability α is derived.

BETAOVERLAP=ADJUST | NOADJUST**OVERLAP=ADJUST | NOADJUST**

specifies whether to check for overlapping of the lower and upper β boundaries for the two corresponding one-sided tests. This option applies to two-sided designs with STOP=ACCEPT or STOP=BOTH that are constructed with error spending methods, and this type of overlapping might result from a small β spending at an interim stage. When you specify BETAOVERLAP=ADJUST, the procedure checks for this type of overlapping. If such overlapping is found, the β boundaries for the two-sided design at that stage are set to missing, and the β spending values at subsequent stages are adjusted, as described in the section “[Boundary Adjustments for Overlapping Lower and Upper \$\beta\$ Boundaries](#)” on page 7039”.

You can specify BETAOVERLAP=NOADJUST to request that no adjustment be made. The default is BETAOVERLAP=ADJUST.

BOUNDARYKEY=ALPHA | BETA | BOTH | NONE

specifies types of errors to be maintained in the resulting boundary. The default is BOUNDARYKEY=ALPHA if both ALTREF= and MAXINFO= options are specified. Otherwise, the default is BOUNDARYKEY=NONE for Whitehead methods with the STOP=BOTH option, and it is BOUNDARYKEY=BOTH for others.

See the section “[Applicable Boundary Keys](#)” on page 7041 for a detailed description of applicable boundary keys.

INFO=EQUAL**INFO=CUM(numbers)**

specifies relative information levels for all stages in the design. The INFO=EQUAL option specifies equally spaced information levels, and the INFO=CUM option specifies cumulative relative information levels. The default is INFO=EQUAL.

If the number of information levels specified in the INFO=CUM option is less than the number of stages specified in the NSTAGES= option, the last available information increment is used as the information increment for each subsequent stage.

METHOD=WHITEHEAD < (TAU= τ < (< LOWER= τ_l > < UPPER= τ_u >) >) >**METHOD=method****METHOD(boundary) = method**

specifies the methods for the boundaries in the design, where $0 \leq \tau < 0.5$.

For a one-sided design, an α boundary is created with the STOP=REJECT or STOP=BOTH option, and a β boundary is created with the STOP=ACCEPT or STOP=BOTH option. For a two-sided design, lower and upper α boundaries are created with the STOP=REJECT or STOP=BOTH option, and lower and upper β boundaries are created with the STOP=ACCEPT or STOP=BOTH option.

There are three types of methods available in the SEQDESIGN procedure. The unified family methods and Haybittle-Peto methods derive boundary values with fixed boundary shape; the Whitehead methods derive boundary values by adjusting the boundary values generated from continuous monitoring; and the error spending methods derive the boundary values from the specified errors used at each stage. You can specify different methods for the same design, but all methods must be from the same group.

For a design with early stopping to reject or accept the null hypothesis, the METHOD=WHITEHEAD option uses Whitehead’s triangular design and double-triangular design for a one-sided design and

two-sided design, respectively (Whitehead and Stratton 1983; Whitehead 1997, 2001). For a design with early stopping only to reject the null hypothesis or only to accept the null hypothesis, you can specify the slope of the boundary line in the score statistic scale with the `TAU= τ` option. The default is `TAU=0.25`. See the section “[Whitehead Methods](#)” on page 7030 for a detailed description of the Whitehead methods.

The following options specify available error spending methods for the boundary. Each of these methods can be specified with the `METHOD=` option for all boundaries, or with the `METHOD(boundary)` = option for an individual boundary. See the section “[Error Spending Methods](#)” on page 7034 for a detailed description of these error spending methods.

ERRFUNCGAMMA < (GAMMA= γ) >

specifies a gamma cumulative error spending function for the boundary (Hwang, Shih, and DeCani 1990). The `GAMMA=` option specifies the gamma parameter γ in the function, where $\gamma \leq 3$. The boundaries created with $\gamma = 1$ are similar to the boundaries from the Pocock method, and the boundaries created with $\gamma = -4$ or $\gamma = -5$ are similar to the boundaries from the O’Brien-Fleming method. The default is `GAMMA=-2`, which is the average of $\gamma = 1$ and $\gamma = -5$.

ERRFUNCOBF

specifies the O’Brien-Fleming-type cumulative error spending function for the boundary (Lan and DeMets 1983).

ERRFUNCPOC

specifies the Pocock-type cumulative error spending function for the boundary (Lan and DeMets 1983).

ERRFUNCPOW < (RHO= ρ) >

specifies a power cumulative error spending function for the boundary (Jennison and Turnbull 2000, p. 148). The `RHO=` option specifies the power parameter ρ in the function, where $\rho \geq 0.25$. The boundaries created with $\rho = 1$ are similar to the boundaries from the Pocock method, and the boundaries created with $\rho = 3$ are similar to the boundaries from the O’Brien-Fleming method. The default is `RHO=2`, which is the average of $\rho = 1$ and $\rho = 3$.

ERRSPEND (*numbers*)

specifies the relative cumulative error spending at each stage.

With a fixed boundary shape, you can use the following available Haybittle-Peto methods and unified family methods to derive the boundary. You can specify each of these methods in the `METHOD=` option for all boundaries, or in the `METHOD(boundary)` = option for an individual boundary. See the section “[Haybittle-Peto Method](#)” on page 7029 for a detailed description of the Haybittle-Peto methods, and see the section “[Unified Family Methods](#)” on page 7025 for a detailed description of unified family methods.

HP | HAYBITTLE | PETO < (Z= *numbers* | PVALUE= *numbers*) >

specifies the Haybittle-Peto method (Haybittle 1971; Peto et al. 1976). The values specified are used to create the boundary values. The boundary value at the final stage can be derived in the procedure to maintain the Type I and Type II error probability levels. The default is `Z=3`.

OBF | OBRIENFLEMING

specifies the O'Brien-Fleming method (O'Brien and Fleming 1979). The O'Brien-Fleming method is equivalent to a power family method with $RHO=0.5$.

POC | POCOCK

specifies the Pocock method (Pocock 1977). The Pocock method is equivalent to a power family method with $RHO=0$.

POW | POWER < (RHO= ρ) >

specifies a power family method (Wang and Tsiatis 1987; Emerson and Fleming 1989; Pampallona and Tsiatis 1994). The $RHO=$ option specifies the power parameter ρ in the power family method, where $\rho \geq -0.25$. The power family method with $\rho = 0$ corresponds to the Pocock method, and the power family method with $\rho = 0.5$ corresponds to the O'Brien-Fleming method. The default is $RHO=0.25$, a value halfway between the Pocock and O'Brien-Fleming methods. A power family method is equivalent to a unified family method with $RHO=\rho$ and $TAU=0$.

TRI | TRIANGULAR < (TAU= τ) >

specifies a unified family triangular method (Kittelson and Emerson 1999), where $0 \leq \tau \leq 1$. The default is $TAU=1.0$. The triangular method is identical to the unified family method with $RHO=0.5$ and $TAU=\tau$. Note that this unified family triangular method is different from Whitehead's triangular method.

UNI | UNIFIED < (<TAU= τ > <RHO= ρ >) >

specifies a unified family method (Kittelson and Emerson 1999). The $TAU=$ and $RHO=$ options specify the τ and ρ parameters in a unified family method, respectively, where $\rho \geq 0$ and $0 \leq \tau \leq 2\rho$. The defaults are $TAU=0$ and $RHO=0.25$. See the section "[Unified Family Methods](#)" on page 7025 for a detailed description of the unified family methods.

The O'Brien-Fleming, Pocock, power family, and triangular methods are all special cases of the unified family methods. [Table 83.3](#) summarizes the corresponding parameters in the unified family for these methods.

Table 83.3 Parameters in the Unified Family for Various Methods

Method	Option	Unified Family	
		Rho	Tau
Pocock	POC	0	0
O'Brien-Fleming	OBF	0.5	0
Power family	POW ($RHO=\rho$)	ρ	0
Triangular	TRI ($TAU=\tau$)	0.5	τ

Note that the power parameter $\rho = 1/2 - \Delta = \rho^* - 1/2$, where Δ is the power parameter used in Jennison and Turnbull (2000) and Wang and Tsiatis (1987) and ρ^* is the power parameter used in Kittelson and Emerson (1999).

If a method with specified parameters is used for all boundaries in the design, you can use the **METHOD=** option to specify the method. Otherwise, you can use the following **METHOD(boundary)=** options to specify different methods from the same group for the boundaries.

METHOD(ALPHA)=method

METHOD(REJECT)=method

specifies the method for the α boundary of a one-sided design or the lower and upper α boundaries for a two-sided design.

METHOD(LOWERALPHA)=method

METHOD(LOWERREJECT)=method

specifies the method for the lower α boundary of a two-sided design.

METHOD(UPPERALPHA)=method

METHOD(UPPERREJECT)=method

specifies the method for the upper α boundary of a two-sided design.

METHOD(BETA)=method

METHOD(ACCEPT)=method

specifies the method for the β boundary of a one-sided design or the lower and upper β boundaries for a two-sided design.

METHOD(LOWERBETA)=method

METHOD(LOWERACCEPT)=method

specifies the method for the lower β boundary of a two-sided design.

METHOD(UPPERBETA)=method

METHOD(UPPERACCEPT)=method

specifies the method for the upper β boundary of a two-sided design.

NSTAGES=number

specifies the number of stages for the design. This option is required in the **DESIGN** statement, and the maximum allowed number of stages is 25.

STOP=ACCEPT

STOP=REJECT

STOP=BOTH < (BETABOUNDARY=BINDING | NONBINDING) >

specifies the early stopping criterion for the design. The keywords **ACCEPT**, **REJECT**, and **BOTH** correspond to early stopping only to accept, only to reject, and either to accept or reject the null hypothesis H_0 , respectively. The default is **STOP=REJECT**. With **STOP=BOTH**, the **BETABOUNDARY=BINDING** suboption computes the Type I error probability with the acceptance boundary, and the **BETABOUNDARY=NONBINDING** suboption computes the Type I error probability without the acceptance boundary. The default is **BETABOUNDARY=BINDING**. The **BETABOUNDARY=NONBINDING** option is not applicable with **METHOD=WHITEHEAD**.

SAMPLESIZE Statement

SAMPLESIZE < **MODEL=** *option* > ;

If each observation in the data set provides one unit of information in a hypothesis testing such as a one-sample test for the mean, the SAMPLESIZE statement computes the required sample sizes for the sequential design specified in each DESIGN statement. However, for a survival analysis, an individual in the survival time data might provide only partial information because of censoring. For this hypothesis, the SAMPLESIZE statement computes the required numbers of events. With additional accrual information in a survival analysis, the sample sizes can also be computed.

Only one SAMPLESIZE statement can be specified. For each specified group sequential design, the SAMPLESIZE statement computes the required sample sizes or numbers of events. The SAMPLESIZE statement is not required if the SEQDESIGN procedure is used only to compare features among different designs. [Table 83.4](#) summarizes the options available in the SAMPLESIZE statement.

Table 83.4 SAMPLESIZE Statement Options

Option	Description
Fixed-Sample Models	
INPUTNOBS	Specifies the sample size for fixed-sample design
INPUTNEVENTS	Specifies the number of events for fixed-sample design
One-Sample Models	
ONESAMPLEMEAN	Specifies the one-sample Z test for mean
ONESAMPLEFREQ	Specifies the one-sample test for binomial proportion
Two-Sample Models	
TWOSAMPLEMEAN	Specifies the two-sample Z test for mean difference
TWOSAMPLEFREQ	Specifies the two-sample test for binomial proportions
TWOSAMPLESURVIVAL	Specifies the log-rank test for two survival distributions
Regression Models	
REG	Specifies the test for a regression parameter
LOGISTIC	Specifies the test for a logistic regression parameter
PHREG	Specifies the test for a proportional hazards regression parameter

The MODEL= option specifies the input sample size or number of events from a fixed-sample study, or it specifies a statistical model to compute the required sample size. The MODEL=INPUTNOBS option specifies the input sample size from a fixed-sample study of nonsurvival data, and the MODEL=INPUTNEVENTS option specifies the number of events from a fixed-sample study of survival data. The remaining MODEL= options specify the statistical models used to compute the required sample size. The default is MODEL=TWOSAMPLEMEAN, the two-sample Z test for the mean difference.

With the MODEL=INPUTNOBS or MODEL=INPUTNEVENTS option, the required sample size or number of events for the group sequential trial is computed by multiplying the input sample size or number of events by the ratio between the design information level and its corresponding fixed-sample information level. This ratio can be obtained by dividing the Max Information (Percent Fixed-Sample) in the “Design Information” table by 100. See the section “[Design Information](#)” on page 7068 for a description of the “Design Information” table.

Fixed-Sample Models

The following two options compute the required sample size or number of events for a group sequential trial by using the sample size or number of events for the fixed-sample design.

MODEL=INPUTNOBS (*options*)

specifies the sample size information for a fixed-sample design. The available options are as follows:

- N= n
- SAMPLE= ONE | TWO
- WEIGHT= $w_a < w_b >$
- MATCHNOBS= YES | NO

The required N= n option specifies the sample size n for the fixed-sample design. The SAMPLE=ONE option specifies a one-sample test, and the SAMPLE=TWO option specifies a two-sample test. The default is SAMPLE=ONE.

With a two-sample test, the WEIGHT= option specifies the sample size allocation weights for the two groups. If w_b is not specified, $w_b = 1$ is used. The default is WEIGHT=1, equal allocation for the two groups. The derived fractional sample sizes are rounded up to integers, and the MATCHNOBS=YES option requests these integer sample sizes to match the sample size allocation.

See the section “[Input Sample Size for Fixed-Sample Design](#)” on page 7044 for a detailed description of the input sample size for the fixed-sample design in sample size computation.

MODEL=INPUTNEVENTS (D= d < *options* >)

specifies the sample size information for a fixed-sample survival test. The required D= d option specifies the fixed-sample number of events d . To derive the sample size, you need to specify additional *options* from the following list:

- ACCNOBS= n_a
- ACCRATE= r_a
- ACCRUAL= UNIFORM | EXP(PARM= γ_0)
- ACCTIME= T_a
- FOLTIME= T_f
- HAZARD= $h_a < h_b >$
- LOSS= NONE | EXP(HAZARD= τ | MEDLOSSTIME= t_τ)
- MEDSURVTIME= $t_a < t_b >$
- SAMPLE= ONE | TWO
- TOTALTIME= T
- WEIGHT= $w_a < w_b >$

The SAMPLE=ONE option specifies a one-sample test, and the SAMPLE=TWO option specifies a two-sample test. The default is SAMPLE=ONE. With a two-sample test, the WEIGHT= option specifies the sample size allocation weights for the two groups. If w_b is not specified, $w_b=1$ is used. The default is WEIGHT=1.

For a one-sample test, the HAZARD= h_a option specifies the hazard rate h_a explicitly, and the MEDSURVTIME= t_a option specifies the hazard rate implicitly through the median survival time t_a . Similarly, for a two-sample test, the HAZARD= $h_a h_b$ option specifies the hazard rates h_a and h_b for groups A and B explicitly, and the MEDSURVTIME= $t_a t_b$ option specifies hazard rates for groups A and B implicitly through the median survival times t_a and t_b . Also, for a two-sample test, $h_b = h_a$ if h_b is not specified and $t_b = t_a$ if t_b is not specified.

The ACCRUAL= option specifies the method for individual accrual. The default ACCRUAL=UNIFORM option specifies that the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a , and the ACCRUAL=EXP(PARM= γ_0) option specifies that the individual accrual is truncated exponential with a scaled power parameter γ_0 , where $\gamma_0 \geq -10$ and $\gamma_0 \neq 0$. With a scaled parameter γ_0 , the power parameter for the truncated exponential with the accrual time T_a is given by $\gamma = \gamma_0 / T_a$.

The ACCTIME= and FOLTIME= options specify the accrual time T_a and follow-up time T_f , respectively. The TOTALTIME= option specifies the total study time, $T = T_a + T_f$.

The ACCRATE= option specifies the constant accrual rate r_a . If you specify the ACCRATE= option, then you must also specify one of the ACCTIME=, FOLTIME=, and TOTALTIME= options for the sample size computation. Otherwise, you must specify two of the ACCTIME=, FOLTIME=, and TOTALTIME= options to compute the accrual rate and sample size.

The ACCNOBS= option specifies the total number of individuals in the study. If you specify the ACCNOBS= option, then you must also specify one of the ACCTIME=, FOLTIME=, and TOTALTIME= options for the sample size computation. Otherwise, you must specify two of the ACCTIME=, FOLTIME=, and TOTALTIME= options to compute the accrual rate and sample size.

The LOSS= option specifies the individual loss to follow up in the sample size computation. The default LOSS=NONE option specifies no loss to follow up, and the LOSS=EXP option specifies exponential loss function. The HAZARD= τ suboption specifies the exponential loss hazard rate τ , and the MEDLOSSTIME= t_τ suboption specifies the exponential loss hazard rate through the median loss times t_τ .

See the section “[Input Number of Events for Fixed-Sample Design](#)” on page 7044 for a detailed description of the input number of events for the fixed-sample design in sample size computation.

One-Sample Models

The following two options compute the required sample size for a one-sample group sequential test:

MODEL=ONESAMPLEMEAN < (options) >

specifies the one-sample Z test for mean. The available options are as follows:

- MEAN= μ_1
- STDDEV= σ

The MEAN= option specifies the alternative reference μ_1 and is required if the alternative reference is not specified or derived in the procedure. If the MEAN=option is not specified, the specified or derived alternative reference is used.

The STDDEV= option specifies the standard deviation σ . The default is STDDEV=1. See the section “[Test for a Normal Mean](#)” on page 7050 for a detailed description of the one-sample Z test for mean.

Note that the one-sample Z test for mean also includes the paired difference in two-treatment comparison (Jennison and Turnbull 2000, pp. 51–52), where μ_1 is the mean of differences within pairs under the alternative hypothesis and σ is the standard deviation for the mean of differences within pairs.

MODEL=ONESAMPLEFREQ < (options) >

specifies the one-sample test for binomial proportion with the null hypothesis $H_0 : \theta = 0$ and the alternative hypothesis $H_1 : \theta = \theta_1$, where $\theta = p - p_0$ and $\theta_1 = p_1 - p_0$. The available options are as follows:

- NULLPROP= p_0
- PROP= p_1
- REF= NULLPROP | PROP

The NULLPROP= and PROP= options specify the proportions under the null and alternative hypotheses, respectively. The default for the null reference is NULLPROP=0.5. The PROP= option is required if the alternative reference is not specified or derived in the procedure. If the PROP= option is not specified, the specified or derived alternative reference θ_1 is used to compute the alternative reference $p_1 = p_0 + \theta_1$.

The REF= option specifies the hypothesis under which the proportion is used in the sample size computation. The REF=NULLPROP option uses the null hypothesis, and the REF=PROP option uses the alternative hypothesis to compute the sample size. The default is REF=PROP. See the section “[Test for a Binomial Proportion](#)” on page 7051 for a detailed description of the one-sample tests for proportion.

Two-Sample Models

The following three options compute the required sample size or number of events for a two-sample group sequential trial.

MODEL=TWOSAMPLEMEAN < (options) >

specifies the two-sample Z test for mean difference. The available options are as follows:

- MEANDIFF= θ_1
- STDDEV= σ_a < σ_b >
- WEIGHT= w_a < w_b >
- MATCHNOBS= YES | NO

The MEANDIFF= option specifies the alternative reference θ_1 and is required if the alternative reference is not specified or derived in the procedure. If the MEANDIFF= option is not specified, the specified or derived alternative reference is used.

The STDDEV= option specifies the standard deviations σ_a and σ_b . If σ_b is not specified, $\sigma_b = \sigma_a$. The default is STDDEV=1.

The WEIGHT= option specifies the sample size allocation weights for the two groups. If w_b is not specified, $w_b = 1$ is used. The default is WEIGHT=1, equal sample size for the two groups. The derived fractional sample sizes are rounded up to integers, and the MATCHNOBS=YES option requests these integer sample sizes to match the sample size allocation. The default is MATCHNOBS=NO.

See the section “[Test for the Difference between Two Normal Means](#)” on page 7053 for a detailed description of the two-sample Z test for mean difference.

MODEL=TWOSAMPLEFREQ < (options) >

specifies the two-sample test for binomial proportions. The available options are as follows:

- NULLPROP= $p_{0a} < p_{0b} >$
- PROP= p_{1a}
- TEST= PROP | LOGOR | LOGRR
- REF= NULLPROP | PROP | AVGNULPROP | AVGPROP
- WEIGHT= $w_a < w_b >$
- MATCHNOBS= YES | NO

The NULLPROP= option specifies proportions $p_a = p_{0a}$ and $p_b = p_{0b}$ in groups A and B, respectively, under the null hypothesis. If p_{0b} is not specified, $p_{0b} = p_{0a}$. The default is NULLPROP=0.5.

The PROP= option specifies proportion $p_a = p_{1a}$ in group A under the alternative hypothesis. The proportion p_{1b} in group B under the alternative hypothesis is given by $p_{1b} = p_{0b}$. The PROP= option is required if the alternative reference is not specified or derived in the procedure. If the PROP= option is not specified, the specified or derived alternative reference is used to compute p_{1a} , the proportion in group A under the alternative hypothesis.

The TEST= option specifies the null hypothesis $H_0 : \theta = 0$ in the test. The TEST=PROP option uses the difference in proportions $\theta = (p_a - p_b) - (p_{0a} - p_{0b})$, the TEST=LOGOR option uses the log odds-ratio test $\theta = \delta - \delta_0$, where

$$\delta = \log \left(\frac{p_a(1 - p_b)}{p_b(1 - p_a)} \right) \quad \delta_0 = \log \left(\frac{p_{0a}(1 - p_{0b})}{p_{0b}(1 - p_{0a})} \right)$$

and the TEST=LOGRR option uses the log relative risk test with $\theta = \delta - \delta_0$, where

$$\delta = \log \left(\frac{p_a}{p_b} \right) \quad \delta_0 = \log \left(\frac{p_{0a}}{p_{0b}} \right)$$

The default is TEST=LOGOR.

The REF= option specifies the hypothesis under which the proportions are used in the sample size computation. The REF=NULLPROP option uses the null proportions p_{0a} and p_{0b} , the REF=PROP option uses the alternative proportions p_{1a} and p_{1b} , the REF=AVGNULPROP option uses the average null proportion, and the REF=AVGPROP option uses the average alternative proportion. The default is REF=PROP.

The WEIGHT= option specifies the sample size allocation weights for the two groups. If w_b is not specified, $w_b = 1$ is used. The default is WEIGHT=1, equal sample size for the two groups. The derived fractional sample sizes are also rounded up to integers, and the MATCHNOBS=YES option requests that these integer sample sizes match the sample size allocation.

See the section “[Test for the Difference between Two Binomial Proportions](#)” on page 7054, the section “[Test for Two Binomial Proportions with a Log Odds Ratio Statistic](#)” on page 7056, and the section “[Test for Two Binomial Proportions with a Log Relative Risk Statistic](#)” on page 7057 for a detailed description of the two-sample tests for proportions.

MODEL=TWOSAMPLESURVIVAL < (options) >

MODEL=TWOSAMPLESURV < (options) >

specifies the log-rank test for two survival distributions with the null hypothesis $H_0 : \theta = \delta - \delta_0 = 0$, where the parameter $\delta = -\log(h_a/h_b)$, δ_0 is the value of δ under the null hypothesis and the values h_a and h_b are the constant hazard rates for groups A and B, respectively.

The available options for the number of events are as follows:

- NULLHAZARD= $h_{0a} < h_{0b} >$
- NULLMEDSURVTIME= $t_{0a} < t_{0b} >$
- HAZARD= h_{1a}
- HAZARDRATIO= λ_1
- MEDSURVTIME= t_{1a}

The NULLHAZARD= option specifies hazard rates $h_a = h_{0a}$ and $h_b = h_{0b}$ for groups A and B, respectively, under the null hypothesis. If h_{0b} is not specified, $h_{0b} = h_{0a}$. The NULLMEDSURVTIME= option specifies the median survival times $t_a = t_{0a}$ and $t_b = t_{0b}$ under the null hypothesis. If t_{0b} is not specified, $t_{0b} = t_{0a}$. If both NULLHAZARD= and NULLMEDSURVTIME= option are not specified, NULLHAZARD=0.06931, which corresponds to NULLMEDSURVTIME=10, is used.

The hazard rate for group B under the alternative hypothesis, h_{1b} , is identical to the hazard rate under the null hypothesis, h_{0b} . The HAZARD=, MEDSURVTIME=, and HAZARDRATIO= options specify the group A hazard rate h_{1a} , the group A median survival time t_{1a} , and the hazard ratio $\lambda_1 = h_{1a}/h_{1b}$, respectively, under the alternative hypothesis. The HAZARD=, MEDSURVTIME=, or HAZARDRATIO= option is required if the alternative reference is not specified or derived in the procedure. If these three options are not specified, the specified or derived alternative reference θ_1 is used to compute h_{1a} from the equation:

$$\theta_1 = -\log\left(\frac{h_{1a}}{h_{1b}}\right) - \left(-\log\left(\frac{h_{0a}}{h_{0b}}\right)\right) = -\log\left(\frac{h_{1a}}{h_{0a}}\right)$$

To derive the sample size, you need to specify additional *options* from the following list:

- ACCNOBS= n_a
- ACCRATE= r_a
- ACCRUAL= UNIFORM | EXP(PARM= γ_0)
- ACCTIME= T_a
- FOLTIME= T_f
- LOSS= NONE | EXP(HAZARD= τ | MEDLOSSTIME= t_τ)
- REF= NULLHAZARD | HAZARD
- TOTALTIME= T
- WEIGHT= $w_a < w_b >$

The REF= option specifies the hypothesis under which the hazard is used in the sample size computation. The REF=NULLHAZARD option uses the null hypothesis, and the REF=HAZARD option uses the alternative hypothesis. The default is REF=HAZARD.

The WEIGHT= option specifies the sample size allocation weights for the two groups. If w_b is not specified, $w_b = 1$ is used. The default is WEIGHT=1, equal sample size for the two groups.

The ACCRUAL= option specifies the method for individual accrual. The default ACCRUAL=UNIFORM option specifies that the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a , and the ACCRUAL=EXP(PARM= γ_0) option specifies that the individual accrual is truncated exponential with a scaled power parameter γ_0 , where $\gamma_0 \geq -10$ and $\gamma_0 \neq 0$. With a scaled parameter γ_0 , the power parameter for the truncated exponential with the accrual time T_a is given by $\gamma = \gamma_0 / T_a$.

The ACCTIME= and FOLTIME= options specify the accrual time T_a and follow-up time T_f , respectively. The TOTALTIME= option specifies the total study time, $T = T_a + T_f$.

The ACCRATE= option specifies the constant accrual rate r_a . If you specify the ACCRATE= option, then you must also specify one of the ACCTIME=, FOLTIME=, and TOTALTIME= options for the sample size computation. Otherwise, you must specify two of the ACCTIME=, FOLTIME=, and TOTALTIME= options to compute the accrual rate and sample size.

The ACCNOBS= option specifies the total number of individuals in the study. If you specify the ACCNOBS= option, then you must also specify one of the ACCTIME=, FOLTIME=, and TOTALTIME= options for the sample size computation. Otherwise, you must specify two of the ACCTIME=, FOLTIME=, and TOTALTIME= options to compute the accrual rate and sample size.

The LOSS= option specifies the individual loss to follow up in the sample size computation. The default LOSS=NONE option specifies no loss to follow up, and the LOSS=EXP option specifies exponential loss function. The HAZARD= τ suboption specifies the exponential loss hazard rate τ , and the MEDLOSSTIME= t_τ suboption specifies the exponential loss hazard rate through the median loss times t_τ .

See the section “[Test for Two Survival Distributions with a Log-Rank Test](#)” on page 7059 for a detailed description of the two-sample log-rank test for survival data.

Regression Models

The following three options compute the required sample size or number of events for group sequential tests on a regression parameter.

MODEL=REG < (options) >

specifies the Z test for a normal regression parameter. The available options are as follows:

- BETA= β_1
- VARIANCE= σ_y^2
- XVARIANCE= σ_x^2
- XRSQUARE= r_x^2

The BETA= option specifies the alternative reference β_1 and is required if the alternative reference is not specified or derived in the procedure. If the BETA= option is not specified, $\beta_1 = \theta_1$, the specified or derived alternative reference.

The VARIANCE= and XVARIANCE= options specify the variances for the response variable Y and covariate X, respectively. The defaults are VARIANCE=1 and XVARIANCE=1. For a model with

more than one covariate, the XRSQUARE= option can be used to derive the variance of X after adjusting for other covariates. The default is XRSQUARE=0.

See the section “[Test for a Parameter in the Regression Model](#)” on page 7061 for a detailed description of the Z test for the regression parameter.

MODEL=LOGISTIC < (options) >

specifies the Z test for a logistic regression parameter. The available options are as follows:

- BETA= β_1
- PROP= p
- XVARIANCE= σ_x^2
- XRSQUARE= r_x^2

The BETA= option specifies the alternative reference β_1 and is required if the alternative reference is not specified or derived in the procedure. If the BETA= option is not specified, $\beta_1 = \theta_1$, the specified or derived alternative reference.

The PROP= option specifies the proportion of the binary response variable Y. The default is PROP=0.5. The XVARIANCE= option specifies the variance of the covariate X. The default is XVARIANCE=1. For a model with more than one covariate, the XRSQUARE= option can be used to derive the variance of X after adjusting for other covariates. The default is XRSQUARE=0.

See the section “[Test for a Parameter in the Logistic Regression Model](#)” on page 7062 for a detailed description of the Z test for the logistic regression parameter.

MODEL=PHREG < (options) >

specifies the Z test for a proportional hazards regression parameter. The available options for the number of events are as follows:

- BETA= β_1
- XVARIANCE= σ_x^2
- XRSQUARE= r_x^2

The BETA= option specifies the alternative reference β_1 and is required if the alternative reference is not specified or derived in the procedure. If the BETA= option is not specified, $\beta_1 = \theta_1$, the specified or derived alternative reference.

The XVARIANCE= option specifies the variance of the covariate X. The default is XVARIANCE=1. For a model with more than one covariate, the XRSQUARE= option can be used to derive the variance of X after adjusting for other covariates. The default is XRSQUARE=0.

To derive the sample size, you need to specify additional *options* from the following list:

- ACCNOBS= n_a
- ACCRATE= r_a
- ACCRUAL= UNIFORM | EXP(PARM= γ_0)
- ACCTIME= T_a
- FOLTIME= T_f

- HAZARD= h_a
- LOSS= NONE | EXP(HAZARD= τ | MEDLOSSTIME= t_τ)
- MEDSURVTIME= t_a
- TOTALTIME= T

The hazard rate is required for the sample size computation. The HAZARD= h_a option specifies the hazard rate h_a explicitly, and the MEDSURVTIME= t_a option specifies the hazard rate implicitly through the median survival time t_a .

The ACCRUAL= option specifies the method for individual accrual. The default ACCRUAL=UNIFORM option specifies that the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a , and the ACCRUAL=EXP(PARM= γ_0) option specifies that the individual accrual is truncated exponential with a scaled power parameter γ_0 , where $\gamma_0 \geq -10$ and $\gamma_0 \neq 0$. With a scaled parameter γ_0 , the power parameter for the truncated exponential with the accrual time T_a is given by $\gamma = \gamma_0/T_a$.

The ACCTIME= and FOLTIME= options specify the accrual time T_a and follow-up time T_f , respectively. The TOTALTIME= option specifies the total study time, $T = T_a + T_f$.

The ACCRATE= option specifies the constant accrual rate r_a . If you specify the ACCRATE= option, then you must also specify one of the ACCTIME=, FOLTIME=, and TOTALTIME= options for the sample size computation. Otherwise, you must specify two of the ACCTIME=, FOLTIME=, and TOTALTIME= options to compute the accrual rate and sample size.

The ACCNOBS= option specifies the total number of individuals in the study. If you specify the ACCNOBS= option, then you must also specify one of the ACCTIME=, FOLTIME=, and TOTALTIME= options for the sample size computation. Otherwise, you must specify two of the ACCTIME=, FOLTIME=, and TOTALTIME= options to compute the accrual rate and sample size.

The LOSS= option specifies the individual loss to follow up in the sample size computation. The default LOSS=NONE option specifies no loss to follow up, and the LOSS=EXP option specifies exponential loss function. The HAZARD= τ suboption specifies the exponential loss hazard rate τ , and the MEDLOSSTIME= t_τ suboption specifies the exponential loss hazard rate through the median loss times t_τ .

See the section “[Test for a Parameter in the Proportional Hazards Regression Model](#)” on page 7063 for a detailed description of the Z test for the proportional hazards regression parameter.

Details: SEQDESIGN Procedure

Fixed-Sample Clinical Trials

A clinical trial is a research study in consenting human beings to answer specific health questions. One type of trial is a treatment trial, which tests the effectiveness of an experimental treatment. An example is a planned experiment designed to assess the efficacy of a treatment in humans by comparing the outcomes in a group of patients who receive the test treatment with the outcomes in a comparable group of patients who

receive a placebo control treatment, where patients in both groups are enrolled, treated, and followed over the same time period.

A clinical trial is conducted according to a plan called a protocol. The protocol provides detailed description of the study. For a fixed-sample trial, the study protocol contains detailed information such as the null hypothesis, the one-sided or two-sided test, and the Type I and II error probability levels. It also includes the test statistic and its associated critical values in the hypothesis testing.

Generally, the efficacy of a new treatment is demonstrated by testing a hypothesis $H_0 : \theta = 0$ in a clinical trial, where θ is the parameter of interest. For example, to test whether a population mean μ is greater than a specified value μ_0 , $\theta = \mu - \mu_0$ can be used with an alternative $\theta > 0$.

A one-sided test is a test of the hypothesis with either an upper (greater) or a lower (lesser) alternative, and a two-sided test is a test of the hypothesis with a two-sided alternative. The drug industry often prefers to use a one-sided test to demonstrate clinical superiority based on the argument that a study should not be run if the test drug would be worse (Chow, Shao, and Wang 2003, p. 28). But in practice, two-sided tests are commonly performed in drug development (Senn 1997, p. 161). For a fixed Type I error probability α , the sample sizes required by one-sided and two-sided tests are different. See Senn (1997, pp. 161–167) for a detailed description of issues involving one-sided and two-sided tests.

For independent and identically distributed observations y_1, y_2, \dots, y_n of a random variable, the likelihood function for θ is

$$L(\theta) = \prod_{j=1}^n L_i(\theta)$$

where θ is the population parameter and $L_i(\theta)$ is the probability or probability density of y_i . Using the likelihood function, two statistics can be derived that are useful for inference: the maximum likelihood estimator and the score statistic.

Maximum Likelihood Estimator

The maximum likelihood estimate (MLE) of θ is the value $\hat{\theta}$ that maximizes the likelihood function for θ . Under mild regularity conditions, $\hat{\theta}$ is an asymptotically unbiased estimate of θ with variance $1/E_\theta(I(\theta))$, where $I(\theta)$ is the Fisher information

$$I(\theta) = -\frac{\partial^2 \log(L(\theta))}{\partial \theta^2}$$

and $E_\theta(I(\theta))$ is the expected Fisher information (Diggle et al. 2002, p. 340)

$$E_\theta(I(\theta)) = -E_\theta \left(\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} \right)$$

The score function for θ is defined as

$$S(\theta) = \frac{\partial \log(L(\theta))}{\partial \theta}$$

and usually, the MLE can be derived by solving the likelihood equation $S(\theta) = 0$. Asymptotically, the MLE is normally distributed (Lindgren 1976, p. 272):

$$\hat{\theta} \sim N \left(\theta, \frac{1}{E_\theta(I(\theta))} \right)$$

If the Fisher information $I(\theta)$ does not depend on θ , then $I(\theta)$ is known. Otherwise, either the expected information evaluated at the MLE $\hat{\theta}$ ($E_{\theta=\hat{\theta}}(I(\theta))$) or the observed information $I(\hat{\theta})$ can be used for the Fisher information (Cox and Hinkley 1974, p. 302; Efron and Hinkley 1978, p. 458), where the observed Fisher information

$$I(\hat{\theta}) = - \left(\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} \mid \theta = \hat{\theta} \right)$$

If the Fisher information $I(\theta)$ does depend on θ , the observed Fisher information is recommended for the variance of the maximum likelihood estimator (Efron and Hinkley 1978, p. 457).

Thus, asymptotically, for large n ,

$$\hat{\theta} \sim N \left(\theta, \frac{1}{I} \right)$$

where I is the information, either the expected Fisher information $E_{\theta=0}(I(\theta))$ or the observed Fisher information $I(\hat{\theta})$.

So to test $H_0 : \theta = 0$ versus $H_1 : \theta \neq 0$, you can use the standardized Z test statistic

$$Z = \frac{\hat{\theta}}{\sqrt{\text{Var}(\hat{\theta})}} = \hat{\theta} \sqrt{I} \sim N(0, 1)$$

and the two-sided p -value is given by

$$\text{Prob}(|Z| > |z_0|) = 1 - 2\Phi(|z_0|)$$

where Φ is the cumulative standard normal distribution function and z_0 is the observed Z statistic.

If the BOUNDARYSCALE=SCORE is specified in the SEQDESIGN procedure, the boundary values for the test statistic are displayed in the score statistic scale. With the standardized Z statistic, the score statistic $S = Z\sqrt{I} = \hat{\theta}I$ and

$$S \sim N(0, I)$$

Score Statistic

The score statistic is based on the score function for θ ,

$$S(\theta) = \frac{\partial \log(L(\theta))}{\partial \theta}$$

Under the null hypothesis $H_0 : \theta = 0$, the score statistic $S(0)$ is the first derivative of the log likelihood evaluated at the null reference 0:

$$S(0) = \frac{\partial \log(L(\theta))}{\partial \theta} \mid \theta = 0$$

Under regularity conditions, $S(0)$ is asymptotically normally distributed with mean zero and variance $E_{\theta=0}(I(\theta))$, the expected Fisher information evaluated at the null hypothesis $\theta = 0$ (Kalbfleisch and Prentice 1980, p. 45), where $I(\theta)$ is the Fisher information

$$I(\theta) = -E \left(\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} \right)$$

That is, for large n ,

$$S(0) \sim N(0, E_{\theta=0}(I(\theta)))$$

Asymptotically, the variance of the score statistic $S(0)$, $E_{\theta=0}(I(\theta))$, can also be replaced by the expected Fisher information evaluated at the MLE $\theta = \hat{\theta}$ ($E_{\theta=\hat{\theta}}(I(\theta))$), the observed Fisher information evaluated at the null hypothesis $\theta = 0$ ($I(0)$), or the observed Fisher information evaluated at the MLE $\theta = \hat{\theta}$ ($I(\hat{\theta})$) (Kalbfleisch and Prentice 1980, p. 46), where

$$I(0) = - \left(\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} \mid \theta = 0 \right)$$

$$I(\hat{\theta}) = - \left(\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} \mid \theta = \hat{\theta} \right)$$

Thus, asymptotically, for large n ,

$$S(0) \sim N(0, I)$$

where I is the information, either an expected Fisher information ($E_{\theta=0}(I(\theta))$ or $E_{\theta=\hat{\theta}}(I(\theta))$) or a observed Fisher information ($I(0)$ or $I(\hat{\theta})$).

So to test $H_0 : \theta = 0$ versus $H_1 : \theta \neq 0$, you can use the standardized Z test statistic

$$Z = \frac{S(0)}{\sqrt{I}}$$

If the BOUNDARYSCALE=MLE is specified in the SEQDESIGN procedure, the boundary values for the test statistic are displayed in the MLE scale. With the standardized Z statistic, the MLE statistic $\hat{\theta} = Z/\sqrt{I} = U(0)/I$ and

$$\hat{\theta} \sim N\left(0, \frac{1}{I}\right)$$

One-Sample Test for Mean

The following one-sample test for mean is used to demonstrate fixed-sample clinical trials in the section “One-Sided Fixed-Sample Tests in Clinical Trials” on page 7007 and the section “Two-Sided Fixed-Sample Tests in Clinical Trials” on page 7010.

Suppose y_1, y_2, \dots, y_n are n observations of a response variable Y from a normal distribution

$$y_i \sim N(\theta, \sigma^2)$$

where θ is the unknown mean and σ^2 is the known variance.

Then the log likelihood function for θ is

$$\log(L(\theta)) = \sum_{j=1}^n -\frac{1}{2} \frac{(y_j - \theta)^2}{\sigma^2} + c$$

where c is a constant. The first derivative is

$$\frac{\partial \log(L(\theta))}{\partial \theta} = \frac{1}{\sigma^2} \sum_{j=1}^n (y_j - \theta) = \frac{n}{\sigma^2} (\bar{y} - \theta)$$

where \bar{y} is the sample mean.

Setting the first derivative to zero, the MLE of θ is $\hat{\theta} = \bar{y}$, the sample mean. The variance for $\hat{\theta}$ can be derived from the Fisher information

$$I(\theta) = -\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} = \frac{n}{\sigma^2}$$

Since the Fisher information $I_0 = I(\theta)$ does not depend on θ in this case, $1/I_0$ is used as the variance for $\hat{\theta}$. Thus the sample mean \bar{y} has a normal distribution with mean θ and variance σ^2/n :

$$\hat{\theta} = \bar{y} \sim N\left(\theta, \frac{1}{I_0}\right) = N\left(\theta, \frac{\sigma^2}{n}\right)$$

Under the null hypothesis $H_0 : \theta = 0$, the score statistic

$$S(0) = \frac{\partial \log(L(\theta))}{\partial \theta} \Big|_{\theta=0} = \frac{n}{\sigma^2} \bar{y}$$

has a mean zero and variance

$$I(\theta) = -\frac{\partial^2 \log(L(\theta))}{\partial \theta^2} = \frac{n}{\sigma^2}$$

With the MLE $\hat{\theta}$, the corresponding standardized statistic is computed as $Z = \hat{\theta} \sqrt{I_0} = \bar{y}/(\sigma/\sqrt{n})$, which has a normal distribution with variance 1:

$$Z \sim N\left(\theta \sqrt{I_0}, 1\right) = N\left(\frac{\theta}{\sigma/\sqrt{n}}, 1\right)$$

Also, the corresponding score statistic is computed as $S = \hat{\theta} I_0 = n\bar{y}/\sigma^2$ and

$$S \sim N\left(\theta I_0, I_0\right) = N\left(\frac{n\theta}{\sigma^2}, \frac{n}{\sigma^2}\right)$$

which is identical to $S(0)$ computed under the null hypothesis $H_0 : \theta = 0$.

Note that if the variable Y does not have a normal distribution, then it is assumed that the sample size n is large such that the sample mean has an approximately normal distribution.

One-Sided Fixed-Sample Tests in Clinical Trials

A one-sided test has either an upper (greater) or a lower (lesser) alternative. This section describes one-sided tests with upper alternatives only. Corresponding results for one-sided tests with lower alternatives can be derived similarly.

For a one-sided test of $H_0 : \delta \leq \delta_0$ with an upper alternative $H_1 : \delta > \delta_0$, an equivalent null hypothesis is $H_0 : \theta \leq 0$ with an upper alternative $H_1 : \theta > 0$, where $\theta = \delta - \delta_0$. A fixed-sample test rejects H_0 if the

standardized test statistic $Z_0 = \hat{\theta} \sqrt{I_0} \geq C_\alpha$, where $\hat{\theta}$ is the sample estimate of θ and $C_\alpha = \Phi^{-1}(1 - \alpha)$ is the critical value.

The p -value of the test is given by $1 - \Phi(Z_0)$, and the hypothesis H_0 is rejected if the p -value is less than α . An upper $(1 - \alpha)$ confidence interval has the lower limit

$$\theta_l = \hat{\theta} - \frac{\Phi^{-1}(1 - \alpha)}{\sqrt{I_0}} = \frac{Z_0 - \Phi^{-1}(1 - \alpha)}{\sqrt{I_0}}$$

The hypothesis H_0 is rejected if the confidence interval for the parameter θ does not contain zero—that is, if the lower limit θ_l is greater than 0.

With an alternative reference $\theta = \theta_1$, $\theta_1 > 0$, a Type II error probability is defined as

$$\beta = P_{\theta=\theta_1}(Z_0 < C_\alpha)$$

which is equivalent to

$$\beta = P_{\theta=\theta_1}(Z_0 - \theta_1 \sqrt{I_0} < C_\alpha - \theta_1 \sqrt{I_0}) = \Phi(C_\alpha - \theta_1 \sqrt{I_0})$$

Thus, $\Phi^{-1}(\beta) = C_\alpha - \theta_1 \sqrt{I_0}$. Then, with $C_\alpha = \Phi^{-1}(1 - \alpha)$,

$$\theta_1 \sqrt{I_0} = \Phi^{-1}(1 - \alpha) + \Phi^{-1}(1 - \beta)$$

The drift parameter $\theta_1 \sqrt{I_0}$ can be computed for specified α and β and the maximum information is given by

$$I_0 = \left(\frac{\Phi^{-1}(1 - \alpha) + \Phi^{-1}(1 - \beta)}{\theta_1} \right)^2$$

If the maximum information is available, then the required sample size can be derived. For example, in a one-sample test for the mean with a specific standard deviation σ , the sample size n required for the test is

$$n = \sigma^2 I_0 = \sigma^2 \left(\frac{\Phi^{-1}(1 - \alpha) + \Phi^{-1}(1 - \beta)}{\theta_1} \right)^2$$

On the other hand, if the alternative reference θ_1 , standard deviation σ , and sample size n are all specified, then α can be derived for a given β and, similarly, β can be derived for a given α .

With an alternative reference $\theta = \theta_1$, $\theta_1 > 0$, the power $1 - \beta$ is the probability of correctly rejecting the null hypothesis H_0 at θ_1 :

$$1 - \beta = 1 - P_{\theta=\theta_1}(Z_0 < C_\alpha) = \Phi(\theta_1 \sqrt{I_0} - C_\alpha)$$

Superiority Trials

A superiority trial that tests the response to a new drug is clinically superior to a comparative placebo control or active control therapy. If a positive value indicates a beneficial effect, a test for superiority has

$$H_0 : \theta \leq 0 \quad H_1 : \theta > 0$$

where H_0 is the hypothesis of nonsuperiority and H_1 is the alternative hypothesis of superiority.

The superiority test rejects the hypothesis H_0 and declares superiority if the standardized statistic $Z_0 = \hat{\theta} \sqrt{I_0} \geq C_\alpha$, where the critical value $C_\alpha = \Phi^{-1}(1 - \alpha)$.

For example, if θ is the response difference between the treatment and placebo control groups, then a superiority trial can be

$$H_0 : \theta \leq 0 \quad H_1 : \theta = 6$$

with a Type I error probability level $\alpha = 0.025$ and a power $1 - \beta = 0.90$ at $\theta_1 = 6$.

Noninferiority Trials

A noninferiority trial does not compare the response to a new treatment with the response to a placebo. Instead, it demonstrates the effectiveness of a new treatment compared with that of a nonexistent placebo by showing that the response of a new treatment is not clinically inferior to the response of a standard therapy with an established effect. That is, this type of trial attempts to demonstrate that the new treatment effect is not worse than the standard therapy effect by an acceptable margin. These trials are often performed when there is an existing effective therapy for a serious disease, and therefore a placebo control group cannot be ethically included.

It can be difficult to specify an appropriate noninferiority margin. One practice is to choose with reference to the effect of the active control in historical placebo-controlled trials (Snapinn 2000, p. 20). With this practice, there is some basis to imply that the new treatment is better than the placebo for a positive noninferiority trial.

If a positive value indicates a beneficial effect, a test for noninferiority has a null hypothesis $\delta \leq -\delta_0$ and an alternative hypothesis $\delta = \delta_1 > -\delta_0$, where $\delta_0 > 0$ is the specified noninferiority margin.

An equivalent test has

$$H_0 : \theta \leq 0 \quad H_1 : \theta = \theta_1 > 0$$

where the parameter $\theta = \delta + \delta_0$, H_0 is the null hypothesis of inferiority, and H_1 is the alternative hypothesis of noninferiority,

The noninferiority test rejects the hypothesis H_0 and declares noninferiority if the standardized statistic $Z_0 = \hat{\theta} \sqrt{I_0} = (\hat{\delta} + \delta_0) \sqrt{I_0} \geq C_\alpha$, where the critical value $C_\alpha = \Phi^{-1}(1 - \alpha)$.

For example, if δ is the response difference between the treatment and active control groups and $\delta_0 = 2$ is the noninferiority margin, then a noninferiority trial with a power $1 - \beta = 0.90$ at $\delta_1 = 1$ might be

$$H_0 : \theta \leq 0 \quad H_1 : \theta = 3$$

where $\theta = \delta + \delta_0 = \delta + 2$.

Two-Sided Fixed-Sample Tests in Clinical Trials

A two-sided test is a test of a hypothesis with a two-sided alternative. Two-sided tests include simple symmetric tests and more complicated asymmetric tests that might have distinct lower and upper alternative references.

Symmetric Two-Sided Tests for Equality

For a symmetric two-sided test with the null hypothesis $\delta = \delta_0$ against the alternative $\delta \neq \delta_0$, an equivalent null hypothesis is $H_0 : \theta = 0$ with a two-sided alternative $H_1 : \theta \neq 0$, where $\theta = \delta - \delta_0$. A fixed-sample test rejects H_0 if $|\hat{\theta}\sqrt{I_0}| \geq C_{\alpha/2}$, where $\hat{\theta}$ is a sample estimate of θ and $C_{\alpha/2} = \Phi^{-1}(1 - \alpha/2)$ is the critical value.

A common two-sided test is the test for the response difference between a treatment group and a control group. The null and alternative hypotheses are $H_0 : \theta = 0$ and $H_1 : \theta \neq 0$, respectively, where θ is the response difference between the two groups. If a greater value indicates a beneficial effect, then there are three possible results:

- The test rejects the hypothesis H_0 of equality and indicates that the treatment is significantly better if the standardized statistic $Z_0 = \hat{\theta}\sqrt{I_0} \geq C_{\alpha/2}$.
- The test rejects the hypothesis H_0 and indicates the treatment is significantly worse if the standardized statistic $Z_0 = \hat{\theta}\sqrt{I_0} \leq -C_{\alpha/2}$.
- The test indicates no significant difference between the two responses if $-C_{\alpha/2} < \hat{\theta}\sqrt{I_0} < C_{\alpha/2}$.

The p -value of the test is $2(1 - \Phi(Z_0))$ if $Z_0 > 0$ and $2\Phi(Z_0)$ if $Z_0 \leq 0$. The hypothesis H_0 is rejected if the p -value of the test is less than α —that is, if $1 - \Phi(Z_0) < \alpha/2$ or $\Phi(Z_0) < \alpha/2$. A symmetric $(1 - \alpha)$ confidence interval for θ has lower and upper limits

$$\left(\hat{\theta} - \frac{C_{\alpha/2}}{\sqrt{I_0}}, \hat{\theta} + \frac{C_{\alpha/2}}{\sqrt{I_0}} \right)$$

which is

$$\left(\frac{1}{\sqrt{I_0}} (Z_0 - C_{\alpha/2}), \frac{1}{\sqrt{I_0}} (Z_0 + C_{\alpha/2}) \right)$$

The hypothesis H_0 is rejected if the confidence interval for the parameter θ does not contain zero. That is, the lower limit is greater than zero or the upper limit is less than zero.

With an alternative reference $\theta = \theta_1 > 0$, a Type II error probability is defined as

$$\beta = P_{\theta=\theta_1}(-C_{\alpha/2} < Z_0 < C_{\alpha/2})$$

which is

$$\beta = P_{\theta=\theta_1} \left((-C_{\alpha/2} - \theta_1\sqrt{I_0}) < (Z_0 - \theta_1\sqrt{I_0}) < (C_{\alpha/2} - \theta_1\sqrt{I_0}) \right)$$

Thus

$$\beta = \Phi(C_{\alpha/2} - \theta_1 \sqrt{I_0}) - \Phi(-C_{\alpha/2} - \theta_1 \sqrt{I_0})$$

The resulting power $1 - \beta$ is the probability of correctly rejecting the null hypothesis, which includes the probability for the lower alternative and the probability for the upper alternative. The SEQDESIGN procedure uses only the probability of correctly rejecting the null hypothesis for the correct alternative in the power computation.

Thus, under the upper alternative hypothesis, the power in the SEQDESIGN procedure is computed as the probability of rejecting the null hypothesis for the upper alternative, $1 - \Phi(C_{\alpha/2} - \theta_1 \sqrt{I_0}) = \Phi(\theta_1 \sqrt{I_0} - C_{\alpha/2})$, and a very small probability of rejecting the null hypothesis for the lower alternative, $\Phi(-C_{\alpha/2} - \theta_1 \sqrt{I_0})$, is ignored. This power computation is more rational than the power based on the probability of correctly rejecting the null hypothesis (Whitehead 1997, p. 75).

That is,

$$\beta = P_{\theta=\theta_1}((Z_0 - \theta_1 \sqrt{I_0}) < (C_{\alpha/2} - \theta_1 \sqrt{I_0})) = \Phi(C_{\alpha/2} - \theta_1 \sqrt{I_0})$$

Then with $\Phi^{-1}(\beta) = C_{\alpha/2} - \theta_1 \sqrt{I_0}$,

$$\theta_1 \sqrt{I_0} = C_{\alpha/2} - \Phi^{-1}(\beta) = \Phi^{-1}(1 - \alpha/2) + \Phi^{-1}(1 - \beta)$$

The drift parameter $\theta_1 \sqrt{I_0}$ can be derived for specified α and β , and the maximum information is given by

$$I_0 = \left(\frac{\Phi^{-1}(1 - \alpha/2) + \Phi^{-1}(1 - \beta)}{\theta_1} \right)^2$$

If the maximum information is available, then the required sample size can be derived. For example, in a one-sample test for mean, if the standard deviation σ is known, the sample size n required for the test is

$$n = \sigma^2 I_0 = \sigma^2 \left(\frac{\Phi^{-1}(1 - \alpha/2) + \Phi^{-1}(1 - \beta)}{\theta_1} \right)^2$$

On the other hand, if the alternative reference θ_1 , standard deviation σ , and sample size n are all known, then α can be derived with a given β and, similarly, β can be derived with a given α .

Generalized Two-Sided Tests for Equality

For a generalized two-sided test with the null hypothesis $\delta = \delta_0$ against the alternative $\delta \neq \delta_0$, an equivalent null hypothesis is $H_0 : \theta \leq 0$ with a two-sided alternative $H_1 : \theta \neq 0$, where $\theta = \delta - \delta_0$. A fixed-sample test rejects H_0 if the standardized statistic $Z_0 = \hat{\theta} \sqrt{I_0} < -C_{\alpha_l}$ or $Z_0 = \hat{\theta} \sqrt{I_0} > C_{\alpha_u}$, where the critical values $C_{\alpha_l} = \Phi^{-1}(1 - \alpha_l)$ and $C_{\alpha_u} = \Phi^{-1}(1 - \alpha_u)$.

With the lower alternative reference $\theta_{1l} < 0$, a lower Type II error probability is defined as

$$\beta_l = P_{\theta=\theta_{1l}}(-C_{\alpha_l} \leq Z_{0l} \sqrt{I_0}) = P_{\theta=\theta_{1l}}(-C_{\alpha_l} - \theta_{1l} \sqrt{I_0} \leq Z_{0l} \sqrt{I_0} - \theta_{1l} \sqrt{I_0})$$

This implies

$$\beta_l = 1 - \Phi(-C_{\alpha_l} - \theta_{1l} \sqrt{I_0})$$

and the power is the probability of correctly rejecting the null hypothesis for the lower alternative,

$$1 - \beta_l = \Phi(-C_{\alpha_l} - \theta_{1l} \sqrt{I_0})$$

The lower drift parameter is derived as

$$\theta_{1l} \sqrt{I_0} = -(\Phi^{-1}(1 - \alpha_l) + \Phi^{-1}(1 - \beta_l))$$

Then, with specified α_l and β_l , if the maximum information is known, the lower alternative reference θ_{1l} can be derived. If the maximum information is unknown, then with the specified lower alternative reference θ_{1l} , the maximum information required is

$$I_{0l} = \left(\frac{\Phi^{-1}(1 - \alpha_l) + \Phi^{-1}(1 - \beta_l)}{-\theta_{1l}} \right)^2$$

Similarly, the upper drift parameter is derived as

$$\theta_{1u} \sqrt{I_0} = \Phi^{-1}(1 - \alpha_u) + \Phi^{-1}(1 - \beta_u)$$

For a given α_u , β_u , and the upper alternative reference θ_{1u} , the maximum information required is

$$I_{0u} = \left(\frac{\Phi^{-1}(1 - \alpha_u) + \Phi^{-1}(1 - \beta_u)}{\theta_{1u}} \right)^2$$

Thus, the maximum information required for the design is given by

$$I_0 = \max(I_{0l}, I_{0u})$$

Note that with the maximum information level I_0 , if $I_{0l} < I_0$, then the derived power from the lower alternative is larger than the specified $1 - \beta_l$. Similarly, if $I_{0u} < I_0$, then the derived power from the upper alternative is larger than the specified $1 - \beta_u$.

If maximum information is available, the required sample size can be derived. For example, in a one-sample test for mean, if the standard deviation σ is known, the sample size n required for the test is $n = \sigma^2 I_0$.

On the other hand, if the alternative references, Type I error probabilities α_l and α_u , standard deviation σ , and sample size n are all specified, then the Type II error probabilities β_l and β_u and the corresponding powers can be derived.

Group Sequential Methods

A group sequential design provides interim analyses before the formal completion of a trial. The monitoring process provides possible early stopping for either positive or negative results and thus reduces the time to complete the trial. With a specified number of stages, the design creates critical values such that at each

interim analysis, a hypothesis can be rejected, accepted, or continued to the next time point. At the final stage, a hypothesis is either rejected or accepted. Usually, the critical values are derived such that the specified overall Type I and Type II error probability levels are maintained in the design.

For example, to test a null hypothesis H_0 with an upper alternative in a fixed-sample design, a critical value c_α is created. The null hypothesis H_0 is rejected if the test statistic is greater than or equal to the critical value c_α . Otherwise, H_0 is accepted. But, for a group sequential design with early stopping to reject or accept the null hypothesis H_0 , there are two critical values created at each interim analysis: an α critical value $c_{\alpha k}$ to reject the null hypothesis and a β critical value $c_{\beta k}$ to accept the null hypothesis. The null hypothesis H_0 is rejected if the test statistic is greater than or equal to the α critical value $c_{\alpha k}$, and H_0 is accepted if the test statistic is less than the β critical value $c_{\beta k}$. If the test statistic is between these two critical values, the process continues to the next stage. At the final stage, the two critical values are equal, and the hypothesis is either rejected or accepted.

Armitage, McPherson, and Rowe (1969) showed that repeated significance tests at a fixed level on accumulating data increase the probability of obtaining a significant result under the null hypothesis. For example, with a significance level 0.05 in a two-sided fixed-sample test, the critical value is 1.96. If this value is used in a five-stage group sequential trial with early stopping to reject the null hypothesis, then the probability of rejecting the null hypothesis at or before the fifth stage is 0.14169, much larger than the nominal value 0.05 (Armitage, McPherson, and Rowe 1969, p. 239).

Pocock (1977) applied these repeated significance tests to group sequential trials with equally spaced information levels and derives a constant critical value on the standardized normal Z scale across all stages that maintains the Type I error probability level. For example, with a significance level 0.05 in a two-sided test, the derived critical value at each stage is 2.413 on the standardized normal Z scale, larger than the fixed-sample critical value 1.96. The corresponding nominal p -value is 0.0158, which is smaller than the fixed-sample p -value 0.025 (Pocock 1977, p. 193).

O'Brien and Fleming (1979) proposed a sequential procedure that has boundary values decrease over the stages on the standardized normal Z scale to make the early stop less likely. The procedure has conservative stopping boundary values at very early stages, and boundary values at the final stage are close to the fixed-sample design. For example, with a significance level 0.05 in a two-sided test, the derived critical values at these five stages on the standardized normal Z scale are 4.562, 3.226, 2.634, 2.281, and 2.040.

The following references: Wang and Tsatis (1987); Emerson and Fleming (1989); Pampallona and Tsatis (1994) generalized the Pocock and O'Brien-Fleming methods to the power family, where a power parameter is used to allow a continuous set of designs between the Pocock and O'Brien-Fleming methods.

Kittelson and Emerson (1999) extended the methods in the power family even further to the unified family, which also includes the exact triangular method. The shape and location of each of the four boundaries can be independently specified in the unified family methods.

Whitehead and Stratton (1983) and Whitehead (1997, 2001) developed triangular methods by adapting tests for continuous monitoring to discrete monitoring. With early stopping to reject or accept the null hypothesis in a one-sided test, the derived continuation region has a triangular shape for the score-scaled boundaries. Only elementary calculations are needed to derive the boundary values for Whitehead's triangular methods.

For a sequential design, you can derive the α and β error probabilities at each stage from the boundaries. On the other hand, you can derive the boundaries from specified α and β error probabilities at each stage. The error spending function approach (Lan and DeMets 1983) uses the error spending function to specify the error probabilities at each stage and then uses these probabilities to derive the boundaries. You can specify α and β explicitly or implicitly with an error spending function for the cumulative probabilities.

See Jennison and Turnbull (2000, pp. 5–11) for a more detailed history of group sequential methods.

The following three types of methods are available in the SEQDESIGN procedure to derive boundaries in a sequential design:

- fixed boundary shape methods, which derive boundaries with specified boundary shapes. These include the unified family method and Haybittle-Peto method.
- Whitehead methods, which adjust the boundaries from continuous monitoring for discrete monitoring
- error spending methods

You can use the SEQDESIGN procedure to specify methods from the same group for each design. A different method can be specified for each boundary separately, but all methods in a design must be from the same group.

Fixed Boundary Shape Methods

The fixed boundary shape methods include the unified family method (Kittelson and Emerson 1999) and the Haybittle-Peto method (Haybittle 1971; Peto et al. 1976). The unified family methods derive the boundary values with the specified boundary shape. The unified family methods include the Pocock method (Pocock 1977), the O'Brien-Fleming method (O'Brien and Fleming 1979), the power family method (Wang and Tsatis 1987; Emerson and Fleming 1989; Pampallona and Tsatis 1994), and the triangular method (Kittelson and Emerson 1999). See the section “[Unified Family Methods](#)” on page 7025 for a detailed description of the methods that use the unified family approach.

The Haybittle-Peto method uses a value of 3 for the critical values in interim stages, so that the critical value at the final stage is close to the original design without interim monitoring. In the SEQDESIGN procedure, the Haybittle-Peto method has been generalized to allow for different boundary values at different stages. See the section “[Haybittle-Peto Method](#)” on page 7029 for a detailed description of the Haybittle-Peto method.

Whitehead Methods

The Whitehead methods (Whitehead and Stratton 1983; Whitehead 1997, 2001) derive the boundary values by adapting the continuous monitoring tests to the discrete monitoring of group sequential tests. The Type I error probability and power corresponding to the resulting boundaries are extremely close but differ slightly from the specified values because of the approximations used in deriving the tests (Jennison and Turnbull 2000, p. 106). The SEQDESIGN procedure provides the BOUNDARYKEY= option to adjust the boundary value at the final stage for the exact Type I or Type II error probability level. See the section “[Whitehead Methods](#)” on page 7030 for a detailed description of Whitehead's methods.

Error Spending Methods

An error spending method (Lan and DeMets 1983) uses the error spending function to specify the error spending at each stage and then uses these error probabilities to derive the boundary values. You can specify these errors explicitly or with an error spending function for these cumulative errors. See the section “[Error Spending Methods](#)” on page 7034 for a detailed description of the error spending methods.

Error spending methods derive boundary values at each stage sequentially and require much more computation than other types of methods for group sequential trials with a large number of stages, especially for a two-sided asymmetric design with early stopping to accept H_0 , or to reject or accept H_0 .

The sample size requirement for some applicable tests can also be computed in the procedure. After the actual data from a clinical trial are collected, you can then use the boundary information created in the SEQDESIGN procedure to perform a group sequential test in the SEQTEST procedure.

Statistical Assumptions for Group Sequential Designs

The SEQDESIGN procedure assumes that with a total number of stages K , the sequence of the standardized test statistics $\{Z_1, Z_2, \dots, Z_K\}$ has the canonical joint distribution with information levels $\{I_1, I_2, \dots, I_K\}$ for the parameter θ (Jennison and Turnbull 2000, p. 49):

- (Z_1, Z_2, \dots, Z_K) is multivariate normal
- $Z_k \sim N(\theta\sqrt{I_k}, 1), k = 1, 2, \dots, K$
- $\text{Cov}(Z_{k_1}, Z_{k_2}) = \sqrt{(I_{k_1}/I_{k_2})}, 1 \leq k_1 \leq k_2 \leq K$

In terms of the maximum likelihood estimator, $\hat{\theta}_k = Z_k/\sqrt{I_k}, k = 1, 2, \dots, K$, the canonical joint distribution can be expressed as follows:

- $(\hat{\theta}_1, \hat{\theta}_2, \dots, \hat{\theta}_K)$ is multivariate normal
- $\hat{\theta}_k \sim N(\theta, 1/I_k), k = 1, 2, \dots, K$
- $\text{Cov}(\hat{\theta}_{k_1}, \hat{\theta}_{k_2}) = 1/I_{k_2}, 1 \leq k_1 \leq k_2 \leq K$

Furthermore, in terms of the score statistics $S_k = Z_k\sqrt{I_k}, k = 1, 2, \dots, K$, the canonical joint distribution can be expressed as follows:

- (S_1, S_2, \dots, S_K) is multivariate normal
- $S_k \sim N(\theta I_k, I_k), k = 1, 2, \dots, K$
- $\text{Cov}(S_{k_1}, S_{k_2}) = \text{Var}(S_{k_1}) = I_{k_1}, 1 \leq k_1 \leq k_2 \leq K$

That is, the increments $S_1, S_2 - S_1, \dots$, and $S_K - S_{(K-1)}$ are independently distributed.

If the test statistic is computed from the data that are not from a normal distribution, such as a binomial distribution, then it is assumed that the test statistic is computed from a large sample such that the statistic has an approximately normal distribution.

If the increments $S_1, S_2 - S_1, \dots$, and $S_K - S_{(K-1)}$ are not independently distributed, then it is inappropriate to use group sequential methods in the SEQDESIGN procedure. One such example is the Gehan statistic, which is a weighted log-rank statistic for censored data. See Jennison and Turnbull (2000, pp.

232–233, 276–277) and Proschan, Lan, and Wittes (2006, pp. 150–151) for a description of statistics with nonindependent increments.

If a trial stops at an early interim stage with only a small number of responses observed, it can lead to a distrust of the statistical findings, which rely on the assumption that the sample is large (Whitehead 1997, p. 167). A group sequential design can be specified such that at the first interim analysis, there are a sufficient number of responses to ensure that the analysis to be conducted is both reliable and persuasive (Whitehead 1997, p. 167).

Alternatively, a method such as the O'Brien-Fleming method can be used to derive conservative stopping boundary values at very early stages to make the early stop less likely. That is, the trial is stopped in early stages only with overwhelming evidence.

A simple example of the group sequential tests is the test for a normal mean, $\mu = \mu_0$. Suppose y_1, y_2, \dots, y_n are n observations of a response variable Y in a data set from a normal distribution with an unknown mean μ and a known variance σ^2 . Then the maximum likelihood estimate of μ is the sample mean

$$\bar{y} = \frac{1}{n} \sum_{j=1}^n y_j$$

The sample mean has a normal distribution with mean μ and variance σ^2/n :

$$\bar{y} \sim N\left(\mu, \frac{\sigma^2}{n}\right)$$

An equivalent hypothesis for $\mu = \mu_0$ is $H_0 : \theta = 0$, where $\theta = \mu - \mu_0$. The MLE statistic for θ ,

$$\hat{\theta} = \bar{y} - \mu_0 \sim N(\theta, I_0^{-1})$$

where the information $I_0 = n/\sigma^2$.

For a group sequential test with K stages, there are N_1, N_2, \dots, N_K observations available at these stages. At stage k , the sample mean is computed as

$$\bar{y}_k = \frac{1}{N_k} \sum_{j=1}^{N_k} y_{kj}$$

where y_{kj} is the value of the j th observation available at the k th stage and N_k is the cumulative sample size at stage k , which includes the N_{k-1} observations collected at previous stages and the $N_k - N_{k-1}$ observations collected at the current stage.

The maximum likelihood estimate

$$\hat{\theta}_k = \bar{y}_k - \mu_0 \sim N(\theta, I_k^{-1})$$

where the information

$$I_k = \frac{1}{\text{Var}(\bar{y}_k)} = \frac{N_k}{\sigma^2}$$

is the inverse of the variance.

Thus, the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} = (\bar{y}_k - \mu_0) \sqrt{I_k} \sim N(\theta \sqrt{I_k}, 1)$$

The covariance of Z_{k_1} and Z_{k_2} , $1 \leq k_1 \leq k_2 \leq K$ can be expressed as

$$\text{Cov}(Z_{k_1}, Z_{k_2}) = \frac{1}{\sqrt{(I_{k_1} I_{k_2})}} \text{Cov}(S_{k_1}, S_{k_2})$$

where $S_{k_1} = Z_{k_1} \sqrt{I_{k_1}}$ and $S_{k_2} = Z_{k_2} \sqrt{I_{k_2}}$.

Since $S_{k_2} - S_{k_1}$ is independent of S_{k_1} , $\text{Cov}(S_{k_1}, S_{k_2}) = \text{Var}(S_{k_1}) = I_{k_1}$ and

$$\text{Cov}(Z_{k_1}, Z_{k_2}) = \frac{1}{\sqrt{(I_{k_1} I_{k_2})}} I_{k_1} = \sqrt{I_{k_1}/I_{k_2}}$$

Thus the statistics $\{Z_1, Z_2, \dots, Z_K\}$ has the canonical joint distribution with information levels $\{I_1, I_2, \dots, I_K\}$ for the parameter μ . See the section “[Applicable One-Sample Tests and Sample Size Computation](#)” on page 7050, the section “[Applicable Two-Sample Tests and Sample Size Computation](#)” on page 7052, and the section “[Applicable Regression Parameter Tests and Sample Size Computation](#)” on page 7061 for more examples of applicable tests in group sequential trials.

Boundary Scales

The boundaries computed by the SEQDESIGN procedure are applied to test statistics computed during the analysis, and so generally, the scale you select for the boundaries is determined by the scale of the statistics that you will be using.

The following scales are available in the SEQDESIGN procedure:

- MLE, maximum likelihood estimate
- standardized Z
- score statistic S
- p-value

These scales are all equivalent for a given set of boundary values—that is, there exists a unique transformation between any two of these scales. If you know the boundary values in terms of statistics from one scale, you can uniquely derive the boundary values of statistics for other scales. You can specify the scale with the BOUNDARYSCALE= option; the default is BOUNDARYSCALE=STDZ, the standardized Z scale.

You can also select the boundary scale to better examine the features of an individual group sequential design or to compare features among multiple designs. For example, with the standardized Z scale, the boundary values for the Pocock design are identical across all stages, and the O’Brien-Fleming design has boundary values (in absolute value) that decrease over the stages.

The remaining section demonstrates the transformations from one scale to the other scales. If the maximum likelihood estimate $\hat{\theta}$ is computed by the analysis, then

$$\hat{\theta} \sim N\left(\theta, \frac{1}{I}\right)$$

where I is the Fisher information if it does not depend on θ . Otherwise, I is either the expected Fisher information evaluated at $\hat{\theta}$ or the observed Fisher information. See the section “[Maximum Likelihood Estimator](#)” on page 7004 for a detailed description of these statistics.

With the MLE statistic $\hat{\theta}$, the corresponding standardized Z statistic is computed as

$$Z = \hat{\theta} \sqrt{I} \sim N\left(\theta \sqrt{I}, 1\right)$$

and the corresponding score statistic is computed as

$$S = \hat{\theta} I \sim N(\theta I, I)$$

Similarly, if a score statistic S is computed by the analysis, then with

$$S \sim N(\theta I, I)$$

where I is the information, either an expected Fisher information ($E_{\theta=0}(I(\theta))$ or $E_{\theta=\hat{\theta}}(I(\theta))$) or an observed Fisher information ($I(0)$ or $I(\hat{\theta})$).

The corresponding standardized Z statistic is computed as

$$Z = \frac{S}{\sqrt{I}} \sim N\left(\theta \sqrt{I}, 1\right)$$

and the corresponding MLE-scaled statistic is computed as

$$\hat{\theta} = \frac{S}{I} \sim N\left(\theta, \frac{1}{I}\right)$$

With a standardized normal Z statistic, the corresponding fixed-sample nominal p -value depends on the type of alternative hypothesis. With an upper alternative, the nominal p -value is defined as the one-sided p -value under the null hypothesis $H_0 : \theta = 0$ with an upper alternative:

$$p_k = 1 - \Phi(Z)$$

With a lower alternative or a two-sided alternative, the nominal p -value is defined as the one-sided p -value under the null hypothesis $H_0 : \theta = 0$ with a lower alternative:

$$p_k = \Phi(Z)$$

which is an increasing function of the standardized Z statistic (Emerson, Kittelson, and Gillen 2005, p. 12).

The BOUNDARYSCALE= MLE, STDZ, SCORE, and PVALUE options display the boundary values in the MLE, standardize Z , score, and p -value scales, respectively. For example, suppose $y_{k1}, y_{k2}, \dots, y_{kn_k}$

are n_k observations of a response variable Y in a data set from a normal distribution with an unknown mean μ and a known variance σ^2 . Then

$$y_{kj} \sim N(\mu, \sigma^2)$$

for $k = 1, 2, \dots, K$, where K is the number of groups and n_k is the number of observations at group k .

If N_k is the cumulative number of observations for the first k groups, then the sample mean from these N_k observations

$$\bar{y}_k = \frac{1}{N_k} \sum_{j=1}^{N_k} y_{kj}$$

has a normal distribution with mean θ and variance σ^2/N_k :

$$\bar{y}_k \sim N\left(\theta, \frac{\sigma^2}{N_k}\right)$$

To test the null hypothesis $\mu = \mu_0$, $H_0 : \theta = 0$, where $\theta = \mu - \mu_0$ can be used. The MLE of θ is $\hat{\theta}_k = \bar{y}_k - \mu_0$ and

$$\hat{\theta}_k \sim N\left(\theta, \frac{1}{I_k}\right)$$

where the information is the inverse of the variance of \bar{y}_k ,

$$I_k = \frac{N_k}{\sigma^2}$$

The corresponding standardized Z statistic is

$$Z_k = \hat{\theta}_k I_k^{\frac{1}{2}} \sim N\left(\theta I_k^{\frac{1}{2}}, 1\right)$$

The score statistic in the SEQDESIGN procedure is then given by

$$S_k = \hat{\theta}_k I_k = Z_k I_k^{\frac{1}{2}} \sim N(\theta I_k, I_k)$$

For a null hypothesis $H_0 : \theta = 0$ with an upper alternative, the nominal p -value of the standardized Z statistic is $p_k = 1 - \Phi(Z_k)$. For a null hypothesis $H_0 : \theta = 0$ with a lower alternative or a two-sided alternative, the nominal p -value of the standardized Z statistic is $p_k = \Phi(Z_k)$.

Boundary Variables

The boundaries created in group sequential trials depend on the type of the alternative hypothesis and the early stopping criterion. Table 83.5 shows the boundaries created with various design specifications.

Table 83.5 Boundary Variables

Specifications		Boundary Variables			
Alternative Hypothesis	Early Stopping	Lower		Upper	
		Alpha	Beta	Beta	Alpha
Lower	Accept H_0		X		
	Reject H_0	X			
	Accept/Reject H_0	X	X		
Upper	Accept H_0			X	
	Reject H_0				X
	Accept/Reject H_0			X	X
Two-sided	Accept H_0		X	X	
	Reject H_0	X			X
	Accept/Reject H_0	X	X	X	X

Up to four boundaries can be generated in a group sequential design:

- the upper α boundary, to reject the null hypothesis for the upper alternative
- the upper β boundary, to accept the null hypothesis with an upper alternative
- the lower β boundary, to accept the null hypothesis with a lower alternative
- the lower α boundary, to reject the null hypothesis for the lower alternative

For a two-sided design, the null hypothesis is accepted only if both the hypothesis is accepted with an upper alternative and the hypothesis is accepted with a lower alternative.

For a one-sided design with a lower alternative, only the lower boundaries are created. Similarly, for a one-sided design with an upper alternative, only the upper boundaries are created. For example, Figure 83.10 shows the boundary plot for a one-sided test with an upper alternative.

Figure 83.10 Boundary Plot for One-Sided Test

Figure 83.10 corresponds to a one-sided sequential design with early stopping to reject or accept the null hypothesis. For a sequential test with early stopping only to reject the null hypothesis, there are no acceptance boundary values at interim stages. The acceptance boundary value and its associated acceptance region are displayed only at the final stage. Similarly, for a sequential test with early stopping only to accept the null hypothesis, there are no rejection boundary values at interim stages. The rejection boundary value and its associated rejection region are displayed only at the final stage.

For a two-sided design, both the lower and upper boundaries are created. For a design with early stopping to reject the null hypothesis, α boundaries are created. Similarly, for a design with early stopping to accept the null hypothesis, β boundaries are created. For a design with early stopping to accept or reject the null hypothesis, both the α and β boundaries are created.

For example, Figure 83.11 shows the boundary plot for a two-sided test.

Figure 83.11 Boundary Plot for Two-Sided Test

Figure 83.11 corresponds to a two-sided sequential design with early stopping to reject or accept the null hypothesis. For a sequential test with early stopping only to reject the null hypothesis, there are no acceptance boundary values at interim stages. The acceptance boundary value and its associated acceptance region are displayed only at the final stage. Similarly, for a sequential test with early stopping only to accept the null hypothesis, there are no rejection boundary values at interim stages. The rejection boundary value and its associated rejection region are displayed only at the final stage.

Type I and Type II Errors

The Type I error is the error of rejecting the null hypothesis when the null hypothesis is correct, and the Type II error is the error of not rejecting the null hypothesis when the null hypothesis is incorrect. The level of significance α is the probability of making a Type I error. The Type II error depends on the hypothetical reference of the alternative hypothesis, and the Type II error probability β is defined as the probability of not rejecting the null hypothesis when a specific alternative reference is true. The power $1 - \beta$ is then defined as the probability of rejecting the null hypothesis at the alternative reference.

In a sequential design, if the maximum information and alternative reference are not both specified, the critical values are created such that both the specified Type I and the specified Type II error probability

levels are maintained in the design. Otherwise, the critical values are created such that either the specified Type I error probability or the specified Type II error probability is maintained.

One-Sided Tests

For a K -stage group sequential design with an upper alternative hypothesis $H_1 : \theta = \theta_1$ and early stopping to reject or accept the null hypothesis $H_0 : \theta = 0$, the boundaries contain the upper α critical values a_k and upper β critical values b_k , $k = 1, 2, \dots, K$. At each interim stage, $b_k < a_k$, the null hypothesis H_0 is rejected if the observed statistic $z_k \geq a_k$, H_0 is accepted if $z_k < b_k$, or the process is continued to the next stage if $b_k \leq z_k < a_k$. At the final stage $b_K = a_K$, the hypothesis is either rejected or accepted.

The overall Type I error probability α is given by

$$\alpha = \sum_{k=1}^K \alpha_k$$

where α_k is the α spending at stage k . That is, at stage 1,

$$\alpha_1 = P_{\theta=0}(z_1 \geq a_1)$$

At a subsequent stage k ,

$$\alpha_k = P_{\theta=0}(b_j \leq z_j < a_j, j = 1, 2, \dots, k-1, z_k \geq a_k)$$

Similarly, the Type II error probability

$$\beta = \sum_{k=1}^K \beta_k$$

where β_k is the β spending at stage k . That is, at stage 1,

$$\beta_1 = P_{\theta=\theta_1}(z_1 < b_1)$$

At a subsequent stage k ,

$$\beta_k = P_{\theta=\theta_1}(b_j \leq z_j < a_j, j = 1, 2, \dots, k-1, z_k < b_k)$$

With an upper alternative hypothesis $H_1 : \theta = \theta_1 > 0$, the power $1 - \beta$ is the probability of rejecting the null hypothesis for the upper alternative.

$$1 - \beta = 1 - \sum_{k=1}^K \beta_k = \sum_{k=1}^K P_{\theta=\theta_1}(b_j \leq z_j < a_j, j = 1, 2, \dots, k-1, z_k \geq a_k)$$

For a design with early stopping to reject H_0 only, the interim upper β critical values are set to $-\infty$, $b_k = -\infty$, $k = 1, 2, \dots, K-1$, and $\beta = \beta_K$. For a design with early stopping to accept H_0 only, the interim upper α critical values are set to ∞ , $a_k = \infty$, $k = 1, 2, \dots, K-1$, and $\alpha = \alpha_K$.

Similarly, the Type I and Type II error probabilities for a K -stage design with a lower alternative hypothesis $H_0 : \theta = -\theta_1$ can also be derived.

Two-Sided Tests

For a K -stage group sequential design with two-sided alternative hypotheses $H_{1u} : \theta = \theta_{1u}$ and $H_{1l} : \theta = \theta_{1l}$, and early stopping to reject or accept the null hypothesis $H_0 : \theta = 0$, the boundaries contain the upper α critical values a_k , upper β critical values b_k , lower β critical values $_{b_k}$, and lower α critical values $_{a_k}$, $k = 1, 2, \dots, K$. At each interim stage, $_{a_k} < _{b_k} \leq b_k < a_k$, the null hypothesis H_0 is rejected if the observed statistic $z_k \geq a_k$ or $z_k \leq _{a_k}$, H_0 is accepted if $_{b_k} < z_k < b_k$, or the process is continued to the next stage if $b_k \leq z_k < a_k$ or $_{a_k} < z_k \leq _{b_k}$. At the final stage $b_K = a_K$ and $_{b_K} = _{a_K}$, the hypothesis is either rejected or accepted.

The overall upper Type I error probability α_u is given by

$$\alpha_u = \sum_{k=1}^K \alpha_{uk}$$

where α_{uk} is the α spending at stage k for the upper alternative. That is, at stage 1,

$$\alpha_{u1} = P_{\theta=0}(z_1 \geq a_1)$$

At a subsequent stage k ,

$$\alpha_{uk} = P_{\theta=0}(_{a_j} < z_j \leq _{b_j} \text{ or } b_j \leq z_j < a_j, j = 1, 2, \dots, k-1, z_k \geq a_k)$$

Similarly, the overall lower Type I error probability α_l can also be derived, and the overall Type I error probability $\alpha = \alpha_l + \alpha_u$.

The overall upper Type II error probability β_u is given by

$$\beta_u = \sum_{k=1}^K \beta_{uk}$$

where β_{uk} is the upper β spending at stage k . That is, at stage 1,

$$\beta_{u1} = P_{\theta=\theta_{1u}}(z_1 < _{a_1} \text{ or } _{b_1} < z_1 < b_1)$$

At a subsequent stage k ,

$$\beta_{uk} = P_{\theta=\theta_{1u}}(_{a_j} < z_j \leq _{b_j} \text{ or } b_j \leq z_j < a_j, j = 1, 2, \dots, k-1, z_k < _{a_k} \text{ or } _{b_k} < z_k < b_k)$$

With an upper alternative hypothesis $H_1 : \theta = \theta_{1u} > 0$, the power $1 - \beta_u$ is the probability of rejecting the null hypothesis for the upper alternative:

$$1 - \beta_u = 1 - \sum_{k=1}^K \beta_{uk}$$

which is

$$P_{\theta=\theta_{1u}}(_{a_j} < z_j \leq _{b_j} \text{ or } b_j \leq z_j < a_j, j = 1, 2, \dots, k-1, z_k \geq a_k)$$

The overall lower Type II error probability β_l and power $1 - \beta_l$ can be similarly derived.

For a design with early stopping only to reject H_0 , both the interim lower and upper β critical values are set to missing, $k = 1, 2, \dots, K - 1$, and $\beta_{lK} = \beta_l$, $\beta_{uK} = \beta_u$. For a design with early stopping only to accept H_0 , the interim upper α critical values are set to ∞ , $\alpha_{uk} = \infty$, and the interim lower α critical values are set to $-\infty$, $\alpha_{lk} = -\infty$, $k = 1, 2, \dots, K - 1$, and $\alpha_{uK} = \alpha_u$, $\alpha_{lK} = \alpha_l$.

Unified Family Methods

Unified family methods (Kittelson and Emerson 1999) derive boundary values with a specified boundary shape. For example, Pocock's method (Pocock 1977) derives equal boundary values for all stages in the standardized Z scale. In addition to Pocock's method, the unified family methods include the O'Brien-Fleming, power family, and unified family triangular methods.

The boundary values at each stage depend on the information fractions

$$\Pi_k = \frac{I_k}{I_X}$$

where I_k is the information available at stage k and I_X is the maximum information, the information available at the end of the trial if the trial does not stop early.

Boundary Values in Standardized Z Scale

With the unified family method, the boundary values for the upper α boundary $Z_{\alpha u}$, upper β boundary $Z_{\beta u}$, lower β boundary $Z_{\beta l}$, and lower α boundary $Z_{\alpha l}$, using the standardized normal scale, are given by the following:

- $Z_{\alpha u}(\Pi_k) = f_{\alpha u}(\Pi_k) C_{\alpha u}$
- $Z_{\beta u}(\Pi_k) = \theta_{1u} I_k^{\frac{1}{2}} - f_{\beta u}(\Pi_k) C_{\beta u}$
- $Z_{\beta l}(\Pi_k) = \theta_{1l} I_k^{\frac{1}{2}} + f_{\beta l}(\Pi_k) C_{\beta l}$
- $Z_{\alpha l}(\Pi_k) = -f_{\alpha l}(\Pi_k) C_{\alpha l}$

where $\theta_{1l} (< 0)$ and $\theta_{1u} (> 0)$ are the lower and upper alternative references, $f_{\alpha l}(\Pi_k)$, $f_{\beta l}(\Pi_k)$, $f_{\beta u}(\Pi_k)$, and $f_{\alpha u}(\Pi_k)$ are the specified shape functions, and $C_{\alpha l}$, $C_{\beta l}$, $C_{\beta u}$, and $C_{\alpha u}$ are the critical values derived to achieve the specified α and β levels.

If a derived lower β boundary value $Z_{\beta l}(\Pi_k)$ is greater than its corresponding upper β boundary value $Z_{\beta u}(\Pi_k)$, then both values are set to missing.

Note that the drift parameters $d_l = \theta_{1l} \sqrt{I_X}$ and $d_u = \theta_{1u} \sqrt{I_X}$ are derived in the SEQDESIGN procedure. The boundary values in standardized Z scale can be derived without specifying the maximum information and alternative reference.

Shape Parameters

The shape function in the SEQDESIGN procedure is given by

$$f(\Pi_k) = f(\Pi_k; \tau, \rho) = \tau \Pi_k^{\frac{1}{2}} + \Pi_k^{-\rho} = \Pi_k^{\frac{1}{2}} (\tau + \Pi_k^{-(\rho + \frac{1}{2})})$$

where the parameters $\rho \geq 0$ and $0 \leq \tau \leq 2\rho$ can be specified for each boundary separately.

The parameters τ and ρ determine the shape of the boundaries. Special cases of the unified family methods also include power family methods and triangular methods. Table 83.6 summarizes the corresponding parameter values in the unified family for these methods.

Table 83.6 Parameters in the Unified Family for Various Methods

Method	Option	Unified Family	
		Rho	Tau
Pocock	POC	0	0
O'Brien-Fleming	OFB	0.5	0
Power family	POW (RHO= ρ)	ρ	0
Triangular	TRI (TAU= τ)	0.5	τ

Note that the power parameter $\rho = 1/2 - \Delta = \rho^* - 1/2$, where Δ is the power parameter used in Jennison and Turnbull (2000) and Wang and Tsatis (1987) and ρ^* is the power parameter used in Kittelson and Emerson (1999).

Also note that instead of the three parameters used in the unified family methods by Kittelson and Emerson (1999), only two parameters are used in the SEQDESIGN procedure. The other parameter is fixed at zero.

Boundary Values in MLE Scale

If the maximum information is available, the boundary values derived from a unified family method can also be displayed in the MLE scale:

- $\theta_{\alpha u}(\Pi_k) = I_k^{-\frac{1}{2}} f_{\alpha u}(\Pi_k) C_{\alpha u}$
- $\theta_{\beta u}(\Pi_k) = \theta_{1u} - I_k^{-\frac{1}{2}} f_{\beta u}(\Pi_k) C_{\beta u}$
- $\theta_{\beta l}(\Pi_k) = \theta_{1l} + I_k^{-\frac{1}{2}} f_{\beta l}(\Pi_k) C_{\beta l}$
- $\theta_{\alpha l}(\Pi_k) = -I_k^{-\frac{1}{2}} f_{\alpha l}(\Pi_k) C_{\alpha l}$

These MLE scale boundary values are computed by multiplying $I_k^{-\frac{1}{2}}$ by the standardized Z scale boundary values at stage k .

Boundary Values in Score Scale

If the maximum information is available, the boundary values derived from a unified family method can also be displayed in the score scale:

- $S_{\alpha u}(\Pi_k) = I_k^{\frac{1}{2}} f_{\alpha u}(\Pi_k) C_{\alpha u}$
- $S_{\beta u}(\Pi_k) = \theta_{1u} I_k - I_k^{\frac{1}{2}} f_{\beta u}(\Pi_k) C_{\beta u}$
- $S_{\beta l}(\Pi_k) = \theta_{1l} I_k + I_k^{\frac{1}{2}} f_{\beta l}(\Pi_k) C_{\beta l}$
- $S_{\alpha l}(\Pi_k) = -I_k^{\frac{1}{2}} f_{\alpha l}(\Pi_k) C_{\alpha l}$

These MLE scale boundary values are computed by multiplying $I_k^{\frac{1}{2}}$ by the standardized Z scale boundary values at stage k .

Boundary Values in p -Value Scale

For a design with a lower alternative or a two-sided alternative, the p -value scale boundary values are the cumulative normal distribution function values of the standardized Z boundary values:

- $P_{\alpha u}(\Pi_k) = \Phi(Z_{\alpha u}(\Pi_k))$
- $P_{\beta u}(\Pi_k) = \Phi(Z_{\beta u}(\Pi_k))$
- $P_{\beta l}(\Pi_k) = \Phi(Z_{\beta l}(\Pi_k))$
- $P_{\alpha l}(\Pi_k) = \Phi(Z_{\alpha l}(\Pi_k))$

These nominal p -values are the one-sided fixed-sample p -values under the null hypothesis with a lower alternative.

For a one-sided design with an upper alternative, the p -value scale boundary values are the one-sided fixed-sample p -values under the null hypothesis with an upper alternative:

- $P_{\alpha u}(\Pi_k) = 1 - \Phi(Z_{\alpha u}(\Pi_k))$
- $P_{\beta u}(\Pi_k) = 1 - \Phi(Z_{\beta u}(\Pi_k))$

Pocock's Method

The shape function for Pocock's method (Pocock 1977) is given by

$$f(\Pi_k) = 1$$

The resulting boundary values for a two-sided design with an early stopping to reject the null hypothesis $H_0 : \theta = 0$ are as follows:

- $Z_{\alpha u}(\Pi_k) = C_{\alpha u}$
- $Z_{\alpha l}(\Pi_k) = -C_{\alpha l}$

That is, the rejection boundary values are constant over all stages of different information levels in the standardized Z scale.

Note that compared with other designs, Pocock's design tends to stop the trials early with a larger p -value. For a new treatment, Pocock's design to stop a trial early with a large p -value might not be persuasive enough to make a new treatment widely accepted (Pocock and White 1999). A Pocock design is illustrated in [Example 83.3](#).

O'Brien-Fleming Method

The shape function for the O'Brien-Fleming method (O'Brien and Fleming 1979) is given by

$$f(\Pi_k) = \Pi_k^{-\frac{1}{2}}$$

The resulting boundary values for a two-sided design with early stopping to reject the null hypothesis $H_0 : \theta = 0$ are as follows:

- $Z_{\alpha u}(\Pi_k) = \Pi_k^{-\frac{1}{2}} C_{\alpha u}$
- $Z_{\alpha l}(\Pi_k) = -\Pi_k^{-\frac{1}{2}} C_{\alpha l}$

That is, the rejection boundaries are inversely proportional to the square root of the information levels in the standardized Z scale.

In the score scale, these boundaries can be displayed as follows:

- $S_{\alpha u}(\Pi_k) = C_{\alpha u} I_X^{\frac{1}{2}}$
- $S_{\alpha l}(\Pi_k) = -C_{\alpha l} I_X^{\frac{1}{2}}$

which are constants over all stages in the score scale. An O'Brien-Fleming design is illustrated in [Example 83.2](#).

Power Family Method

The shape function for a power family method (Wang and Tsatis 1987; Emerson and Fleming 1989; Pampallona and Tsatis 1994) is given by

$$f(\Pi_k) = \Pi_k^{-\rho}$$

The resulting boundary values for a two-sided design with early stopping to reject the null hypothesis $H_0 : \theta = 0$ are as follows:

- $Z_{\alpha u}(\Pi_k) = \Pi_k^{-\rho} C_{\alpha u}$
- $Z_{\alpha l}(\Pi_k) = -\Pi_k^{-\rho} C_{\alpha l}$

The rejection boundaries depend on the power parameter ρ . The power family includes the Pocock and O'Brien-Fleming methods, and the power parameter is used to allow continuous movement between these two methods.

Triangular Method

The shape function for a triangular method (Kittelson and Emerson 1999) in the unified family is given by

$$f(\Pi_k) = \Pi_k^{-\frac{1}{2}} + \tau \Pi_k^{\frac{1}{2}}$$

The resulting boundary values for a two-sided design with early stopping to reject the null hypothesis $H_0 : \theta = 0$ are as follows:

- $Z_{\alpha u}(\Pi_k) = (\Pi_k^{-\frac{1}{2}} + \tau \Pi_k^{\frac{1}{2}}) C_{\alpha u} = C_{\alpha u} \Pi_k^{-\frac{1}{2}} (1 + \tau \Pi_k)$
- $Z_{\alpha l}(\Pi_k) = -(\Pi_k^{-\frac{1}{2}} + \tau \Pi_k^{\frac{1}{2}}) C_{\alpha l} = -C_{\alpha l} \Pi_k^{-\frac{1}{2}} (1 + \tau \Pi_k)$

In the score scale, these boundaries are as follows:

- $S_{\alpha u}(\Pi_k) = C_{\alpha u} I_X^{\frac{1}{2}} (1 + \tau \Pi_k) = C_{\alpha u} I_X^{\frac{1}{2}} + C_{\alpha u} \tau I_X^{-\frac{1}{2}} I_k$
- $S_{\alpha l}(\Pi_k) = -C_{\alpha l} I_X^{\frac{1}{2}} (1 + \tau \Pi_k) = -C_{\alpha l} I_X^{\frac{1}{2}} - C_{\alpha l} \tau I_X^{-\frac{1}{2}} I_k$

Thus, in the score scale, the boundary function is a linear function of the information I_k . With these straight-line boundaries, a triangular method for a one-sided trial with early stopping to reject or accept the null hypothesis produces a triangular continuation region. Similarly, for a two-sided design, the continuation region is a union of two separate triangular regions. A triangular method is illustrated in [Example 83.6](#).

Haybittle-Peto Method

The Haybittle-Peto method (Haybittle 1971; Peto et al. 1976) uses a value of 3 for the critical values in interim stages, so that the critical value at the final stage is close to the original design without interim monitoring.

In the SEQDESIGN procedure, the Haybittle-Peto method has been generalized to allow for different boundary values at different stages. That is, with the standardized normal scale, the boundary values are given by the following:

- $Z_{\alpha u}(\Pi_k) = z_{\alpha u k}$
- $Z_{\beta u}(\Pi_k) = \theta_{1u} I_k^{\frac{1}{2}} - z_{\beta u k}$

- $Z_{\beta l}(\Pi_k) = \theta_{1l} I_k^{\frac{1}{2}} + z_{\beta lk}$
- $Z_{\alpha l}(\Pi_k) = -z_{\alpha lk}$

where θ_{1l} and θ_{1u} are the lower and upper alternative references and the boundary values $z_{\alpha uk}$, $z_{\beta uk}$, $z_{\beta lk}$, and $z_{\alpha lk}$ are specified either explicitly with the HP(*Z= numbers*) option or implicitly with the HP(*PVALUE= numbers*) option. The HP(*PVALUE= numbers*) option specifies the nominal p -values p_k for the corresponding boundary values z_k :

$$z_k = \Phi^{-1}(1 - p_k)$$

The Haybittle-Peto method is illustrated in [Example 83.5](#).

Whitehead Methods

The Whitehead methods (Whitehead and Stratton 1983; Whitehead 1997, 2001) derive boundary values by adjusting the boundary values generated from continuous monitoring. With continuous monitoring, the boundary values are on a straight line in the score scale for each boundary. For a group sequential design, the boundary values at an interim stage k depend on the information fractions

$$\Pi_k = \frac{I_k}{I_X}$$

where I_k is the information available at stage k and I_X is the maximum information, the information available at the end of the trial if the trial does not stop early.

One-Sided Symmetric Designs

A one-sided symmetric design is a one-sided design with identical Type I and Type II error probabilities. For a one-sided symmetric design with an upper alternative, $\alpha_u = \beta_u$, the boundary values in the score scale from continuous monitoring are as follows:

- $S_{\alpha u}(\Pi_k) = C_u \theta_u^{-1} + \tau_u \theta_u I_k$
- $S_{\beta u}(\Pi_k) = \theta_u I_k - (C_u \theta_u^{-1} - \tau_u \theta_u I_k)$

where θ_u is the upper alternative reference, τ_u is a specified constant for the slope, $0 \leq \tau_u < \frac{1}{2}$, and C_u is a constant, fixed for STOP=BOTH and derived for STOP=ACCEPT and STOP=REJECT.

The upper β boundary value can also be expressed as

- $S_{\beta u}(\Pi_k) = -C_u \theta_u^{-1} + (1 - \tau_u) \theta_u I_k$

Thus, these straight-line boundaries form a triangle in the score statistic scale.

To adjust for the nature of discrete monitoring, the group sequential boundary values are given by the following:

- $S_{\alpha u}(\Pi_k) = C_u \theta_u^{-1} + \tau_u \theta_u I_k - g_k$
- $S_{\beta u}(\Pi_k) = -C_u \theta_u^{-1} + (1 - \tau_u) \theta_u I_k + g_k$

where $g_1 = 0.583\sqrt{I_1}$ and $g_k = 0.583\sqrt{I_k - I_{(k-1)}}$, $k > 1$ are the adjustments.

Note that with the adjustment g_k , the resulting boundaries form a Christmas tree shape within the original triangle and are referred to as the Christmas tree boundaries (Whitehead 1997, p. 73).

One-Sided Asymmetric Designs

For a one-sided asymmetric design with an upper alternative, $\alpha_u \neq \beta_u$, the boundary values computed using the score scale, are given by the following:

- $S_{\alpha u}(\Pi_k) = C_u \tilde{\theta}_u^{-1} + \tau_u \tilde{\theta}_u I_k - g_k$
- $S_{\beta u}(\Pi_k) = -C_u \tilde{\theta}_u^{-1} + (1 - \tau_u) \tilde{\theta}_u I_k + g_k$

where $\tilde{\theta}_u$ is the modified alternative reference

$$\tilde{\theta}_u = \frac{2\Phi^{-1}(1 - \alpha_u)}{\Phi^{-1}(1 - \alpha_u) + \Phi^{-1}(1 - \beta_u)} \theta_u$$

The modified alternative reference $\tilde{\theta}_u = \theta_u$ if $\alpha_u = \beta_u$.

For a design with early stopping to reject or accept the null hypothesis, $S_{\alpha u}(1) = S_{\beta u}(1)$, the boundary values at the final stage are equal. The modified drift parameter \tilde{d}_u is given by

$$\tilde{d}_u = \tilde{\theta}_u \sqrt{I_X} = \frac{1}{1 - 2\tau_u} \left(\sqrt{h_K^2 + 2C_u(1 - 2\tau_u) - h_K} \right)$$

where $h_K = g_K I_X^{-\frac{1}{2}} = 0.583\sqrt{1 - \Pi_{(K-1)}}$.

A one-sided Whitehead design with early stopping to reject or accept the null hypothesis is illustrated in [Example 83.7](#).

Two-Sided Designs

The boundary values for a two-sided design are generated by combining boundary values from two one-sided designs. With the STOP=BOTH option, this produces a double triangular design (Whitehead 1997, p. 98).

The boundary values for a two-sided design, using the score scale, are then given by the following:

- $S_{\alpha u}(\Pi_k) = C_u \tilde{\theta}_u^{-1} + \tau_u \tilde{\theta}_u I_k - g_k$
- $S_{\beta u}(\Pi_k) = -C_u \tilde{\theta}_u^{-1} + (1 - \tau_u) \tilde{\theta}_u I_k + g_k$
- $S_{\beta l}(\Pi_k) = -C_l \tilde{\theta}_l^{-1} + (1 - \tau_l) \tilde{\theta}_l I_k - g_k$
- $S_{\alpha l}(\Pi_k) = C_l \tilde{\theta}_l^{-1} + \tau_l \tilde{\theta}_l I_k + g_k$

where the modified alternative references are

$$\tilde{\theta}_u = \frac{2\Phi^{-1}(1 - \alpha_u)}{\Phi^{-1}(1 - \alpha_u) + \Phi^{-1}(1 - \beta_u)} \theta_u$$

$$\tilde{\theta}_l = \frac{2\Phi^{-1}(1 - \alpha_l)}{\Phi^{-1}(1 - \alpha_l) + \Phi^{-1}(1 - \beta_l)} \theta_l$$

The modified alternative reference $\tilde{\theta}_u = \theta_u$ if $\alpha_u = \beta_u$ and $\tilde{\theta}_l = \theta_l$ if $\alpha_l = \beta_l$.

For a design with early stopping to reject or accept the null hypothesis, the two upper boundary values at the final stage are identical and the two lower boundary values at the final stage are identical. That is, $S_{\alpha l}(1) = S_{\beta l}(1)$ and $S_{\alpha u}(1) = S_{\beta u}(1)$. These modified drift parameters are then given by

$$\tilde{d}_l = \tilde{\theta}_l \sqrt{I_X} = \frac{1}{1 - 2\tau_l} \left(\sqrt{h_K^2 + 2C_l(1 - 2\tau_l)} - h_K \right)$$

$$\tilde{d}_u = \tilde{\theta}_u \sqrt{I_X} = \frac{1}{1 - 2\tau_u} \left(\sqrt{h_K^2 + 2C_u(1 - 2\tau_u)} - h_K \right)$$

where $h_K = g_K I_X^{-\frac{1}{2}} = 0.583 \sqrt{1 - \Pi_{(K-1)}}$.

For a design with early stopping to reject the null hypothesis, or a design with early stopping to accept the null hypothesis, you can specify the slope parameters τ_u and τ_l in the TAU= option, and then the intercept parameters C_u and C_l , and the resulting boundary values are derived. If both the maximum information and alternative references are specified, the procedure derives C_u and C_l by maintaining either the overall α levels (BOUNDARYKEY=ALPHA) or the overall β levels (BOUNDARYKEY=BETA). If the maximum information and alternative reference are not both specified, the procedure derives the boundary values C_u and C_l by maintaining both the overall α and overall β levels.

For a design with early stopping to reject or accept the null hypothesis (STOP=BOTH), Whitehead's triangular test uses $\tau_u = \tau_l = 0.25$ and compute $C_u = -2\log(2\alpha_u)$ and $C_l = -2\log(2\alpha_l)$ for the boundary values. If the maximum information and alternative reference are both specified, the BOUNDARYKEY=ALPHA option uses the specified α values to compute the β values and boundary values. The final-stage boundary values are modified to maintain the overall α levels if they exist. Similarly, the BOUNDARYKEY=BETA option uses the specified β values to compute the α values and boundary values. The final-stage boundary values are modified to maintain the overall β levels if they exist.

If the maximum information and alternative reference are not both specified, the specified α and β values are used to derive boundary values. The BOUNDARYKEY=NONE option uses these boundary values without adjustment. The BOUNDARYKEY=ALPHA option modifies the final-stage boundary values to maintain the overall α levels if they exist. Similarly, the BOUNDARYKEY=BETA option modifies the final-stage boundary values to maintain the overall β levels if they exist.

Applicable Boundary Keys

Table 83.7 lists applicable boundary keys for a design that uses Whitehead methods.

Table 83.7 Applicable Boundary Keys for Whitehead Methods

Early Stopping	Specified Parameters		Boundary Keys			
	(Alt Ref – Max Info)	Tau	Alpha	Beta	None	Both
Reject H_0	X	X	X	X		
Accept H_0	X	X	X	X		
Reject/Accept H_0	X	0.25	X	X		
Reject H_0		X				X
Accept H_0		X				X
Reject/Accept H_0		0.25	X	X	X	

Note that the symbol “X” under “(Alt Ref – Max Info)” indicates that both alternative reference and maximum information are specified.

For a design with early stopping to reject the null hypothesis, or a design with early stopping to accept the null hypothesis, you can specify the slope parameter τ_u in the TAU= option, and then the intercept parameter C_u and the resulting boundary values are derived. If both the maximum information and alternative reference are specified, the procedure derives C_u by maintaining either the overall α levels (BOUNDARYKEY=ALPHA) or the overall β levels (BOUNDARYKEY=BETA). If the maximum information and alternative reference are not both specified, the procedure derives the boundary values and C_u by maintaining both the overall α and overall β levels.

For a design with early stopping to reject or accept the null hypothesis (STOP=BOTH), Whitehead’s triangular test uses $\tau_u = 0.25$ and solves $C_u = 2 \log(\frac{1}{2\alpha_u})$ for the boundary values. If the maximum information and alternative reference are both specified, the BOUNDARYKEY=ALPHA option uses the specified α value to compute the β value and boundary values. The final-stage boundary value is modified to maintain the overall α level if it exists. Similarly, the BOUNDARYKEY=BETA option uses the specified β value to compute the α value and boundary values. The final-stage boundary value is modified to maintain the overall β level if it exists.

If the maximum information and alternative reference are not both specified, the specified α and β values are used to derive boundary values. The BOUNDARYKEY=NONE option uses these boundary values without adjustment. The BOUNDARYKEY=ALPHA option modifies the final-stage boundary value to maintain the overall α level if it exists. Similarly, the BOUNDARYKEY=BETA option modifies the final-stage boundary value to maintain the overall β level if it exists.

Error Spending Methods

For each sequential design, the α and β errors spent at each stage can be computed from the boundary values. For example, for a K -stage design with an upper alternative hypothesis $H_1 : \theta = \theta_1$ and early stopping to reject the null hypothesis $H_0 : \theta = 0$, the boundary values in a standardized Z scale are the upper α critical values $a_k, k = 1, 2, \dots, K$. At each interim stage, the null hypothesis H_0 is rejected if the observed standardized Z statistic $z_k \geq a_k$. Otherwise, the process continues to the next stage. At the final stage, the hypothesis is rejected if $z_K \geq a_K$. Otherwise, the null hypothesis is accepted.

The boundary values a_k are derived such that the overall Type I error probability

$$\alpha = \sum_{k=1}^K \alpha_k$$

where α_k is the α spending at stage k . That is, at stage 1,

$$\alpha_1 = P_{\theta=0} (z_1 \geq a_1)$$

At a subsequent stage k ,

$$\alpha_k = P_{\theta=0} (z_j < a_j, j = 1, 2, \dots, k-1, z_k \geq a_k)$$

Since each design can be uniquely identified by the α and β errors spent at each stage, a design can then be derived by specifying the α and β errors to be used at each stage. The error spending method (Lan and DeMets 1983) distributes the error to be used at each stage and then derives the boundary values. Numerous forms of the error spending function are available. Kim and DeMets (1987) examine the functions $f(t) = t$, $f(t) = t^{\frac{3}{2}}$, and $f(t) = t^2$, where t is the information fraction. Jennison and Turnbull (2000, p. 148) generalize these functions to the power functions $f(t; \rho) = t^\rho, \rho > 0$.

The ERRFUNCPOC option uses the cumulative error spending function (Lan and DeMets 1983)

$$E(t) = \begin{cases} 1 & \text{if } t \geq 1 \\ \log(1 + (e-1)t) & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

With a specified error of α or β , the cumulative error spending at stage k is $\alpha E(\Pi_k)$ or $\beta E(\Pi_k)$, where $\Pi_k = I_k/I_X$ is the information fraction at stage k . The method produces boundaries similar to those produced with Pocock's method.

The ERRFUNCOBF option uses the cumulative error spending function (Lan and DeMets 1983)

$$E(t; a) = \begin{cases} 1 & \text{if } t \geq 1 \\ \frac{1}{a} 2 (1 - \Phi(\frac{z(1-a/2)}{\sqrt{t}})) & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

where a is either α for the α spending function or β for the β spending function. That is, with a specified error of α or β , the cumulative error spending at stage k is $\alpha E(\Pi_k; \alpha)$ or $\beta E(\Pi_k; \beta)$. The method produces boundaries similar to those produced with the O'Brien-Fleming method.

The ERRFUNCGAMMA option uses the gamma cumulative error spending function (Hwang, Shih, and DeCani 1990)

$$E(t; \gamma) = \begin{cases} 1 & \text{if } t \geq 1 \\ \frac{1-e^{-\gamma t}}{1-e^{-\gamma}} & \text{if } 0 < t < 1, \gamma \neq 0 \\ t & \text{if } 0 < t < 1, \gamma = 0 \\ 0 & \text{otherwise} \end{cases}$$

where γ is the parameter γ specified in the GAMMA= option. That is, with a specified error of α or β , the cumulative error spending at stage k is $\alpha E(\Pi_k; \gamma)$ or $\beta E(\Pi_k; \gamma)$.

The ERRFUNCPOW option uses the cumulative error spending function (Jennison and Turnbull 2000, p. 148)

$$E(t; \rho) = \begin{cases} 1 & \text{if } t \geq 1 \\ t^\rho & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

where ρ is the power parameter specified in the RHO= option. That is, with a specified error of α or β , the cumulative error spending at stage k is $\alpha E(\Pi_k; \rho)$ or $\beta E(\Pi_k; \rho)$.

Error spending methods derive boundary values at each stage sequentially and require much more computation than other types of methods for group sequential trials with a large number of stages, especially for a two-sided asymmetric design with early stopping to accept H_0 , or to reject or accept H_0 .

Note that for a two-sided design with the STOP=BOTH or STOP=ACCEPT option, at each interim stage, the SEQDESIGN procedure first produces the lower and upper β boundary values based on the one-sided β spending. If the lower β boundary value is greater than or equal to its corresponding upper β boundary value, there is no early stopping to accept the null hypothesis at this stage, and the corresponding β spending is distributed proportionally to the remaining stages.

For the error spending functions not available in the SEQDESIGN procedure, you can first compute the corresponding error spending at each stage explicitly, then use the SEQDESIGN procedure with the ERRSPEND= option to specify these errors directly.

For example, if the information levels are equally spaced in a five-stage design, the option ERRFUNCPOW (RHO=2) produces relative cumulative errors of $(1/5)^2$, $(2/5)^2$, $(3/5)^2$, $(4/5)^2$, and 1. This is equivalent to using the option ERRSPEND (1 4 9 16 25).

A one-sided error spending design is illustrated in [Example 83.8](#) and a two-sided asymmetric error spending design is illustrated in [Example 83.11](#).

Acceptance (β) Boundary

In a group sequential trial, the rejection boundary is derived under the null hypothesis H_0 and is used to stop the trial early to reject H_0 . Similarly, the acceptance boundary is derived under the alternative hypothesis and is used to stop the trial early to accept H_0 . But, for a trial with early stopping either to reject or to accept the null hypothesis, dependency exists between these two boundaries. This section describes the effects of the acceptance boundary on the derivation of the rejection boundary in a group sequential trial.

The following statements create a one-sided four-stage group sequential design with early stopping either to reject or to accept H_0 :

```
ods graphics on;
proc seqdesign altref=10;
  ErrSpendPower_2: design nstages=4
                    method=errfuncpow(rho=2)
                    alt=upper    stop=both
                    alpha=0.025 beta=0.10;
run;
ods graphics off;
```

The ALTREF=10 option specifies the alternative reference 10. The METHOD=ERRFUNCPOW(RHO=2) option uses a $\rho = 2$ power family error spending method to generate the rejection boundary. The ALPHA=0.025 and BETA=0.10 options specify the Type I error level 0.025 and Type II error level 0.10, respectively.

The power parameter $\rho = 2$ used in the design lies between $\rho = 1$ and $\rho = 3$, where the boundaries created with the $\rho = 1$ power family error spending method are similar to the boundaries created from the Pocock method, and the boundaries created with $\rho = 3$ are similar to the boundaries created from the O'Brien-Fleming method.

The “Boundary Information” table in Figure 83.12 shows the rejection and acceptance boundary values at the stages. With an error spending function method, the boundary values are derived sequentially. In particular, the rejection boundary value at a stage is derived conditionally on both rejection and acceptance boundary values at the previous stage. See the section “Error Spending Methods” on page 7034 for a detailed description of the error spending methods.

Figure 83.12 Boundary Information

The SEQDESIGN Procedure					
Design: ErrSpendPower_2					
Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values-----	
	Proportion	Actual	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2500	0.028605	1.69130	-0.80640	2.95517
2	0.5000	0.05721	2.39186	0.37356	2.55934
3	0.7500	0.085815	2.92942	1.24940	2.29904
4	1.0000	0.11442	3.38261	2.04182	2.04182

With ODS Graphics enabled, the “Boundary Plot” is displayed by default, as shown in Figure 83.13. The continuation region is affected by the acceptance boundary, and the rejection boundary is thus adjusted for this acceptance boundary to maintain the Type I error level.

Figure 83.13 Boundary Plot

For a design with early stopping either to accept or to reject H_0 , the shapes of boundaries affect the critical value at the final stage. For the acceptance boundary, a liberal method at early stages, such as a $\rho = 1$ power family error spending method, lowers the critical value at the final stage. For the rejection boundary, a conservative method at early stages, such as a $\rho = 3$ power family error spending method, also lowers the critical value at the final stage. In addition, a larger Type II error level also lowers the critical value at the final stage. The resulting critical value at the final stage might even be less than the critical value for the corresponding fixed-sample design.

To illustrate how this can occur, the following statements use a $\rho = 1$ power family error spending method for the acceptance boundary and a $\rho = 3$ power family error spending method for the rejection boundary to create a group sequential design:

```
proc seqdesign altref=10;
  ErrSpendPower_3_1: design nstages=4
    method(alpha)=errfuncpow(rho=3)
    method(beta)= errfuncpow(rho=1)
    alt=upper stop=both
    alpha=0.025 beta=0.10;
run;
```

The resulting “Boundary Information” table in Figure 83.14 shows that the boundary value at the final stage 1.9267 is less than 1.96, the critical value of the corresponding fixed-sample design.

Figure 83.14 Boundary Information

The SEQDESIGN Procedure					
Design: ErrSpendPower_3_1					
Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values-----	
	Proportion	Actual	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2500	0.029725	1.72410	-0.23587	3.35935
2	0.5000	0.05945	2.43824	0.63117	2.76024
3	0.7500	0.089175	2.98622	1.31554	2.35119
4	1.0000	0.1189	3.44819	1.92672	1.92672

That is, H_0 can be rejected even if the test statistic at the final stage is less than the critical value for the corresponding fixed-sample design, which is not desirable. Therefore, for a design with an acceptance boundary, the design should be used with care.

Another reason why the rejection boundary should not be affected by the acceptance boundary is that a Data and Safety Monitoring Board (DSMB) might not strictly adhere to this acceptance boundary, and thus the Type I error level might not be maintained. Therefore, it might not be desirable for the rejection boundary to be affected by the acceptance boundary (Lan and DeMets 2009, p. 103).

To use a design whose rejection boundary is not affected by the acceptance boundary and that can still stop the trial early to accept H_0 , you can use one of the following strategies:

- You can use the conditional power approach for a design that stops early only to reject H_0 . For this design, the conditional power at an interim stage k can be defined as the total probability of rejecting H_0 at any future stages under a specified hypothetical reference, given the observed statistic at stage k . A small conditional power indicates a small probability of success (rejecting H_0) given the current data, and the trial can be stopped early to accept H_0 (Lan, Simon, and Halperin 1982; Lan and DeMets 2009, p. 101). For a detailed description of conditional power, see the section “Stochastic Curtailment” in Chapter 84, “The SEQTEST Procedure.”
- You can use a design with a nonbinding acceptance boundary (Zhu, Ni, and Yao 2011, pp. 132–133). For this design, the rejection boundary is created by ignoring the acceptance boundary. Thus, the Type I error level is maintained even when a trial is allowed to continue for a test statistic that falls in the acceptance region, and the rejection boundary values (with the standardized Z statistic scale) are identical to the boundary values that are derived in the corresponding design that stops early only to reject H_0 .

Boundary Adjustments for Overlapping Lower and Upper β Boundaries

For the fixed boundary shape methods and Whitehead methods, the boundary values for all stages are derived simultaneously for each boundary. For a two-sided design with STOP=ACCEPT or STOP=BOTH, simultaneous derivation might result in overlapping of the lower and upper β boundaries. That is, at an interim stage k , the lower β boundary value might be greater than its corresponding upper β boundary value. In this case, these two β boundary values are set to missing and the design does not stop at stage k to accept the null hypothesis (Jennison and Turnbull 2000, p. 113).

For the error spending methods, the boundary values are derived sequentially for the stages. For a two-sided design with STOP=ACCEPT or STOP=BOTH, a small β spending at an interim stage might result in overlapping of the lower and upper β boundaries for the two corresponding one-sided tests. Specifically, this form of overlapping occurs at an interim stage k if the upper β boundary value derived from the one-sided test for the upper alternative is less than the lower β boundary value derived from the one-sided test for the lower alternative (Kittelson and Emerson 1999, pp. 881–882; Rudser and Emerson 2007, p. 6). You can use the BETAOVERLAP= option to specify how this type of overlapping is to be handled.

If BETAOVERLAP=ADJUST (which is the default) is specified, the procedure derives the boundary values for the two-sided design and then checks for overlapping of the two one-sided β boundaries at interim stages. If overlapping occurs at a particular stage, the β boundary values for the two-sided design are set to missing (so the trial does not stop to accept the null hypothesis at this stage), and the β spending values at subsequent stages are adjusted proportionally as follows.

If the β boundary values are set to missing at stage k in a K -stage trial, the adjusted β spending value at stage k , e'_k , is updated for these missing β boundary values, and then the β spending values at subsequent stages are adjusted proportionally by

$$e'_j = e'_k + \frac{e_j - e_k}{e_K - e_k} (e_K - e'_k)$$

for $j = k + 1, \dots, K$, where e_j and e'_j are the cumulative β spending values at stage j before and after the adjustment, respectively.

After all these adjusted β spending values are computed, the boundary values are then further modified for these adjusted β spending values.

If you specify BETAOVERLAP=NOADJUST, no adjustment is made when overlapping of one-sided β boundaries occurs. The BETAOVERLAP= option is illustrated in [Example 83.10](#).

Specified and Derived Parameters

In the SEQDESIGN procedure, the type of alternative hypothesis (ALT= option) and the condition for early stopping (STOP= option) must be specified for each sequential design. The drift parameters are derived for each design specified. Other parameters, such as Type I error probability α , Type II error probability β , the alternative reference θ_1 , and maximum information are either specified or derived in the SEQDESIGN procedure.

Table 83.8 summarizes the available combinations for the specified and derived parameters in the SEQDESIGN procedure.

Table 83.8 Specified and Derived Parameters in the SEQDESIGN Procedure

Specified Parameters				Derived Parameters				
Alt Ref	Max Info	Alpha	Beta	Alt Ref	Max Info	Alpha	Beta	Drift
Z	X	X					X	X
Z	X		X			X		X
Z	X					X	X	X
Z		X	X		X			X
	X	X	X	X				X
		X	X					X

The symbol “X” indicates that the parameter is either specified or derived in the design and the symbol “Z” indicates that the alternative reference is either specified explicitly with the ALTREF= option or derived from the SAMPLESIZE statement. The drift parameter is always derived in the SEQDESIGN procedure.

For example, if the ALTREF= option is specified without the MAXINFO= option being specified, then the maximum information is derived in the SEQDESIGN procedure with the specified α and β , as illustrated in Example 83.5.

The drift parameter is the standardized reference difference at the final stage. For a design, the drift parameter is

$$d_l = \theta_{1l} \sqrt{I_X}$$

if it has a lower alternative, and

$$d_u = \theta_{1u} \sqrt{I_X}$$

if it has an upper alternative, where I_X is the maximum information and θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively.

If the alternative reference and the maximum information are not both specified, then the specified α and β are used to derive the drift parameter. Then if either the alternative reference or the maximum information is specified, the other is derived from the drift parameter.

If both the alternative reference and the maximum information are specified, then either the α error or the β error is derived in the procedure. However, for a Haybittle-Peto method with the BOUNDARYKEY=NONE option, both α and β errors are derived from the completely specified boundary values.

For a nonsymmetric two-sided design with different lower and upper specifications (such as different lower and upper α errors, β errors, or alternative references in absolute values), the derived lower and upper boundaries are not symmetric. If the alternative references θ_{1l} and θ_{1u} are not both specified, then the SEQDESIGN procedure assumes symmetric alternative references, $\theta_1 = \theta_{1u} = -\theta_{1l}$, for the computation of the boundary values.

Applicable Boundary Keys

In the SEQDESIGN procedure, the BOUNDARYKEY= option in the DESIGN statement specifies the types of errors to be maintained for the design. Table 83.9 lists applicable boundary keys for designs that use unified family and Haybittle-Peto methods, designs that use error spending methods, and designs that use the Haybittle-Peto method only.

Table 83.9 Applicable Boundary Keys for Designs without Whitehead Methods

Method	Specified Parameters (Alt Ref – Max Info)	Boundary Keys			
		Alpha	Beta	None	Both
Unified	X	X	X		
Unified/Haybittle-Peto	X	X	X		
Error spending	X	X	X		
Haybittle-Peto	X	X	X	X	
Unified/Haybittle-Peto					X
Error spending					X
Haybittle-Peto					X

Note that the symbol “X” under “(Alt Ref – Max Info)” indicates that both the alternative reference and maximum information are specified, and the method “Unified/Haybittle-Peto” indicates that both the unified method and the Haybittle-Peto method are used in the same design.

If the ALTREF= and MAXINFO= options are both specified, then Type I and Type II error probability levels cannot be met simultaneously if both error probabilities are specified. The BOUNDARYKEY=ALPHA option maintains the Type I error probability level α and derives Type II error probability β . The BOUNDARYKEY=BETA option maintains the Type II error probability level β and derives Type I error probability α .

If the Haybittle-Peto method is used for all boundaries, the BOUNDARYKEY=NONE option uses the specified α boundary value (STOP=REJECT or STOP=BOTH) and the specified β boundary value (STOP=ACCEPT) at the final stage for the design.

If the ALTREF= and MAXINFO= options are not both specified, the BOUNDARYKEY=BOTH option derives boundary values that maintain both Type I and Type II error probability levels.

Table 83.10 lists applicable boundary keys for a design that uses Whitehead methods.

Table 83.10 Applicable Boundary Keys for Whitehead Methods

Early Stopping	Specified Parameters		Boundary Keys			
	(Alt Ref – Max Info)	Tau	Alpha	Beta	None	Both
Reject H_0	X	X	X	X		
Accept H_0	X	X	X	X		
Reject/Accept H_0	X	0.25	X	X		
Reject H_0		X				X
Accept H_0		X				X
Reject/Accept H_0		0.25	X	X	X	

Note that the symbol “X” under “(Alt Ref – Max Info)” indicates that both alternative reference and maximum information are specified.

If the ALTREF= and MAXINFO= options are both specified, then Type I and Type II error probability levels cannot be achieved simultaneously if both are specified. the BOUNDARYKEY=ALPHA option maintains the Type I error probability level α and derives Type II error probability β . The BOUNDARYKEY=BETA option maintains the Type II error probability level β and derives the Type I error probability α .

If the ALTREF= and MAXINFO= options are not both specified, then for a design with the STOP=REJECT or STOP=ACCEPT option, the BOUNDARYKEY=BOTH option derives boundary values that maintain both Type I and Type II error probability levels. If the STOP=BOTH option is specified, Whitehead’s triangular method produces boundaries with approximate Type I and Type II error probabilities. The BOUNDARYKEY=NONE option specifies no adjustment to these boundaries. The BOUNDARYKEY=ALPHA and BOUNDARYKEY=BETA options maintain the Type I error probability level α and Type II error probability level β , respectively, by adjusting boundary values at the final stage.

Sample Size Computation

The SEQDESIGN procedure assumes that the data are from a multivariate normal distribution and the sequence of the standardized test statistics $\{Z_1, Z_2, \dots, Z_K\}$ has the following canonical joint distribution:

- (Z_1, Z_2, \dots, Z_K) is multivariate normal
- $Z_k \sim N(\theta \sqrt{I_k}, 1)$
- $\text{Cov}(Z_{k_1}, Z_{k_2}) = \sqrt{I_{k_1}/I_{k_2}}, 1 \leq k_1 \leq k_2 \leq K$

where K is the total number of stages and I_k is the information available at stage k .

If the test statistic is computed from the data that are not from a normal distribution, such as a binomial distribution, then it is assumed that the test statistic is computed from a large sample such that the statistic has an approximately normal distribution.

In a typical clinical trial, the sample size required depends on the Type I error probability level α , alternative reference θ_1 , power $1 - \beta$, and variance of the response variable. Given a one-sided null hypothesis $H_0 : \theta = 0$ with an upper alternative hypothesis $H_1 : \theta = \theta_1$, the information required for a fixed-sample test is given by

$$I_0 = \frac{(\Phi^{-1}(1 - \alpha) + \Phi^{-1}(1 - \beta))^2}{\theta_1^2}$$

The parameter θ and the subsequent alternative reference θ_1 depend on the test specified in the clinical trial. For example, suppose you are comparing two binomial populations $p_a = p_b$; then $\theta = p_a - p_b$ is the difference between two proportions if the proportion difference statistic is used, and $\theta = \log\left(\frac{p_a(1-p_b)}{p_b(1-p_a)}\right)$, the log odds ratio for the two proportions if the log odds ratio statistic is used.

If the maximum likelihood estimate $\hat{\theta}$ from the likelihood function can be derived, then the asymptotic variance for $\hat{\theta}$ is $\text{Var}(\hat{\theta}) = 1/I$, where I is Fisher information for θ . The resulting statistic $\hat{\theta}$ corresponds to the MLE statistic scale as specified in the BOUNDARYSCALE=MLE option in the PROC SEQDESIGN statement, $\hat{\theta}\sqrt{I}$ corresponds to the standardized Z scale (BOUNDARYSCALE=STDZ), and $\hat{\theta} I$ corresponds to the score statistic scale (BOUNDARYSCALE=SCORE).

Alternatively, if the score statistic S is derived in a statistical procedure, it can be used as the test statistic and its asymptotic variance is given by Fisher information, I . In this case, S/\sqrt{I} corresponds to the standardized Z scale and S/I corresponds to the MLE statistic scale.

For a group sequential trial, the maximum information I_X is derived in the SEQDESIGN procedure with the specified α , β , and θ_1 . With the maximum information

$$I_X = \frac{1}{\text{Var}(\hat{\theta})}$$

the sample size required for a specified test statistic in the trial can be evaluated or estimated from the known or estimated variance of the response variable. Note that different designs might produce different maximum information levels for the same hypothesis, and this in turn might require a different number of observations for the trial.

If each observation in the data set provides one unit of information in a hypothesis testing, such as a one-sample test for the mean, the required sample size for the sequential design can be derived from the maximum information. However, for a survival analysis, an individual in the survival time data might provide only partial information because of censoring. In this case, the required number of events can be derived from the maximum information. With addition accrual information, the sample size can also be computed.

The SEQDESIGN procedure provides sample size computation for some one-sample and two-sample tests in the SAMPLESIZE statement. It also provides sample size computation for tests of a parameter in regression models such as normal regression, logistic regression, and proportional hazards regression. In addition, the procedure can also compute the required sample size or number of events from the corresponding number in the fixed-sample design.

Table 83.11 lists the options available in the SAMPLESIZE statement.

Table 83.11 SAMPLESIZE Statement Options

Option	Description
Fixed-Sample Models	
INPUTNOBS	Specifies sample size for fixed-sample design
INPUTNEVENTS	Specifies number of events for fixed-sample design
One-Sample Models	
ONESAMPLEMEAN	Specifies one-sample Z test for mean
ONESAMPLEFREQ	Specifies one-sample test for binomial proportion
Two-Sample Models	
TWOSAMPLEMEAN	Specifies two-sample Z test for mean difference
TWOSAMPLEFREQ	Specifies two-sample test for binomial proportions
TWOSAMPLESURVIVAL	Specifies log-rank test for two survival distributions
Regression Models	
REG	Specifies test for a regression parameter
LOGISTIC	Specifies test for a logistic regression parameter
PHREG	Specifies test for a proportional hazards regression parameter

The MODEL=INPUTNOBS and MODEL=INPUTNEVENTS options are described next, and the remaining options are described in the next three sections.

Input Sample Size for Fixed-Sample Design

The MODEL=INPUTNOBS option derives the sample size required for a group sequential trial from the sample size n_0 for the corresponding fixed-sample design. With the N= n_0 option specifying the sample size n_0 for a fixed-sample design, the sample size required for a group sequential trial is then computed as

$$N_X = \frac{I_X}{I_0} n_0$$

where I_X is the maximum information for the group sequential design and I_0 is the information for the corresponding fixed-sample design. The information ratio between I_X and I_0 is derived in the SEQDESIGN procedure.

The SAMPLE=ONE option specifies a one-sample test, and the SAMPLE=TWO option specifies a two-sample test. For a two-sample test, the WEIGHT= option specifies the sample size allocation weights for the two groups.

Input Number of Events for Fixed-Sample Design

The MODEL=INPUTNEVENTS option derives the number of events required for a group sequential trial from the number of events d_0 for the corresponding fixed-sample design. With the D= d_0 option specifying the number of events d_0 for a fixed-sample survival analysis, the number of events required for a group sequential trial is then computed as

$$d_X = \frac{I_X}{I_0} d_0$$

where I_X is the maximum information for the group sequential design and I_0 is the information for the corresponding fixed-sample design. The information ratio between I_X and I_0 is derived in the SEQDESIGN procedure.

The SAMPLE=ONE option specifies a one-sample test, and the SAMPLE=TWO option specifies a two-sample test. For a two-sample test, the WEIGHT= option specifies the sample size allocation weights for the two groups.

The ACCRUAL= option specifies the method for individual accrual. The default ACCRUAL=UNIFORM option specifies that the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a , and the ACCRUAL=EXP(PARM= γ_0) option specifies that the individual accrual is truncated exponential with a scaled power parameter γ_0 , where $\gamma_0 \geq -10$ and $\gamma_0 \neq 0$. With a scaled parameter γ_0 , the power parameter for the truncated exponential with the accrual time T_a is given by $\gamma = \gamma_0/T_a$.

The LOSS= option specifies the individual loss to follow up in the sample size computation. The default LOSS=NONE option specifies no loss to follow up, and the EXP(POWER= τ) option specifies exponential loss function with a power parameter τ .

With the computed number of events d_X for a group sequential survival design, the required total sample size and sample size at each stage can be derived from specifications of hazard rates, accrual information, and losses to follow-up information. For each study group, the hazard rate h is constant (which corresponds to an exponential survival distribution) in the sample size computation.

The next four subsections describe required sample sizes for uniform accrual (with and without losses to follow up) and for truncated exponential accrual (with and without losses to follow up).

Uniform Accrual without Losses to Follow Up

For a study group with a constant hazard rate h , if the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a , Kim and Tsatis (1990, pp. 83–84) show that the expected number of events by time t is given by

$$D_h(t) = \begin{cases} r_a \left(t - \frac{1-e^{-ht}}{h} \right) & \text{if } t \leq T_a \\ r_a \left(T_a - \frac{e^{-ht}}{h} (e^{hT_a} - 1) \right) & \text{if } t > T_a \end{cases}$$

For a one-sample design (such as a proportional hazards regression), the expected number of events by time t is $E(t) = D_h(t)$, where h is the hazard rate for the group. For a two-sample design (such as a log-rank test for two survival distributions), the expected number of events by time t is

$$E(t) = \frac{R}{R+1} D_{h_a}(t) + \frac{1}{R+1} D_{h_b}(t)$$

where h_a and h_b are hazard rates in groups A and B, respectively, and R is the ratio of the sample size allocation weights w_a/w_b .

If the accrual rate r_a is specified with one of the three time parameters—the accrual time, follow-up time, and total study time—then PROC SEQDESIGN derives the other two time parameters by solving the equation for the expected number of events. Similarly, if the accrual rate r_a is not specified but two of the three time parameters are specified, then PROC SEQDESIGN derives the accrual rate.

If the accrual rate r_a is specified without the accrual time T_a , follow-up time T_f , and total study time $T = T_a + T_f$, the minimum and maximum accrual times can be computed from the following equation, as described in Kim and Tsiatis (1990, p. 85):

$$\frac{d_X}{r_a} \leq T_a \leq E^{-1}(d_X)$$

With the accrual rate r_a and the accrual time T_a , the total sample size is

$$N_X = r_a T_a$$

At each stage k , the number of events is given by

$$d_k = \frac{I_k}{I_X} d_X$$

The corresponding time T_k can be derived from the equation for the expected number of events, $E(t) = d_k$, and the resulting sample size is computed as

$$N_k = \begin{cases} r_a T_k & \text{if } T_k \leq T_a \\ r_a T_a & \text{if } T_k > T_a \end{cases}$$

Uniform Accrual with Losses to Follow Up

With the LOSS=EXP(HAZARD= τ) option, the individual loss to follow up has an exponential loss distribution function

$$H(t) = 1 - e^{-\tau t}$$

where $\tau \geq 0$ is the loss hazard rate. The loss hazard rate can also be specified implicitly with the MEDTIME= t_τ suboption through the median loss time t_τ .

For a study group with a constant hazard rate h , if the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a and the individual loss to follow up has an exponential loss distribution function $H(t)$, Lachin and Foulkes (1986, p. 511) derive the expected number of events by time t (where $t > T_a$) as

$$D_h(t, T_a) = r_a T_a \frac{h}{h + \tau} \left(1 - \frac{1}{(h + \tau) T_a} e^{-(h + \tau)t} (e^{(h + \tau)T_a} - 1) \right)$$

For $t \leq T_a$, the SEQDESIGN procedure estimates the expected number of events by time t as

$$D_h(t, T_a) = r_a t \frac{h}{h + \tau} \left(1 - \frac{1}{(h + \tau)t} (1 - e^{-(h + \tau)t}) \right)$$

For a one-sample design (such as a proportional hazards regression), the expected number of events by time t is $E(t, T_a) = D_h(t, T_a)$, where h is the hazard rate for the group. For a two-sample design (such as a log-rank test for two survival distributions), the expected number of events by time t is

$$E(t, T_a) = \frac{R}{R + 1} D_{h_a}(t, T_a) + \frac{1}{R + 1} D_{h_b}(t, T_a)$$

where h_a and h_b are hazard rates in groups A and B, respectively, and R is the ratio of the sample size allocation weights w_a/w_b .

If the accrual rate r_a is specified with one of the three time parameters—the accrual time, follow-up time, and total study time—then PROC SEQDESIGN derives the other two time parameters by solving the equation for the expected number of events. Similarly, if the accrual rate r_a is not specified, but two of the three time parameters are specified, then PROC SEQDESIGN derives the accrual rate.

If the accrual rate r_a is specified without the accrual time T_a , follow-up time T_f , and total study time $T = T_a + T_f$, the SEQDESIGN procedure computes the minimum accrual time T_a by solving the equation

$$E(\infty, T_a) = d_X$$

A closed-form solution is then given by

$$\frac{d_X}{r_a} \left(\frac{R}{R+1} \frac{h_a}{h_a + \tau} + \frac{1}{R+1} \frac{h_b}{h_b + \tau} \right)^{-1}$$

Similarly, the SEQDESIGN procedure derives the maximum accrual time T_a by solving the equation

$$E(T_a, T_a) = d_X$$

The maximum accrual time T_a is then obtained by an iterative process.

With the accrual rate r_a and the accrual time T_a , the total sample size is

$$N_X = r_a T_a$$

At each stage k , the number of events is given by

$$d_k = \frac{I_k}{I_X} d_X$$

The corresponding time T_k can be derived from the equation for the expected number of events, $E(t) = d_k$, and the resulting sample size is computed as

$$N_k = \begin{cases} r_a T_k & \text{if } T_k \leq T_a \\ r_a T_a & \text{if } T_k > T_a \end{cases}$$

Truncated Exponential Accrual without Losses to Follow Up

For a study group with a constant hazard rate h , if the individual accrual is truncated exponential with parameter γ over the accrual period from 0 to T_a with distribution

$$F(t) = \frac{1 - e^{-\gamma t}}{1 - e^{-\gamma T_a}} \quad \text{for } 0 \leq t \leq T_a$$

Lachin and Foulkes (1986, p. 510) derive the expected number of events by time t (where $t > T_a$) as

$$D_h(t, N) = N \left(1 + \frac{\gamma}{h - \gamma} \frac{e^{-ht} - e^{-h(t-T_a)} e^{-\gamma T_a}}{1 - e^{-\gamma T_a}} \right)$$

where N is the total sample size.

For $t \leq T_a$, the SEQDESIGN procedure estimates the expected number of events by time t as

$$D_h(t, N) = N F(t) \left(1 + \frac{\gamma}{h - \gamma} \frac{e^{-ht} - e^{-\gamma t}}{1 - e^{-\gamma t}} \right)$$

For the truncated exponential accrual function with a parameter γ over the accrual period from 0 to T_a , you specify the scaled parameter $\gamma_0 = \gamma T_a$ in the ACCRUAL=EXP(PARM= γ_0) option, where $\gamma_0 \geq -10$ and $\gamma_0 \neq 0$.

For a one-sample design (such as a proportional hazards regression), the expected number of events by time t is $E(t, N) = D_h(t, N)$, where h is the hazard rate for the group. For a two-sample design (such as a log-rank test for two survival distributions), the expected number of events by time t is

$$E(t, N) = \frac{R}{R + 1} D_{h_a}(t, N) + \frac{1}{R + 1} D_{h_b}(t, N)$$

where h_a and h_b are hazard rates in groups A and B, respectively, and R is the ratio of the sample size allocation weights w_a/w_b .

If the total sample size N is specified, then at least one of the three time parameters—the accrual time, follow-up time, and total study time—must be specified, and then PROC SEQDESIGN derives the other two time parameters by solving the equation for the expected number of events. Similarly, if the total sample size N is not specified, then at least two of the three time parameters must be specified, and PROC SEQDESIGN derives the sample size.

If the accrual sample size N is not specified, the SEQDESIGN procedure computes the minimum accrual sample size by solving the equation

$$E(\infty, N) = d_X$$

That is, $N = d_X$.

Similarly, if the total sample size N is not specified but the accrual time T_a is specified, the SEQDESIGN procedure derives the maximum accrual sample size N by solving the equation

$$E(T_a, N) = d_X$$

At each stage k , the number of events is given by

$$d_k = \frac{I_k}{I_X} d_X$$

The corresponding time T_k can be derived from the equation for the expected number of events, $E(t) = d_k$, and the resulting sample size is computed as

$$N_k = \begin{cases} N F(T_k) & \text{if } T_k \leq T_a \\ N & \text{if } T_k > T_a \end{cases}$$

Truncated Exponential Accrual with Losses to Follow Up

With the LOSS=EXP(HAZARD= τ) option, the individual loss to follow up has an exponential loss distribution function

$$H(t) = 1 - e^{-\tau t}$$

where $\tau \geq 0$ is the loss hazard rate. The loss hazard rate can also be specified implicitly with the MEDTIME= t_τ suboption through the median loss time t_τ .

For a study group with a constant hazard rate h , if the individual accrual is truncated exponential with parameter γ over the accrual period from 0 to T_a with distribution

$$F(t) = \frac{1 - e^{-\gamma t}}{1 - e^{-\gamma T_a}} \quad \text{for } 0 \leq t \leq T_a$$

and the individual loss to follow up has an exponential loss distribution function $H(t)$, Lachin and Foulkes (1986, p. 513) derive the expected number of events by time t (where $t > T_a$) as

$$D_h(t, N) = N \frac{h}{h + \tau} \left(1 + \frac{\gamma}{h + \tau - \gamma} \frac{e^{-(h+\tau)t} - e^{-(h+\tau)(t-T_a)} e^{-\gamma T_a}}{1 - e^{-\gamma T_a}} \right)$$

For $t \leq T_a$, the SEQDESIGN procedure estimates the expected number of events by time t as

$$D_h(t, N) = N F(t) \frac{h}{h + \tau} \left(1 + \frac{\gamma}{h + \tau - \gamma} \frac{e^{-(h+\tau)t} - e^{-\gamma t}}{1 - e^{-\gamma t}} \right)$$

For the truncated exponential accrual function with a parameter γ over the accrual period from 0 to T_a , you specify the scaled parameter $\gamma_0 = \gamma T_a$ in the ACCRUAL=EXP(PARM= γ_0) option, where $\gamma_0 \geq -10$ and $\gamma_0 \neq 0$.

For a one-sample design (such as a proportional hazards regression), the expected number of events by time t is $E(t, N) = D_h(t, N)$, where h is the hazard rate for the group. For a two-sample design (such as a log-rank test for two survival distributions), the expected number of events by time t is

$$E(t, N) = \frac{R}{R + 1} D_{h_a}(t, N) + \frac{1}{R + 1} D_{h_b}(t, N)$$

where h_a and h_b are hazard rates in groups A and B, respectively, and R is the ratio of the sample size allocation weights w_a/w_b .

If the total sample size N is specified, then at least one of the three time parameters—the accrual time, follow-up time, and total study time—must be specified, and then PROC SEQDESIGN derives the other two time parameters by solving the equation for the expected number of events. Similarly, if the total sample size N is not specified, then at least two of the three time parameters must be specified, and PROC SEQDESIGN derives the sample size.

If the accrual sample size is not specified, the SEQDESIGN procedure computes the minimum sample size N by solving the equation

$$E(\infty, N) = d_X$$

A closed-form solution is then given by

$$d_X \left(\frac{R}{R+1} \frac{h_a}{h_a + \tau} + \frac{1}{R+1} \frac{h_b}{h_b + \tau} \right)^{-1}$$

Similarly, if the accrual sample size N is not specified but the accrual time T_a is specified, the SEQDESIGN procedure derives the maximum accrual sample size N by solving the equation

$$E(T_a, N) = d_X$$

At each stage k , the number of events is given by

$$d_k = \frac{I_k}{I_X} d_X$$

The corresponding time T_k can be derived from the equation for the expected number of events, $E(t) = d_k$, and the resulting sample size is computed as

$$N_k = \begin{cases} N F(T_k) & \text{if } T_k \leq T_a \\ N & \text{if } T_k > T_a \end{cases}$$

The following three sections describe examples of test statistics with their resulting information levels, which can then be used to derive the required sample size. The maximum likelihood estimators are used for all tests except to compare two survival distributions with a log-rank test, where a score statistic is used.

Applicable One-Sample Tests and Sample Size Computation

The SEQDESIGN procedure provides sample size computation for two one-sample tests: normal mean and binomial proportion. The required sample size depends on the variance of the response variable—that is, the sample proportion for a binomial proportion test.

In a typical clinical trial, a hypothesis is designed to reject, not accept, the null hypothesis to show the evidence for the alternative hypothesis. Thus, in most cases, the proportion under the alternative hypothesis is used to derive the required sample size. For a test of the binomial proportion, the REF=NULLPROP and REF=PROP options use proportions under the null and alternative hypotheses, respectively.

Test for a Normal Mean

The MODEL=ONESAMPLEMEAN option in the SAMPLESIZE statement derives the sample size required to test a normal mean by using the sample mean statistic for the null hypothesis $\mu = \mu_0$. At stage k , the sample mean is computed as

$$\bar{y}_k = \frac{1}{N_k} \sum_{j=1}^{N_k} y_{kj}$$

where y_{kj} is the value of the j th observation available in the k th stage and N_k is the cumulative sample size at stage k .

An equivalent hypothesis is $H_0 : \theta = 0$, where $\theta = \mu - \mu_0$.

The MLE statistic for θ ,

$$\hat{\theta}_k = \bar{y}_k - \mu_0 \sim N(\theta, I_k^{-1})$$

where the information

$$I_k = \frac{1}{\text{Var}(\hat{\theta})} = \frac{1}{\text{Var}(\bar{y}_k)} = \frac{N_k}{\sigma^2}$$

is the inverse of the variance.

That is, the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} = (\bar{y}_k - \mu_0) \sqrt{I_k} \sim N(\theta \sqrt{I_k}, 1)$$

Thus, to test the hypothesis $H_0 : \theta = 0$ against a two-sided alternative $H_1 : \theta = \theta_1$, H_0 is rejected at stage k if the statistic Z_k is less than or equal to the lower α boundary value or if Z_k is greater than or equal to the upper α boundary value at stage k .

If the variance σ^2 is unknown, the sample variance can be used if it is assumed that the sample variance is computed from a large sample such that the test statistic has an approximately normal distribution.

The maximum information is needed to derive the required sample size. If the maximum information is not specified or derived with the ALTREF= option in the procedure, the MEAN= θ_1 option in the SAMPLESIZE statement is used to specify the alternative reference and thus to derive the maximum information.

In the SEQDESIGN procedure, the computed total sample size

$$N_K = \sigma^2 I_X$$

where I_X is the maximum information and σ is the specified standard deviation. With an available maximum information, you can specify the MODEL=ONESAMPLEMEAN(STDDEV= σ) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC MEANS can be used to derive a one-sample Z test for a normal mean.

Test for a Binomial Proportion

The MODEL=ONESAMPLEFREQ option in the SAMPLESIZE statement derives the sample size required to test a binomial proportion by using the null hypothesis $p = p_0$, where p is the proportion of a binomial population. At stage k , the MLE for p is computed as

$$\hat{p}_k = \frac{1}{N_k} \sum_{j=1}^{N_k} y_{kj}$$

where y_{kj} is the value of the j th observation available in the k th stage and N_k is the cumulative sample size at stage k .

An equivalent hypothesis is $H_0 : \theta = 0$, where $\theta = p - p_0$. If p_0 is not close to 0 or 1, then for a large sample, $\hat{\theta}_k = \hat{p}_k - p_0$ has an approximately normal distribution

$$\hat{\theta}_k \sim N(\theta, I_k^{-1})$$

where the information $I_k = (p(1-p)/N_k)^{-1}$ is the inverse of the variance $\text{Var}(\hat{\theta})$.

Then the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} \sim N(\theta \sqrt{I_k}, 1)$$

In practice, the estimated sample proportion \hat{p} at stage k can be used to derive the information I_k and test statistic Z_k . Thus, to test the hypothesis H_0 against an upper alternative $H_1 : \theta = \theta_1 > 0$, H_0 is rejected at stage k if the statistic Z_k is greater than or equal to the upper α boundary at stage k .

The maximum information I_X is needed to derive the required sample size. If the maximum information is not specified or derived with the ALTREF= option in the procedure, the PROP= option in the SAMPLESIZE statement is used to specify the alternative reference and to derive the maximum information for the sample size calculation.

It is assumed that the sample size is sufficiently large such that the test statistic has an approximately normal distribution. With the hypotheses $H_0 : p = p_0$ and $H_1 : p = p_1$, the SEQDESIGN procedure derives the total sample size

$$N_X = p^*(1 - p^*) I_X$$

where $p^* = p_0$ if REF=NULLPROP is specified. Otherwise, $p^* = p_1$.

If the PROP= option in the SAMPLESIZE statement is not specified, then the alternative reference θ_1 derived in the SEQDESIGN procedure is used to compute $p_1 = p_0 + \theta_1$.

The ALTREF= option in the PROC statement can be used to specify θ_1 . Otherwise, the PROP= option in the SAMPLESIZE statement must be specified.

For example, with $H_0 : p = 0.5$, $H_1 : p = 0.6$, and REF=PROP (which is the default),

$$N_K = p^*(1 - p^*) I_X = (0.6 \times 0.4) I_X = 0.24 I_X$$

You can specify the MODEL=ONESAMPLEFREQ option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC GENMOD with the default DIST=NORMAL option in the MODEL statement can be used to derive the Z test for a binomial proportion.

Applicable Two-Sample Tests and Sample Size Computation

The SEQDESIGN procedure provides sample size computation for two-sample tests: the test for the difference between two normal means, tests for binomial proportions, and the log-rank test for two survival distributions. These tests for binomial proportions include the test for the difference between two binomial proportions, the log odds ratio test for binomial proportions, and the log relative risk test for binomial proportions,

For a test of difference between two sample means, the required sample size depends on the assumed sample variances. Similarly, for a test of two-sample proportions, the required sample size depends on the assumed sample proportions. For a log-rank test of two survival distributions, the required sample size depends on the assumed sample hazard rates, accrual rate, and accrual time.

If the REF=NULLPROP or REF=NULLHAZARD option is specified, the proportions or hazard rates under the null hypothesis are used to derive the required sample size or number of events. Otherwise, the REF=PROP option (which is the default in the MODEL=TWOSAMPLEFREQ option) or the REF=HAZARD option (which is the default in the MODEL=TWOSAMPLESURVIVAL option) uses proportions or hazard rates under the alternative hypothesis to derive the required sample size or number of events.

Test for the Difference between Two Normal Means

The MODEL=TWOSAMPLEMEAN option in the SAMPLESIZE statement derives the sample size required to test the difference between the means of two normal populations μ_a and μ_b by using the null hypothesis $H_0 : \theta = 0$, where $\theta = \mu_a - \mu_b$.

At stage k , the MLE for θ is computed as

$$\hat{\theta}_k = \bar{y}_{ak} - \bar{y}_{bk} = \frac{1}{N_{ak}} \sum_{j=1}^{N_{ak}} y_{akj} - \frac{1}{N_{bk}} \sum_{j=1}^{N_{bk}} y_{bjk}$$

where y_{akj} and y_{bjk} are the values of the j th observation available in the k th stage groups A and B, respectively, and N_{ak} and N_{bk} are the cumulative sample sizes at stage k for these two groups.

The statistic $\hat{\theta}_k$ has a normal distribution

$$\hat{\theta}_k \sim N(\theta, I_k^{-1})$$

where the information I_k is the inverse of the variance $\text{Var}(\hat{\theta}_k) = \sigma_a^2/N_{ak} + \sigma_b^2/N_{bk}$.

Then the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} \sim N(\theta \sqrt{I_k}, 1)$$

Thus, to test the hypothesis $H_0 : \theta = 0$ against an upper alternative $H_1 : \theta = \theta_1, \theta_1 > 0$, H_0 is rejected at stage k if the statistic $Z_k \geq a_k$, the upper α boundary for the standardized Z statistic at stage k .

If the variances σ_a^2 and σ_b^2 are unknown, the sample variances can be used to derive the information I_k if it is assumed that each sample variance is computed from a large sample such that the test statistic has an approximately normal distribution.

The maximum information is needed to derive the required sample size. If the maximum information is not specified or derived in the procedure, the alternative reference θ_1^* specified in the MEANDIFF option is used to derive the maximum information.

Note that in order to derive the sample sizes N_{ak} and N_{bk} uniquely from the information, $N_{ak} = R N_{bk}$ is assumed for $k = 1, 2, \dots, K$, where $R = w_a/w_b$ is the constant allocation ratio computed from the WEIGHT= $w_a w_b$ option in the SAMPLESIZE statement.

In PROC SEQDESIGN, the computed total sample sizes for the two groups are

$$N_{aK} = (\sigma_a^2 + R \sigma_b^2) I_X = R \left(\frac{\sigma_a^2}{R} + \sigma_b^2 \right) I_X$$

$$N_{bK} = \left(\frac{\sigma_a^2}{R} + \sigma_b^2 \right) I_X$$

where I_X is the maximum information derived in the SEQDESIGN procedure, R is the constant allocation ratio, and σ_a and σ_b are the specified standard deviations.

For $R = 1$, the two sample sizes are equal, then

$$N_{aK} = N_{bK} = \frac{N_K}{2} = (\sigma_a^2 + \sigma_b^2) I_X$$

If the variances from the two groups are equal, $\sigma_a^2 = \sigma_b^2 = \sigma^2$, then the total sample sizes for the two groups are

$$N_{aK} = (1 + R) \sigma^2 I_X$$

$$N_{bK} = \left(1 + \frac{1}{R} \right) \sigma^2 I_X$$

and the total sample size is

$$N_X = N_{aK} + N_{bK} = \frac{(R + 1)^2}{R} \sigma^2 I_X$$

Furthermore, for $R = 1$, the two sample sizes are equal, then

$$N_{aK} = N_{bK} = \frac{N_X}{2} = 2 \sigma^2 I_X$$

With an available maximum information, you can specify the MODEL=TWOSAMPLEMEAN(WEIGHT= R STDDEV= σ_a σ_b) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC GLM can be used to derive the two-sample Z test for the mean difference.

Test for the Difference between Two Binomial Proportions

The MODEL=TWOSAMPLEFREQ(TEST=PROP) option in the SAMPLESIZE statement derives the sample size required to test the difference between two binomial populations with $H_0 : \theta = 0$, where $\theta = p_a - p_b$. At stage k , the MLE for θ is

$$\hat{\theta}_k = \hat{p}_{ak} - \hat{p}_{bk} = \frac{1}{N_{ak}} \sum_{j=1}^{N_{ak}} y_{akj} - \frac{1}{N_{bk}} \sum_{j=1}^{N_{bk}} y_{bkj}$$

where y_{akj} and y_{bkj} are the values of the j th observation available in the k th stage for groups A and B, respectively, and N_{ak} and N_{bk} are the cumulative sample sizes at stage k for these two groups.

For sufficiently large sample sizes N_{ak} and N_{bk} , the statistic $\hat{\theta}_k$ has an approximate normal distribution

$$\hat{\theta}_k \sim N(\theta, I_k^{-1})$$

where the information is the inverse of the variance

$$\text{Var}(\hat{\theta}_k) = \frac{p_a(1-p_a)}{N_{ak}} + \frac{p_b(1-p_b)}{N_{bk}}$$

Thus, the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} \sim N(\theta \sqrt{I_k}, 1)$$

In practice, $p_a = \hat{p}_a$ and $p_b = \hat{p}_b$, the estimated sample proportions for groups A and B, respectively, at stage k , can be used to derive the information I_k and the test statistic Z_k . Thus, to test the hypothesis H_0 against an upper alternative $H_1 : \theta > 0$, H_0 is rejected at stage k if the statistic $Z_k \geq a_k$, the upper α boundary for the standardized Z statistic at stage k .

The maximum information I_X is needed to derive the required sample size. If the maximum information is not specified or derived with the ALTREF= option in the procedure, the PROP= option in the SAMPLESIZE statement is used to provide proportions under the alternative hypothesis for the alternative reference and then to derive the maximum information.

The proportions in the two groups are needed to derive the sample size. Also, in order to derive the sample sizes N_{ak} and N_{bk} uniquely from the information, $N_{ak} = R N_{bk}$ is assumed for $k = 1, 2, \dots, K$, where $R = w_a/w_b$ is the constant allocation ratio computed from the WEIGHT= w_a w_b option in the SAMPLESIZE statement. Then

$$I_X = \left(\frac{p_a(1-p_a)}{N_{aK}} + \frac{p_b(1-p_b)}{N_{bK}} \right)^{-1} = \frac{N_{aK}}{p_a(1-p_a) + R p_b(1-p_b)}$$

In PROC SEQDESIGN, the total sample sizes in the two groups are computed as

$$N_{aK} = (p_a^*(1-p_a^*) + R p_b^*(1-p_b^*)) I_X$$

$$N_{bK} = \frac{1}{R} N_{aK}$$

where $R = w_a/w_b$ is the constant allocation ratio, and p_a^* and p_b^* are proportions specified with the REF= option:

- REF=NULLPROP uses proportions under H_0 : $p_a^* = p_{0a}$, $p_b^* = p_{0b}$
- REF=AVGNULLPROP uses the average proportion under H_0 : $p_a^* = p_b^* = (R p_{0a} + p_{0b})/(R + 1)$
- REF=PROP uses proportions under H_1 : $p_a^* = p_{1a}$, $p_b^* = p_{1b}$
- REF=AVGPROP uses the average proportion under H_1 : $p_a^* = p_b^* = (R p_{1a} + p_{1b})/(R + 1)$

The total sample size is given by

$$N_X = N_{aK} + N_{bK} = (R + 1) \left(\frac{1}{R} p_a^* (1 - p_a^*) + p_b^* (1 - p_b^*) \right) I_X$$

For $R = 1$, the two sample sizes are equal,

$$N_{aK} = N_{bK} = \frac{N_X}{2} = (p_a^* (1 - p_a^*) + p_b^* (1 - p_b^*)) I_X$$

You can specify the `MODEL=TWOSAMPLEFREQ(TEST=PROP WEIGHT=R)` option in the `SAMPLESIZE` statement to compute the required total sample size and individual sample size at each stage. A procedure such as `PROC GENMOD` with the default `DIST=NORMAL` option in the `MODEL` statement can be used to derive the two-sample Z test for proportion difference.

Test for Two Binomial Proportions with a Log Odds Ratio Statistic

The `MODEL=TWOSAMPLEFREQ(TEST=LOGOR)` option in the `SAMPLESIZE` statement derives the sample size required to test two binomial proportions by using a log odds ratio statistic. The odds ratio is the ratio of the odds in one group to the odds in the other group, and the log odds ratio is the logarithm of the odds ratio

$$\theta = \log \left(\frac{p_a / (1 - p_a)}{p_b / (1 - p_b)} \right) = \log \left(\frac{p_a (1 - p_b)}{p_b (1 - p_a)} \right)$$

The hypothesis of no difference between two proportions, $p_a = p_b$, can be tested through the null hypothesis $H_0 : \theta = 0$, where θ is the log odds ratio. For example, with $H_0 : p_a = p_b = 0.6$ and $H_1 : p_a = 0.8, p_b = 0.6$, it corresponds to the equivalent hypothesis $H_0 : \theta = 0$ and $H_1 : \theta = \log \left(\frac{0.8(1-0.6)}{0.6(1-0.8)} \right) = \log(8/3) = 0.98083$.

The maximum likelihood estimate of θ is given by

$$\hat{\theta} = \log \left(\frac{\hat{p}_a (1 - \hat{p}_b)}{\hat{p}_b (1 - \hat{p}_a)} \right)$$

with an asymptotic variance

$$\text{Var}(\hat{\theta}) = I^{-1} = \frac{1}{N_a p_a (1 - p_a)} + \frac{1}{N_b p_b (1 - p_b)}$$

where I is the information (Diggle et al. 2002, pp. 341–342). That is, the standardized statistic

$$Z_k = \hat{\theta}_k \sqrt{I_k} \sim N \left(\theta \sqrt{I_k}, 1 \right)$$

In practice, $p_a = \hat{p}_a$ and $p_b = \hat{p}_b$, the estimated sample proportions for groups A and B, respectively, at stage k , can be used to derive the information I_k and the test statistic $Z_k = \hat{\theta}_k \sqrt{I_k}$ if the two sample sizes N_a and N_b are sufficiently large such that the test statistic has an approximately normal distribution.

The maximum information I_X is needed to derive the required sample size. If the maximum information is not specified or derived with the ALTREF= option in the procedure, the PROP= option in the SAMPLESIZE statement is used to provide proportions under the alternative hypothesis for the alternative reference and then to derive the maximum information.

In order to derive the sample sizes N_{ak} and N_{bk} uniquely from the information, $N_{ak} = R N_{bk}$ is assumed for $k = 1, 2, \dots, K$, where $R = w_a/w_b$ is the constant allocation ratio computed from the WEIGHT= w_a/w_b option in the SAMPLESIZE statement. Then with

$$I_X = N_{bK} \left(\frac{1}{R p_a(1 - p_a)} + \frac{1}{p_b(1 - p_b)} \right)^{-1}$$

the sample size can be computed.

In PROC SEQDESIGN, the total sample sizes in the two groups are computed as

$$N_{bK} = I_X \left(\frac{1}{R p_a^*(1 - p_a^*)} + \frac{1}{p_b^*(1 - p_b^*)} \right)$$

$$N_{aK} = R N_{bK}$$

where $R = w_a/w_b$ is the constant allocation ratio, and p_a^* and p_b^* are proportions specified with the REF= option:

- REF=NULLPROP uses proportions under H_0 : $p_a^* = p_{0a}$, $p_b^* = p_{0b}$
- REF=AVGNULLPROP uses the average proportion under H_0 : $p_a^* = p_b^* = (R p_{0a} + p_{0b})/(R + 1)$
- REF=PROP uses proportions under H_1 : $p_a^* = p_{1a}$, $p_b^* = p_{1b}$
- REF=AVGPROP uses the average proportion under H_1 : $p_a^* = p_b^* = (R p_{1a} + p_{1b})/(R + 1)$

You can specify the MODEL=TWOSAMPLEFREQ(TEST=LOGOR WEIGHT= R) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC LOGISTIC can be used to derive the log odds ratio statistic.

Test for Two Binomial Proportions with a Log Relative Risk Statistic

The MODEL=TWOSAMPLEFREQ(TEST=LOGRR) option in the SAMPLESIZE statement derives the sample size required to test two binomial proportions by using a log relative risk statistic. The relative risk is the ratio of the proportion in one group to the proportion in the other group. The log relative risk statistic is the logarithm of the relative risk

$$\theta = \log \left(\frac{p_a}{p_b} \right)$$

The hypothesis of no difference between two proportions, $p_a = p_b$, can be tested through the null hypothesis $H_0 : \theta = 0$. For example, with $H_0 : p_a = p_b = 0.6$ and $H_1 : p_a = 0.8$, $p_b = 0.6$, it corresponds to the equivalent hypothesis $H_0 : \theta = 0$ and $H_1 : \theta = \log \left(\frac{0.8}{0.6} \right) = \log(4/3) = 0.28768$.

The maximum likelihood estimate of θ is given by

$$\hat{\theta} = \log \left(\frac{\hat{p}_a}{\hat{p}_b} \right)$$

with an asymptotic variance

$$I^{-1} = \frac{1 - p_a}{N_a p_a} + \frac{1 - p_b}{N_b p_b}$$

where I is the information (Chow and Liu 1998, p. 329).

In practice, $p_a = \hat{p}_a$ and $p_b = \hat{p}_b$, the estimated sample proportions for groups A and B, respectively, at stage k , are used to derive the information I_k and the test statistic $Z_k = \hat{\theta}_k \sqrt{I_k}$.

The maximum information I_X and proportions p_a and p_b are needed to derive the required sample size. If the maximum information is not specified or derived with the ALTREF= option in the procedure, the PROP= option in the SAMPLESIZE statement is used to provide proportions under the alternative hypothesis for the alternative reference and then to derive the maximum information.

Note that in order to derive the sample sizes N_{ak} and N_{bk} uniquely from the information, $N_{ak} = R N_{bk}$ is assumed for $k = 1, 2, \dots, K$, where $R = w_a/w_b$ is the constant allocation ratio computed from the WEIGHT= $w_a w_b$ option in the SAMPLESIZE statement. Then the sample size can be computed from

$$I_X = N_{bK} \left(\frac{1 - p_a}{R p_a} + \frac{1 - p_b}{p_b} \right)^{-1}$$

In PROC SEQDESIGN, the computed sample sizes in the two groups are

$$N_{bK} = I_X \left(\frac{1 - p_a^*}{R p_a^*} + \frac{1 - p_b^*}{p_b^*} \right)$$

$$N_{aK} = R N_{bK}$$

where $R = w_a/w_b$ is the constant allocation ratio, and p_a^* and p_b^* are proportions specified with the REF= option:

- REF=NULLPROP uses proportions under H_0 : $p_a^* = p_{0a}$, $p_b^* = p_{0b}$
- REF=AVGNULLPROP uses the average proportion under H_0 : $p_a^* = p_b^* = (R p_{0a} + p_{0b})/(R + 1)$
- REF=PROP uses proportions under H_1 : $p_a^* = p_{1a}$, $p_b^* = p_{1b}$
- REF=AVGPROP uses the average proportion under H_1 : $p_a^* = p_b^* = (R p_{1a} + p_{1b})/(R + 1)$

You can specify the MODEL=TWOSAMPLEFREQ(TEST=LOGRR WEIGHT= R) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A procedure such as PROC LOGISTIC can be used to derive the log relative risk statistic.

Test for Two Survival Distributions with a Log-Rank Test

The MODEL=TWOSAMPLESURV option in the SAMPLESIZE statement derives the number of events required for a log-rank test of two survival distributions. The analysis of survival data involves the survival times for both censored and uncensored data. A noncensored survival time is the time from treatment to an event such as remission or relapse for an individual. A censored survival time is the time from treatment to the time of analysis for an individual surviving at that time, and the status is unknown beyond that time.

Let T be the random variable of the survival time. Then the survival function

$$S(t) = \Pr(T > t)$$

is the probability that an individual from the population has a survival time that exceeds t . And the hazard function is given by

$$h(t) = \frac{f(t)}{S(t)}$$

where $f(t)$ is the density function of T .

The hazard functions can be used to test the equality of two survival distributions $S_a(t) = S_b(t)$ with the null hypothesis $H_0 : h_a(t) = h_b(t), t > 0$, where $S_a(t)$ and $S_b(t)$ are survival functions for groups A and B, respectively, and $h_a(t)$ and $h_b(t)$ are the corresponding hazard functions.

If the two hazards are proportional, $h_a(t) = \lambda h_b(t)$, where λ is a constant, then an equivalent null hypothesis is

$$H_0 : \lambda = \frac{h_a(t)}{h_b(t)} = 1$$

Alternatively, another equivalent null hypothesis is given by

$$H_0 : \theta = -\log(\lambda) = 0$$

Suppose that the hazard rate h is a constant. Then with a specified median survival time T_m , the hazard rate can be derived from the equation

$$e^{-h T_m} = \frac{1}{2}$$

Denote the distinct event times at stage k as $\tau_{kj}, j = 1, 2, \dots, t_k$, where t_k is the total number of distinct event times. Then the score statistic is the log-rank statistic (Jennison and Turnbull 2000, pp. 259–261; Whitehead 1997, pp. 36–39)

$$S_k = \sum_{j=1}^{t_k} (d_{akj} - e_{akj})$$

where d_{akj} is the number of events from group A and e_{akj} is the number of expected events from A. The number of expected events from A is computed as

$$e_{akj} = d_{kj} \frac{r_{akj}}{r_{kj}}$$

where d_{kj} is the number of events from both groups, r_{akj} is the number of individuals from the treatment group who survived up to time τ_{kj} , and r_{bkj} is the number of individuals from both groups who survived up to time τ_{kj} .

If the number of events d_{kj} is small relative to r_{kj} , the number of individuals survived up to time τ_{kj} , then with a sufficiently large sample size, S_k has an approximately normal distribution

$$S_k \sim N(\theta I_k, I_k)$$

where the variance of S_k is the estimated information

$$I_k = \sum_{j=1}^{t_k} \frac{r_{akj} r_{bkj} d_{kj}}{r_{kj}^2}$$

In order to derive the number of events from the information I_k , $N_{ak} = R N_{bk}$ is assumed for $k = 1, 2, \dots, K$, where $R = w_a/w_b$ is the constant allocation ratio computed from the WEIGHT= $w_a w_b$ option in the SAMPLESIZE statement.

The maximum information I_X is needed to derive the required sample size. If the maximum information is specified or derived with the ALTREF= option in the procedure, the HAZARD=, MEDSURVTIME=, and HAZARDRATIO= options are not applicable. Otherwise, the HAZARD=, MEDSURVTIME=, or HAZARDRATIO= option is used to compute the alternative reference and then to derive the maximum information for the sample size calculation.

With $N_{aK} = R N_{bK}$, if the number of events is few relative to the number of individuals who survived, then $r_{aKj} \approx R r_{bKj}$, and

$$I_X \approx \sum_{j=1}^{t_K} \frac{R}{(R+1)^2} d_{Kj} = \frac{R}{(R+1)^2} D_X$$

where D_X is the total number of events.

Thus, the required total number of events

$$D_X = \frac{(R+1)^2}{R} I_X$$

For a study group, if the hazard rate is constant, corresponding to an exponential survival distribution, and the individual accrual is uniform in the accrual time T_a with a constant accrual rate r_a , then the required total sample size and sample size at each stage can be derived. See the section “[Input Number of Events for Fixed-Sample Design](#)” on page 7044 for a detailed description of the sample size computation that uses hazard rates, accrual rate, and accrual time.

You can specify the MODEL=TWOSAMPLESURVIVAL option in the SAMPLESIZE statement to compute the required total number of events and individual number of events at each stage. With the specifications of hazard rates, accrual rate, and accrual time, the required total sample size and individual sample size at each stage can also be derived. If the REF=NULLHAZARD option is specified, the hazard rates under the null hypothesis, h_{0a} and h_{0b} , are used in the sample size computation. Otherwise, the hazard rates under the alternative hypothesis, h_{1a} and h_{1b} , are used. A procedure such as PROC LIFETEST can be used to derive the log-rank statistic.

Applicable Regression Parameter Tests and Sample Size Computation

The SEQDESIGN procedure provides sample size computation for tests of a regression parameter in three regression models: normal regression, logistic regression, and proportional hazards regression.

To test a parameter β_1 in a regression model, the variance of the parameter estimate $\hat{\beta}_1$ is needed for the sample size computation. In a simple regression model with one covariate X_1 , the variance of $\hat{\beta}_1$ is inversely related to the variance of X_1 , σ_x^2 . That is,

$$\text{Var}(\hat{\beta}_1) \propto \frac{1}{N \sigma_x^2}$$

for the normal regression and logistic regression models, where N is the sample size, and

$$\text{Var}(\hat{\beta}_1) \propto \frac{1}{D \sigma_x^2}$$

for the proportional hazards regression model, where D is the number of events.

For a regression model with more than one covariate, the variance of $\hat{\beta}_1$ for the normal regression and logistic regression models is inversely related to the variance of X_1 after adjusting for other covariates. That is,

$$\text{Var}(\hat{\beta}_1) \propto \frac{1}{N (1 - r_x^2) \sigma_x^2}$$

where $\hat{\beta}_1$ is the estimate of the parameter β_1 in the model and r_x^2 is the R square from the regression of X_1 on other covariates—that is, the proportion of the variance σ_x^2 explained by these covariates.

Similarly, for a proportional hazards regression model,

$$\text{Var}(\hat{\beta}_1) \propto \frac{1}{D (1 - r_x^2) \sigma_x^2}$$

Thus, with the derived maximum information, the required sample size or number of events can also be computed for the testing of a parameter in a regression model with covariates.

Test for a Parameter in the Regression Model

The MODEL=REG option in the SAMPLESIZE statement derives the sample size required for a Z test of a normal regression. For a normal linear regression model, the response variable is normally distributed with the mean equal to a linear function of the explanatory variables and the constant variance σ^2 .

The normal linear model is

$$\mathbf{y} \sim N(\mathbf{X}\boldsymbol{\beta}, \sigma_y^2 \mathbf{I}_{(N)})$$

where $\mathbf{Y}_{(N \times 1)}$ is the vector of the N observed responses, $\mathbf{X}_{(N \times p)}$ is the design matrix for these N observations, $\boldsymbol{\beta}_{(p \times 1)}$ is the parameter vector, and $\mathbf{I}_{(N)}$ is the $(N \times N)$ identity matrix.

The least squares estimate is

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{Y}$$

and is normally distributed with mean β and variance

$$\text{Var}(\hat{\beta}) = \sigma_y^2 (\mathbf{X}'\mathbf{X})^{-1}$$

For a model with only one covariate X1,

$$\hat{\beta}_1 \sim N(\beta_1, \text{Var}(\hat{\beta}_1))$$

where the variance

$$\text{Var}(\hat{\beta}_1) = I_{\beta_1}^{-1} = \sigma_y^2 \frac{1}{N \sigma_x^2}$$

Thus, with the derived maximum information $I_X = I_{\beta_1}$, the required sample size is given by

$$N = I_X \frac{\sigma_y^2}{\sigma_x^2}$$

For a normal linear model with more than one covariate, the variance of a single parameter β_1 is

$$\text{Var}(\hat{\beta}_1) = \sigma_y^2 (\mathbf{X}'\mathbf{X})_{(11)}^{-1} = \sigma_y^2 \frac{1}{N \sigma_x^2 (1 - r_x^2)}$$

where $(\mathbf{X}'\mathbf{X})_{(11)}^{-1}$ is the diagonal element of the $(\mathbf{X}'\mathbf{X})^{-1}$ matrix corresponding to the parameter β_1 , σ_x^2 is the variance of the variable X1, and r_x^2 is the proportion of variance of X1 explained by other covariates. The value $\sigma_x^2 (1 - r_x^2)$ represents the variance of X1 after adjusting for all other covariates.

Thus, with the derived maximum information I_X , the required sample size is

$$N = I_X \frac{\sigma_y^2}{(1 - r_x^2) \sigma_x^2}$$

In the SEQDESIGN procedure, you can specify the MODEL=REG(VARIANCE= σ_y^2 XVARIANCE= σ_x^2 XRSQUARE= r_x^2) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage. A SAS procedure such as PROC REG can be used to compute the parameter estimate and its standard error at each stage.

Test for a Parameter in the Logistic Regression Model

The MODEL=LOGISTIC option in the SAMPLESIZE statement derives the sample size required for a Z test of a logistic regression parameter. The linear logistic model has the form

$$\text{logit}(p) = \log\left(\frac{p}{1-p}\right) = \mathbf{x}\beta$$

where p is the response probability to be modeled and β is a vector of parameters.

Following the derivation in the section “Test for a Parameter in the Regression Model” on page 7061, the required sample size for testing a parameter in β is given by

$$N = I_X \frac{\sigma_y^2}{(1 - r_x^2) \sigma_x^2}$$

With the variance of the logit response, $\sigma_y^2 = 1/(p(1 - p))$,

$$N = I_X \frac{1}{p(1 - p)} \frac{1}{(1 - r_x^2) \sigma_x^2}$$

where σ_x^2 is the variance of X and r_x^2 is the proportion of variance explained by other covariates.

In the SEQDESIGN procedure, you can specify the MODEL=LOGISTIC(PROP= p XVARIANCE= σ_x^2 XRSQUARE= r_x^2) option in the SAMPLESIZE statement to compute the required total sample size and individual sample size at each stage.

A SAS procedure such as PROC LOGISTIC can be used to compute the parameter estimate and its standard error at each stage.

Test for a Parameter in the Proportional Hazards Regression Model

The MODEL=PHREG option in the SAMPLESIZE statement derives the number of events required for a Z test of a proportional hazards regression parameter. For analyses of survival data, Cox's semiparametric model is often used to examine the effect of explanatory variables on hazard rates. The survival time of each observation in the population is assumed to follow its own hazard function, $h_i(t)$, expressed as

$$h_i(t) = h(t; \mathbf{X}_i) = h_0(t) \exp(\mathbf{X}_i' \boldsymbol{\beta})$$

where $h_0(t)$ is an arbitrary and unspecified baseline hazard function, \mathbf{x}_i is the vector of explanatory variables for the i th individual, and $\boldsymbol{\beta}$ is the vector of regression parameters associated with the explanatory variables.

Hsieh and Lavori (2000, p. 553) show that the required number of events for testing a parameter in $\boldsymbol{\beta}$, β_1 , associated with the variable X1 is given by

$$D_X = I_X \frac{1}{(1 - r_x^2) \sigma_x^2}$$

where σ_x^2 is the variance of X1 and r_x^2 is the proportion of variance of X1 explained by other covariates.

In the SEQDESIGN procedure, you can specify the MODEL=PHREG(XVARIANCE= σ_x^2 XRSQUARE= r_x^2) option in the SAMPLESIZE statement to compute the required number of events and individual number of events at each stage.

A SAS procedure such as PROC PHREG can be used to compute the parameter estimate and its standard error at each stage.

Note that for a two-sample test, X1 is an indicator variable and is the only covariate in the model. Thus, if the two sample sizes are equal, then the variance $\sigma_x^2 = 1/4$ and the required number of events for testing the parameter β_1 is given by

$$D_X = I_X \frac{1}{\sigma_x^2} = 4 I_X$$

See the section “[Input Number of Events for Fixed-Sample Design](#)” on page 7044 for a detailed description of the sample size computation that uses hazard rates, accrual rate, and accrual time.

Aspects of Group Sequential Designs

This section summarizes various aspects of group sequential designs that are encountered in applications of the SEQDESIGN procedure. Features are illustrated through two-sided designs with $\alpha = 0.05$ and $\beta = 0.10$. The null hypothesis $H_0 : \theta = 0$ and an alternative reference $\theta_1 = \pm 0.25$ are used for the designs with early stopping only to reject the null hypothesis.

Canonical Joint Distribution

The SEQDESIGN procedure assumes that with a total number of stages K , the sequence of the standardized test statistics $\{Z_1, Z_2, \dots, Z_K\}$ has the canonical joint distribution with information levels $\{I_1, I_2, \dots, I_K\}$ for the parameter θ (Jennison and Turnbull 2000, p. 49):

- (Z_1, Z_2, \dots, Z_K) is multivariate normal
- $Z_k \sim N(\theta \sqrt{I_k}, 1), k = 1, 2, \dots, K$
- $\text{Cov}(Z_{k_1}, Z_{k_2}) = \sqrt{(I_{k_1}/I_{k_2})}, 1 \leq k_1 \leq k_2 \leq K$

Normality Assumption

The SEQDESIGN procedure derives the boundary values by assuming that the sequence of the standardized test statistics $\{Z_1, Z_2, \dots, Z_K\}$ has the canonical joint distribution with information levels $\{I_1, I_2, \dots, I_K\}$ for the parameter θ . If the test statistic Z_k does not have a normal distribution, it is assumed that the test statistic is computed from a large sample, so that the resulting statistic has an approximately normal distribution.

Number of Stages

For group sequential trials with fixed significance level α , power $1 - \beta$, and alternative reference, if the number of stages is increased, the required maximum information is also increased, but the average sample number under the alternative hypothesis is likely to decrease.

For example, for two-sided designs with early stopping only to reject the null hypothesis $H_0 : \theta = 0$, $\alpha = 0.05$, and $\beta = 0.10$ at the alternative reference $\theta_1 = \pm 0.25$, the O'Brien-Fleming method increases the maximum information from 168.12 for a fixed-sample design to 169.32 for a two-stage design, 172.57 for a five-stage design, and then 174.42 for a ten-stage design. In the mean time, the average sample number (as a percentage of fixed-sample) under the alternative hypothesis decreases from 100 for a fixed-sample design to 85.11 for a two-stage design, 75.03 for a five-stage design, and then 71.80 for a ten-stage design. The reduction in average sample number decreases as the number of stages increases. Thus there seems to be little to gain from choosing a design with more than five stages (Pocock 1982, p. 155).

Alternative Reference

The alternative reference θ_1 is the hypothetical reference under the alternative hypothesis at which the power is computed. It is a treatment value that the investigators would hope to detect with high probability (Jennison and Turnbull 2000, p. 21).

For a group sequential design with specified parameters such as α and β errors, the drift parameter $\theta_1 \sqrt{I_X}$ is always derived in the SEQDESIGN procedure. Thus, with a smaller alternative reference θ_1 , a larger maximum information level I_X is needed. That is, in order to detect a smaller difference with the same high power, a larger sample size is required.

Maximum Information

In a clinical trial, the amount of information about an unknown parameter available from the data can be measured by the Fisher information, the variance of the score statistic. The maximum information is the information level needed at the final stage of the group sequential trial if the trial does not stop at an interim stage. For a group sequential design, the maximum information can be derived with the specified alternative reference.

The maximum information is proportional to the sample size or number of events required for the design. Thus, it can also be used to compare different designs. Generally, a design with a larger probability to stop the trial early tends to have a larger maximum information. For example, for two-sided four-stage designs with early stopping only to reject H_0 , $\alpha = 0.05$, and $\beta = 0.10$ at the alternative reference $\theta_1 = \pm 0.25$, the Pocock method has a maximum information of 198.91 and the O'Brien-Fleming method has a maximum information of 171.84, indicating a much larger information level required for the Pocock method.

Drift Parameter

The drift parameter $\theta_1 \sqrt{I_X}$ is derived for each design in the SEQDESIGN procedure, where θ_1 is the alternative reference. It is proportional to the square root of maximum information required for the design and can be used to compare maximum information for different designs with the same alternative reference. For example, for two-sided four-stage designs with early stopping only to reject H_0 , $\alpha = 0.05$, and $\beta = 0.10$, the Pocock method has a drift parameter 3.526 and the O'Brien-Fleming method has a drift parameter 3.277, indicating that a larger maximum information level is required for the Pocock method than for the O'Brien-Fleming method.

Average Sample Number

The average sample number is the expected sample size (for nonsurvival data) or expected number of events (for survival data) of the design under a specific hypothetical reference. The percent average sample numbers with respect to the corresponding fixed-sample design are displayed in the SEQDESIGN procedure.

The design that requires a larger maximum information level tends to have a smaller average sample number under the alternative hypothesis. For example, for two-sided four-stage designs with early stopping only to reject H_0 , $\alpha = 0.05$, and $\beta = 0.10$ at the alternative reference $\theta_1 = \pm 0.25$, the Pocock design has a maximum information of 198.91 and an average sample number (in percentage of fixed-sample design) of 69.75 under the alternative hypothesis, and the O'Brien-Fleming design has a maximum information of 171.84 and an average sample number of 76.74.

Sample Size

The maximum information for the sequential design expressed as a percentage of its corresponding fixed-sample information is derived in the SEQDESIGN procedure. The sample size or number of events needed for a group sequential trial is computed by multiplying the sample size or number of events for the corresponding fixed-sample design by the derived percentage.

If the sample size or number of events for the fixed-sample design is available, you can use the `MODEL=INPUTNOBS` or `MODEL=INPUTNEVENTS` option in the `SAMPLESIZE` statement to derive the sample size or number of events needed at each stage. Otherwise, with the specified or derived maximum information, you can use the `MODEL=` option in the `SAMPLESIZE` statement to specify a hypothesis test and then to derive the sample size or number of events needed at each stage. See the section “[Sample Size Computation](#)” on page 7042 for the sample size computation for commonly used tests.

Summary of Methods in Group Sequential Designs

There are three different types of methods available in the SEQDESIGN procedure: fixed boundary shape methods for specified boundary shape, Whitehead methods for boundaries from continuous monitoring, and error spending methods for specified error spending at each stage.

The fixed boundary shape methods include unified family methods and Haybittle-Peto methods. The unified family methods include Pocock, O’Brien-Fleming, power family, and triangular methods.

Pocock Method

Pocock derives the constant boundary on the standardized Z scale to demonstrate the sequential design while maintaining the overall α and β levels (Pocock 1977). The resulting boundary tends to stop the trials early with a larger p -value. This boundary is commonly called a Pocock boundary, but Pocock himself does not advocate these boundary values for stopping a trial early to reject the null hypothesis, because large p -values might not be persuasive enough (Pocock and White 1999). Also, the nominal p -value at the final stage is much smaller than the overall p -value of the design. That is, the trial might stop at the final stage with a small nominal p -value, but the test is not rejected, which might not be easy to justify.

O’Brien-Fleming Method

O’Brien-Fleming boundary values are inversely proportional to the square root of information levels on the standardized Z scale (O’Brien and Fleming 1979). The O’Brien-Fleming boundary is conservative in the early stages and tends to stop the trials early only with a small p -value. But the nominal value at the final stage is close to the overall p -value of the design.

Power Family Method

The power family method (Wang and Tsiatis 1987; Emerson and Fleming 1989; Pampallona and Tsiatis 1994) generalizes the Pocock and O’Brien-Fleming methods with a power parameter to allow continuous movement between the Pocock and O’Brien-Fleming methods. The power parameter is $\rho = 0$ for the Pocock method and $\rho = 0.5$ for the O’Brien-Fleming method.

Triangular Method

The unified family triangular method (Kittelson and Emerson 1999) contains straight-line boundaries on the score scale. For a one-sided trial with early stopping either to reject and to accept the null hypothesis, the method produces a triangular continuation region. The boundary shape is specified with the slope parameter τ .

Unified Family Method

The unified family method (Kittelson and Emerson 1999) extends power family methods to incorporate the triangular method, which contains straight-line boundaries on the score scale.

Haybittle-Peto Method

The Haybittle-Peto method (Haybittle 1971; Peto et al. 1976) uses a Z value of 3 for the critical values in interim stages and derives the critical value at the final stage. With this method, the final-stage critical value is close to the original design without interim monitoring. The SEQDESIGN procedure extends this method further to allow for different Z or nominal p -values for the boundaries.

Whitehead Method

Whitehead methods (Whitehead and Stratton 1983; Whitehead 1997, 2001) derive the boundary values by adapting the continuous monitoring tests to the discrete monitoring of group sequential tests. With early stopping to reject or accept the null hypothesis in a one-sided test, the derived continuation region has a triangular shape on the score-scaled boundaries. Only elementary calculations are needed to derive the boundary values in Whitehead's triangular methods. The resulting Type I error probability and power are extremely close but differ slightly from the specified values due to the approximations used in deriving the tests (Jennison and Turnbull 2000, p. 106). The SEQDESIGN procedure provides the BOUNDARYKEY= option to adjust the boundary value at the final stage for the exact Type I or Type II error probability levels.

Error Spending Method

The error spending method uses the specified α and β errors to be used at each stage of the design to derive the boundary values.

Error Spending Function Method

The error spending function method uses the error spending function to compute the α and β errors to be used at each stage of the design and then to derive the boundary values for these errors. The following four error spending functions are available in the SEQDESIGN procedure:

- The Pocock-type error spending function (Lan and DeMets 1983) produces boundaries similar to those produced with Pocock's method.
- The O'Brien-Fleming-type error spending function (Lan and DeMets 1983) produces boundaries similar to those produced with the O'Brien-Fleming method.
- The gamma error spending function (Hwang, Shih, and DeCani 1990) specifies a gamma cumulative error spending function indexed by the gamma parameter γ . The boundaries created with $\gamma = 1$ are similar to the boundaries from the Pocock method, and the boundaries created with $\gamma = -4$ or $\gamma = -5$ are similar to the boundaries from the O'Brien-Fleming method.
- The power error spending function (Jennison and Turnbull 2000, p. 148) specifies a power cumulative error spending function indexed by the power parameter ρ . The boundaries created with $\rho = 1$ are similar to the boundaries from the Pocock method, and the boundaries created with $\rho = 3$ are similar to the boundaries from the O'Brien-Fleming method.

Table Output

For each design, the SEQDESIGN procedure displays the “Design Information,” “Method Information,” and “Boundary Information” tables by default.

Boundary Information

The “Boundary Information” table displays the following information at each stage:

- proportion of information
- actual information level, if the maximum information is either specified or derived
- alternative references with the specified statistic scale. If a p -value scale is specified, the standardized Z scale is used.
- boundary values with the specified statistic scale to reject or accept the null hypothesis

Note that implicitly, the boundary information table also contains variables for the boundary scale, stopping criterion, and type of alternative hypothesis. That is, if an ODS statement is used to save the table, the data set also contains the variables `_Scale_` for the boundary scale, `_Stop_` for the stopping criterion, and `_ALT_` for the type of alternative hypothesis.

Design Information

The “Design Information” table displays the design specifications and derived statistics. The derived Max Information (Percent Fixed-Sample) is the maximum information for the sequential design in percentage of the corresponding fixed-sample information.

The Null Ref ASN (Percent Fixed-Sample) is the average sample number (expected sample size for nonsurvival data or expected number of events for survival data) required under the null hypothesis for the group sequential design in percentage of the corresponding fixed-sample design. Similarly, the Alt Ref ASN (Percent Fixed-Sample) is the average sample number required under the alternative reference for the group sequential design in percentage of the corresponding fixed-sample design.

If both the maximum information (MAXINFO= option) and the alternative reference θ_1 (ALTREF= option) are specified, then either the ALPHA= option is used to derive the Type II error probability β (BOUNDARYKEY=ALPHA) or the BETA= option is used to derive the Type I error probability α (BOUNDARYKEY=BETA).

Error Spending Information

The “Error Spending Information” table displays the following information at each stage:

- proportion of information
- actual information level, if the maximum information is either specified or derived
- cumulative error spending for each boundary

Method Information

The “Method Information” table displays detailed method information for the design. For each boundary, it displays the following:

- the group sequential method used
- the α or β errors
- the specified parameter ρ , if an error spending function is used
- the specified parameters ρ and τ with the derived critical value C , if a unified family method is used
- the alternative reference θ_1 , if either the ALTREF= or the MAXINFO= option is specified
- the derived drift parameter, $\theta_1 \sqrt{I_X}$, where I_X is the maximum information and θ_1 is the alternative reference

Note that the alternative references are displayed with the MLE scale in the “Method Information” table. In contrast, the alternative references in the “Boundary Information” table are displayed with the specified statistic scale (if the p -value scale is not specified) or the standardized Z scale (if the p -value scale is specified).

Powers and Expected Sample Sizes

The “Powers and Expected Sample Sizes” table displays the following information under each of the specified hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option.

- coefficient c_i for the hypothetical references. The value $c_i = 0$ corresponds to the null hypothesis and $c_i = 1$ corresponds to the alternative hypothesis
- power
- expected sample size, as percentage of fixed-sample size

For a one-sided design, the power and expected sample sizes under the hypothetical references $\theta = c_i \theta_1$ are displayed.

For a two-sided symmetric design, the power and expected sample sizes under each of the hypothetical references $\theta = c_i \theta_{1u}$ are displayed, where θ_{1u} is the upper alternative reference.

For a two-sided asymmetric design, the power and expected sample sizes under each of the hypothetical references $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively.

For a two-sided design, the power is the probability of correctly rejecting the null hypothesis for the correct alternative. Thus, under the null hypothesis, the displayed power corresponds to a one-sided Type I error probability level—that is, the lower α level or the upper α level.

The expected sample size as a percentage of the corresponding fixed-sample design is

$$100 \times \frac{\sum_{k=1}^K p_k I_k}{I_0}$$

where p_k is the stopping probability at stage k , $\sum_{k=1}^K p_k I_k$ is the expected information level, and I_0 is the information level for the fixed-sample design.

Sample Size Summary

When you use the SAMPLESIZE statement with the SEQDESIGN procedure, the “Sample Size Summary” table displays parameters for the sample size computation. It also displays the expected sample sizes or numbers of events for the model under both the null and alternative hypotheses.

The expected sample size is the average sample size

$$\frac{\sum_{k=1}^K p_k I_k}{I_0} N_0$$

where p_k is the stopping probability at stage k , $\sum_{k=1}^K p_k I_k$ is the expected information level, I_0 is the information level for the fixed-sample design, and N_0 is the sample size for the fixed-sample design.

The expected number of events is the average number of events

$$\frac{\sum_{k=1}^K p_k I_k}{I_0} D_0$$

where D_0 is the fixed-sample number of events for the model.

Sample Size Information

The “Sample Sizes (N)” table displays the required sample sizes and information levels at each stage, in both fractional and integer numbers. The derived fractional sample sizes are under the heading “Fractional N.” These sample sizes are rounded up to integers under the heading “Ceiling N.” The matched integer sample sizes are also displayed for two-sample tests.

The “Required Number of Events (D)” table displays the required number of events required and information level at each stage.

The “Number of Events (D) and Sample Sizes (N)” table displays the number of events and sample size required at each stage with the study time. The derived times under the heading “Fractional Time” are not integers. These times are rounded up to integers under the heading “Ceiling Time.”

Stopping Probabilities

The “Expected Cumulative Stopping Probabilities” table displays the following information under each of the specified hypothetical references $\theta = c_i \theta_1$, where c_i are values specified in the CREF= option, and θ_1 is the alternative reference:

- coefficient c_i for the hypothetical references. The value $c_i = 0$ corresponds to the null hypothesis, and $c_i = 1$ corresponds to the alternative hypothesis

- expected stopping stage
- source of the stopping probability: reject H_0 (with STOP=REJECT or STOP=BOTH), accept H_0 (with STOP=ACCEPT or STOP=BOTH), or either reject or accept H_0 (with STOP=BOTH)
- expected cumulative stopping probabilities at each stage

For a one-sided design, the expected cumulative stopping probabilities under the hypothetical references $\theta = c_i \theta_{1l}$ are displayed.

For a two-sided design, the expected cumulative stopping probabilities under each of the hypothetical references $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively.

Note that for a symmetric two-sided design, only the expected cumulative stopping probabilities under the hypothetical references $\theta = c_i \theta_{1u}$ are derived.

The expected stopping stage is given by $k_0 + d$, where the integer k_0 and the fraction d ($0 \leq d < 1$) are derived from the expected information level equation

$$\sum_{k=1}^K p_k I_k = I_{k_0} + d (I_{(k_0+1)} - I_{k_0})$$

where p_k is the stopping probability at stage k .

For equally spaced information levels, the expected stopping stage is reduced to the weighted average

$$\sum_{k=1}^K p_k k$$

ODS Table Names

PROC SEQDESIGN assigns a name to each table it creates. You must use these names to reference tables when using the Output Delivery System (ODS). These names are listed in [Table 83.12](#). For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

Table 83.12 ODS Tables Produced by PROC SEQDESIGN

ODS Table Name	Description	Statement	Option
Boundary	Boundary values		
Design	Design information		
ErrSpend	Error spending		ERRSPEND
Method	Method information		
PowerSampleSize	Power and expected sample size		PSS
SampleSize	Derived sample sizes	SAMPLESIZE	
SampleSizeSummary	Sample size summary	SAMPLESIZE	
StopProb	Stopping probabilities		STOPPROB

Graphics Output

This section describes the use of ODS for creating graphics with the SEQDESIGN procedure. To request these graphs, ODS Graphics must be enabled and you must specify the associated graphics options in the PROC SEQDESIGN statement. Except for the PLOTS=BOUNDARY option, where a detailed boundary plot is generated for each design separately, each option produces a plot for all designs together. For more information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS.”

Sequential ASN Plot

The PLOTS=ASN option displays the average sample numbers (expected sample sizes for nonsurvival data or expected numbers of events for survival data) under various hypothetical references. The average sample numbers are connected for each design, and these connected curves for all designs are displayed in the “Sequential ASN Plot” graph.

For a one-sided design, average sample numbers under the hypothetical references $\theta = c_i \theta_1$ are displayed, where c_i are the values specified in the CREF= option and θ_1 is the alternative reference. The horizontal axis displays the c_i values of these hypothetical references.

For a two-sided design, average sample numbers under each of the hypothetical references $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The horizontal axis displays $-c_i$ values for lower hypothetical references $\theta = c_i \theta_{1l}$ and c_i values for upper hypothetical references $\theta = c_i \theta_{1u}$.

Note that for a symmetric two-sided design, only average sample numbers under the hypothetical references $\theta = c_i \theta_{1u}$ are derived.

Sequential Boundary Plot

The PLOTS=BOUNDARY option displays boundary values and the acceptance and rejection regions at each stage for each design separately in the “Detailed Boundary Information” graph. The BOUNDARYSCALE= option is used to specify the scale of the boundaries on the vertical axis. The keywords MLE, SCORE, STDZ, and PVALUE in the BOUNDARYSCALE= option correspond to the boundary with the MLE scale, score statistic scale, standardized normal Z scale, and p -value scale, respectively.

The stage numbers are displayed on the horizontal axis. In addition, the HSCALE= option in the PLOTS=BOUNDARY option can be used to specify the scale on the horizontal axis. The keywords INFO and SAMPLESIZE in the HSCALE= option correspond to the information levels and sample sizes, respectively.

Combined Sequential Boundary Plot

The PLOTS=COMBINEDBOUNDARY option displays boundary values. The boundary values are connected for each boundary in each design, and these connected curves for all designs are displayed in the “Sequential Boundary Information” graph. The BOUNDARYSCALE= option is used to specify the scale of the boundaries on the vertical axis. The keywords MLE, SCORE, STDZ, and PVALUE in the BOUNDARYSCALE= option correspond to the boundary with the MLE scale, score statistic scale, standardized normal Z scale, and p -value scale, respectively.

The HSCALE= option in the PLOTS=COMBINEDBOUNDARY option can be used to specify the scale on the horizontal axis. The keywords INFO, SAMPLESIZE, and STAGE in the HSCALE= option correspond to the information levels, sample sizes, and stage numbers, respectively.

Sequential Error Spending Plot

The PLOTS=ERRSPEND option displays the cumulative error spending at each stage on each boundary in the “Sequential Error Spending Plot” graph. A legend table uses the design labels to identify the curves for the corresponding design in the plot. Another legend table uses symbols to identify boundaries in the plot.

Sequential Power Plot

The PLOTS=POWER option displays the powers under various hypothetical references. The powers are connected for each design, and these connected curves for all designs are displayed in the “Sequential Power Plot” graph.

For a one-sided design, powers under hypothetical references $\theta = c_i \theta_1$ are displayed, where c_i are the values specified in the CREF= option and θ_1 is the alternative reference. The horizontal axis displays the c_i values of these hypothetical references.

For a two-sided design, powers under hypothetical references $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The horizontal axis displays $-c_i$ values for lower hypothetical references $\theta = c_i \theta_{1l}$ and c_i values for upper hypothetical references $\theta = c_i \theta_{1u}$.

Note that for a symmetric two-sided design, only powers under hypothetical references $\theta = c_i \theta_{1u}$ are derived.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

PROC SEQDESIGN assigns a name to each graph it creates. You can use these names to reference the graphs when using ODS. To request these graphs, ODS Graphics must be enabled and you must specify the options indicated in [Table 83.13](#).

Table 83.13 Graphs Produced by PROC SEQDESIGN

ODS Graph Name	Plot Description	Option
ASNPlot	Average sample numbers	PLOTS=ASN
BoundaryPlot	Detailed boundary values	PLOTS=BOUNDARY
CombinedBoundaryPlot	Boundary values	PLOTS=COMBINEDBOUNDARY
ErrSpendPlot	Error spending	PLOTS=ERRSPEND
PowerPlot	Power curves	PLOTS=POWER

Examples: SEQDESIGN Procedure

The following examples demonstrate the usage of group sequential methods. [Example 83.1](#) uses the NSTAGES=1 option to derive boundaries of critical values for a fixed-sample design. The remaining examples use different methods to create boundaries for various group sequential designs.

Example 83.1: Creating Fixed-Sample Designs

This example demonstrates a one-sided fixed-sample design and a two-sided fixed-sample design. The following statements request a fixed-sample design with an upper alternative:

```
ods graphics on;
proc seqdesign pss
    ;
    OneSidedFixedSample: design nstages=1
                           alt=upper
                           alpha=0.025 beta=0.10
    ;
    samplesize model=onesamplemean(mean=0.25);
run;
ods graphics off;
```

In the DESIGN statement, the label **OneSidedFixedSample** identifies the design in the output tables. The NSTAGES=1 option specifies that the design has only one stage; this corresponds to a fixed-sample design. In the SEQDESIGN procedure, the null hypothesis for the design is $H_0 : \theta = 0$ and the ALT=UPPER option specifies an upper alternative hypothesis $H_1 : \theta = \theta_1 > 0$. The MEAN=0.25 option in the SAMPLESIZE statement specifies the upper alternative reference $\theta_1 = 0.25$.

The options ALPHA=0.025 and BETA=0.10 specify the Type I error probability level $\alpha = 0.025$ and the Type II error probability level $\beta = 0.10$. That is, the design has a power $1 - \beta = 0.90$ at $\theta_1 = 0.25$.

The “Design Information” table in [Output 83.1.1](#) displays design specifications and the derived statistics such as power. As expected, the derived statistics such as maximum information and average sample number (in percentage of its corresponding fixed-sample information) are 100 for the fixed-sample design (NSTAGES=1). Also, for a fixed-sample design, the STOP= and METHOD= options in the DESIGN statement are not applicable.

Output 83.1.1 One-Sided Fixed-Sample Design Information

The SEQDESIGN Procedure	
Design: OneSidedFixedSample	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Alternative Reference	0.25
Number of Stages	1
Alpha	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	100
Max Information	168.1188
Null Ref ASN (Percent of Fixed Sample)	100
Alt Ref ASN (Percent of Fixed Sample)	100

The “Method Information” table in [Output 83.1.2](#) displays the α and β error levels. It also displays the derived drift parameter, which is the standardized reference improvement, $\theta_1 \sqrt{I_0}$, where θ_1 is the alternative reference and I_0 is the maximum information for the design. If either θ_1 or I_0 is specified, the other statistic is derived in the SEQDESIGN procedure. For a fixed-sample design,

$$\theta_1 \sqrt{I_0} = \Phi^{-1}(1 - \alpha) + \Phi^{-1}(1 - \beta) = \Phi^{-1}(0.975) + \Phi^{-1}(0.90) = 3.2415$$

Output 83.1.2 Method Information

Method Information				
Boundary	Alpha	Beta	Alternative Reference	Drift
Upper Alpha	0.02500	0.10000	0.25	3.241516

The “Boundary Information” table in [Output 83.1.3](#) displays information level, alternative reference, and boundary value at each stage. The information proportion indicates the proportion of maximum information available at the stage. With only one stage for a fixed-sample design, the proportion is 1. With the SAMPLESIZE statement, the required sample size N is also displayed under the heading “Information Level.”

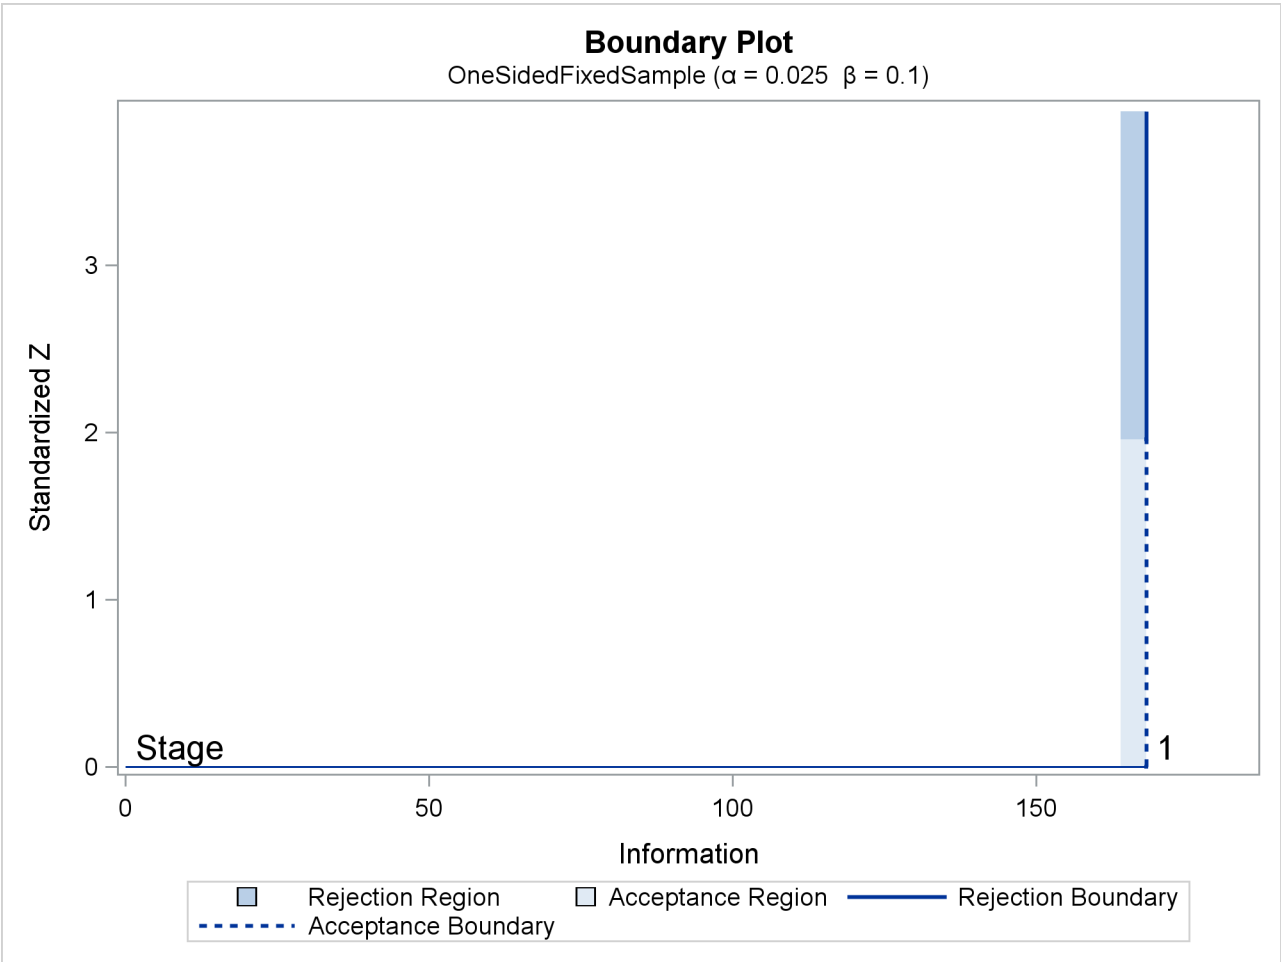

Output 83.1.3 Boundary Information

Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-Alternative- --Reference--	-Boundary Values-
	Proportion	Actual	N	Upper	-----Upper----- Alpha
1	1.0000	168.1188	168.1188	3.24152	1.95996

By default (or equivalently if you specify BOUNDARYSCALE=STDZ), output alternative references and boundaries are displayed with the standardized normal Z scale. The alternative reference on the standardized Z scale at stage 1 is given by $\theta_1 \sqrt{I_1}$, where I_1 is the information level at stage 1. With a boundary value 1.96, the hypothesis of $\theta = 0$ is rejected if the standardized normal statistic $Z \geq 1.96$.

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.1.4](#). The boundary values in the “Boundary Information” table in [Figure 83.1.3](#) are displayed in the plot.

Output 83.1.4 Boundary Plot

The “Sample Size Summary” table in [Output 83.1.5](#) displays parameters for the sample size computation of the test for a normal mean.

Output 83.1.5 Sample Size Summary

Sample Size Summary	
Test	One-Sample Mean
Mean	0.25
Standard Deviation	1
Max Sample Size	168.1188
Expected Sample Size (Null Ref)	168.1188
Expected Sample Size (Alt Ref)	168.1188

The “Sample Sizes (N)” table in [Output 83.1.6](#) displays the derived sample sizes, in both fractional and integer numbers. With the resulting integer sample sizes, the corresponding information level is slightly larger than the level from the design. This can increase the power slightly if the integer sample size is used in the trial.

Output 83.1.6 Derived Sample Sizes

Sample Sizes (N)				
One-Sample Z Test for Mean				
Stage	-----Fractional N-----		-----Ceiling N-----	
	N	Information	N	Information
1	168.12	168.1	169	169.0

The following statements request a two-sided fixed-sample design with a specified alternative reference:

```
ods graphics on;
proc seqdesign altref=1.2
    pss
    ;
    TwoSidedFixedSample: design nstages=1
        alt=twosided
        alpha=0.05 beta=0.10
    ;
    samplesize model=twosamplemean(stddev=2 weight=2);
run;
ods graphics off;
```

In the SEQDESIGN procedure, the null hypothesis for the design is $H_0 : \theta = 0$. The ALT=TWOSIDED option specifies a two-sided alternative hypothesis $H_1 : \theta = \theta_1 \neq 0$. The ALTREF=1.2 option in the PROC SEQDESIGN statement specifies the alternative reference $\theta_1 = \pm 1.2$.

The ALPHA=0.05 option (which is the default) specifies the two-sided Type I error probability level $\alpha = 0.05$. That is, the lower and upper Type I error probabilities $\alpha_l = \alpha_u = 0.025$. The BETA=0.10 option (which is the default) specifies the Type II error probability level $\beta = 0.10$, and the design has a power $1 - \beta = 0.90$ at the alternative reference $\theta_1 = \pm 1.2$.

The “Design Information” table in [Output 83.1.7](#) displays design specifications and the derived power. With a specified alternative reference, the maximum information is derived.

Output 83.1.7 Two-Sided Fixed-Sample Design Information

The SEQDESIGN Procedure	
Design: TwoSidedFixedSample	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Alternative Reference	1.2
Number of Stages	1
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	100
Max Information	7.296822
Null Ref ASN (Percent of Fixed Sample)	100
Alt Ref ASN (Percent of Fixed Sample)	100

The “Method Information” table in [Output 83.1.8](#) displays the α and β errors, alternative references, and drift parameter. For a fixed-sample design, the derived drift parameter

$$\theta_1 \sqrt{I_0} = \Phi^{-1}\left(1 - \frac{\alpha}{2}\right) + \Phi^{-1}(1 - \beta) = \Phi^{-1}(0.975) + \Phi^{-1}(0.90) = 3.2415$$

Output 83.1.8 Method Information

Method Information				
Boundary	Alpha	Beta	Alternative Reference	Drift
Upper Alpha	0.02500	0.10000	1.2	3.241516
Lower Alpha	0.02500	0.10000	-1.2	-3.24152

With a specified alternative reference $\theta_1 = 1.2$, the maximum information

$$I_0 = \left(\frac{3.2415}{1.2} \right)^2 = 7.2968$$

The default “Boundary Information” table in [Output 83.1.9](#) displays information level, alternative reference, and boundary values. By default (or equivalently if you specify BOUNDARYSCALE=STDZ), the alternative reference and boundary values are displayed with the standardized normal Z scale. Thus, the standardized alternative references $\pm\theta_1\sqrt{I_0}$ are displayed.

Output 83.1.9 Boundary Information

Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-----Alternative-----	
	Proportion	Actual	N	-----Reference-----	
				Lower	Upper
1	1.0000	7.296822	131.3428	-3.24152	3.24152
Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Boundary Values-----				
	---Lower---	---Upper---			
	Alpha	Alpha			
1	-1.95996	1.95996			

With boundary values of -1.96 and 1.96 , the hypothesis of $\theta = 0$ is rejected if the standardized normal statistic $Z \geq 1.96$ or $Z \leq -1.96$.

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.1.10](#). The boundary values in the “Boundary Information” table in [Figure 83.1.9](#) are displayed in the plot.

Output 83.1.10 Boundary Plot

The “Sample Size Summary” table in [Output 83.1.11](#) displays parameters for the sample size computation of the test for a normal mean.

Output 83.1.11 Sample Size Summary

Sample Size Summary	
Test	Two-Sample Means
Mean Difference	1.2
Standard Deviation	2
Max Sample Size	131.3428
Expected Sample Size (Null Ref)	131.3428
Expected Sample Size (Alt Ref)	131.3428
Weight (Group A)	2
Weight (Group B)	1

The “Sample Sizes (N)” table in [Output 83.1.12](#) displays the derived sample sizes, in both fractional and integer numbers. With the WEIGHT=2 option, the allocation ratio is 2 for the first group and 1 for the second group. With the resulting integer sample sizes, the corresponding information level is slightly larger

than the level from the design. This can increase the power slightly if the integer sample size is used in the trial.

Output 83.1.12 Derived Sample Sizes

Sample Sizes (N)				
Two-Sample Z Test for Mean Difference				
-----Fractional N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	131.34	87.56	43.78	7.2968
Sample Sizes (N)				
Two-Sample Z Test for Mean Difference				
-----Ceiling N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	132	88	44	7.3333

Example 83.2: Creating a One-Sided O'Brien-Fleming Design

This example demonstrates a group sequential design for a clinical study. A clinic is conducting a study on the effect of vitamin C supplements in treating flu symptoms. The study groups consist of patients in the clinic with their first sign of flu symptoms within the last 24 hours. These individuals are randomly assigned to either the control group, which receives the placebo pills, or the treatment group, which receives large doses of vitamin C supplements. At the end of a five-day period, the flu symptoms of each individual are recorded.

Suppose that from past experience, 60% of individuals experiencing flu symptoms have the symptoms disappeared within five days. The clinic wants to detect a 75% symptoms disappearance with a high probability in the trial. A test that compares the proportions directly is to specify a null hypothesis $H_0 : \theta = p_a - p_b = 0$ with a Type I error probability level $\alpha = 0.025$, where p_a and p_b are the proportions of symptoms' disappearance in the treatment group and control group, respectively. A one-sided alternative $H_1 : \theta > 0$ is also specified with a power of $1 - \beta = 0.90$ at $H_1 : \theta = 0.15$.

For a one-sided fixed-sample design, the critical value for the standardized Z test statistic is given by $C_\alpha = \Phi^{-1}(1 - \alpha) = 1.96$. That is, at the end of study, if the test statistic $z \geq C_\alpha$, then the null hypothesis is rejected and the efficacy of vitamin C supplements is declared. Otherwise, the null hypothesis is not rejected and the effect of vitamin C supplements is not significant.

To achieve a $1 - \beta = 0.90$ power at $H_1 : \theta = 0.15$ for a fixed-sample design, the information required is given by

$$I_0 = \frac{(\Phi^{-1}(1 - \alpha) + \Phi^{-1}(1 - \beta))^2}{0.15^2} = \frac{(1.96 + 1.28155)^2}{0.0225} = 466.99$$

With an equal sample size on the treatment and control groups, $N_a = N_b$, the sample size required for each group under H_1 is computed from the information I_0 :

$$N_a = N_b = (p_{1a}(1 - p_{1a}) + p_{1b}(1 - p_{1b})) I_0$$

where $p_{1a} = 0.75$ and $p_{1b} = 0.60$ are proportions in the treatment and control groups under H_1 . That is,

$$N_a = N_b = (0.75 \times 0.25 + 0.6 \times 0.4) \times 466.99 = 199.64$$

Thus, 200 individuals are required for each group in the fixed-sample study. See the section “[Test for the Difference between Two Binomial Proportions](#)” on page 7054 for a detailed derivation of these required sample sizes.

Instead of a fixed-sample design for the trial, a group sequential design is used to stop the trial early for ethical concerns of possible harm or an unexpected strong efficacy outcome of the new drug. It can also save time and resources in the process. The following statements invoke the SEQDESIGN procedure and request a four-stage group sequential design that uses an O’Brien-Fleming method for normally distributed statistics. The design uses a one-sided alternative hypothesis H_1 with early stopping to reject or accept H_0 .

```
ods graphics on;
proc seqdesign altref=0.15
    ;
    OneSidedOBrienFleming: design nstages=4
                           method=obf
                           alt=upper    stop=both
                           alpha=0.025 beta=0.10
    ;
    sample size model=twosamplefreq(nullprop=0.6 test=prop);
ods output Boundary=Bnd_Prop;
run;
ods graphics off;
```

In a sequential design, a hypothesis can be rejected, accepted, or continued to the next time point at each interim stage. The STOP=BOTH option specifies early stopping to reject or accept the null hypothesis. The “Design Information,” “Method Information,” and “Boundary Information” tables are displayed by default.

The “Design Information” table in [Output 83.2.1](#) displays design specifications and derived statistics such as power and maximum information. With a specified alternative reference, ALTREF=0.15, the maximum information I_X is derived.

Output 83.2.1 Design Information

The SEQDESIGN Procedure	
Design: OneSidedOBrienFleming	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	0.15
Number of Stages	4
Alpha	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	107.6741
Max Information	502.8343
Null Ref ASN (Percent of Fixed Sample)	61.12891
Alt Ref ASN (Percent of Fixed Sample)	75.89782

The Max Information (Percent Fixed-Sample) is the ratio in percentage between the maximum information for the group sequential design and the information required for a corresponding fixed-sample design:

$$100 \times \frac{I_X}{I_0} = 100 \times \frac{502.83}{466.99} = 107.67$$

That is, if the group sequential trial does not stop at any interim stages, the information needed is 7.67% more than is needed for the corresponding fixed-sample design. For a two-sample test for binomial proportions, the information is proportional to the sample size. Thus, 7.67% more observations are needed for the group sequential trial.

The Null Ref ASN (Percent Fixed-Sample) is the ratio in percentage between the expected sample size required under the null hypothesis for the group sequential design and the sample size required for the corresponding fixed-sample design. With a ratio of 61.1%, the expected sample size for the group sequential trial under the null hypothesis is 61.1% of the sample size in the corresponding fixed-sample design.

Similarly, the Alt Ref ASN (Percent Fixed-Sample) is the ratio in percentage between the expected sample size required under the alternative hypothesis for the group sequential design and the sample size required for the corresponding fixed-sample design. With a ratio of 75.9%, the expected sample size for the group sequential trial under the alternative hypothesis is 75.9% of the sample size in the corresponding fixed-sample design.

For a one-sided design with an upper alternative and early stopping to reject or accept the null hypothesis, upper α and β boundaries are created. The “Method Information” table in [Output 83.2.2](#) displays the Type I error probability α , the Type II error probability β , and the derived drift parameter. The drift parameter is the standardized reference improvement between the alternative and null hypotheses at the final stage. It is also the standardized alternative reference at the final stage if the null reference is zero.

Output 83.2.2 Method Information

Method Information						
Boundary	Method	Alpha	Beta	-----Unified Family-----		
				Rho	Tau	C
Upper Alpha	O'Brien-Fleming	0.02500	.	0.5	0	1.9784
Upper Beta	O'Brien-Fleming	.	0.10000	0.5	0	1.3852
Method Information						
		Alternative Reference		Drift		
Boundary						
Upper Alpha		0.15		3.363595		
Upper Beta		0.15		3.363595		

With the METHOD=OBF option, the O'Brien-Fleming method is used for each boundary. The O'Brien-Fleming method is one of the unified family methods, and the “Method Information” table displays the corresponding parameter ρ in the unified family method. The table also displays the critical values $C_\alpha = 1.9784$ for the α boundary and $C_\beta = 1.3852$ for the β boundary. These critical values are used to create the boundary values.

The “Boundary Information” table in [Output 83.2.3](#) displays information level, alternative reference, and boundary values at each stage. By default (or equivalently if you specify `BOUNDARYSCALE=STDZ`), the alternative references and boundary values are displayed with the standardized Z statistic scale. The resulting standardized alternative reference at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information level at stage k , $k = 1, 2, 3, 4$.

Output 83.2.3 Boundary Information

Boundary Information (Standardized Z Scale)						
Null Reference = 0						
Stage	-----Information Level-----			-Alternative- --Reference--	----Boundary Values----	
	Proportion	Actual	N	Upper	Beta	Alpha
1	0.2500	125.7086	107.4808	1.68180	-1.08860	3.95679
2	0.5000	251.4171	214.9617	2.37842	0.41946	2.79788
3	0.7500	377.1257	322.4425	2.91296	1.31347	2.28446
4	1.0000	502.8343	429.9233	3.36360	1.97840	1.97840

By default (or equivalently if you specify `INFO=EQUAL`), equally spaced information levels are used. An information proportion is the proportion of maximum information available at each stage. With the derived maximum information, the actual information level at each stage is also displayed. With the `SAMPLESIZE` statement, the required sample size N is also displayed under the heading “Information Level.”

At each interim stage, if the standardized Z test statistic is larger than or equal to the corresponding upper α boundary, then the hypothesis $H_0 : \theta = 0$ is rejected. If the test statistic is less than the corresponding upper β boundary, then the trial is stopped and the hypothesis H_0 is accepted. Otherwise, the process continues to the next stage. At the final stage, stage 4, the trial stops and the hypothesis H_0 is rejected if the standardized Z statistic $Z_4 \geq 1.9784$. Otherwise, the trial is accepted.

The `ODS OUTPUT` statement with the `BOUNDARY=BND_PROP` option creates an output data set that contains the resulting boundary information. After the actual data from the clinical trial are collected and analyzed at each stage with a procedure such as `PROC GENMOD`, the `SEQTEST` procedure is used to test the resulting statistics at stage 1 with the boundary information stored in the `BOUND_PROP` data set.

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.2.4](#).

Output 83.2.4 Boundary Plot

The horizontal axis indicates the information levels for the design. The stages are indicated by vertical lines with accompanying stage numbers. If at any stage a test statistic is in a rejection region, the trial stops and the hypothesis is rejected. If a test statistic is in an acceptance region, then the trial also stops and the hypothesis is accepted. If the statistic is not in a rejection region or an acceptance region, the trial continues to the next stage. The boundary plot also displays the information level and the critical value for the corresponding fixed-sample design.

The SEQDESIGN procedure derives the drift parameter $\theta_1 \sqrt{I_X}$, where θ_1 is the alternative reference and I_X is the maximum information. If either θ_1 or I_X is specified, the other can be derived. With the SAMPLESIZE statement, the maximum information is used to compute the required sample size for the study.

The “Sample Size Summary” table in [Output 83.2.5](#) displays parameters for the sample size computation. With the MODEL=TWOSAMPLEFREQ(NULLPROP=0.6 TEST=PROP) option in the SAMPLESIZE statement, the total sample size in each group for testing the difference between two proportions is computed. By default (or equivalently if you specify REF=PROP in the MODEL=TWOSAMPLEFREQ option), the required sample sizes are computed under the alternative hypothesis. That is,

$$N_a = N_b = (p_{1a}(1 - p_{1a}) + p_{1b}(1 - p_{1b})) I_X$$

where $p_{1b} = 0.60$ and $p_{1a} = p_{1b} + \theta_1 = 0.75$ are the proportions in the control and treatment groups, respectively, under the alternative hypothesis H_1 . See the section “[Test for the Difference between Two Binomial Proportions](#)” on page 7054 for a detailed description of these parameters.

Output 83.2.5 Sample Size Summary

Sample Size Summary	
Test	Two-Sample Proportions
Null Proportion	0.6
Proportion (Group A)	0.75
Test Statistic	Z for Proportion
Reference Proportions	Alt Ref
Max Sample Size	429.9233
Expected Sample Size (Null Ref)	244.0768
Expected Sample Size (Alt Ref)	303.0464

The “Sample Sizes (N)” table in [Output 83.2.6](#) displays the required sample sizes at each stage, in both fractional and integer numbers. The derived fractional sample sizes are under the heading “Fractional N.” These sample sizes are rounded up to integers under the heading “Ceiling N.” In practice, integer sample sizes are used, and the resulting information levels increase slightly. Thus, 54, 108, 162, and 215 individuals are needed in each group for the four stages, respectively.

Output 83.2.6 Derived Sample Sizes

Sample Sizes (N) Two-Sample Z Test for Proportion Difference				
-----Fractional N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	107.48	53.74	53.74	125.7
2	214.96	107.48	107.48	251.4
3	322.44	161.22	161.22	377.1
4	429.92	214.96	214.96	502.8

Sample Sizes (N) Two-Sample Z Test for Proportion Difference				
-----Ceiling N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	108	54	54	126.3
2	216	108	108	252.6
3	324	162	162	378.9
4	430	215	215	502.9

Example 83.3: Creating Two-Sided Pocock and O'Brien-Fleming Designs

This example requests two 4-stage group sequential designs for normally distributed statistics with equally spaced information levels at all stages. One design uses Pocock's method and the other uses the O'Brien-Fleming method. The following statements invoke the SEQDESIGN procedure and request these two designs:

```
proc seqdesign altref=0.4
    pss
    stopprob
    errspend
    ;
    TwoSidedPocock:      design nstages=4 method=poc;
    TwoSidedOBrienFleming: design nstages=4 method=obf;
    samplesize model=twosamplemean(stddev=0.8 weight=2);
run;
```

By default (or equivalently if you specify ALT=TWOSIDED and STOP=REJECT in the DESIGN statement), each design has a null hypothesis H_0 with a two-sided alternative with early stopping to reject H_0 .

The “Design Information” table in [Output 83.3.1](#) displays design specifications and derived statistics for the Pocock’s design. With the specified ALTREF= option, the maximum information $I_X = 77.6984$ is also derived.

Output 83.3.1 Pocock Design Information

The SEQDESIGN Procedure	
Design: TwoSidedPocock	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	Pocock
Boundary Key	Both
Alternative Reference	0.4
Number of Stages	4
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	118.3143
Max Information	77.69844
Null Ref ASN (Percent of Fixed Sample)	115.6074
Alt Ref ASN (Percent of Fixed Sample)	69.74805

With the corresponding fixed-sample information

$$I_0 = \frac{(\Phi^{-1}(1 - \alpha/2) + \Phi^{-1}(1 - \beta))^2}{0.4^2} = \frac{(1.96 + 1.28155)^2}{0.16} = 65.6728$$

the fixed-sample information ratio is $77.6984/65.6728 = 1.1831$.

For a two-sided design with early stopping to reject the null hypothesis, lower and upper α boundaries are created. The “Method Information” table in [Output 83.3.2](#) displays the α and β errors, alternative references, and derived drift parameters, which are the standardized alternative references at the final stage.

Output 83.3.2 Method Information

Method Information						
Boundary	Method	Alpha	Beta	-----Unified Family-----		
				Rho	Tau	C
Upper Alpha	Pocock	0.02500	0.10000	0	0	2.36129
Lower Alpha	Pocock	0.02500	0.10000	0	0	2.36129
Method Information						
Boundary	Alternative		Drift			
	Reference					
Upper Alpha	0.4		3.525869			
Lower Alpha	-0.4		-3.52587			

With the METHOD=POC option, the Pocock method is used for each boundary. The Pocock method is one of the unified family methods, and the table also displays its corresponding parameters $\rho = 0$ as a unified family method and the derived parameters $C = 2.3613$ for the boundary values.

With the PSS option, the “Power and Expected Sample Sizes” table in [Output 83.3.3](#) displays powers and expected sample sizes under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option. By default, $c_i = 0, 0.5, 1.0, 1.5$.

Output 83.3.3 Power and Expected Sample Size Information

Powers and Expected Sample Sizes		
Reference = CRef * (Alt Reference)		
CRef	Power	-Sample Size-
		Percent
		Fixed-Sample
0.0000	0.02500	115.6074
0.5000	0.34252	104.0615
1.0000	0.90000	69.7480
1.5000	0.99869	43.6600

Note that at $c_i = 0$, the null reference $\theta = 0$, and the power 0.025 corresponds to the one-sided Type I error probability 0.025. At $c_i = 1$, $\theta = \theta_1$, the power 0.9 is the power of the design. The expected sample sizes are displayed in a percentage scale to its corresponding fixed-sample size design. With the specified SAMPLESIZE statement, the expected sample sizes for the specified model in the SAMPLESIZE statement are also displayed.

With the STOPPROB option, the “Expected Cumulative Stopping Probabilities” table in [Output 83.3.4](#) displays the expected cumulative stopping stage and cumulative stopping probability to reject the null hypothesis H_0 at each stage under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option. By default, $c_i = 0, 0.5, 1.0, 1.5$.

Output 83.3.4 Stopping Probabilities

Expected Cumulative Stopping Probabilities Reference = CRef * (Alt Reference)							
CRef	Expected Stopping Stage	Source	-----Stopping Probabilities-----				
			Stage_1	Stage_2	Stage_3	Stage_4	
0.0000	3.908	Reject Null	0.01821	0.03155	0.04176	0.05000	
0.5000	3.518	Reject Null	0.07005	0.15939	0.25242	0.34327	
1.0000	2.358	Reject Null	0.27482	0.58074	0.78638	0.90002	
1.5000	1.476	Reject Null	0.61145	0.92348	0.98900	0.99869	

Note that at $c_i = 0$, the cumulative stopping probability to reject H_0 at the final stage is the overall Type I error probability 0.05. At $c_i = 1$, the alternative hypothesis $H_1 : \theta = \theta_1$, the cumulative stopping probability to reject H_0 includes both the probability in the lower rejection region and the probability in the upper rejection region. This stopping probability to reject H_0 at the final stage, 0.90002, is slightly greater than the power $1 - \beta = 0.90$, which corresponds to the cumulative stopping probability in the upper rejection region only. See the section “[Type I and Type II Errors](#)” on page 7022 for a detailed description of the Type II error probability β .

The “Boundary Information” table in [Output 83.3.5](#) displays the information level, alternative references, and boundary values at each stage. By default (or equivalently if you specify BOUNDARYSCALE=STDZ), the standardized Z scale is used to display the alternative references and boundary values. The resulting standardized alternative reference at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information level at stage k , $k = 1, 2, 3, 4$.

Output 83.3.5 Boundary Information

Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-----Alternative-----	
	Proportion	Actual	N	-----Reference-----	
				Lower	Upper
1	0.2500	19.42461	55.94288	-1.76293	1.76293
2	0.5000	38.84922	111.8858	-2.49317	2.49317
3	0.7500	58.27383	167.8286	-3.05349	3.05349
4	1.0000	77.69844	223.7715	-3.52587	3.52587

Boundary Information (Standardized Z Scale)		
Null Reference = 0		
Stage	-----Boundary Values-----	
	---Lower--- Alpha	---Upper--- Alpha
1	-2.36129	2.36129
2	-2.36129	2.36129
3	-2.36129	2.36129
4	-2.36129	2.36129

By default (or equivalently if you specify INFO=EQUAL in the DESIGN statement), equally spaced information levels are used. With the SAMPLESIZE statement, the required sample size N is also displayed under the heading “Information Level.” With the Pocock method, the standardized Z boundary values are identical at all stages for each α boundary.

At each interim stage, the hypothesis of $H_0 : \theta = 0$ is rejected if the standardized normal test statistic $z \leq -2.36129$, the lower α boundary, or $z \geq 2.36129$, the upper α boundary. Otherwise, the trial continues to the next stage. At the final stage, stage 4, the trial stops and the hypothesis is rejected if the test statistic $|z_4| \geq 2.36129$. Otherwise, the hypothesis is accepted.

The “Error Spending Information” in [Output 83.3.6](#) displays cumulative error spending at each stage for each boundary. It shows that more α errors are used in early stages than in later stages.

Output 83.3.6 Error Spending Information

Error Spending Information					
Stage	-Information Level- Proportion	-----Cumulative Error Spending-----			
		-----Lower-----		-----Upper-----	
		Alpha	Beta	Beta	Alpha
1	0.2500	0.00911	0.00002	0.00002	0.00911
2	0.5000	0.01577	0.00002	0.00002	0.01577
3	0.7500	0.02088	0.00002	0.00002	0.02088
4	1.0000	0.02500	0.10000	0.10000	0.02500

The “Sample Size Summary” table in [Output 83.3.7](#) displays the specified parameters for the sample size computation of the two-sample test for mean difference.

Output 83.3.7 Sample Size Summary

Sample Size Summary	
Test	Two-Sample Means
Mean Difference	0.4
Standard Deviation	0.8
Max Sample Size	223.7715
Expected Sample Size (Null Ref)	218.652
Expected Sample Size (Alt Ref)	131.9167
Weight (Group A)	2
Weight (Group B)	1

The “Sample Sizes (N)” table in [Output 83.3.8](#) displays the derived sample sizes at each stage, in both fractional and integer numbers. With the WEIGHT=2 option, the allocation ratio is 2 for the first group and 1 for the second group. See the section “[Test for the Difference between Two Normal Means](#)” on page 7053 for the derivation of these sample sizes. With the fixed-sample information ratio 1.1831, the derived sample sizes in fractional numbers are derived by multiplying 1.1831 by the corresponding sample sizes in the fixed-sample design.

Output 83.3.8 Sample Sizes

Sample Sizes (N)				
Two-Sample Z Test for Mean Difference				
-----Fractional N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	55.94	37.30	18.65	19.4246
2	111.89	74.59	37.30	38.8492
3	167.83	111.89	55.94	58.2738
4	223.77	149.18	74.59	77.6984
Sample Sizes (N)				
Two-Sample Z Test for Mean Difference				
-----Ceiling N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	57	38	19	19.7917
2	113	75	38	39.4082
3	168	112	56	58.3333
4	225	150	75	78.1250

These fractional sample sizes are rounded up to integers under the heading “Ceiling N.” When the resulting integer sample sizes are used, the corresponding information levels are slightly larger than the levels from the design. This can increase the power slightly if a trial uses these integer sample sizes.

Note that compared with other designs, a Pocock design can stop the trial early with a larger p -value. However, this might not be persuasive enough to make a new treatment widely accepted (Pocock and White 1999).

The “Design Information” table in [Output 83.3.9](#) displays design specifications and the derived statistics for the O’Brien-Fleming design. With the specified ALTREF= option, the maximum information $I_X = 67.1268$ is derived.

Output 83.3.9 O’Brien-Fleming Design Information

The SEQDESIGN Procedure	
Design: TwoSidedOBrienFleming	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	0.4
Number of Stages	4
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	102.2163
Max Information	67.12682
Null Ref ASN (Percent of Fixed Sample)	101.5728
Alt Ref ASN (Percent of Fixed Sample)	76.7397

With the corresponding fixed-sample information

$$I_0 = \frac{(\Phi^{-1}(1 - \alpha/2) + \Phi^{-1}(1 - \beta))^2}{0.4^2} = \frac{(1.96 + 1.28155)^2}{0.16} = 65.6728$$

the fixed-sample information ratio is $67.1268/65.6728 = 1.022$. That is, the maximum information for the O’Brien-Fleming design is only 2.2% more than for the corresponding fixed-sample design.

The “Method Information” table in [Output 83.3.10](#) displays the Type I α level and Type II β level. It also displays the derived drift parameter $\theta_1 \sqrt{I_X}$, which is the standardized alternative reference at the final stage.

Output 83.3.10 Method Information

Method Information						
Boundary	Method	Alpha	Beta	-----Unified Family-----		
				Rho	Tau	C
Upper Alpha	O'Brien-Fleming	0.02500	0.10000	0.5	0	2.02429
Lower Alpha	O'Brien-Fleming	0.02500	0.10000	0.5	0	2.02429
Method Information						
Boundary	Alternative Reference		Drift			
Upper Alpha	0.4		3.277238			
Lower Alpha	-0.4		-3.27724			

With the METHOD=OBF option, the O'Brien-Fleming method is used for each boundary. The O'Brien-Fleming method is one of the unified family methods, and the table also displays its corresponding parameters $\rho = 0.5$ as a unified family method and the derived parameter $C = 2.0243$ for the boundary values.

With the PSS option, the "Power and Expected Sample Sizes" table in [Output 83.3.11](#) displays powers and expected sample sizes under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option.

Output 83.3.11 Power and Expected Sample Size Information

Powers and Expected Sample Sizes		
Reference = CRef * (Alt Reference)		
CRef	Power	-Sample Size-
		Percent
		Fixed-Sample
0.0000	0.02500	101.5728
0.5000	0.36495	96.3684
1.0000	0.90000	76.7397
1.5000	0.99821	57.2590

Compared with the corresponding Pocock design, the O'Brien-Fleming design has a smaller maximum sample size, and smaller expected sample sizes under hypothetical references $\theta = 0$ and $\theta = 0.5 \theta_1$, but larger expected sample sizes under hypothetical references $\theta = \theta_1$ and $\theta = 1.5 \theta_1$.

With the STOPPROB option, the "Expected Cumulative Stopping Probabilities" table in [Output 83.3.12](#) displays the expected stopping stage and cumulative stopping probability to reject the null hypothesis at each stage under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option.

Output 83.3.12 Stopping Probabilities

Expected Cumulative Stopping Probabilities Reference = CRef * (Alt Reference)							
CRef	Expected Stopping Stage	Source	-----Stopping Probabilities-----				
			Stage_1	Stage_2	Stage_3	Stage_4	
0.0000	3.975	Reject Null	0.00005	0.00422	0.02091	0.05000	
0.5000	3.771	Reject Null	0.00062	0.04430	0.18392	0.36515	
1.0000	3.003	Reject Null	0.00798	0.29296	0.69603	0.90000	
1.5000	2.241	Reject Null	0.05584	0.73031	0.97315	0.99821	

Compared with the corresponding Pocock design, the O'Brien-Fleming design has smaller stopping probabilities in early stages under each hypothetical reference.

The "Boundary Information" table in [Output 83.3.13](#) displays the boundary values for the design that uses the O'Brien-Fleming method. Compared with the Pocock method, the standardized statistics α boundary values derived from the O'Brien-Fleming method in absolute values are larger in early stages and smaller in later stages. This makes the O'Brien-Fleming design less likely to reject the null hypothesis in early stages than the Pocock design. With the derived parameter $C = 2.0243$ for the α boundary, the α boundaries at stage j are computed as $C\sqrt{4/j}$, $j = 1, \dots, 4$.

Output 83.3.13 Boundary Information

Boundary Information (Standardized Z Scale) Null Reference = 0					
Stage	-----Information Level-----			-----Alternative----- -----Reference-----	
	Proportion	Actual	N	Lower	Upper
1	0.2500	16.7817	48.33131	-1.63862	1.63862
2	0.5000	33.56341	96.66262	-2.31736	2.31736
3	0.7500	50.34511	144.9939	-2.83817	2.83817
4	1.0000	67.12682	193.3252	-3.27724	3.27724

Boundary Information (Standardized Z Scale) Null Reference = 0			
Stage	-----Boundary Values-----		
	---Lower--- Alpha	---Upper--- Alpha	
1	-4.04859	4.04859	
2	-2.86278	2.86278	
3	-2.33745	2.33745	
4	-2.02429	2.02429	

The “Error Spending Information” in [Output 83.3.14](#) displays cumulative error spending at each stage for each boundary. With smaller α spending in early stages for the O'Brien-Fleming method, it also indicates that the O'Brien-Fleming design is less likely to reject the null hypothesis in early stages than the Pocock design.

Output 83.3.14 Error Spending Information

Error Spending Information					
Stage	-Information Level- Proportion	-----Cumulative Error Spending-----			
		-----Lower-----		-----Upper-----	
		Alpha	Beta	Beta	Alpha
1	0.2500	0.00003	0.00000	0.00000	0.00003
2	0.5000	0.00211	0.00000	0.00000	0.00211
3	0.7500	0.01046	0.00000	0.00000	0.01046
4	1.0000	0.02500	0.10000	0.10000	0.02500

The “Sample Size Summary” table in [Output 83.3.15](#) displays the specified parameters for the sample size computation of the two-sample test for mean difference.

Output 83.3.15 Sample Size Summary

Sample Size Summary	
Test	Two-Sample Means
Mean Difference	0.4
Standard Deviation	0.8
Max Sample Size	193.3252
Expected Sample Size (Null Ref)	192.1081
Expected Sample Size (Alt Ref)	145.1404
Weight (Group A)	2
Weight (Group B)	1

The “Sample Sizes (N)” table in [Output 83.3.16](#) displays the derived sample sizes at each stage, in both fractional and integer numbers. With the fixed-sample information ratio 1.0222, the required sample sizes in fractional numbers are derived by multiplying 1.0222 by the corresponding sample sizes in the fixed-sample design.

Output 83.3.16 Derived Sample Sizes

Sample Sizes (N)				
Two-Sample Z Test for Mean Difference				
-----Fractional N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	48.33	32.22	16.11	16.7817
2	96.66	64.44	32.22	33.5634
3	144.99	96.66	48.33	50.3451
4	193.33	128.88	64.44	67.1268

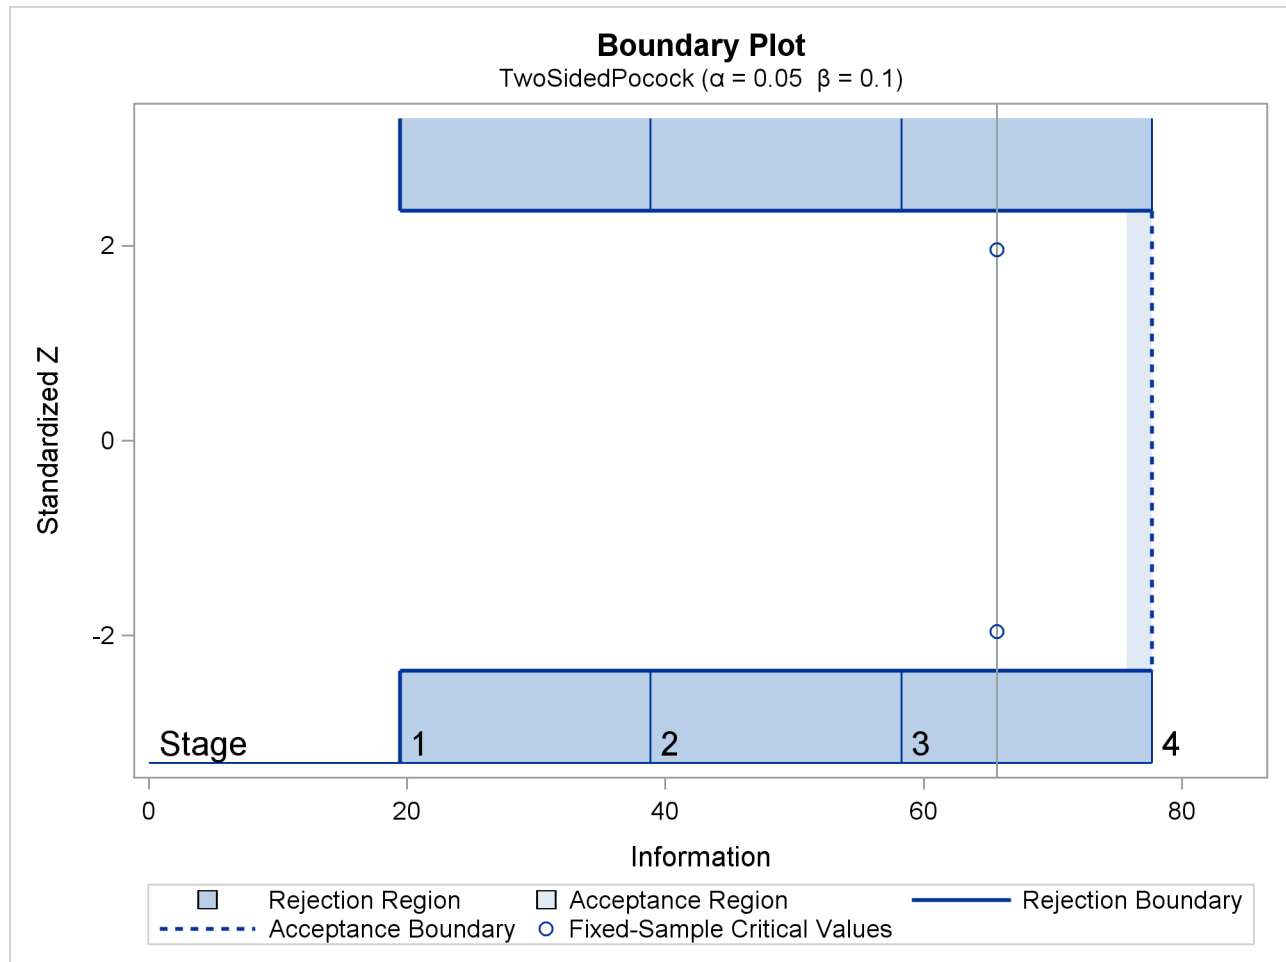

Sample Sizes (N)				
Two-Sample Z Test for Mean Difference				
-----Ceiling N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	50	33	17	17.5313
2	98	65	33	34.1996
3	146	97	49	50.8669
4	194	129	65	67.5338

Example 83.4: Generating Graphics Display for Sequential Designs

This example creates the same group sequential design as in [Example 83.3](#) and creates graphics by using ODS Graphics. The following statements request all available graphs in the SEQDESIGN procedure:

```
ods graphics on;
proc seqdesign altref=0.4
    plots=all
    ;
    TwoSidedPocock:      design nstages=4 method=poc;
    TwoSidedOBrienFleming: design nstages=4 method=obf;
run;
ods graphics off;
```

With the PLOTS=ALL option, a detailed boundary plot with the rejection region and acceptance region is displayed for the Pocock design, as shown in [Output 83.4.1](#). By default (or equivalently if you specify STOP=REJECT), the rejection boundaries are also generated at interim stages.

Output 83.4.1 Pocock Boundary Plot

The plot shows identical boundary values in each boundary in the standardized Z scale for the Pocock design. The information level and the critical value for the corresponding fixed-sample design are also displayed.

With the PLOTS=ALL option, a detailed boundary plot with the rejection region and acceptance region is also displayed for the O'Brien-Fleming design, as shown in [Output 83.4.2](#). The plot shows that the rejection boundary values are decreasing as the trial advances in the standardized Z scale.

Output 83.4.2 O'Brien-Fleming Boundary Plot

With the PLOTS=ALL option, the procedure displays a plot of average sample numbers (expected sample sizes for nonsurvival data or expected numbers of events for survival data) under various hypothetical references for all designs simultaneously, as shown in [Output 83.4.3](#). By default, the option CREF= 0, 0.01, 0.02, ..., 1.50 and expected sample sizes under the hypothetical references $\theta = c_i \theta_1$ are displayed, where c_i are values specified in the CREF= option. These CREF= values are displayed on the horizontal axis.

Output 83.4.3 ASN Plot

The plot shows that the Pocock design has a larger expected sample size than the O'Brien-Fleming design under the null hypothesis ($c_i = 0$) and has a smaller expected sample size under the alternative hypothesis ($c_i = 1$).

With the PLOTS=ALL option, the procedure displays a plot of the power curves under various hypothetical references for all designs simultaneously, as shown in [Output 83.4.4](#). By default, the option CREF= 0, 0.01, 0.02, ..., 1.50 and powers under hypothetical references $\theta = c_i \theta_1$ are displayed, where c_i are values specified in the CREF= option. These CREF= values are displayed on the horizontal axis.

Output 83.4.4 Power Plot

Under the null hypothesis, $c_i = 0$, the power is 0.025, the upper Type I error probability. Under the alternative hypothesis, $c_i = 1$, the power is 0.9, one minus the Type II error probability. The plot shows only minor difference between the two designs.

With the PLOTS=ALL option, the procedure displays a plot of sequential boundaries for all designs simultaneously, as shown in [Output 83.4.5](#). By default (or equivalently if you specify HSCALE=INFO in the COMBINEDBOUNDARY option), the information levels are used on the horizontal axis.

Output 83.4.5 Combined Boundary Plot

The plot shows that the α boundary values (in absolute value) created from the O'Brien-Fleming method are greater in early stages and smaller in later stages than the boundary values from the Pocock method. The plot also shows that the information level in the Pocock design is larger than the corresponding level in the O'Brien-Fleming design at each stage.

With the PLOTS=ALL option, the procedure displays a plot of cumulative error spends for all boundaries in the designs simultaneously, as shown in [Output 83.4.6](#). With a symmetric two-sided design, cumulative error spending is displayed only for the upper α boundary. The plot shows that for the upper α boundary, the O'Brien-Fleming method spends fewer errors in early stages and more errors in later stages than the corresponding Pocock method.

Output 83.4.6 Error Spending Plot

Example 83.5: Creating Designs Using Haybittle-Peto Methods

This example requests two 3-stage group sequential designs for normally distributed statistics. Each design uses a Haybittle-Peto method with a two-sided alternative and early stopping to reject the hypothesis. One design uses the specified interim boundary Z values and derives the final-stage boundary value for the specified α and β errors. The other design uses the specified boundary Z values and derives the overall α and β errors.

The following statements specify the interim boundary Z values and derive the final-stage boundary value for the specified $\alpha = 0.05$ and $\beta = 0.10$:

```
ods graphics on;
proc seqdesign altref=0.25
    errspend
    stopprob
    plots=errspend
;
```

```

OneSidedPeto: design nstages=3
               method=peto( z=3)
               alt=upper    stop=reject
               alpha=0.05   beta=0.10;

run;
ods graphics off;

```

The “Design Information” table in [Output 83.5.1](#) displays design specifications and maximum information in percentage of its corresponding fixed-sample design.

Output 83.5.1 Haybittle-Peto Design Information

The SEQDESIGN Procedure	
Design: OneSidedPeto	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Reject Null
Method	Haybittle-Peto
Boundary Key	Both
Alternative Reference	0.25
Number of Stages	3
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	100.2466
Max Information	137.3592
Null Ref ASN (Percent of Fixed Sample)	100.1192
Alt Ref ASN (Percent of Fixed Sample)	87.35

The “Method Information” table in [Output 83.5.2](#) displays the α and β errors and the derived drift parameter, which is the standardized alternative reference at the final stage.

Output 83.5.2 Method Information

Method Information					
Boundary	Method	Alpha	Beta	Alternative Reference	Drift
Upper Alpha	Haybittle-Peto	0.05000	0.10000	0.25	2.930009

With the STOPPROB option, the “Expected Cumulative Stopping Probabilities” table in [Output 83.5.3](#) displays the expected stopping stage and cumulative stopping probability to reject the null hypothesis at each stage under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ are the default values in the CREF= option.

Output 83.5.3 Stopping Probabilities

Expected Cumulative Stopping Probabilities Reference = CRef * (Alt Reference)						
CRef	Expected Stopping Stage	Source		----Stopping Probabilities----		
				Stage_1	Stage_2	Stage_3
0.0000	2.996	Reject	Null	0.00135	0.00246	0.05000
0.5000	2.941	Reject	Null	0.01561	0.04372	0.42762
1.0000	2.614	Reject	Null	0.09538	0.29057	0.90000
1.5000	1.944	Reject	Null	0.32185	0.73442	0.99698

The “Boundary Information” table in [Output 83.5.4](#) displays information level, alternative references, and boundary values. By default (or equivalently if you specify BOUNDARYSCALE=STDZ), the standardized Z scale is used to display the alternative references and boundary values. The resulting standardized alternative reference at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information level at stage k , $k = 1, 2, 3$.

Output 83.5.4 Boundary Information

Boundary Information (Standardized Z Scale) Null Reference = 0				
Stage	---Information Level---		-Alternative- --Reference--	-Boundary Values-
	Proportion	Actual	Upper	-----Upper----- Alpha
1	0.3333	45.7864	1.69164	3.00000
2	0.6667	91.57281	2.39234	3.00000
3	1.0000	137.3592	2.93001	1.65042

At each interim stage, if the standardized statistic $z \geq 3$, the trial is stopped and the null hypothesis is rejected. If the statistic $z < 3$, the trial continues to the next stage. At the final stage, the null hypothesis is rejected if the statistic $z_3 > 1.65$. Otherwise, the hypothesis is accepted. Note that the boundary values at the final stage, 1.65, are close to the critical values 1.645 in the corresponding fixed-sample design.

The “Error Spending Information” in [Output 83.5.5](#) displays cumulative error spending at each stage for each boundary. The stage 1 α spending 0.00135 corresponds to the one-sided p -value for a standardized Z statistic, $Z > 3$.

Output 83.5.5 Error Spending Information

Error Spending Information				
Stage	-Information Level- Proportion	-Cumulative Error Spending- -----Upper-----		
		Beta	Alpha	
1	0.3333	0.00000	0.00135	
2	0.6667	0.00000	0.00246	
3	1.0000	0.10000	0.05000	

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.5.6](#). With the STOP=REJECT option, the interim rejection boundaries are displayed.

Output 83.5.6 Boundary Plot

With the PLOTS=ERRSPEND option, the procedure displays a plot of error spending for each boundary, as shown in [Output 83.5.7](#). The error spending values in the “Error Spending Information” in [Output 83.5.4](#) are displayed in the plot. As expected, the error spending at each of the first two stages is small, with the standardized Z boundary value 3.

Output 83.5.7 Error Spending Plot

The following statements specify the boundary Z values and derive the α and β errors from these completely specified boundary values:

```
ods graphics on;
proc seqdesign altref=0.25
    maxinfo=200
    errspend
    stopprob
    plots=errspend
;
    OneSidedPeto: design nstages=3
        method=peto(z=3 2.5 2)
        alt=upper stop=reject
        boundarykey=none
;
run;
ods graphics off;
```

The “Design Information” table in [Output 83.5.8](#) displays design specifications and derived α and β error levels.

Output 83.5.8 Design Information

The SEQDESIGN Procedure	
Design: OneSidedPeto	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Reject Null
Method	Haybittle-Peto
Boundary Key	None
Alternative Reference	0.25
Number of Stages	3
Alpha	0.02532
Beta	0.06035
Power	0.93965
Max Information (Percent of Fixed Sample)	101.6769
Max Information	200
Null Ref ASN (Percent of Fixed Sample)	101.3933
Alt Ref ASN (Percent of Fixed Sample)	73.74031

The “Method Information” table in [Output 83.5.9](#) displays the α and β errors and the derived drift parameter for each boundary.

Output 83.5.9 Method Information

Method Information					
Boundary	Method	Alpha	Beta	Alternative Reference	Drift
Upper Alpha	Haybittle-Peto	0.02532	0.06035	0.25	3.535534

With the STOPPROB option, the “Expected Cumulative Stopping Probabilities” table in [Output 83.5.10](#) displays the expected stopping stage and cumulative stopping probability to reject the null hypothesis at each stage under various hypothetical references $\theta = c_i\theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ are the default values in the CREF= option.

Output 83.5.10 Stopping Probabilities

Expected Cumulative Stopping Probabilities Reference = CRef * (Alt Reference)						
CRef	Expected Stopping Stage	Source		----Stopping Probabilities----		
				Stage_1	Stage_2	Stage_3
0.0000	2.992	Reject	Null	0.00135	0.00702	0.02532
0.5000	2.826	Reject	Null	0.02389	0.15030	0.41775
1.0000	2.176	Reject	Null	0.16884	0.65544	0.93965
1.5000	1.508	Reject	Null	0.52466	0.96708	0.99954

The “Boundary Information” table in [Output 83.5.11](#) displays information level, alternative references, and boundary values.

Output 83.5.11 Boundary Information

Boundary Information (Standardized Z Scale) Null Reference = 0				
Stage	---Information Level---		-Alternative- --Reference--	-Boundary Values-
	Proportion	Actual	Upper	-----Upper----- Alpha
1	0.3333	66.66667	2.04124	3.00000
2	0.6667	133.3333	2.88675	2.50000
3	1.0000	200	3.53553	2.00000

The “Error Spending Information” in [Output 83.5.12](#) displays cumulative error spending at each stage for each boundary. The first-stage α spending 0.00135 corresponds to the one-sided p -value for a standardized Z statistic, $Z > 3$.

Output 83.5.12 Error Spending Information

Error Spending Information				
Stage	-Information Level-		-Cumulative Error Spending-	
	Proportion		-----Upper----- Beta	Alpha
1	0.3333		0.00000	0.00135
2	0.6667		0.00000	0.00702
3	1.0000		0.06035	0.02532

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.5.13](#). With the STOP=REJECT option, the interim rejection boundaries are displayed.

Output 83.5.13 Boundary Plot

With the PLOTS=ERRSPEND option, the procedure displays a plot of error spending for each boundary, as shown in [Output 83.5.14](#). The error spending values in the “Error Spending Information” table in [Output 83.5.10](#) are displayed in the plot.

Output 83.5.14 Error Spending Plot

Example 83.6: Creating Designs with Various Stopping Criteria

This example requests three 5-stage group sequential designs for normally distributed statistics. Each design uses a triangular method with the specified one-sided upper alternative reference $\theta_1 = 0.2$. The resulting boundary values are displayed with the score scale. Note that these unified family triangular designs are different from Whitehead's triangular designs.

The following statements request three designs with different stopping criterion:

```
ods graphics on;
proc seqdesign altref=0.2
    bscale=score
    errspend
    plots=(combinedboundary errspend(hscale=info))
;
    StopToRejectAccept: design nstages=5 method=tri alt=upper stop=both;
    StopToReject:       design nstages=5 method=tri alt=upper stop=reject;
    StopToAccept:       design nstages=5 method=tri alt=upper stop=accept;
run;
ods graphics off;
```

The first design has early stopping to reject or accept the null hypothesis H_0 .

The “Design Information” table in [Output 83.6.1](#) displays design specifications and derived statistics. With the specified alternative reference, the maximum information is derived.

Output 83.6.1 Triangular Design Information

The SEQDESIGN Procedure	
Design: StopToRejectAccept	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Score
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Method	Triangular
Boundary Key	Both
Alternative Reference	0.2
Number of Stages	5
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	140.0293
Max Information	299.797
Null Ref ASN (Percent of Fixed Sample)	59.11973
Alt Ref ASN (Percent of Fixed Sample)	66.94909

The “Method Information” table in [Output 83.6.2](#) displays the α and β errors and the derived drift parameter, which is the standardized alternative reference at the final stage. The table also shows the corresponding parameters for a triangular method as a unified family method.

Output 83.6.2 Method Information

Method Information						
Boundary	Method	Alpha	Beta	-----Unified Family-----		
				Rho	Tau	C
Upper Alpha	Triangular	0.05000	.	0.5	1	0.94394
Upper Beta	Triangular	.	0.10000	0.5	1	0.78753
Method Information						
Boundary	Alternative Reference		Drift			
Upper Alpha	0.2		3.46293			
Upper Beta	0.2		3.46293			

The “Boundary Information” table in [Output 83.6.3](#) displays information level, alternative reference, and boundary values. With the specified BOUNDARYSCALE=SCORE option, the alternative reference and boundary values are displayed in the score statistic scale. With a score scale, the alternative reference is $\theta_1 I_k$, where θ_1 is the specified alternative reference and I_k is the information level at stage k , $k = 1, 2, \dots, 5$.

Output 83.6.3 Boundary Information

Boundary Information (Score Scale)					
Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values-----	
	Proportion	Actual	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2000	59.9594	11.99188	-4.37102	19.61274
2	0.4000	119.9188	23.98376	4.89371	22.88154
3	0.6000	179.8782	35.97564	14.15845	26.15033
4	0.8000	239.8376	47.96752	23.42318	29.41912
5	1.0000	299.797	59.95940	32.68791	32.68791

The “Error Spending Information” table in [Output 83.6.4](#) displays cumulative error spending at each stage for each boundary.

Output 83.6.4 Error Spending Information

Error Spending Information				
Stage	-Information Level-		-Cumulative Error Spending-	
	Proportion		-----Upper----- Beta	Alpha
1	0.2000		0.01729	0.00566
2	0.4000		0.04927	0.02138
3	0.6000		0.07611	0.03643
4	0.8000		0.09357	0.04641
5	1.0000		0.10000	0.05000

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.6.5](#). With the STOP=BOTH option, both the acceptance and rejection boundaries at interim stages are displayed. With the score scale, the acceptance and rejection boundaries are straight lines and form a triangular-shape continuation region.

Output 83.6.5 Boundary Plot with Score Statistics

The second design has early stopping only to reject the null hypothesis H_0 .

The “Design Information” table in [Output 83.6.6](#) displays design specifications and derived statistics. With the specified alternative reference, the maximum information is derived.

Output 83.6.6 Triangular Design Information

The SEQDESIGN Procedure	
Design: StopToReject	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Score
Alternative Hypothesis	Upper
Early Stop	Reject Null
Method	Triangular
Boundary Key	Both
Alternative Reference	0.2

4	0.8000	196.9556	39.39112	16.18834
5	1.0000	246.1945	49.23890	23.45803

The “Error Spending Information” table in [Output 83.6.14](#) displays cumulative error spending at each stage for each boundary.

Output 83.6.14 Error Spending Information

Error Spending Information				
Stage	-Information Level-		-Cumulative Error Spending-	
	Proportion		-----Upper----- Beta	Alpha
1	0.2000		0.01375	0.00000
2	0.4000		0.04149	0.00000
3	0.6000		0.06594	0.00000
4	0.8000		0.08513	0.00000
5	1.0000		0.10000	0.05000

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.6.15](#). For a triangular design, these rejection boundaries form a straight line with the score scale.

Output 83.6.15 Boundary Plot with Score Scale

With the PLOTS=COMBINEDBOUNDARY option, a plot of the resulting sequential boundaries for all designs is displayed, as shown in [Output 83.6.16](#). The plot shows that the design with early stopping to reject and to accept H_0 has larger maximum information than the other two designs.

Output 83.6.16 Combined Boundary Plot with Score Scale

With the `PLOTS=ERRSPEND(HSCALE=INFO)` option, the error spending plot is displayed with the information level on the horizontal axis, as shown in [Output 83.6.17](#). The design with early stopping to reject or accept the null hypothesis H_0 has larger α spending and larger β spending in early stages than the other two designs.

Output 83.6.17 Error Spending Plot

Example 83.7: Creating Whitehead's Triangular Designs

This example requests three 4-stage Whitehead's triangular designs for normally distributed statistics. Each design has a one-sided alternative hypothesis with early stopping to reject or accept the null hypothesis H_0 . Note that Whitehead's triangular designs are different from unified family triangular designs.

Suppose that a clinic is conducting a study of the effect of a new cancer treatment. The study consists of exposing mice to a carcinogen and randomly assigning them to either the control group or the treatment group. The event of interest is death from cancer induced by the carcinogen, and the response is the time from randomization to death.

Following the derivations in the section “Test for Two Survival Distributions with a Log-Rank Test” on page 7059, the hypothesis $H_0 : \theta = -\log(\lambda) = 0$ with an alternative hypothesis $H_1 : \theta = \theta_1 > 0$ is used, where λ is the hazard ratio between the treatment group and the control group.

Also suppose that from past experience, the median survival time for the control group is $t_0 = 20$ weeks, and the study wants to detect a $t_1 = 40$ weeks' median survival time with a 80% power in the trial. Assuming exponential survival functions for the two groups, the hazard rates can be computed from

$$S_j(t_j) = e^{-h_j t_j} = \frac{1}{2}$$

where $j = 0, 1$.

Thus, with $h_0 = 0.03466$ and $h_1 = 0.01733$, the hazard ratio $\lambda_1 = h_1/h_0 = 1/2$, and the alternative reference is

$$\theta_1 = -\log(\lambda_1) = -\log\left(\frac{1}{2}\right) = 0.693147$$

The following statements invoke the SEQDESIGN procedure and specify three Whitehead's triangular designs:

```
ods graphics on;
proc seqdesign altref=0.693147
    bscale=score
    plots=combinedboundary
    ;
    BoundaryKeyNone: design nstages=4
                        method=whitehead
                        boundarykey=none
                        alt=upper    stop=both
                        alpha=0.05   beta=0.20
                        ;
    BoundaryKeyAlpha: design nstages=4
                           method=whitehead
                           boundarykey=alpha
                           alt=upper    stop=both
                           alpha=0.05   beta=0.20
                           ;
```

```

BoundaryKeyBeta:  design nstages=4
                   method=whitehead
                   boundarykey=beta
                   alt=upper    stop=both
                   alpha=0.05   beta=0.20
                   ;

run;
ods graphics off;

```

Whitehead methods with early stopping to reject or accept the null hypothesis create boundaries that approximately satisfy the Type I and Type II error probability specification. The BOUNDARYKEY=NONE option specifies no adjustment to the boundary value at the final stage to maintain either a Type I or a Type II error probability level.

The “Design Information” table in [Output 83.7.1](#) displays design specifications and maximum information. Note that with the BOUNDARYKEY=NONE option, the derived errors $\alpha = 0.05071$ and $\beta = 0.19771$ are not the same as the specified errors $\alpha = 0.05$ and $\beta = 0.20$.

Output 83.7.1 Whitehead Design Information

The SEQDESIGN Procedure	
Design: BoundaryKeyNone	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Score
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Method	Whitehead
Boundary Key	None
Alternative Reference	0.693147

The “Boundary Information” table in [Output 83.7.11](#) displays information level, alternative reference, and boundary values.

Output 83.7.11 Boundary Information

Boundary Information (Score Scale)					
Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values-----	
	Proportion	Actual	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2500	4.176597	2.89500	-0.95755	4.78775
2	0.5000	8.353195	5.78999	1.91510	5.74530
3	0.7500	12.52979	8.68499	4.78775	6.70285
4	1.0000	16.70639	11.57998	7.78899	7.78899

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.7.12](#).

Output 83.7.12 Boundary Plot

With the PLOTS=COMBINEDBOUNDARY option, a combined plot of group sequential boundaries for all designs is displayed, as shown in [Output 83.7.13](#). It shows that three designs are similar, with a slightly smaller boundary value at the final stage for the design with the BOUNDARYKEY=NONE option.

Output 83.7.13 Combined Boundary Plot

The following statements invoke the SEQDESIGN procedure and specify the SAMPLESIZE statement to derive required sample sizes for a log-rank test comparing two survival distributions for the treatment effect (Jennison and Turnbull 2000, pp. 77–79; Whitehead 1997, pp. 36–39):

```
proc seqdesign altref=0.693147
    bscale=score
    ;
    BoundaryKeyAlpha: design nstages=4
        method=whitehead
        boundarykey=alpha
        alt=upper    stop=both
        alpha=0.05  beta=0.20
    ;
    samplesize model=twosamplesurvival
        ( nullhazard=0.03466 accrate=10);
run;
```

The design is identical to the previous design with the BOUNDARYKEY=ALPHA option except with the addition of the sample size computation.

The “Sample Size Summary” table in [Output 83.7.14](#) displays parameters for the sample size computation. Since the ACCTIME= option is not specified for the accrual time, the minimum and maximum accrual times are derived for the specified accrual rate.

Output 83.7.14 Sample Size Summary

The SEQDESIGN Procedure		
Design: BoundaryKeyAlpha		
Sample Size Summary		
Test	Two-Sample	Survival
Null Hazard Rate		0.03466
Hazard Rate (Group A)		0.01733
Hazard Rate (Group B)		0.03466
Hazard Ratio		0.5
log(Hazard Ratio)		-0.69315
Reference Hazards		Alt Ref
Accrual		Uniform
Accrual Rate		10
Min Accrual Time		6.682556
Min Sample Size		66.82556
Max Accrual Time		25.40111
Max Sample Size		254.0111
Max Number of Events		66.82556

If the ACCTIME=20 option is specified in the SAMPLESIZE statement, the “Sample Size Summary” table in [Output 83.7.15](#) also displays the follow-up time and maximum sample size with the specified accrual time.

Output 83.7.15 Sample Size Summary

The SEQDESIGN Procedure		
Design: WhiteheadKeyAlpha		
Sample Size Summary		
Test	Two-Sample	Survival
Null Hazard Rate		0.03466
Hazard Rate (Group A)		0.01733
Hazard Rate (Group B)		0.03466
Hazard Ratio		0.5
log(Hazard Ratio)		-0.69315
Reference Hazards		Alt Ref
Accrual		Uniform
Accrual Rate		10
Accrual Time		20
Follow-up Time		6.474376
Total Time		26.47438
Max Number of Events		66.82556
Max Sample Size		200
Expected Sample Size (Null Ref)		161.5941
Expected Sample Size (Alt Ref)		172.4693

The “Number of Events (D) and Sample Sizes (N)” table in [Output 83.7.16](#) displays the required time at each stage, in both fractional and integer numbers. The derived times under the heading “Fractional Time” are not integers. These times are rounded up to integers under the heading “Ceiling Time.” The table also displays the numbers of events and sample sizes at each stage.

Output 83.7.16 Number of Events and Sample Sizes

Numbers of Events (D) and Sample Sizes (N) Two-Sample Log-Rank Test							
-----Fractional Time-----							
Stage	D	D(Grp 1)	D(Grp 2)	Time	N	N(Grp 1)	N(Grp 2)

Example 83.8: Creating a One-Sided Error Spending Design

This example requests a five-stage, one-sided group sequential design for normally distributed statistics. The design uses an O’Brien-Fleming-type error spending function for the α boundary and a Pocock-type error spending function for the β boundary. The following statements request a one-sided design by using different α and β spending functions:

```

ods graphics on;
proc seqdesign altref=0.2 errspend
    pss(cref=0 0.5 1)
    stopprob(cref=0 0.5 1)
    plots=(asn power errspend)
;
    OneSidedErrorSpending: design nstages=5
        method(alpha)=errfuncobf
        method(beta)=errfuncpoc
        alt=upper stop=both
        alpha=0.025
;
run;
ods graphics off;

```

The “Design Information” table in [Output 83.8.1](#) displays design specifications and the derived statistics. With the specified alternative reference, the maximum information is derived.

Output 83.8.1 Error Spending Method Design Information

The SEQDESIGN Procedure	
Design: OneSidedErrorSpending	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Method	Error Spending
Boundary Key	Both
Alternative Reference	0.2
Number of Stages	5
Alpha	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	119.4278
Max Information	313.7196
Null Ref ASN (Percent of Fixed Sample)	50.35408
Alt Ref ASN (Percent of Fixed Sample)	78.77223

The “Method Information” table in [Output 83.8.2](#) displays the α and β errors, alternative reference, and derived drift parameter, which is the standardized alternative reference at the final stage.

Output 83.8.2 Method Information

Method Information				
Boundary	Method	Alpha	Beta	----Error Spending----
Upper Alpha	Error Spending	0.02500	.	Approx O'Brien-Fleming
Upper Beta	Error Spending	.	0.10000	Approx Pocock
Method Information				
Boundary	Alternative Reference		Drift	
Upper Alpha	0.2		3.542426	
Upper Beta	0.2		3.542426	

With the STOPPROB option, the “Expected Cumulative Stopping Probabilities” table in [Output 83.8.3](#) displays the expected stopping stage and cumulative stopping probability to reject the null hypothesis at each stage under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option.

Output 83.8.3 Stopping Probabilities

Expected Cumulative Stopping Probabilities			
Reference = CRef * (Alt Reference)			
CRef	Expected Stopping Stage	Source	
0.0000	2.108	Reject	Null
0.0000	2.108	Accept	Null
0.0000	2.108	Total	
0.5000	3.296	Reject	Null
0.5000	3.296	Accept	Null
0.5000	3.296	Total	
1.0000	3.298	Reject	Null
1.0000	3.298	Accept	Null
1.0000	3.298	Total	

Expected Cumulative Stopping Probabilities					
Reference = CRef * (Alt Reference)					
CRef	-----Stopping Probabilities-----				
	Stage_1	Stage_2	Stage_3	Stage_4	Stage_5
0.0000	0.00000	0.00039	0.00381	0.01221	0.02500
0.0000	0.38080	0.69133	0.86162	0.94170	0.97500
0.0000	0.38080	0.69173	0.86543	0.95391	1.00000
0.5000	0.00002	0.01265	0.09650	0.24465	0.38724
0.5000	0.13665	0.28063	0.41080	0.52230	0.61276
0.5000	0.13667	0.29328	0.50730	0.76695	1.00000
1.0000	0.00050	0.13209	0.52642	0.80390	0.90000
1.0000	0.02954	0.05231	0.07085	0.08648	0.10000
1.0000	0.03004	0.18440	0.59728	0.89039	1.00000

With the PSS option, the “Power and Expected Sample Sizes” table in [Output 83.8.4](#) displays powers and expected sample sizes under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ are the default values in the CREF= option.

Output 83.8.4 Power and Expected Sample Size Information

Powers and Expected Sample Sizes Reference = CRef * (Alt Reference)		
CRef	Power	-Sample Size- Percent Fixed-Sample
0.0000	0.02500	50.3541
0.5000	0.38724	78.7219
1.0000	0.90000	78.7722

With the PLOTS=ASN option, the procedure displays a plot of expected sample sizes under various hypothetical references, as shown in [Output 83.8.5](#). By default, expected sample sizes under the hypotheses $\theta = c_i \theta_1$, $c_i = 0, 0.01, 0.02, \dots, 1.50$, are displayed, where θ_1 is the alternative reference.

Output 83.8.5 ASN Plot

With the PLOTS=POWER option, the procedure displays a plot of the power curves under various hypothetical references for all designs simultaneously, as shown in [Output 83.8.6](#). By default, the option CREF= 0, 0.01, 0.02, ..., 1.50 and powers under hypothetical references $\theta = c_i \theta_1$ are displayed, where c_i are values specified in the CREF= option. These CREF= values are displayed on the horizontal axis.

Under the null hypothesis, $c_i = 0$, the power is 0.025, the upper Type I error probability. Under the alternative hypothesis, $c_i = 1$, the power is 0.9, one minus the Type II error probability. The plot shows only minor difference between the two designs.

Output 83.8.6 Power Plot

The “Boundary Information” table in [Output 83.8.7](#) displays information level, alternative reference, and boundary values. By default (or equivalently if you specify BOUNDARYSCALE=STDZ), the alternative reference and boundary values are displayed with the standardized Z scale. That is, the resulting standardized alternative reference at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the specified alternative reference and I_k is the information level at stage k , $k = 1, 2, \dots, 5$.

Output 83.8.7 Boundary Information

Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values-----	
	Proportion	Actual	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2000	62.74393	1.58422	-0.30338	4.87688
2	0.4000	125.4879	2.24043	0.41667	3.35706
3	0.6000	188.2318	2.74395	0.97165	2.67766
4	0.8000	250.9757	3.16844	1.43627	2.26535
5	1.0000	313.7196	3.54243	1.87522	1.87522

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.8.8](#). This plot displays the boundary values in the “Boundary Information” table in [Output 83.8.7](#).

Output 83.8.8 Boundary Plot

The “Error Spending Information” table in [Output 83.8.9](#) displays cumulative error spending at each stage for each boundary.

Output 83.8.9 Error Spending Information

Error Spending Information				
Stage	-Information Level- Proportion	-Cumulative Error Spending- -----Upper-----		
		Beta	Alpha	
1	0.2000	0.02954	0.00000	
2	0.4000	0.05231	0.00039	
3	0.6000	0.07085	0.00381	
4	0.8000	0.08648	0.01221	
5	1.0000	0.10000	0.02500	

With the PLOTS=ERRSPEND option, the procedure displays a plot of error spending for each boundary, as shown in [Output 83.8.10](#). This plot displays the cumulative error spending at each stage in the “Error Spending Information” table in [Output 83.8.9](#). The O’Brien-Fleming-type α spending function is conservative in early stages because it uses much less at early stages than in the later stages. In contrast, the Pocock-type β spending function uses more at early stages than in the later stages.

Output 83.8.10 Error Spending Plot

Example 83.9: Creating Designs with Various Number of Stages

This example requests three group sequential designs for normally distributed statistics. Each design uses the power family error spending function with the default power parameter $\rho = 2$. The specified error spending method is between the approximated Pocock method ($\rho = 1$) and the approximated O'Brien-Fleming method ($\rho = 3$) (Jennison and Turnbull 2000, p. 148). The three designs are identical except for the specified number of stages. The following statements request these three group sequential designs:

```
ods graphics on;
proc seqdesign plots=( asn
                      power
                      combinedboundary
                      errspend(hscale=info)
                      )
;
  TwoStageDesign: design nstages=2
                  method=errfuncpow
                  alt=upper stop=reject
;
  FiveStageDesign: design nstages=5
                   method=errfuncpow
                   alt=upper stop=reject
;
  TenStageDesign: design nstages=10
                   method=errfuncpow
                   alt=upper stop=reject
;
run;
ods graphics off;
```

The “Design Information” table in [Output 83.9.1](#) displays design information for the two-stage design.

Output 83.9.1 Design Information

The SEQDESIGN Procedure	
Design: TwoStageDesign	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Reject Null
Method	Error Spending
Boundary Key	Both
Number of Stages	2
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	102.4167
Null Ref ASN (Percent of Fixed Sample)	101.7766
Alt Ref ASN (Percent of Fixed Sample)	79.81021

The “Boundary Information” table in [Output 83.9.2](#) displays the information level, alternative reference, and boundary values. By default (or equivalently if you specify `BOUNDARYSCALE=STDZ`), the alternative reference and boundary values are displayed with the standardized normal Z scale. The resulting standardized alternative reference at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information level at stage k , $k = 1, 2$.

Output 83.9.2 Boundary Information in Z Scale

Boundary Information (Standardized Z Scale)			
Null Reference = 0			
Stage	-Information Level- Proportion	-Alternative- --Reference--	-Boundary Values-
		Upper	-----Upper----- Alpha
1	0.5000	2.09414	2.24140
2	1.0000	2.96156	1.69970

The “Design Information” table in [Output 83.9.3](#) displays design information for the five-stage design. Compared with the two-stage design in [Output 83.9.1](#), the maximum information increases from 102.42 to 105.62, and the average sample number under the alternative reference (Alt Ref ASN) decreases from 79.81 to 69.64.

Output 83.9.3 Design Information

The SEQDESIGN Procedure	
Design: FiveStageDesign	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Reject Null
Method	Error Spending
Boundary Key	Both
Number of Stages	5
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	105.6235
Null Ref ASN (Percent of Fixed Sample)	104.356
Alt Ref ASN (Percent of Fixed Sample)	69.64322

The “Boundary Information” table in [Output 83.9.4](#) displays the information level, alternative reference, and boundary values with the default standardized normal Z scale.

Output 83.9.4 Boundary Information in Z Scale

Boundary Information (Standardized Z Scale)				
Null Reference = 0				
Stage	-Information Level- Proportion	-Alternative- --Reference-- Upper	-Boundary Values- -----Upper----- Alpha	
1	0.2000	1.34502	2.87816	
2	0.4000	1.90215	2.47023	
3	0.6000	2.32965	2.20095	
4	0.8000	2.69005	1.98182	
5	1.0000	3.00756	1.79024	

The “Design Information” table in [Output 83.9.5](#) displays design information for the ten-stage design. Compared with the five-stage design in [Output 83.9.3](#), the maximum information increases further from 105.62 to 107.26 and under the alternative reference, the average sample number decreases further from 69.64 to 66.36.

Output 83.9.5 Design Information

The SEQDESIGN Procedure	
Design: TenStageDesign	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Reject Null
Method	Error Spending
Boundary Key	Both
Number of Stages	10
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	107.256
Null Ref ASN (Percent of Fixed Sample)	105.7276
Alt Ref ASN (Percent of Fixed Sample)	66.35565

The “Boundary Information” table in [Output 83.9.6](#) displays the information level, alternative reference, and boundary values with the default standardized normal Z scale.

Output 83.9.6 Boundary Information in Z Scale

Boundary Information (Standardized Z Scale)			
Null Reference = 0			
<u>_Stage_</u>	-Information Level- Proportion	-Alternative- --Reference-- Upper	-Boundary Values- -----Upper----- Alpha
1	0.1000	0.95840	3.29053
2	0.2000	1.35538	2.94037
3	0.3000	1.65999	2.72115
4	0.4000	1.91679	2.54808
5	0.5000	2.14304	2.40114
6	0.6000	2.34758	2.27127
7	0.7000	2.53568	2.15359
8	0.8000	2.71076	2.04503
9	0.9000	2.87519	1.94355
10	1.0000	3.03072	1.84765

With the PLOTS=ASN option, the procedure displays a plot of average sample numbers under various hypothetical references for all designs simultaneously, as shown in [Output 83.9.7](#). By default, the option CREF= 0, 0.01, 0.02, . . . , 1.50 and expected sample sizes under the hypothetical references $\theta = c_i \theta_1$ are displayed, where c_i are values specified in the CREF= option. These CREF= values are displayed on the horizontal axis.

Output 83.9.7 ASN Plot

The plot shows that as the number of stages increases, the average sample number as a percentage of the fixed-sample design increases under the null hypothesis ($c_i = 0$) but decreases under the alternative hypothesis ($c_i = 1$).

With the PLOTS=POWER option, the procedure displays a plot of the power curves under various hypothetical references for all designs simultaneously, as shown in [Output 83.9.8](#). By default, the option CREF= 0, 0.01, 0.02, ..., 1.50 and powers under hypothetical references $\theta = c_i \theta_1$ are displayed, where c_i are values specified in the CREF= option. These CREF= values are displayed on the horizontal axis.

Output 83.9.8 Power Plot

Under the null hypothesis, $c_i = 0$, the power is 0.05, the upper Type I error probability. Under the alternative hypothesis, $c_i = 1$, the power is 0.9, one minus the Type II error probability. The plot shows only minor difference among the three designs.

With the `PLOTS=COMBINEDBOUNDARY` option, the procedure displays a plot of sequential boundaries for all designs simultaneously, as shown in [Output 83.9.9](#). By default (or equivalently if you specify `COMBINEDBOUNDARY(HSCALE=INFO)`), the information levels are used on the horizontal axis. Since the maximum information is not available for the design, the percent information ratios with respect to the corresponding fixed-sample design are displayed in the plot.

Output 83.9.9 Combined Boundary Plot

The plot shows that as the number of stages increases, the maximum information increases and the α boundary values also increase.

With the `PLOTS=ERRSPEND(HSCALE=INFO)` option, the procedure displays a plot of cumulative error spends for all boundaries in the designs simultaneously, as shown in [Output 83.9.10](#).

Output 83.9.10 Error Spending Plot

The plot shows similar error spending for these three designs since all three designs are generated from the same power family error spending function.

Example 83.10: Creating Two-Sided Error Spending Designs with and without Overlapping Lower and Upper β Boundaries

This example requests two three-stage group sequential designs for normally distributed statistics. Each design uses a power family error spending function with a specified two-sided alternative hypothesis $H_1 : \theta_1 = \pm 0.2$ and early stopping only to accept the null hypothesis H_0 .

The first design uses the BETAOVERLAP=NOADJUST option to derive acceptance boundary values without adjusting for the possible overlapping of the lower and upper β boundaries computed from the two corresponding one-sided tests. The second design uses the BETAOVERLAP=ADJUST option to test the overlapping of the β boundaries at each interim stage based on the two corresponding one-sided tests and then to set the β boundary values at the stage to missing if overlapping occurs at that stage.

The following statements request a two-sided design with the BETAOVERLAP=NOADJUST option:

```
ods graphics on;
proc seqdesign altref=0.2 errspend;
  design nstages=3
    method=errfuncpow
    alt=twosided stop=accept
    betaoverlap=noadjust
    beta=0.09
  ;
run;
ods graphics off;
```

The “Design Information” table in [Output 83.10.1](#) displays design specifications and the derived statistics for the first design. With the specified alternative reference $\theta_1 = 0.2$, the maximum information is derived.

Output 83.10.1 Design Information

The SEQDESIGN Procedure	
Design: Design_1	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Accept Null
Method	Error Spending
Boundary Key	Both
Alternative Reference	0.2
Number of Stages	3
Alpha	0.05
Beta	0.09
Power	0.91
Max Information (Percent of Fixed Sample)	103.8789
Max Information	282.9328
Null Ref ASN (Percent of Fixed Sample)	79.20197
Alt Ref ASN (Percent of Fixed Sample)	102.1476

The “Boundary Information” table in [Output 83.10.2](#) displays the information level, alternative reference, and boundary values. With a specified alternative reference θ_1 , the maximum information is derived from the procedure, and the actual information level at each stage is displayed in the table. By default (or equivalently if you specify `BOUNDARYSCALE=STDZ`), the alternative reference and boundary values are displayed with the standardized Z scale. The alternative reference at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the specified alternative reference and I_k is the information level at stage k , $k = 1, 2, 3$.

Output 83.10.2 Boundary Information

Boundary Information (Standardized Z Scale)						
Null Reference = 0						
Stage	--Information Level--		-----Alternative-----		----Boundary Values----	
	Proportion	Actual	-----Reference-----		---Lower---	---Upper---
			Lower	Upper	Beta	Beta
1	0.3333	94.31094	-1.94228	1.94228	-0.08239	0.08239
2	0.6667	188.6219	-2.74679	2.74679	-0.90351	0.90351
3	1.0000	282.9328	-3.36412	3.36412	-1.92519	1.92519

The “Error Spending Information” table in [Output 83.10.3](#) displays the cumulative error spending at each stage for each boundary.

Output 83.10.3 Error Spending Information

Error Spending Information					
Stage	-Information Level- Proportion	-----Cumulative Error Spending-----			
		-----Lower-----		-----Upper-----	
		Alpha	Beta	Beta	Alpha
1	0.3333	0.00000	0.01000	0.01000	0.00000
2	0.6667	0.00000	0.04000	0.04000	0.00000
3	1.0000	0.02500	0.09000	0.09000	0.02500

With the `STOP=ACCEPT` option, the design does not stop at interim stages to reject H_0 , and the α spending at each interim stage is zero. For the power family error spending function with the default parameter $\rho = 2$, the beta spending at stage 1 is $(1/3)^\rho \beta = (1/3)^2 0.09 = 0.01$, and the cumulative beta spending at stage 2 is $(2/3)^\rho \beta = (2/3)^2 0.09 = 0.04$.

With ODS Graphics enabled, a detailed boundary plot with the acceptance and rejection regions is displayed, as shown in [Output 83.10.4](#).

Output 83.10.4 Boundary Plot

The following statements request a two-sided design with the BETAOVERLAP=ADJUST option, which is the default:

```
ods graphics on;
proc seqdesign altref=0.2 errspend;
  design nstages=3
    method=errfuncpow
    alt=twosided
    stop=accept
    betaoverlap=adjust
    beta=0.09
  ;
run;
ods graphics off;
```

With the BETAOVERLAP=ADJUST option, the procedure first derives the usual β boundary values for the two-sided design and then checks for overlapping of the β boundaries for the two corresponding one-sided tests at each stage. If this type of overlapping occurs at a particular stage, the β boundary values for that stage are set to missing, the β spending values at that stage are reset to zero, and the β spending values at subsequent stages are adjusted proportionally.

The boundary values without adjusting for the possible overlapping of the two one-sided β boundaries are identical to the boundary values derived in the first design (with the BETAOVERLAP=NOADJUST option, as shown in [Output 83.10.2](#)). At stage 1, the upper β boundary value for the corresponding one-sided test is

$$\theta_1 \sqrt{I_1} - \Phi^{-1}(1 - \beta_1) = 0.2 \sqrt{94.31094} - \Phi^{-1}(0.99) = 1.94228 - 2.32635 = -0.38407$$

where $\theta_1 = 0.2$ is the upper alternative reference, $I_1 = 94.31094$ is the information level at stage 1, and $\beta_1 = 0.01$ is the β spending at stage 1 (as shown in [Output 83.10.3](#)).

Similarly, the lower β boundary value for the corresponding one-sided test is computed as 0.38407. Since the upper β boundary value is less than the lower β boundary at stage 1, overlapping occurs, and so the β boundary values for the two-sided design are set to missing at stage 1.

With the β boundary values set to missing at stage 1 and the β spending $\beta'_1 = 0$ the β spending values at subsequent interim stages are adjusted proportionally. In this example, the adjusted β spending at stage 2 is computed as

$$\beta'_2 = \beta'_1 + \frac{\beta_2 - \beta_1}{\beta_3 - \beta_1} (\beta_3 - \beta'_1) = 0 + \frac{0.04 - 0.01}{0.09 - 0.01} 0.09 = 0.03375$$

where β_k is the cumulative β spending at stage k before the adjustment, $k = 1, 2, 3$.

The “Design Information” table in [Output 83.10.5](#) displays design specifications and derived statistics for the design.

Output 83.10.5 Design Information

The SEQDESIGN Procedure

2	0.6667		0.00000	0.03375	0.03375	0.00000
3	1.0000		0.02500	0.09000	0.09000	0.02500

With ODS Graphics enabled, a detailed boundary plot with the acceptance and rejection regions is displayed, as shown in [Output 83.10.8](#).

Output 83.10.8 Boundary Plot

Example 83.11: Creating a Two-Sided Asymmetric Error Spending Design with Early Stopping to Reject H_0

This example requests a three-stage two-sided asymmetric group sequential design for normally distributed statistics.

The O'Brien-Fleming boundary can be approximated using a power family error spending function with parameter $\rho = 3$, and the Pocock boundary can be approximated using a power family error spending function with parameter $\rho = 1$ (Jennison and Turnbull 2000, p. 148). The following statements use the power family error spending function to create a two-sided asymmetric design with early stopping to reject the null hypothesis H_0 :

```
ods graphics on;
proc seqdesign altref=1.0
    pss(cref=0 0.5 1)
    stopprob(cref=0 0.5 1)
    errspend
    plots=(asn power errspend)
;

    TwoSidedErrorSpending: design nstages=3
        method(upperalpha)=errfuncpow(rho=3)
        method(loweralpha)=errfuncpow(rho=1)
        info=cum(2 3 4)
        alt=twosided
        stop=reject
        alpha=0.075(upper=0.025)
;

run;
ods graphics off;
```

The design uses power family error spending functions with $\rho = 1$ for the lower α boundary and $\rho = 3$ for the upper α boundary. Thus, the design is conservative in the early stages and tends to stop the trials early only with a small p -value for the upper α boundary. The upper α level 0.025 is specified explicitly, and the lower α level is computed as $0.075 - 0.025 = 0.05$.

The “Design Information” table in [Output 83.11.1](#) displays design specifications and the derived maximum information. Note that in order to attain the same information level for the asymmetric lower and upper boundaries, the derived power at the lower alternative 0.92963 is larger than the default 0.90.

Output 83.11.1 Design Information

The SEQDESIGN Procedure	
Design: TwoSidedErrorSpending	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	Error Spending
Boundary Key	Both
Alternative Reference	1
Number of Stages	3
Alpha	0.075
Alpha (Lower)	0.05
Alpha (Upper)	0.025
Beta (Lower)	0.07037
Beta (Upper)	0.1
Power (Lower)	0.92963
Power (Upper)	0.9
Max Information (Percent of Fixed Sample)	102.4384
Max Information	10.76365
Null Ref ASN (Percent of Fixed Sample)	100.4877
Lower Alt Ref ASN (Percent of Fixed Sample)	64.8288
Upper Alt Ref ASN (Percent of Fixed Sample)	75.98778

The “Method Information” table in [Output 83.11.2](#) displays the specified α and β error levels and the derived drift parameter. With the same information level used for the asymmetric lower and upper boundaries, only one of the β levels is maintained, and the other is derived to have the level less than or equal to the default level.

Output 83.11.2 Method Information

Method Information				
Boundary	Method	Alpha	Beta	----Error Spending---- Function
Upper Alpha	Error Spending	0.02500	0.10000	Power (Rho=3)
Lower Alpha	Error Spending	0.05000	0.07037	Power (Rho=1)
Method Information				
Boundary	Alternative Reference	Drift		
Upper Alpha	1	3.280801		
Lower Alpha	-1	-3.2808		

With the STOPPROB(CREF=0 0.5 1) option, the “Expected Cumulative Stopping Probabilities” table in [Output 83.11.3](#) displays the expected stopping stage and cumulative stopping probability to reject the null hypothesis H_0 at each stage under hypothetical references $\theta = 0$ (null hypothesis H_0), $\theta = 0.5\theta_1$, and $\theta = \theta_1$ (alternative hypothesis H_1), where θ_1 is the alternative reference.

Output 83.11.3 Stopping Probabilities

Expected Cumulative Stopping Probabilities			
Reference = CRef * (Alt Reference)			
CRef	Ref	Expected Stopping Stage	Source
0.0000	Lower Alt	2.924	Rej Null (Lower Alt)

1.0000	Upper Alt	0.33927	0.69357	0.90001

“Rej Null (Lower Alt)” and “Rej Null (Upper Alt)” under the heading “Source” indicate the probabilities of rejecting the null hypothesis for the lower alternative and for the upper alternative, respectively. “Reject Null” indicates the probability of rejecting the null hypothesis for either the lower or upper alternative.

Note that with the STOP=REJECT option, the cumulative stopping probability of accepting the null hypothesis H_0 at each interim stage is zero and is not displayed.

With the PSS(CREF=0.5 1.0) option, the “Power and Expected Sample Sizes” table in [Output 83.11.4](#) displays powers and expected sample sizes under hypothetical references $\theta = 0$ (null hypothesis H_0), $\theta = 0.5\theta_1$, and $\theta = \theta_1$ (alternative hypothesis H_1), where θ_1 is the alternative reference. The expected sample sizes are displayed in a percentage scale relative to the corresponding fixed-sample size design.

Output 83.11.4 Power and Expected Sample Size Information

Powers and Expected Sample Sizes Reference = CRef * (Alt Reference)			
CRef	Ref	Power	-Sample Size- Percent Fixed-Sample
0.0000	Lower Alt	0.05000	100.4877
0.5000	Lower Alt	0.45370	88.5090
1.0000	Lower Alt	0.92963	64.8288
0.0000	Upper Alt	0.02500	100.4877
0.5000	Upper Alt	0.36458	96.2309
1.0000	Upper Alt	0.90000	75.9878

Note that at $c_i = 0$, the null reference $\theta = 0$, the power with the lower alternative is the lower α error 0.05, and the power with the upper alternative is the upper α error 0.025. At $c_i = 1$, the alternative reference $\theta = \theta_1$, the power with the upper alternative is the specified power 0.90, and the power with the lower alternative 0.92963 is greater than the specified power 0.90 because the same information level is used for these two asymmetric boundaries.

With the PLOTS=POWER option, the procedure displays a plot of the power curves under various hypothetical references, as shown in [Output 83.11.5](#). By default, powers under the lower hypotheses $\theta = c_i \theta_{1l}$ and under the upper hypotheses $\theta = c_i \theta_{1u}$ are displayed for a two-sided asymmetric design, where $c_i = 0, 0.01, 0.02, \dots, 1.50$ and $\theta_{1l} = -1$ and $\theta_{1u} = 1$ are the lower and upper alternative references, respectively.

Output 83.11.5 Power Plot

The horizontal axis displays the multiplier of the reference difference. A positive multiplier corresponds to c_i for the upper alternative hypothesis, and a negative multiplier corresponds to $-c_i$ for the lower alternative hypothesis. For lower reference hypotheses, the power is the lower α error 0.05 under the null hypothesis ($c_i = 0$) and is 0.92963 under the alternative hypothesis ($c_i = 1$). For upper reference hypotheses, the power is the upper α error 0.025 under the null hypothesis ($c_i = 0$) and is 0.90 under the alternative hypothesis ($c_i = 1$).

With the PLOTS=ASN option, the procedure displays a plot of expected sample sizes under various hypothetical references, as shown in [Output 83.11.6](#). By default, expected sample sizes under the lower hypotheses $\theta = c_i \theta_{1l}$ and under the upper hypotheses $\theta = c_i \theta_{1u}$, $c_i = 0, 0.01, 0.02, \dots, 1.50$, are displayed for a two-sided asymmetric design, where $\theta_{1l} = -1$ and $\theta_{1u} = 1$ are the lower and upper alternative references, respectively.

Output 83.11.6 ASN Plot

The horizontal axis displays the multiplier of the reference difference. A positive multiplier corresponds to c_i for the upper alternative hypothesis and a negative multiplier corresponds to $-c_i$ for the lower alternative hypothesis.

The “Boundary Information” table in [Output 83.11.7](#) displays the information levels, alternative references, and boundary values. By default (or equivalently if you specify `BOUNDARYSCALE=STDZ`), the standardized Z scale is used to display the alternative references and boundary values. The resulting standardized alternative references at stage k are given by $\pm\theta_1\sqrt{I_k}$, where θ_1 is the specified alternative reference and I_k is the information level at stage k , $k = 1, 2, 3$.

Output 83.11.7 Boundary Information

Boundary Information (Standardized Z Scale)						
Null Reference = 0						
Stage	--Information Level--		-----Alternative-----		----Boundary Values----	
	Proportion	Actual	-----Reference-----		---Lower---	---Upper---
			Lower	Upper	Alpha	Alpha
1	0.5000	5.381827	-2.31988	2.31988	-1.95996	2.73437
2	0.7500	8.07274	-2.84126	2.84126	-1.98394	2.35681
3	1.0000	10.76365	-3.28080	3.28080	-1.90855	2.02853

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.11.8](#).

Output 83.11.8 Boundary Plot

The “Error Spending Information” table in [Output 83.11.9](#) displays the cumulative error spending at each stage for each boundary.

Output 83.11.9 Error Spending Information

Error Spending Information						
Stage	-Information Level- Proportion	-----Cumulative Error Spending-----				
		-----Lower-----		-----Upper-----		
		Alpha	Beta	Beta	Alpha	
1	0.5000	0.02500	0.00000	0.00001	0.00313	
2	0.7500	0.03750	0.00000	0.00001	0.01055	
3	1.0000	0.05000	0.07037	0.10000	0.02500	

With the STOP=REJECT option, there is no early stopping to accept H_0 , and the corresponding β spending at an interim stage is computed from the rejection region. For example, the upper β spending at stage 1 (0.00001) is the probability of rejecting H_0 for the lower alternative under the upper alternative reference.

With the PLOTS=ERRSPEND option, the procedure displays a plot of the cumulative error spending on each boundary at each stage, as shown in [Output 83.11.10](#).

Output 83.11.10 Error Spending Plot

Example 83.12: Creating a Two-Sided Asymmetric Error Spending Design with Early Stopping to Reject or Accept H_0

This example requests a four-stage two-sided asymmetric group sequential design for normally distributed statistics. The O'Brien-Fleming boundary can be approximated by a gamma family error spending function with parameter $\gamma = -4$ or -5 , and the Pocock boundary can be approximated with parameter $\gamma = 1$ (Hwang, Shih, and DeCani 1990, p. 1440). The following statements use the gamma error spending function with early stopping to reject or accept the null hypothesis H_0 :

```
ods graphics on;
proc seqdesign altref=2
    pss(cref=0 0.5 1)
    stopprob(cref=0 1)
    errspend
    plots=(asn power errspend)
;
TwoSidedAsymmetric: design nstages=4
    method=errfuncgamma(gamma=1)
    method(beta)=errfuncgamma(gamma=-2)
    method(upperalpha)=errfuncgamma(gamma=-5)
    alt=twosided
    stop=both
    beta=0.1
;
run;
ods graphics off;
```

The design uses gamma family error spending functions with $\gamma = -5$ for the upper α boundary, $\gamma = 1$ for the lower α boundary, and $\gamma = -2$ for the lower and upper β boundaries.

The “Design Information” table in [Output 83.12.1](#) displays design specifications and the derived maximum information. Note that in order to attain the same information level for the asymmetric lower and upper boundaries, the derived power at the upper alternative 0.93655 is larger than the specified $1 - \beta = 0.90$.

Output 83.12.1 Design Information

“Rej Null (Lower Alt)” and “Rej Null (Upper Alt)” under the heading “Source” indicate the probabilities of rejecting the null hypothesis for the lower alternative and for the upper alternative, respectively. “Reject Null” indicates the probability of rejecting the null hypothesis for either the lower or upper alternative, “Accept Null” indicates the probability of accepting the null hypothesis, and “Total” indicates the total probability of stopping the trial.

With the PSS(CREF=0 0.5 1.0) option, the “Power and Expected Sample Sizes” table in [Output 83.12.4](#) displays powers and expected sample sizes under hypothetical references $\theta = 0$ (null hypothesis H_0), $\theta = 0.5\theta_1$, and $\theta = \theta_1$ (alternative hypothesis H_1), where θ_1 is the alternative reference. The expected sample sizes are displayed in a scale that indicates a percentage of its corresponding fixed-sample size design.

Output 83.12.4 Power and Expected Sample Size Information

Powers and Expected Sample Sizes Reference = CRef * (Alt Reference)			
CRef	Ref	Power	-Sample Size- Percent Fixed-Sample
0.0000	Lower Alt	0.02500	74.1665
0.5000	Lower Alt	0.34601	75.8425
1.0000	Lower Alt	0.90000	59.1027
0.0000	Upper Alt	0.02500	74.1665
0.5000	Upper Alt	0.41647	85.3976
1.0000	Upper Alt	0.93655	73.7880

Note that at $c_i = 0$, the null reference $\theta = 0$, the power with the lower alternative is the lower α error 0.025, and the power with the upper alternative is the upper α error 0.025. At $c_i = 1$, the alternative reference $\theta = \theta_1$, the power with the lower alternative is the specified power 0.90, and the power with the upper alternative 0.93655 is greater than the specified power 0.90 because the same information level is used for these two asymmetric boundaries.

With the PLOTS=POWER option, the procedure displays a plot of the power curves under various hypothetical references, as shown in [Output 83.12.5](#). By default, powers under the lower hypotheses $\theta = c_i\theta_{1l}$ and under the upper hypotheses $\theta = c_i\theta_{1u}$, are displayed for a two-sided asymmetric design, where $c_i = 0, 0.01, 0.02, \dots, 1.50$ and $\theta_{1l} = -1$ and $\theta_{1u} = 1$ are the lower and upper alternative references, respectively.

Output 83.12.5 Power Plot

The horizontal axis displays the multiplier of the reference difference. A positive multiplier corresponds to c_i for the upper alternative hypothesis, and a negative multiplier corresponds to $-c_i$ for the lower alternative hypothesis. For lower reference hypotheses, the power is the lower α error 0.025 under the null hypothesis ($c_i = 0$) and is 0.90 under the alternative hypothesis ($c_i = 1$). For upper reference hypotheses, the power is the upper α error 0.025 under the null hypothesis ($c_i = 0$) and is 0.93655 under the alternative hypothesis ($c_i = 1$).

With the PLOTS=ASN option, the procedure displays a plot of expected sample sizes under various hypothetical references, as shown in [Output 83.12.6](#). By default, expected sample sizes under the lower hypotheses $\theta = c_i \theta_{1l}$ and under the upper hypotheses $\theta = c_i \theta_{1u}$ are displayed for a two-sided asymmetric design, where $c_i = 0, 0.01, 0.02, \dots, 1.50$ and $\theta_{1l} = -1$ and $\theta_{1u} = 1$ are the lower and upper alternative references, respectively.

Output 83.12.6 ASN Plot

The horizontal axis displays the multiplier of the reference difference. A positive multiplier corresponds to c_i for the upper alternative hypothesis, and a negative multiplier corresponds to $-c_i$ for the lower alternative hypothesis.

By default (or equivalently if you specify `BETAOVERLAP=ADJUST`), the `SEQDESIGN` procedure first derives boundary values without adjusting for the possible overlapping of the two one-sided β boundaries based on two corresponding one-sided tests. Then the procedure checks for overlapping of the β boundaries at the interim stages. Since the two β boundaries overlap at stage 1, the β boundary values for stage 1 are set to missing, the β spending values at stage 1 are set to zero, and the β spending values at subsequent stages are adjusted proportionally.

The “Boundary Information” table in [Output 83.12.7](#) displays the information levels, alternative references, and boundary values. By default (or equivalently if you specify `BOUNDARYSCALE=STDZ`), the standardized Z scale is used to display the alternative references and boundary values. The resulting standardized alternative references at stage k is given by $\pm\theta_1\sqrt{I_k}$, where θ_1 is the specified alternative reference and I_k is the information level at stage k , $k = 1, 2, 3, 4$.

Output 83.12.7 Boundary Information

Boundary Information (Standardized Z Scale)				
Null Reference = 0				
Stage	---Information Level---		-----Alternative-----	
	Proportion	Actual	-----Reference-----	
			Lower	Upper
1	0.2500	0.790597	-1.77831	1.77831
2	0.5000	1.581193	-2.51491	2.51491
3	0.7500	2.37179	-3.08012	3.08012
4	1.0000	3.162386	-3.55662	3.55662

Boundary Information (Standardized Z Scale)				
Null Reference = 0				
Stage	-----Boundary Values-----			
	-----Lower-----		-----Upper-----	
	Alpha	Beta	Beta	Alpha
1	-2.37610	.	.	3.33772
2	-2.35714	-0.48408	0.29400	2.94871
3	-2.34861	-1.36183	1.13898	2.50473
4	-2.32105	-2.32105	1.95675	1.95675

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.12.8](#).

Output 83.12.8 Boundary Plot

The “Error Spending Information” in [Output 83.12.9](#) displays the cumulative error spending at each stage for each boundary.

Output 83.12.9 Error Spending Information

Error Spending Information					
Stage	-Information Level- Proportion	-----Cumulative Error Spending-----			
		-----Lower-----		-----Upper-----	
		Alpha	Beta	Beta	Alpha
1	0.2500	0.00875	0.00000	0.00002	0.00042
2	0.5000	0.01556	0.01863	0.01184	0.00190
3	0.7500	0.02087	0.04935	0.03132	0.00704
4	1.0000	0.02500	0.10000	0.06345	0.02500

With the β boundary values missing at stage 1, there is no early stopping to accept H_0 at stage 1, and the corresponding β spending at stage 1 is computed from the rejection region. For example, the upper β spending at stage 1 (0.00002) is the probability of rejecting H_0 for the lower alternative under the upper alternative reference.

With the PLOTS=ERRSPEND option, the procedure displays a plot of the cumulative error spending on each boundary at each stage, as shown in [Output 83.12.10](#).

Output 83.12.10 Error Spending Plot

Example 83.13: Creating a Design with a Nonbinding Beta Boundary

This example requests a two-sided design similar to [Example 83.2](#), but with a nonbinding beta boundary. With a nonbinding acceptance boundary, the trial does not need to stop to accept the null hypothesis when a test statistic falls in the acceptance region at interim stages. The design maintains the specified Type I error level, but at the cost of increased sample size.

The following statements invoke the SEQDESIGN procedure and request a four-stage group sequential design with early stopping to reject or accept H_0 :

```
ods graphics on;
proc seqdesign altref=0.15 errspend
    ;
    NonbindingDesign: design nstages=4
                        method=obf
                        alt=upper
                        stop=both(betaboundary=nonbinding)
                        alpha=0.025 beta=0.10
    ;
    samplesize model=twosamplefreq(nullprop=0.6 test=prop);
run;
ods graphics off;
```

The STOP=BOTH option specifies early stopping to reject or accept the null hypothesis, and the BETABOUNDARY=NONBINDING suboption requests the nonbinding beta boundary.

The “Design Information,” “Method Information,” and “Boundary Information” tables are displayed by default. The “Design Information” table in [Output 83.13.1](#) displays design specifications and derived statistics such as power and maximum information. With a specified alternative reference, ALTREF=0.15, the maximum information I_X is derived.

Output 83.13.1 Design Information

The SEQDESIGN Procedure	
Design: NonbindingDesign	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Accept (Nonbinding) / Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	0.15
Number of Stages	4
Alpha (Binding Beta Boundary)	0.02228
Alpha (Nonbinding Beta Boundary)	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	110.7138
Max Information	517.0296
Null Ref ASN (Percent of Fixed Sample)	62.29796
Alt Ref ASN (Percent of Fixed Sample)	78.5392

With the BETABOUNDARY=NONBINDING option, there are two ways to compute the Type I error level: with or without the beta boundary. Alpha (Binding Beta Boundary) displays the Type I error level with the beta boundary, and Alpha (Nonbinding Beta Boundary) displays the Type I error level without the beta boundary.

The maximum information is the information level at the final stage of the group sequential trial. The Max Information (Percent Fixed-Sample) row displays the maximum information for the sequential design

expressed as a percentage of the information for the corresponding fixed-sample design (which has a Type I error level 0.025). In [Output 83.13.1](#), Max Information (Percent Fixed-Sample) is 110.71%, which means that the information needed for the group sequential trial is 10.71% more than the information needed for the corresponding fixed-sample design if the trial does not stop at any interim stage.

Compared to the corresponding design with a binding beta boundary, which has a Max Information (Percent Fixed-Sample) of 107.67% as displayed in [Output 83.2.1](#), the nonbinding design requires a larger sample size if the trial proceeds to the final stage.

The “Method Information” table in [Output 83.13.2](#) displays the values of $\rho = 0.5$ and $\tau = 0$, which are the parameters for the O’Brien-Fleming method. The table also displays the drift parameter 3.4107, which is greater than the drift parameter 3.3636 in the corresponding binding boundary design, as displayed in [Output 83.2.2](#).

Output 83.13.2 Method Information

Method Information						
Boundary	Method	Alpha	Beta	-----Unified Family-----		
				Rho	Tau	C
Upper Alpha	O'Brien-Fleming	0.02500	.	0.5	0	2.0243
Upper Beta	O'Brien-Fleming	.	0.10000	0.5	0	1.38645
Method Information						
Boundary	Alternative Reference		Drift			
Upper Alpha	0.15		3.410743			
Upper Beta	0.15		3.410743			

The “Boundary Information” table in [Output 83.13.3](#) displays information level, alternative reference, and boundary values at each stage. By default (or equivalently if you specify BOUNDARYSCALE=STDZ), the alternative reference and boundary values are displayed with the standardized Z statistic scale. The resulting standardized alternative reference at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information level at stage k , for $k = 1, 2, 3, 4$.

Output 83.13.3 Boundary Information

Boundary Information (Standardized Z Scale)						
Nonbinding Beta Boundary, Null Reference = 0						
Stage	-----Information Level-----			---Alternative- --Reference--	----Boundary Values----	
	Proportion	Actual	N	Upper	Beta	Alpha
1	0.2500	129.2574	110.5151	1.70537	-1.06752	4.04859
2	0.5000	258.5148	221.0302	2.41176	0.45103	2.86279
3	0.7500	387.7722	331.5452	2.95379	1.35286	2.33746
4	1.0000	517.0296	442.0603	3.41074	2.02430	2.02430

By default (or equivalently if you specify `INFO=EQUAL`), equally spaced information levels are used. With the derived maximum information, the actual information level at each stage is also displayed. With the `SAMPLESIZE` statement, the required sample size N is also displayed under the heading “Information Level.”

Note that with the standardized Z statistic scale, the rejection boundary values are identical to the boundary values that are derived in the corresponding design with early stopping to reject H_0 .

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 83.13.4](#).

Output 83.13.4 Boundary Plot

The horizontal axis indicates the information levels for the design. The stages are indicated by vertical lines with accompanying stage numbers. The boundary plot also displays the information level and the critical value for the corresponding fixed-sample design.

The “Error Spending Information (Nonbinding Beta Boundary)” table in [Output 83.13.5](#) displays cumulative error spending at each stage for each boundary. With a nonbinding beta boundary, the α spending at each stage is computed by using the α boundary only.

Output 83.13.5 Error Spending Information

Error Spending Information (Nonbinding Beta Boundary)				
Stage	-Information Level- Proportion	-Cumulative Error Spending- -----Upper-----		
		Beta	Alpha	
1	0.2500	0.00278	0.00003	
2	0.5000	0.02603	0.00211	
3	0.7500	0.06343	0.01046	
4	1.0000	0.10000	0.02500	

The SEQDESIGN procedure derives the drift parameter $\theta_1 \sqrt{I_X}$, where θ_1 is the alternative reference and I_X is the maximum information. With the SAMPLESIZE statement, the maximum information is used to compute the required sample size for the study.

The “Sample Size Summary” table in [Output 83.13.6](#) displays parameters for the sample size computation. With the MODEL=TWOSAMPLEFREQ(NULLPROP=0.6 TEST=PROP) option in the SAMPLESIZE statement, the total sample size and expected sample sizes under the null and alternative hypotheses for testing the difference between two proportions are displayed.

Output 83.13.6 Sample Size Summary

Sample Size Summary		
Test	Two-Sample Proportions	
Null Proportion	0.6	
Proportion (Group A)	0.75	
Test Statistic	Z for Proportion	
Reference Proportions	Alt Ref	
Max Sample Size	442.0603	
Expected Sample Size (Null Ref)	248.7446	
Expected Sample Size (Alt Ref)	313.5929	

The “Sample Sizes (N)” table in [Output 83.13.7](#) displays the required sample sizes at each stage, in both fractional and integer numbers. The derived fractional sample sizes are under the heading “Fractional N.” These sample sizes are rounded up to integers under the heading “Ceiling N.” As expected, the sample sizes in the table are larger than the corresponding sample sizes in the corresponding design with binding beta boundary.

Output 83.13.7 Derived Sample Sizes

Sample Sizes (N) Two-Sample Z Test for Proportion Difference				
-----Fractional N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	110.52	55.26	55.26	129.3
2	221.03	110.52	110.52	258.5
3	331.55	165.77	165.77	387.8
4	442.06	221.03	221.03	517.0

Sample Sizes (N) Two-Sample Z Test for Proportion Difference				
-----Ceiling N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	112	56	56	131.0
2	222	111	111	259.6
3	332	166	166	388.3
4	444	222	222	519.3

Example 83.14: Computing Sample Size for Survival Data

This example illustrates sample size computation for survival data when the accrual is not uniform and when the data contain individual loss to follow up.

Suppose that a clinic is conducting a study of the effect of a new cancer treatment. The study consists of exposing mice to a carcinogen and randomly assigning them to either the control group or the treatment group. The event of interest is death from cancer induced by the carcinogen, and the response is the time from randomization to death.

Following the derivations in the section “[Test for Two Survival Distributions with a Log-Rank Test](#)” on page 7059, this example uses the hypothesis $H_0 : \theta = -\log(\lambda) = 0$ with an alternative hypothesis $H_1 : \theta = \theta_1 > 0$, where λ is the hazard ratio between the treatment group and the control group.

Suppose that from past experience, the median survival time for the control group is $t_0 = 20$ weeks, and the study wants to detect a $t_1 = 40$ weeks’ median survival time with a 80% power in the trial. If exponential survival functions are assumed for the two groups, the hazard rates can be computed from

$$S_j(t_j) = e^{-h_j t_j} = \frac{1}{2}$$

where $j = 0, 1$.

Thus, with $h_0 = 0.03466$ and $h_1 = 0.01733$, the hazard ratio $\lambda_1 = h_1/h_0 = 1/2$, and the alternative reference is

$$\theta_1 = -\log(\lambda_1) = -\log\left(\frac{1}{2}\right) = 0.693147$$

The following statements invoke the SEQDESIGN procedure:

```
proc seqdesign altref=0.693147
    ;
    OBrienFleming: design nstages=4
                    method=obf
    ;
    samplesize model=twosamplesurvival
                ( nullhazard=0.03466
                  accrual=exp(parm=-0.1)
                  loss=exp(hazard=0.05)
                  acctime=20);
run;
```

The ALTREF= option specifies the alternative reference $\theta_1 = -\log(\frac{1}{2}) = 0.693147$. The DESIGN statement requests a group sequential design, and the METHOD=OBF option specifies the O'Brien-Fleming design. By default, the design has a two-sided alternative hypothesis in which early stopping in the interim stages occurs to reject the null hypothesis. The SAMPLESIZE statement derives required sample sizes for the test, and the MODEL=TWOSAMPLESURVIVAL option specifies a log-rank test to compare two survival distributions for the treatment effect.

The “Design Information” table in [Output 83.14.1](#) displays design specifications and four derived statistics: the actual maximum information, the maximum information, the average sample number under the null hypothesis (Null Ref ASN), and the average sample number under the alternative hypothesis (Alt Ref ASN).

Output 83.14.1 O'Brien-Fleming Design Information

The SEQDESIGN Procedure	
Design: OBrienFleming	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	0.693147
Number of Stages	4
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	102.2163
Max Information	22.35452
Null Ref ASN (Percent of Fixed Sample)	101.5728
Alt Ref ASN (Percent of Fixed Sample)	76.7397

The “Boundary Information” table in [Output 83.14.2](#) displays the information level, including the proportion, actual level, and corresponding number of events at each stage. The table also displays the lower and upper alternative references, and the lower and upper boundary values at each stage.

Output 83.14.2 Boundary Information

Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-----Alternative-----	
	Proportion	Actual	Events	Lower	Upper
1	0.2500	5.58863	22.35452	-1.63862	1.63862
2	0.5000	11.17726	44.70904	-2.31736	2.31736
3	0.7500	16.76589	67.06356	-2.83817	2.83817
4	1.0000	22.35452	89.41808	-3.27724	3.27724
Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Boundary Values-----				
	Lower	Upper			
	Alpha	Alpha			
1	-4.04859	4.04859			
2	-2.86278	2.86278			
3	-2.33745	2.33745			
4	-2.02429	2.02429			

In the SAMPLESIZE statement, the MODEL=TWOSAMPLESURVIVAL option specifies a log-rank test to compare two survival distributions for the treatment effect. The NULLHAZARD=0.03466 option specifies null hazard rates for the two groups under the null hypothesis. The ACCTIME= option specifies the accrual time T_a , and the ACCRUAL=EXP(POWER=-0.1) option specifies that the individual accrual is truncated exponential with a scaled power parameter $\gamma_0 = -0.1$. That is, the truncated exponential accrual has a power parameter $\gamma = \gamma_0 / T_a = -0.1 / 20 = -0.005$ in the accrual time T_a . The LOSS=EXP(HAZARD=0.05) option specifies an exponential loss function with a hazard rate $\tau = 0.05$. Since the ACCNOBS= option is not included with the specified accrual time, the minimum and maximum sample sizes are derived from the specified accrual time. See the section “[Test for Two Survival Distributions with a Log-Rank Test](#)” on page 7059 for a detailed derivation of these required sample sizes.

The “Sample Size Summary” table in [Output 83.14.3](#) displays parameters for the sample size computation. Since the ACCNOBS= option is not included with the specified accrual time, the minimum and maximum sample sizes are derived.

Output 83.14.3 Sample Size Summary

Sample Size Summary	
Test	Two-Sample Survival
Null Hazard Rate	0.03466
Hazard Rate (Group A)	0.01733
Hazard Rate (Group B)	0.03466
Hazard Ratio	0.5
log(Hazard Ratio)	-0.69315
Reference Hazards	Alt Ref
Accrual	Truncated Exponential with Losses
Scaled Exponential Parameter	-0.1
Loss Hazard Rate	0.05
Accrual Time	20
Min Accrual Sample Size	269
Max Accrual Sample Size	553
Max Number of Events	89.41808

The “Numbers of Events (D)” table in [Output 83.14.4](#) displays the required number of events and corresponding information level at each stage.

Output 83.14.4 Derived Sample Sizes

Numbers of Events (D) Two-Sample Log-Rank Test		
Stage	D	Information
1	22.35	5.5886
2	44.71	11.1773
3	67.06	16.7659
4	89.42	22.3545

With the minimum and maximum sample sizes of 269 and 553, respectively, the ACCNOBS=360 option specifies an accrual sample size of 360 for the trial.

```
proc seqdesign altref=0.693147
;
  OBrienFleming: design nstages=4
                  method=obf
;
  samplesize model=twosamplesurvival
              ( nullhazard=0.03466
                accrual=exp(parm=-0.1)
                loss=exp(hazard=0.05)
                accnobs=360 acctime=20);
run;
```

With the specified accrual sample size and accrual time, the “Sample Size Summary” table in [Output 83.14.5](#) also displays the follow-up time and maximum sample size with the specified accrual time.

Output 83.14.5 Sample Size Summary

The SEQDESIGN Procedure	
Design: OBrienFleming	
Sample Size Summary	
Test	Two-Sample Survival
Null Hazard Rate	0.03466
Hazard Rate (Group A)	0.01733
Hazard Rate (Group B)	0.03466
Hazard Ratio	0.5
log(Hazard Ratio)	-0.69315
Reference Hazards	Alt Ref
Accrual	Truncated Exponential with Losses
Scaled Exponential Parameter	-0.1
Loss Hazard Rate	0.05
Accrual Time	20
Follow-up Time	9.100324
Total Time	29.10032
Max Number of Events	89.41808
Max Sample Size	360
Expected Sample Size (Null Ref)	359.7605
Expected Sample Size (Alt Ref)	342.9205

The “Number of Events (D) and Sample Sizes (N)” table in [Output 83.14.6](#) displays the required time at each stage, in both fractional and integer numbers. The derived times under the heading “Fractional Time” are not integers. These times are rounded up to integers under the heading “Ceiling Time.” The table also displays the numbers of events and sample sizes at each stage.

Output 83.14.6 Number of Events and Sample Sizes

Numbers of Events (D) and Sample Sizes (N) Two-Sample Log-Rank Test							
-----Fractional Time-----							
Stage	D	D (Grp 1)	D (Grp 2)	Time	N	N (Grp 1)	N (Grp 2)

Overview: SEQTEST Procedure

The purpose of the SEQTEST procedure is to perform interim analyses for clinical trials. Clinical trials are experiments on human beings to demonstrate the efficacy and safety of new drugs or treatments. A simple example is a trial to test the effectiveness of a new drug in humans by comparing the outcomes in a group of patients who receive the new drug with the outcomes in a comparable group of patients who receive a placebo.

A clinical trial is conducted according to a plan called a *protocol*. A protocol details the objectives of the trial, the data collection process, and the analyses of the data. The protocol contains information such as a null hypothesis and an alternative hypothesis, a test statistic, the probability α of a Type I error (incorrectly rejecting the null hypothesis), the probability β of a Type II error (incorrectly accepting the null hypothesis), the sample size needed to attain a specified power (probability of correctly rejecting the null hypothesis) of $1 - \beta$ at an alternative reference, and critical values that are associated with the test statistic for hypothesis testing.

In a fixed-sample trial, data about all individuals are first collected and then examined at the end of the study. Most major trials have data safety monitoring boards or data monitoring committees that periodically monitor safety and efficacy data during the trial and recommend that a trial be stopped for safety concerns such as an unacceptable toxicity level. In certain rare situations, the board or committee might even recommend that a trial be stopped for efficacy. In contrast to a fixed-sample trial, a group sequential trial provides for interim analyses before the formal completion of the trial while maintaining the specified overall Type I and Type II error probability levels.

A group sequential trial is most useful in situations where it is important to monitor the trial to prevent unnecessary exposure of patients to an unsafe new drug, or alternatively to a placebo treatment if the new drug shows significant improvement. If a group sequential trial stops early, then it usually requires fewer participants than a corresponding fixed-sample trial.

Thus, in most cases, if a group sequential trial stops early for safety of the new treatment, fewer patients will be exposed to the new treatment than in the fixed-sample trial. Also, if a trial stops early for efficacy of the new treatment, the new treatment will be available sooner than it would be in a fixed-sample trial. Furthermore, if a trial stops early, this can also save time and resources.

A group sequential design provides detailed specifications for a group sequential trial. In addition to the usual specification for a fixed-sample design, it provides the total number of stages (the number of interim stages plus a final stage) and a stopping criterion to reject, to accept, or to either reject or accept the null hypothesis at each interim stage. It also provides critical values and the sample size at each stage for the trial.

At each interim stage, the data collected at the current stage in addition to the data collected at previous stages are analyzed, and statistics such as a maximum likelihood test statistic and its associated standard error are computed. The test statistic is then compared with its corresponding critical values at the stage, and the trial is stopped or continued. If a trial continues to the final stage, the null hypothesis is either rejected or accepted. The critical values for each stage are chosen in such a way to maintain the overall α level, the overall β level, or both the overall α and β levels.

Figure 84.1 shows a two-sided symmetric group sequential trial that stops early to reject the null hypothesis that the parameter Trt is zero.

Figure 84.1 Sequential Plot for Two-Sided Test

The trial has four stages, which are indicated by vertical lines with accompanying stage numbers. With early stopping to reject the null hypothesis, the lower rejection boundary is constructed by connecting the lower critical values (boundary values) for the stages. Similarly, the upper rejection boundary is constructed by connecting the upper critical values for the stages. The horizontal axis indicates the sample size for the group sequential trial, and the vertical axis indicates the boundary values and test statistics on the standardized Z scale.

At each interim stage, if the standardized Z test statistic falls into a rejection region (the darker shaded areas in Figure 84.1), the trial stops and the null hypothesis is rejected. Otherwise, the trial continues to the next stage. At the final stage (stage 4), the trial is rejected if Z falls into a rejection region. Otherwise, the trial is accepted. In Figure 84.1, the test statistic does not fall into the rejection regions for stages 1 and 2, and so the trial continues to stage 3. At stage 3, the test statistic falls into the rejection region, and the null hypothesis is rejected.

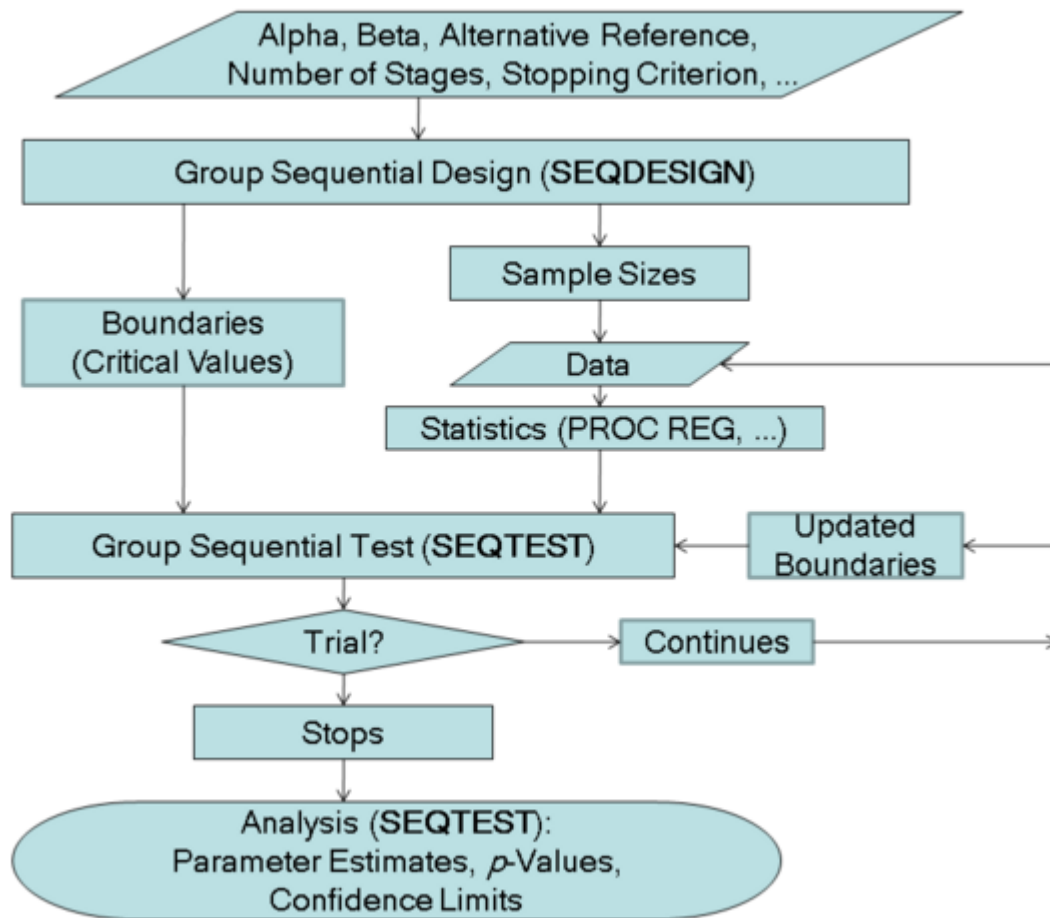

A group sequential trial usually involves six steps:

1. You specify the statistical details of the design, including the null and alternative hypotheses, a test statistic for the hypothesis test, the Type I and II error probabilities, a stopping criterion, the total number of stages, and the relative information level at each stage.
2. You compute the boundary values for the trial based on the specifications in Step 1. You also compute the sample size required at each stage for the specified hypothesis test.
3. At each stage, you collect additional data with the required sample sizes. The data available at each stage include the data collected at previous stages in addition to the data collected at the current stage.
4. At each stage, you analyze the available data with a procedure such as the REG procedure, and you compute the test statistic.
5. At each stage, you compare the test statistic with the corresponding boundary values. You stop the trial to reject or accept the hypothesis, or you continue the trial to the next stage. If you continue the trial to the final stage, you either accept or reject the hypothesis.
6. After the trial stops, you compute parameter estimates, confidence limits for the parameter, and a p -value for the hypothesis test.

You use the companion SEQDESIGN procedure at Step 2 to compute the boundary values and required sample sizes for the trial. You use the SEQTEST procedure at Step 5 to compare the test statistic with its boundary values. At stage 1, the boundary values are derived by using the boundary information tables created by the SEQDESIGN procedure. These boundary information tables are structured for input to the SEQTEST procedure. At each subsequent stage, the boundary values are derived by using the test information tables created by the SEQTEST procedure at the previous stage. These test information tables are also structured for input to the SEQTEST procedure. You also use the SEQTEST procedure at Step 6 to compute parameter estimates, confidence limits, and p -values after the trial stops.

Note that for some clinical trials, the information levels are derived from statistics based on individuals specified in the design plan and might not reach the target maximum information level. For example, if an estimate of the variance is used to compute the required sample size for a group sequential trial, the computed variance at each stage might not be the same as the estimated variance. Thus, instead of specifying the number of individuals in the protocol, the information level can be specified. You can then adjust the sample sizes with the updated variance estimates at interim stages to achieve the target maximum information level for the trial (Jennison and Turnbull 2000, p. 295).

The flowchart in [Figure 84.2](#) summarizes the steps in a typical group sequential trial and the relevant SAS procedures.

Figure 84.2 Group Sequential Trial

Features of the SEQTEST Procedure

At each stage, the data are analyzed with a statistical procedure such as the REG procedure, and a test statistic and its associated information level are computed. The information level is the amount of information available about the unknown parameter. For a maximum likelihood statistic, the information level is the inverse of its variance.

At each stage, you use the SEQTEST procedure to compare the test statistic with its boundary values. At stage 1, the boundary values are derived by using the boundary information tables created by the SEQDESIGN procedure. At each subsequent stage, the boundary values are derived by using the test information tables created by the SEQTEST procedure at the previous stage.

If the observed information level does not match the corresponding information level in the BOUNDARY= data set, the SEQTEST procedure modifies the boundary values to adjust for new information levels at the current and subsequent stages. See the section “[Boundary Adjustments for Information Levels](#)” on page 7223 for a detailed description of these boundary adjustments.

Either you can specify the test statistic and its information level in the DATA= input data set, or you can specify the test statistic and its associated standard error in the PARMS= input data set. With the PARMS=

input data set, the information level for the test statistic is computed from its standard error. See the section “[Input Data Sets](#)” on page 7217 for a detailed description of these input data sets.

At the end of a trial, the parameter estimate is computed. The median unbiased estimate, confidence limits, and p -value depend on the specified sample space ordering. A sample space ordering specifies the ordering for test statistics that result in the stopping of a trial. That is, for all the statistics in the rejection region and in acceptance region, the SEQTEST procedure provides three different sample space orderings: the stagewise ordering uses counterclockwise ordering around the continuation region, the LR ordering uses the distance between the observed Z statistic z and its hypothetical value, and the MLE ordering uses the observed maximum likelihood estimate. See the section “[Available Sample Space Orderings in a Sequential Test](#)” on page 7230 for a detailed description of these orderings.

Output from the SEQTEST Procedure

In addition to the adjusted boundary values and test results for the group sequential trial, the SEQTEST procedure also computes the following quantities:

- average sample numbers (as percentages of the corresponding fixed-sample sizes for nonsurvival data or fixed-sample numbers of events for survival data) under various hypothetical references, including the null and alternative references
- stopping probabilities at each stage under various hypothetical references to indicate how likely it is that the trial will stop at that stage
- conditional power given the most recently observed statistic under specified hypothetical references
- predictive power given the most recently observed statistic
- repeated confidence intervals for the parameter from the observed statistic at each stage
- parameter estimate, p -value for hypothesis testing, and median and confidence limits for the parameter at the conclusion of a sequential trial

Getting Started: SEQTEST Procedure

The following example illustrates a clinical study that uses a two-sided O’Brien-Fleming design (O’Brien and Fleming 1979) to stop the trial early for ethical concerns about possible harm or for unexpectedly strong efficacy of the new drug.

Suppose that a pharmaceutical company is conducting a clinical trial to test the efficacy of a new cholesterol-lowering drug. The primary focus is low-density lipoprotein (LDL), the so-called bad cholesterol, which is a risk factor for coronary heart disease. LDL is measured in mg / dL , milligrams per deciliter of blood.

The trial consists of two groups of equally allocated patients with elevated LDL level: an experimental group given the new drug and a placebo control group. Suppose the changes in LDL level after the treatment for patients in the experimental and control groups are normally distributed with means μ_e and μ_c , respectively,

and have a common variance σ^2 . Then the null hypothesis of no effect for the new drug is $H_0 : \theta = \mu_e - \mu_c = 0$. Also suppose that the alternative reference $\theta = -10$ is the clinically meaningful difference that the trial should detect with a high probability (power), and that a good estimate of the standard deviation for the changes in LDL level is $\hat{\sigma} = 20$.

The following statements invoke the SEQDESIGN procedure and request a four-stage O'Brien-Fleming design for standardized normal test statistics:

```
ods graphics on;
proc seqdesign altref=-10.0;
    TwoSidedOBrienFleming: design nstages=4
                           method=obf
                           ;
    samplesize model=twosamplemean(stddev=20);
    ods output Boundary=Bnd_LDL;
run;
ods graphics off;
```

The ALTREF= option specifies the alternative reference, and the actual maximum information is derived in the SEQDESIGN procedure.

In the DESIGN statement, the label **TwoSidedOBrienFleming** identifies the design in the output tables. By default (or equivalently if you specify ALT=TWOSIDED and STOP=REJECT), the design has a two-sided alternative hypothesis with early stopping in the interim stages only to reject the null hypothesis. That is, at each interim stage, the trial will either be stopped to reject the null hypothesis or continue to the next stage.

The NSTAGES=4 option in the DESIGN statement specifies the total number of stages in the group sequential trial, including three interim stages and a final stage. In the SEQDESIGN procedure, the null hypothesis for the design is $H_0 : \theta = 0$. By default (or equivalently if you specify ALPHA=0.05 and BETA=0.10), the design has a Type I error probability $\alpha = 0.05$, and a Type II error probability $\beta = 0.10$, which corresponds to a power of $1 - \beta = 0.90$ at the alternative reference $H_1 : \theta = -10$.

For a two-sided design with early stopping to reject the null hypothesis, there are two boundaries for the design: an upper α (rejection) boundary that consists of upper rejection critical values and a lower α boundary that consists of lower rejection critical values. Each boundary is a set of critical values, one from each stage. With the METHOD=OBF option in the DESIGN statement, the O'Brien-Fleming method is used for the two boundaries for the design; see [Figure 84.5](#).

The SAMPLESIZE statement with the MODEL=TWOSAMPLEMEAN option uses the derived maximum information to compute required sample sizes for a two-sample test for mean difference.

The ODS OUTPUT statement with the BOUNDARY=BND_LDL option creates an output data set named BND_LDL which contains the resulting boundary information. At each stage of the trial, data are collected and analyzed with a statistical procedure, and a test statistic and its corresponding information level are computed.

In this example, you can use the REG procedure to compute the maximum likelihood estimate $\hat{\theta}$ for the drug effect and the corresponding standard error for $\hat{\theta}$. At stage 1, you can use the SEQTEST procedure to compare the test statistic with adjusted boundaries that are derived from the boundary information stored in the BOUND_LDL data set. At each subsequent stage, you can use the SEQTEST procedure to compare the test statistic with adjusted boundaries that are derived from the boundary information stored in the test information table that was created by the SEQTEST procedure at the previous stage. The test information tables are structured for input to the SEQTEST procedure.

At each interim stage, the trial will either be stopped to reject the null hypothesis or continue to the next stage. At the final stage, the null hypothesis is either rejected or accepted.

By default (or equivalently if you specify `INFO=EQUAL`), the SEQDESIGN procedure derives boundary values with equally spaced information levels for all stages—that is, the same information increment between successive stages.

The “Design Information” table in [Figure 84.3](#) displays design specifications and three derived statistics: the maximum information, the average sample number under the null hypothesis (Null Ref ASN), and the average sample number under the alternative hypothesis (Alt Ref ASN). Each statistic is expressed as a percentage of the identical statistic for the corresponding fixed-sample information. The average sample number is the expected sample size (for nonsurvival data) or expected number of events (for survival data). When you specify an alternative reference (in this case, `ALTREF=-10`), the actual maximum information 0.1074 is also computed. Note that for a symmetric two-sided design, the `ALTREF=-10` option implies a lower alternative reference of -10 and an upper alternative reference of 10 .

Figure 84.3 O'Brien-Fleming Design Information

The SEQDESIGN Procedure	
Design: TwoSidedOBrienFleming	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	-10
Number of Stages	4
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	102.2163
Max Information	0.107403
Null Ref ASN (Percent of Fixed Sample)	101.5728
Alt Ref ASN (Percent of Fixed Sample)	76.7397

The “Boundary Information” table in [Figure 84.4](#) displays the information level, the lower and upper alternative references, and the lower and upper boundary values at each stage. By default (or equivalently if you specify `INFO=EQUAL`), the SEQDESIGN procedure uses equally spaced information levels for all stages.

Figure 84.4 Boundary Information

Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-----Alternative-----	
	Proportion	Actual	N	-----Reference-----	
				Lower	Upper
1	0.2500	0.026851	42.96116	-1.63862	1.63862
2	0.5000	0.053701	85.92233	-2.31736	2.31736
3	0.7500	0.080552	128.8835	-2.83817	2.83817
4	1.0000	0.107403	171.8447	-3.27724	3.27724

Boundary Information (Standardized Z Scale)			
Null Reference = 0			
Stage	-----Boundary Values-----		
	---Lower---	---Upper---	
	Alpha	Alpha	
1	-4.04859	4.04859	
2	-2.86278	2.86278	
3	-2.33745	2.33745	
4	-2.02429	2.02429	

The information proportion is the proportion of maximum information available at each stage. By default (or equivalently if you specify BOUNDARYSCALE=STDZ), the alternative references and boundary values are displayed with the standardized Z statistic scale. The alternative reference in the standardized Z scale at stage k is given by $\theta_1 \sqrt{I_k}$, where θ_1 is the alternative reference and I_k is the information available at stage k , $k = 1, 2, 3, 4$.

In this example, a standardized Z statistic is computed by standardizing the parameter estimate of the effect in LDL level. A lower Z test statistic indicates a beneficial effect. Consequently, at each interim stage, if the standardized Z test statistic is less than or equal to the corresponding lower α boundary value, the hypothesis $H_0 : \theta = 0$ is rejected for efficacy. If the test statistic is greater than or equal to the corresponding upper α boundary value, the hypothesis H_0 is rejected for harmful effect. Otherwise, the process continues to the next stage. At the final stage (stage 4), the hypothesis H_0 is rejected for efficacy if the Z statistic is less than or equal to the corresponding lower α boundary value -2.0243 , and the hypothesis H_0 is rejected for harmful effect if the Z statistic is greater than or equal to the corresponding upper α boundary value 2.0243 . Otherwise, the hypothesis of no significant difference is accepted.

Note that in a typical trial, the actual information levels do not match the information levels specified in the design. Consequently, the SEQTEST procedure modifies the boundary values stored in the BND_LDL data set to adjust for these new information levels.

If ODS Graphics is enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in Figure 84.5.

Figure 84.5 O'Brien-Fleming Boundary Plot

This boundary plot displays the boundary values in the “Boundary Information” table in Figure 84.4. The stages are indicated by vertical lines with accompanying stage numbers. The horizontal axis indicates the information levels for the stages. If a test statistic at an interim stage is in the rejection region (shaded area), the trial stops and the null hypothesis is rejected. If the statistic is not in any rejection region, the trial continues to the next stage. The plot also displays critical values for the corresponding fixed-sample design. The symbol “o” identifies the fixed-sample critical values of -1.96 and 1.96 .

When you specify the SAMPLESIZE statement, the maximum information (either explicitly specified or derived in the SEQDESIGN procedure) is used to compute the required sample sizes for the study. The MODEL=TWOSAMPLEMEAN(STDDEV=20) option specifies the test for the difference between two normal means. See the section “Test for the Difference between Two Normal Means” in the chapter “The SEQDESIGN Procedure” for a detailed description of how these required sample sizes are calculated.

The “Sample Size Summary” table in Figure 84.6 displays the parameters for the sample size computation and the resulting maximum and expected sample sizes.

Figure 84.6 Required Sample Size Summary

Sample Size Summary	
Test	Two-Sample Means
Mean Difference	-10
Standard Deviation	20
Max Sample Size	171.8447
Expected Sample Size (Null Ref)	170.7627
Expected Sample Size (Alt Ref)	129.0137

With the derived maximum information 0.1074 and the specified MODEL=TWOSAMPLEMEAN (STDDEV=20) option in the SAMPLESIZE statement, the total sample size in each group is

$$N_a = N_b = 2\sigma^2 I_X = 2 \times 20^2 \times 0.1074 = 85.92$$

The “Sample Sizes (N)” table in Figure 84.7 displays the required sample sizes at each stage for the trial, in both fractional and integer numbers. The derived fractional sample sizes are displayed under the heading “Fractional N.” These sample sizes are rounded up to integers under the heading “Ceiling N.” By default (or equivalently if you specify WEIGHT=1 in the MODEL=TWOSAMPLEMEAN option), the sample sizes for the two groups are equal for the two-sample test.

Figure 84.7 Required Sample Sizes

Sample Sizes (N)				
Two-Sample Z Test for Mean Difference				
-----Fractional N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	42.96	21.48	21.48	0.0269
2	85.92	42.96	42.96	0.0537
3	128.88	64.44	64.44	0.0806
4	171.84	85.92	85.92	0.1074
Sample Sizes (N)				
Two-Sample Z Test for Mean Difference				
-----Ceiling N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	44	22	22	0.0275
2	86	43	43	0.0538
3	130	65	65	0.0812
4	172	86	86	0.1075

In practice, integer sample sizes are used in the trial, and the resulting information levels increase slightly. Thus, each of the two groups needs 22, 43, 65, and 86 patients for the four stages, respectively.

Suppose that 22 patients are available in each group at stage 1 and that their measurements for LDL are saved in the data set LDL_1. Figure 84.8 lists the first 10 observations in the data set LDL_1.

Figure 84.8 Clinical Trial Data

First 10 Obs in the Trial Data		
Obs	Trt	Ldl
1	0	33.33
2	1	-14.89
3	0	15.30
4	1	4.71
5	0	26.89
6	1	-48.74
7	0	-39.35
8	1	-8.13
9	0	-8.22
10	1	12.35

The variable Trt is an indicator variable with value 1 for patients in the treatment group and value 0 for patients in the placebo control group. The variable Ldl is the LDL level of these patients.

The following statements use the REG procedure to estimate the mean treatment difference and its associated standard error at stage 1:

```
proc reg data=LDL_1;
  model Ldl=Trt;
  ods output ParameterEstimates=Parms_LDL1;
run;
```

The following statements create the data set for the mean treatment difference and its associated standard error as a PARMS= data set, which will subsequently serve as an input data set for PROC SEQTEST. Note that all of the variables are required for a PARMS= data set, as described in the section “[PARMS= Data Set](#)” on page 7219.

```
data Parms_LDL1;
  set Parms_LDL1;
  if Variable='Trt';
  _Scale_='MLE';
  _Stage_= 1;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_LDL1;
  title 'Statistics Computed at Stage 1';
run;
```

Figure 84.9 displays the statistics computed at stage 1.

Figure 84.9 Statistics Computed at Stage 1

Statistics Computed at Stage 1					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Trt	-2.52591	5.68572	MLE	1

Since the sample sizes derived are based on the estimated variance at the designing phase, the information level that corresponds to the test statistic at stage 1 is estimated by

$$I_1 = \frac{1}{s_1^2} = \frac{1}{5.686^2} = 0.0309$$

where s_1 is the standard error of the treatment estimate.

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_LDL
   Parms(Testvar=Trt)=Parms_LDL1
    infoadj=prop
;
ods output Test=Test_LDL1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_LDL1 option specifies the input data set PARMS_LDL1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRT option identifies the test variable TRT in the data set.

By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the maximum information and the Type I error level are maintained. Furthermore, with the INFOADJ=PROP option (which is the default), the information levels at future interim stages (2 and 3) are adjusted proportionally from the levels provided in the BOUNDARY= data set.

The ODS OUTPUT statement with the TEST=TEST_LDL1 option creates an output data set named TEST_LDL1 which contains the updated boundary information for the test at stage 1, and the boundary information that is needed for the group sequential test at the next stage. See the section “[Boundary Adjustments for Information Levels](#)” on page 7223 for details.

The “Design Information” table in [Figure 84.10](#) displays design specifications. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the boundary values are adjusted for the updated information levels to maintain the Type I α level, and the maximum information remains the same as in the BOUNDARY= data set. But the derived Type II error probability β and power $1 - \beta$ are slightly different with new information levels. With the updated power $1 - \beta$, the corresponding fixed-sample design is also updated.

Figure 84.10 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.BND_LDL
Data Set	WORK.PARMS_LDL1
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Number of Stages	4
Alpha	0.05
Beta	0.10074
Power	0.89926
Max Information (Percent of Fixed Sample)	102.4815
Max Information	0.10740291
Null Ref ASN (Percent of Fixed Sample)	101.7765
Alt Ref ASN (Percent of Fixed Sample)	75.4928

The “Test Information” table in Figure 84.11 displays the boundary values for the test statistic. By default (or equivalently if you specify BOUNDARYSCALE=STDZ), these statistics are displayed with the standardized Z scale. With the INFOADJ=PROP option (which is the default), information levels at future interim stages are derived proportionally from the corresponding levels provided in the BOUNDARY= data set.

Stage	-----Test-----	
	-----Trt-----	
	Estimate	Action
1	-0.44426	Continue
2	.	
3	.	
4	.	

At stage 1, the standardized Z statistic -0.44426 is between the lower and upper α boundary values, and so the trial continues to the next stage. With the observed information level at stage 1, $I_1 = 0.0309$ (which is not substantially different from the target information level at stage 1), the trial continues to the next stage without adjustment of the sample size according to the study plan.

If an observed information level is different from its target level at an interim stage, the sample sizes at future stages can be adjusted to achieve the target maximum information level according to the study plan. That is, a study plan might modify the final sample size to achieve the target maximum information level if the observed information level is different from its target level by a specified amount at the interim stage. For example, if the variance estimate is used to compute the required sample size of a two-sample Z test for mean difference, the study plan might use the current variance estimate to update the required sample size for the trial (Jennison and Turnbull 2000, p. 295). See the section “Applicable Two-Sample Tests and Sample Size Computation” in “The SEQDESIGN Procedure” for a description of how to compute the sample size from the variance estimate.

If ODS Graphics is enabled, a detailed test plot with the rejection and acceptance regions is displayed, as shown in Figure 84.12. This plot displays the boundary values in the “Test Information” table in Figure 84.11. The stages are indicated by vertical lines with accompanying stage numbers. The horizontal axis indicates the information levels for the stages. As expected, the test statistic is in the continuation region between the lower and upper α boundaries.

Figure 84.12 Sequential Test Plot

The following statements use the REG procedure with the data available at the first two stages to estimate the mean treatment difference and its associated standard error at stage 2:

```
proc reg data=LDL_2;
  model Ldl=Trt;
  ods output ParameterEstimates=Parms_LDL2;
run;
```

The following statements create and display (in Figure 84.13) the data set for the mean treatment difference and its associated standard error:

```
data Parms_LDL2;
  set Parms_LDL2;
  if Variable='Trt';
  _Scale_='MLE';
  _Stage_= 2;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_LDL2;
  title 'Statistics Computed at Stage 2';
run;
```

Figure 84.13 Statistics Computed at Stage 2

Statistics Computed at Stage 2					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Trt	-8.37628	4.24405	MLE	2

Using the standard error for the treatment estimate available at stage 2, the information level that corresponds to the test statistic at stage 2 is estimated by

$$I_2 = \frac{1}{s_2^2} = \frac{1}{4.244^2} = 0.0555$$

where s_2 is the standard error of the treatment estimate at stage 2.

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
proc seqtest Boundary=Test_LDL1
  Parms (Testvar=Trt)=Parms_LDL2
  infoadj=prop
  ;
  ods output Test=Test_LDL2;
run;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_LDL2 option creates an output data set named TEST_LDL2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Test Information” table in Figure 84.14 displays the boundary values for the test statistic with the default standardized Z scale

Figure 84.14 Sequential Tests

The SEQTEST Procedure						
Test Information (Standardized Z Scale)						
Null Reference = 0						
Stage	--Information Level--		-----Alternative-----		----Boundary Values----	
	Proportion	Actual	-----Reference-----		---Lower---	---Upper---
			Lower	Upper	Alpha	Alpha

Test Information (Standardized Z Scale)						
Null Reference = 0						
Stage			-----Test-----		-----Trt-----	
			Estimate	Action		
1			-0.44426	Continue		
2			-1.97365	Continue		
3			.			
4			.			

At stage 2, the standardized test statistic, $z = -8.37628/4.24405 = -1.97365$, is between its corresponding lower and upper α boundary values. Therefore, the trial continues to the next stage.

The following statements use the REG procedure with the data available at the first three stages to estimate the mean treatment difference and its associated standard error at stage 3:

```
proc reg data=LDL_3;
  model Ldl=Trt;
  ods output ParameterEstimates=Parms_LDL3;
run;
```

The following statements create and display (in [Figure 84.15](#)) the data set for the mean treatment difference and its associated standard error:

```
data Parms_LDL3;
  set Parms_LDL3;
  if Variable='Trt';
  _Scale_='MLE';
  _Stage_= 3;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_LDL3;
  title 'Statistics Computed at Stage 3';
run;
```

Figure 84.15 Statistics Computed at Stage 3

Statistics Computed at Stage 3					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Trt	-9.21369	3.42149	MLE	3

The following statements invoke the SEQTEST procedure to test for early stopping at stage 3:

```
ods graphics on;
proc seqtest Boundary=Test_LDL2
  Parms(Testvar=Trt)=Parms_LDL3
  infoadj=prop
  ;
  ods output Test=Test_LDL3;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 3, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 3, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_LDL3 option creates an output data set named TEST_LDL3 which contains the updated boundary information for the test at stage 3. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Test Information” table in [Figure 84.16](#) displays the boundary values for the test statistic with the default standardized Z scale.

Figure 84.16 Sequential Tests

The SEQTEST Procedure						
Test Information (Standardized Z Scale)						
Null Reference = 0						
Stage	--Information Level--		-----Alternative-----		----Boundary Values----	
	Proportion	Actual	-----Reference-----		---Lower---	---Upper---
			Lower	Upper	Alpha	Alpha
1	0.2880	0.030934	-1.75879	1.75879	-3.39532	3.39532
2	0.5169	0.055519	-2.35624	2.35624	-2.78456	2.78456
3	0.7953	0.085422	-2.92271	2.92271	-2.25480	2.25480
4	1.0000	0.107403	-3.27724	3.27724	-2.04573	2.04573
Test Information (Standardized Z Scale)						
Null Reference = 0						
Stage	-----Test-----		-----Trt-----			
	Estimate	Action				
1	-0.44426	Continue				
2	-1.97365	Continue				
3	-2.69289	Reject Null				
4	.					

The sequential test stops at stage 3 to reject the null hypothesis for the lower alternative because the test statistic -2.69289 is less than the corresponding upper α boundary -2.25480 . That is, the test demonstrates significant beneficial effect for the new drug.

The “Test Plot” displays boundary values for the design and the test statistic at the first three stages, as shown in [Figure 84.17](#). It shows that the test statistic is in the “Rejection Region” below the lower α boundary at stage 3.

Figure 84.17 Sequential Test Plot

When a trial stops, the “Parameter Estimates” table in [Figure 84.18](#) displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and p -value under the null hypothesis $H_0 : \theta = 0$. As expected, the p -value 0.0108 is significant at the two-sided α level, $\alpha = 0.05$, and the confidence interval does not contain the value zero. The p -value, unbiased median estimate, and confidence limits depend on the ordering of the sample space (k, z) , where k is the stage number and z is the standardized Z statistic. See the section “[Analysis after a Sequential Test](#)” on page 7229 for a detailed description of these statistics.

Figure 84.18 Parameter Estimates

Parameter	95% Confidence Limits			
Trt	-15.79845	-2.13138		

Syntax: SEQTEST Procedure

The following statement is available in the SEQTEST procedure:

```
PROC SEQTEST < options > ;
```

PROC SEQTEST Statement

The PROC SEQTEST statement invokes the SEQTEST procedure. Table 84.1 summarizes the options available in the PROC SEQTEST statement.

Table 84.1 Summary of PROC SEQTEST Options

Option	Description
Input Data Sets	
BOUNDARY=	Specifies the data set for boundary information
DATA=	Specifies the data set for parameter estimates and information levels
PARMS=	Specifies the data set for parameter estimates and standard errors
Boundaries	
BETABOUNDARY=	Specifies whether the β boundary is used in the computation of the Type I error level α
BETAOVERLAP=	Checks for overlapping of the lower and upper β boundaries at the current and subsequent interim stages in a two-sided design
BOUNDARYKEY=	Specifies the boundary key to maintain Type I and II error probability levels
BOUNDARYSCALE=	Specifies the boundary scale
ERRSPENDADJ=	Specifies error spending methods for boundary adjustments
ERRSPENDMIN=	Specifies minimum error spending values for the boundaries
INFOADJ=	Specifies whether information levels at future interim stages should be adjusted

Table 84.1 continued

Option	Description
NSTAGES=	Specifies the number of stages
Test Statistics	
DATA(TESTVAR=)	Specifies the test variable in the DATA= data set
PARMS(TESTVAR=)	Specifies the test variable in the PARMS= data set
<i>p</i>-Values and Confidence Intervals	
CIALPHA=	Specifies the significance levels for the confidence interval
CITYPE=	Specifies the types of confidence interval
ORDER=	Specifies the ordering of the sample space used to derive the <i>p</i> -values and confidence limits
Table Output	
CONDPOWER	Displays conditional powers
ERRSPEND	Displays the cumulative error spending at each stage
PREDPOWER	Displays the predictive powers
PSS	Displays the powers and expected sample sizes
RCI	Displays the repeated confidence intervals
STOPPROB	Displays the expected cumulative stopping probabilities
Graphics Output	
PLOTS=ASN	Displays the expected sample numbers plot
PLOTS=CONDPOWER	Displays the conditional powers plot
PLOTS=ERRSPEND	Displays the error spending plot
PLOTS=POWER	Displays the powers plot
PLOTS=RCI	Displays the repeated confidence intervals plot
PLOTS=TEST	Displays the boundary plot with test statistics

The BOUNDARY= option provides the information for the design and is required in the PROC SEQTEST statement. By default, the SEQTEST procedure displays tables of design information and test information. If ODS Graphics is enabled, the procedure also displays a sequential test plot.

The following options can be used in the PROC SEQTEST statement. They are listed in alphabetical order.

BETABOUNDARY=BINDING | NONBINDING

specifies whether the β boundary is used in the computation of the Type I error level α . The BETABOUNDARY=BINDING option computes the Type I error probability with the β (acceptance) boundary, and the BETABOUNDARY=NONBINDING suboption computes the Type I error probability without the β boundary (Zhu, Ni, and Yao 2011, pp. 132–133). For a detailed description of nonbinding acceptance boundary, see the section “Acceptance (β) Boundary” in Chapter 83, “The SEQDESIGN Procedure.” The default is BETABOUNDARY=BINDING.

BETAOVERLAP=ADJUST | NOADJUST

OVERLAP=ADJUST | NOADJUST

specifies whether to check for overlapping of the lower and upper β boundaries for the two corresponding one-sided tests at the current and subsequent interim stages. This option applies to two-sided designs with early stopping to accept H_0 , or to either accept or reject H_0 . This type of over-

lapping might result from a small β spending at an interim stage. When you specify BETAOVERLAP=ADJUST, the procedure checks for this type of overlapping at the current and subsequent interim stages. If such overlapping is found, the β boundaries for the two-sided design at that stage are set to missing, and the β spending values at subsequent stages are adjusted, as described in the section “Boundary Adjustments for Overlapping Lower and Upper β Boundaries” on page 7225.

You can specify BETAOVERLAP=NOADJUST to request that no adjustment be made. The default is BETAOVERLAP=ADJUST.

BOUNDARY=SAS-data-set

names the required SAS data set that contains the design boundary information. At stage 1, the data set is usually created from the “Boundary Information” table created by the SEQDESIGN procedure. At each subsequent stage, the data set is usually created from the “Test Information” table created by the SEQTEST procedure at the previous stage. The data set includes the variables `_Scale_` for the boundary scale, `_Stop_` for the stopping criterion, and `_ALT_` for the type of alternative hypothesis. It also includes `_Stage_` for the stage number, `Info_Prop` for the information proportion, and a set of the boundary variables from `Bound_LA`, `Bound_LB`, `Bound_UB`, and `Bound_UA` for boundary values at each stage.

The data set might also include `_Info_` for the actual information level, `NObs` for the number of observation, and `Events` for the number of events required at each stage.

BOUNDARYKEY=ALPHA | BETA | BOTH

specifies the boundary key to be maintained in the boundary adjustments. The BOUNDARYKEY=ALPHA option maintains the Type I α level and derives the Type II error probability, and the BOUNDARYKEY=BETA option maintains the Type II β level and derives the Type I error probability. The BOUNDARYKEY=BOTH option maintains both α and β levels simultaneously by deriving a new maximum information. The default is BOUNDARYKEY=ALPHA.

BOUNDARYSCALE=MLE | SCORE | STDZ | PVALUE

BSCALE=MLE | SCORE | STDZ | PVALUE

specifies the boundary scale to be displayed in the output boundary table and plot. The BOUNDARYSCALE=MLE, BOUNDARYSCALE=SCORE, BOUNDARYSCALE=STDZ, and BOUNDARYSCALE=PVALUE options correspond to the boundary with the maximum likelihood estimator scale, score statistic scale, standardized normal Z scale, and p -value scale, respectively. The default is BOUNDARYSCALE=STDZ.

With the BOUNDARYSCALE=MLE or BOUNDARYSCALE=SCORE option, either the MAXINFO= option must be specified or the `_Info_` variable must be in the BOUNDARY= data set to provide the necessary information level at each stage to derive the boundary values. Usually, these values are obtained from analysis output in SAS procedures.

Note that for a two-sided design, the p -value scale displays the one-sided fixed-sample p -value under the null hypothesis with a lower alternative hypothesis.

CIALPHA= α < (< LOWER= α_l > < UPPER= α_u >) >

specifies the significance levels for the confidence interval, where $0 < \alpha < 1$, $0 < \alpha_l < 0.5$, and $0 < \alpha_u < 0.5$. The default is CIALPHA=0.05.

For a lower confidence interval (CITYPE=LOWER), the CIALPHA= α option produces a $(1 - \alpha)$ lower confidence interval. For an upper confidence interval (CITYPE=UPPER), the CIALPHA= α

option produces a $(1 - \alpha)$ upper confidence interval. The LOWER= and UPPER= suboptions are applicable only for a two-sided confidence interval (CITYPE=TWOSIDED). The LOWER= suboption specifies the lower significance level α_l and the upper significance level $\alpha_u = 1 - \alpha_l$. The UPPER= suboption specifies the upper significance level α_u and the lower significance level $\alpha_l = 1 - \alpha_u$. If both LOWER= and UPPER= suboptions are not specified, $\alpha_l = \alpha_u = \alpha/2$. The significance levels α_l and α_u are then used for the $(1 - \alpha_l)$ lower confidence limit and $(1 - \alpha_u)$ upper confidence limit, respectively.

CITYPE=LOWER | UPPER | TWOSIDED

specifies the type of confidence interval. The CITYPE=LOWER, CITYPE=UPPER, and CITYPE=TWOSIDED options correspond to the lower confidence interval, upper confidence interval, and two-sided confidence interval, respectively. The default is CITYPE=LOWER for the design with an upper alternative, CITYPE=UPPER for the design with a lower alternative, and CITYPE=TWOSIDED for the design with a two-sided alternative.

DATA < (TESTVAR=variable) >=SAS-data-set

names the SAS data set that contains the test statistic and its associated information level for the stage. The data set includes the stage variable `_Stage_` and a variable to identify or derive the information level: `_Info_` for the information level, `NObs` for the number of observation, or `Events` for the number of events. If the information level that corresponds to the test statistic is not available, the information level derived in the BOUNDARY= data set is used.

If the TESTVAR= option is specified, the data set also includes the test variable specified in the TESTVAR= option and the scale variable `_Scale_` for the test statistic. Usually, these test variable values are obtained from analysis output in SAS procedures.

ERRSPENDADJ=method

ERRSPENDADJ(boundary)=method

BOUNDARYADJ=method

BOUNDARYADJ(boundary)=method

specifies methods to compute the error spending values at the current and future interim stages for the boundaries. This option is applicable only if the observed information level at the current stage does not match the value provided in the BOUNDARY= data set. These error spending values are then used to derive the updated boundary values. The default is ERRSPENDADJ=ERRLINE. Note that the information levels at future interim stages are determined by the INFOADJ= option.

The following options specify available error spending methods for boundary adjustment:

NONE

specifies that the cumulative error spending at each interim stage not be changed, even if the corresponding information level has been changed.

ERRLINE

specifies the linear interpolation method for the adjustment.

ERRFUNCGAMMA < (GAMMA= γ) >

specifies the gamma function method for the adjustment. The GAMMA= suboption specifies the γ parameter in the function, where $\gamma \leq 3$. The default is GAMMA=-2.

ERRFUNCOBF

specifies the approximate O'Brien-Fleming cumulative error spending function for the adjustment.

ERRFUNCPOC

specifies the approximate Pocock cumulative error spending function for the adjustment.

ERRFUNCPOW < (RHO= ρ) >

specifies the power function method for the adjustment. The RHO= suboption specifies the power parameter ρ in the function, where $\rho \geq 0.25$. The default is RHO=2.

See the section “[Boundary Adjustments for Information Levels](#)” on page 7223 for a detailed description of the available error spending methods for boundary adjustment in the SEQTEST procedure.

If an error spending method for boundary adjustments is used for all boundaries in a group sequential test, you can use the ERRSPENDADJ=method option to specify the method. Otherwise, you can use the following ERRSPENDADJ(boundary)=method options to specify different methods for the boundaries.

ERRSPENDADJ(ALPHA)=method

ERRSPENDADJ(REJECT)=method

BOUNDARYADJ(ALPHA)=method

BOUNDARYADJ(REJECT)=method

specifies the adjustment method for the α (rejection) boundary of a one-sided design or the lower and upper α boundaries of a two-sided design.

ERRSPENDADJ(LOWERALPHA)=method

ERRSPENDADJ(LOWERREJECT)=method

BOUNDARYADJ(LOWERALPHA)=method

BOUNDARYADJ(LOWERREJECT)=method

specifies the adjustment method for the lower α boundary of a two-sided design.

ERRSPENDADJ(UPPERALPHA)=method

ERRSPENDADJ(UPPERREJECT)=method

BOUNDARYADJ(UPPERALPHA)=method

BOUNDARYADJ(UPPERREJECT)=method

specifies the adjustment method for the upper α boundary of a two-sided design.

ERRSPENDADJ(BETA)=method

ERRSPENDADJ(ACCEPT)=method

BOUNDARYADJ(BETA)=method

BOUNDARYADJ(ACCEPT)=method

specifies the adjustment method for the β (acceptance) boundary of a one-sided design or the lower and upper β boundaries of a two-sided design.

ERRSPENDADJ(LOWERBETA)=method

ERRSPENDADJ(LOWERACCEPT)=method

BOUNDARYADJ(LOWERBETA)=method

BOUNDARYADJ(LOWERACCEPT)=method

specifies the adjustment method for the lower β boundary of a two-sided design.

ERRSPENDADJ(UPPERBETA)=method

ERRSPENDADJ(UPPERACCEPT)=method

BOUNDARYADJ(UPPERBETA)=method

BOUNDARYADJ(UPPERACCEPT)=method

specifies the adjustment method for the upper β boundary of a two-sided design.

ERRSPENDMIN=numbers

ERRSPENDMIN(boundary)=numbers

specifies the minimum error spending values at the current observed and future interim stages for the boundaries specified in the BOUNDARYKEY= option. The default is ERRSPENDMIN=0.

If a set of numbers is used for each boundary in the design, you can use the ERRSPENDMIN=numbers option. Otherwise, you can use the following ERRSPENDMIN(boundary)=numbers options to specify different sets of minimum error spending values for the boundaries. For a boundary, the error spending value at stage 1 is identical to its nominal p -value.

ERRSPENDMIN(ALPHA)=numbers

ERRSPENDMIN(REJECT)=numbers

specifies the minimum error spending values for the α boundary of a one-sided design or the lower and upper α boundaries of a two-sided design.

ERRSPENDMIN(LOWERALPHA)=numbers

ERRSPENDMIN(LOWERREJECT)=numbers

specifies the minimum error spending values for the lower α boundary of a two-sided design.

ERRSPENDMIN(UPPERALPHA)=numbers

ERRSPENDMIN(UPPERREJECT)=numbers

specifies the minimum error spending values for the upper α boundary of a two-sided design.

ERRSPENDMIN(BETA)=numbers

ERRSPENDMIN(ACCEPT)=numbers

specifies the minimum error spending values for the β boundary of a one-sided design or the lower and upper β boundaries of a two-sided design.

ERRSPENDMIN(LOWERBETA)=numbers

ERRSPENDMIN(LOWERACCEPT)=numbers

specifies the minimum error spending values for the lower β boundary of a two-sided design.

ERRSPENDMIN(UPPERBETA)=numbers

ERRSPENDMIN(UPPERACCEPT)=numbers

specifies the minimum error spending values for the upper β boundary of a two-sided design.

INFOADJ=NONE | PROP

specifies whether information levels at future interim stages are to be adjusted. If you specify INFOADJ=NONE, no adjustment is made, and the information levels are preserved at the levels provided in the BOUNDARY= data set. If you specify INFOADJ=PROP (which is the default), the information levels are adjusted proportionally from the levels provided in the BOUNDARY= data set. The section “[Information Level Adjustments at Future Stages](#)” on page 7223 describes how the adjustments are computed.

Note that if you specify BOUNDARYKEY=BOTH, the INFOADJ=NONE option is not applicable, and the INFOADJ=PROP option is used to adjust the information levels at future stages proportionally from the levels provided in the BOUNDARY= data set to maintain both α and β levels.

NSTAGES=number

specifies the number of stages for the clinical trial. The default is the number derived from the BOUNDARY= data set.

The specified NSTAGES= number might or might not be the same as the number derived in the BOUNDARY= data set. You can use the NSTAGES= option to set the next stage as the final stage to compute the conditional power, as described in the section “[Conditional Power Approach](#)” on page 7226.

ORDER=LR | MLE | STAGEWISE

specifies the ordering of the sample space (k, z) , where k is the stage number and z is the observed standardized Z statistic. The ordering is used to derive the p -values for the observed (k, z) statistic and to create unbiased median estimate and confidence limits from the statistic. The ORDER=LR option specifies the LR ordering that compares the distances between observed standardized Z statistics and their corresponding hypothetical values, the ORDER=MLE option specifies the MLE ordering that compares values in the MLE scale, and the ORDER=STAGEWISE specifies the stagewise ordering that uses counterclockwise ordering around the continuation region. The default is ORDER=STAGEWISE. See the section “[Available Sample Space Orderings in a Sequential Test](#)” on page 7230 for a detailed description of these sample space orderings.

PARMS <(TESTVAR=variable)> =SAS-data-set

names the SAS data set that contains the parameter estimate and its associated standard error for the stage. The data set includes the stage variable `_Stage_`, the test statistic Estimate, the standard error of the estimate StdErr, and the test statistic scale variable `_Scale_`. The standard error is used to derive the information level. If the standard error is not available, the information level derived in the BOUNDARY= data set is used.

The data set also includes the variable Parameter, Effect, Variable, or Parm that contains the test variable specified in the TESTVAR= option. Usually, these test variable values are obtained from analysis output in SAS procedures.

Table Output Options

You can specify the following *options* in the PROC SEQTEST statement to display additional table output. They are listed in alphabetical order.

CONDPower <(options)>

displays conditional powers given the most recently observed statistic under specified hypothetical references.

You can specify the following *options*:

CREF= $c_1 < c_2 \dots >$

specifies the hypothetical references, where $c_i \geq 0$. For a one-sided test, the powers are derived under the hypothetical references $\theta = \hat{\theta}$ and $\theta = c_i \theta_1$, where $\hat{\theta}$ is the observed statistic, θ_1 is the alternative reference, and c_i are the values specified in the CREF= option. For a two-sided test, the powers are derived under hypothetical references $\theta = \hat{\theta}$, $\theta = c_i \theta_{1l}$, and $\theta = c_i \theta_{1u}$, where θ_{1l} is the lower alternative reference and θ_{1u} is the upper alternative reference. The default is CREF= 0 0.5 1.0 1.5.

TYPE=ALLSTAGES | FINALSTAGE

specifies the probability to be computed for the conditional power. Two types of conditional power can be computed: TYPE=ALLSTAGES computes the conditional power as the total probability of rejecting the null hypothesis at all future stages given the observed statistic, and TYPE=FINALSTAGE computes the conditional power as the probability that the test statistic at the final stage would exceed the rejection critical value given the observed statistic. The default is TYPE=ALLSTAGES.

If interim stages exist between the current stage and the final stage, the conditional power that is computed when TYPE=FINALSTAGE is not the conditional probability to reject the null hypothesis H_0 . In this case, you can set the next stage as the final stage, and the resulting conditional power is the conditional probability to reject H_0 .

ERRSPEND

displays the error spending at each stage for each sequential boundary.

PREDPOWER

displays predictive powers given the most recently observed statistic. The predictive power is the posterior probability that the test statistic at the final stage would exceed the rejection critical value given the observed statistic and a prior distribution of the hypothetical reference. A noninformative prior is used in the procedure.

PSS <(CREF= $c_1 < c_2 \dots >$) >

displays powers and expected sample sizes under various hypothetical references, where $c_i \geq 0$.

For a one-sided design with the null reference $\theta_0 = 0$, the power and expected sample sizes under hypotheses $\theta = c_i \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, the power and expected sample sizes under hypotheses $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The default is CREF= 0 0.5 1.0 1.5.

Note that for a symmetric two-sided design, only the power and expected sample sizes under hypotheses $\theta = c_i \theta_{1u}$ are derived.

RCI

displays repeated confidence intervals for the parameter from the observed statistic at each stage. Repeated confidence intervals include both rejection and acceptance confidence intervals.

With the STOP=REJECT or STOP=BOTH option, rejection confidence limits can be derived, and the null hypothesis $H_0 : \theta = 0$ is rejected if the lower rejection confidence limit is greater than 0 or the upper rejection confidence limit is less than 0.

With the STOP=ACCEPT or STOP=BOTH option, acceptance confidence limits can be derived, and the null hypothesis is accepted with alternative hypotheses $H_{1l} : \theta = \theta_{1l}$ and $H_{1u} : \theta = \theta_{1u}$ if the upper acceptance confidence limit is less than θ_{1u} and the lower acceptance confidence limit is greater than θ_{1l} .

STOPPROB <(CREF= $c_1 < c_2 \dots$) >

displays expected cumulative stopping probabilities under various hypothetical references, where $c_i \geq 0$.

For a one-sided design, expected cumulative stopping probabilities at each stage under hypotheses $\theta = c_i \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, expected cumulative stopping probabilities at each stage under hypotheses $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only expected cumulative stopping probabilities under hypotheses $\theta = c_i \theta_{1u}$ are derived. The default is CREF= 0 0.5 1.0 1.5.

Graphics Output Options

The following options can be used in the PROC SEQTEST statement to display plots with ODS Graphics. They are listed in alphabetical order.

PLOTS <(ONLY)> <= *plot-request* >**PLOTS <(ONLY)> <= (*plot-request* < ... *plot-request*) >**

specifies options that control the details of the plots. The default is PLOTS=TEST. The global plot option ONLY suppresses the default plots and displays only plots specifically requested.

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc seqtest Boundary=Bnd_LDL
             Parms(Testvar=Trt)=Parms_LDL1
              Plots=(test errspend);
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The plot request options include the following.

ALL

produces all appropriate plots.

ASN < (**CREF=** $c_1 < c_2 \dots >$) >

displays a plot of the average sample numbers (expected sample sizes for nonsurvival data or expected number of events for survival data) under various hypothetical references, where $c_i \geq 0$.

For a one-sided design, expected sample numbers under hypotheses $\theta = c_i \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, expected sample numbers under hypotheses $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only the average sample numbers under hypotheses $\theta = c_i \theta_{1u}$ are derived. The default is CREF= 0 to 1.5 by 0.01.

CONDPOWER < (*options*) >

displays a plot of conditional powers given the most recently observed statistic under specified hypothetical references.

You can specify the following *options*:

CREF= $c_1 < c_2 \dots >$

specifies the hypothetical references, where $c_i \geq 0$. For a one-sided test, the powers are derived under hypothetical references $\theta = \hat{\theta}$ and $\theta = c_i \theta_1$, where $\hat{\theta}$ is the observed statistic, θ_1 is the alternative reference, and c_i are the values specified in the CREF= option. For a two-sided test, the powers are derived under hypothetical references $\theta = \hat{\theta}$, $\theta = c_i \theta_{1l}$, and $\theta = c_i \theta_{1u}$, where θ_{1l} is the lower alternative reference and θ_{1u} is the upper alternative reference. The default is CREF= 0 to 1.5 by 0.01.

TYPE=ALLSTAGES | FINALSTAGE

specifies the probability to be computed for the conditional power. Two types of conditional power can be computed: TYPE=ALLSTAGES computes the conditional power as the total probability of rejecting the null hypothesis at all future stages given the observed statistic, and TYPE=FINALSTAGE computes the conditional power as the probability that the test statistic at the final stage would exceed the rejection critical value given the observed statistic. The default is TYPE=ALLSTAGES.

ERRSPEND < (**HSCALE=INFO | STAGE**) >

displays a plot of the error spending for all sequential boundaries in the designs simultaneously. You can display the information level (HSCALE=INFO) or the stage number (HSCALE=STAGE) on the horizontal axis. With HSCALE=INFO, the information fractions are used in the plot. The default is HSCALE=STAGE.

NONE

suppresses all plots.

POWER <(CREF= $c_1 < c_2 \dots >$) >

displays a plot of the power curves under various hypothetical references, where $c_i \geq 0$.

For a one-sided design, powers under hypotheses $\theta = c_i \theta_1$ are displayed, where θ_1 is the alternative reference and c_i are the values specified in the CREF= option.

For a two-sided design, powers under hypotheses $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. Note that for a symmetric two-sided design, only powers under hypotheses $\theta = c_i \theta_{1u}$ are derived. The default is CREF= 0 to 1.5 by 0.01.

RCI

displays a plot of repeated confidence intervals. Repeated confidence intervals include both rejection and acceptance confidence intervals.

With the STOP=REJECT or STOP=BOTH option, rejection confidence limits can be derived and the null hypothesis $H_0 : \theta = 0$ is rejected if the lower rejection confidence limit is greater than 0 or the upper rejection confidence limit is less than 0.

With the STOP=ACCEPT or STOP=BOTH option, acceptance confidence limits can be derived and the null hypothesis is accepted with alternative hypotheses $H_{1l} : \theta = \theta_{1l}$ and $H_{1u} : \theta = \theta_{1u}$ if the upper acceptance confidence limit is less than θ_{1u} and the lower acceptance confidence limit is greater than θ_{1l} .

TEST <(HSCALE=INFO | SAMPLESIZE) >

displays a plot of the sequential boundaries and test variables. Either the information level (HSCALE=INFO) or the sample size (HSCALE=SAMPLESIZE) is displayed on the horizontal axis. The HSCALE=SAMPLESIZE option is applicable only if the sample size information is available in both the input BOUNDARY= data set and input DATA= data set. The stage number for each stage is displayed inside the plot. The default is HSCALE=INFO.

Details: SEQTEST Procedure

Input Data Sets

The BOUNDARY= data set option is required, and if neither the DATA= nor the PARMS= data set option is specified, the procedure derives statistics such as Type I and Type II error probabilities from the BOUNDARY= data set. The resulting boundaries are displayed with the scale specified in the BOUNDARYSCALE= option.

BOUNDARY= Data Set

The BOUNDARY= data set provides the boundary information for the sequential test. At stage 1, the data set is usually created with an ODS OUTPUT statement from the “Boundary Information” table created by the SEQDESIGN procedure. At each subsequent stage, the data set is usually created with an ODS OUTPUT statement from the “Test Information” table that was created by the SEQTEST procedure at the

previous stage. See the section “[Getting Started: SEQTEST Procedure](#)” on page 7192 for an illustration of the BOUNDARY= data set option.

The BOUNDARY= data set contains the following variables:

- `_Scale_`, the boundary scale, with the value MLE for the maximum likelihood estimate, STDZ for the standardized Z, SCORE for the score statistic, or PVALUE for the nominal p -value. Note that for a two-sided design, the nominal p -value is the one-sided fixed-sample p -value under the null hypothesis with a lower alternative hypothesis.
- `_Stop_`, the stopping criterion, with the value REJECT for rejecting the null hypothesis H_0 , ACCEPT for accepting H_0 , or BOTH for both rejecting and accepting H_0
- `_ALT_`, the type of alternative hypothesis, with the value UPPER for an upper alternative, LOWER for a lower alternative, or TWOSIDED for a two-sided alternative
- `_Stage_`, the stage number
- the boundary variables, a subset of Bound_LA for lower α boundary, Bound_LB for lower β boundary, Bound_UB for upper β boundary, and Bound_UA for upper α boundary
- AltRef_L, the lower alternative reference, if ALT=LOWER or ALT=TWOSIDED
- AltRef_U, the upper alternative reference, if ALT=UPPER or ALT=TWOSIDED
- `_InfoProp_`, the information proportion at each stage

Optionally, the BOUNDARY= data set also contains the following variables:

- `_Info_`, the information level at each stage
- NObs, the required number of observations for nonsurvival data at each stage
- Events, the required number of events for survival data at each stage
- Parameter, the variable specified in the DATA(TESTVAR=) or PARMS(TESTVAR=) option
- Estimate, the parameter estimate

If the BOUNDARY= data set contains the variable Parameter for the test variable that is specified in the TESTVAR= option, and the variable Estimate for the test statistics, then these test statistics are also displayed in the output test information table and output test plot.

DATA= Data Set

The DATA= data set provides the test variable information for the current stage of the trial. Such data sets are usually created with an ODS OUTPUT statement by using a procedure such as PROC MEANS. See “[Example 84.4: Testing a Binomial Proportion](#)” on page 7284 for an illustration of the DATA= data set option.

The DATA= data set includes the following variables:

- `_Stage_`, the stage number
- `_Scale_`, the scale for the test statistic, with the value MLE for the maximum likelihood estimate, STDZ for the standardized Z, SCORE for the score statistic, or PVALUE for the nominal p -value
- `_Info_`, the information level
- NObs, the number of observations for nonsurvival data at each stage
- Events, the number of events for survival data at each stage
- test variable, specified in the TESTVAR= option, contains the test variable value in the scale specified in the `_Scale_` variable

With the specified DATA= data set, PROC SEQTEST derives boundary values from the information levels in the `_Info_` variable. If the data set does not include the `_Info_` variable, then the information levels are derived from the NObs or Events variable in the DATA= data set if that variable is also in the input BOUNDARY= data set. That is, the information level at stage k is computed as $I_k^* = I_k \times (n_k^*/n_k)$, where I_k and n_k are the information level and sample size, respectively, at stage k in the BOUNDARY= data set and n_k^* is the sample size at stage k in the DATA= data set. Otherwise, the information levels from the BOUNDARY= data set are used.

If the TESTVAR= option is specified, the DATA= data set must also include the test variable for the test statistic and `_Scale_` variable for the corresponding scale. Note that for a two-sided design, the nominal p -value is the one-sided fixed-sample p -value under the null hypothesis with a lower alternative hypothesis.

PARMS= Data Set

The PARMS= data set provides a parameter estimate and associated standard error for the current stage of the trial. Such data sets are usually created with an ODS OUTPUT statement by using procedures such as the GENMOD, GLM, LOGISTIC, and REG procedures. See the section “[Getting Started: SEQTEST Procedure](#)” on page 7192 for an illustration of the PARMS= data set option.

The PARMS= data set includes the following variables:

- `_Stage_`, the stage number
- `_Scale_`, the scale for the test statistic, with the value MLE for the maximum likelihood estimate, STDZ for the standardized Z, SCORE for the score statistic, or PVALUE for the nominal p -value
- Parameter, Effect, Variable, or Parm, which contains the variable specified in the TESTVAR= option
- Estimate, the parameter estimate
- StdErr, standard error of the parameter estimate
- NObs, the number of observations for nonsurvival data at each stage
- Events, the number of events for survival data at each stage

With the specified PARMS= data set, the information level is derived from the StdErr variable. For a score statistic, the information level I_k is the variance of the statistic, \hat{s}_k^2 , where \hat{s}_k is the standard error in the StdErr variable. Otherwise, the information level is the inverse of the variance of the statistic, \hat{s}_k^{-2} . If the data set does not include the StdErr variable, the information levels derived from the BOUNDARY= data set are used.

If the data set does not include the StdErr variable, then the information levels are derived from the NObs or Events variable in the PARMS= data set if that variable is also in the input BOUNDARY= data set. That is, the information level at stage k is computed as $I_k^* = I_k \times (n_k^*/n_k)$, where I_k and n_k are the information level and sample size, respectively, at stage k in the BOUNDARY= data set and n_k^* is the sample size at stage k in the PARMS= data set. Otherwise, the information levels from the BOUNDARY= data set are used.

If the TESTVAR= option is specified, the PARMS= data set also includes the variable Parameter, Effect, Variable, or Parm for the test variable, Estimate for the test statistic, and _Scale_ variable for the corresponding scale. Note that for a two-sided design, the nominal p -value is the one-sided fixed-sample p -value under the null hypothesis with a lower alternative hypothesis.

Boundary Variables

The boundaries created in group sequential trials depend on the type of the alternative hypothesis and the early stopping criterion. Table 84.2 shows the boundaries created with various design specifications.

Table 84.2 Boundary Variables

Specifications		Boundary Variables			
Alternative Hypothesis	Early Stopping	Lower		Upper	
		Alpha	Beta	Beta	Alpha
Lower	Accept H_0		X		
	Reject H_0	X			
	Accept/Reject H_0	X	X		
Upper	Accept H_0			X	
	Reject H_0				X
	Accept/Reject H_0			X	X
Two-sided	Accept H_0		X	X	
	Reject H_0	X			X
	Accept/Reject H_0	X	X	X	X

Up to four different boundaries can be generated in a group sequential design:

- the upper α boundary, used to reject the null hypothesis in favor of an upper alternative hypothesis
- the upper β boundary, used to accept the null hypothesis with an upper alternative hypothesis
- the lower β boundary, used to accept the null hypothesis with a lower alternative hypothesis

- the lower α boundary, used to reject the null hypothesis in favor of a lower alternative hypothesis

For a two-sided design, the null hypothesis is accepted only if both the null hypothesis is accepted with an upper alternative hypothesis and the null hypothesis is accepted with a lower alternative hypothesis.

For a one-sided design with a lower alternative, only the lower boundaries are created. Similarly, for a one-sided design with an upper alternative, only the upper boundaries are created. For example, Figure 84.19 shows the boundary plot for a one-sided test with an upper alternative.

Figure 84.19 Boundary Plot for One-Sided Test

Figure 84.19 corresponds to a one-sided sequential design with early stopping to reject or accept the null hypothesis. For a sequential test with early stopping only to reject the null hypothesis, there are no acceptance boundary values at interim stages. The acceptance boundary value and its associated acceptance region are displayed only at the final stage. Similarly, for a sequential test with early stopping only to accept the null hypothesis, there are no rejection boundary values at interim stages. The rejection boundary value and its associated rejection region are displayed only at the final stage.

For a two-sided design, both the lower and upper boundaries are created. For a design with early stopping to reject the null hypothesis, α boundaries are created. Similarly, for a design with early stopping to accept the null hypothesis, β boundaries are created. For a design with early stopping to accept or reject the null hypothesis, both the α and β boundaries are created.

For example, Figure 84.20 shows the boundary plot for a two-sided test.

Figure 84.20 Boundary Plot for Two-Sided Test

Figure 84.20 corresponds to a two-sided sequential design with early stopping to reject or accept the null hypothesis. For a sequential test with early stopping only to reject the null hypothesis, there are no acceptance boundary values at interim stages. The acceptance boundary value and its associated acceptance region are displayed only at the final stage. Similarly, for a sequential test with early stopping only to accept the null hypothesis, there are no rejection boundary values at interim stages. The rejection boundary value and its associated rejection region are displayed only at the final stage.

Information Level Adjustments at Future Stages

In a group sequential clinical trial, the information level for the observed test statistic at the current stage generally does not match the corresponding information level in the BOUNDARY= data set. By default (or equivalently if you specify INFOADJ=PROP), the SEQTEST procedure accommodates the observed information level by adjusting the information levels at future interim stages. The adjustment of information levels depends on the boundary key to be maintained in the boundary adjustments, which in turn is determined by the BOUNDARYKEY= option.

If you specify BOUNDARYKEY=ALPHA (which is the default) or BOUNDARYKEY=BETA, the maximum information level (the information level at the final stage) provided in the BOUNDARY= data set is maintained. In this case, if an observed information level at the current stage is different from the level provided in the BOUNDARY= data set, you can use the INFOADJ= option to determine whether the information levels at subsequent interim stages are to be adjusted. Specifying INFOADJ=NONE preserves the levels provided in the BOUNDARY= data set without adjustment. Specifying INFOADJ=PROP proportionally adjusts the levels provided in the BOUNDARY= data set as follows.

Denote the information level at stage k for the K -stage design that is stored in the BOUNDARY= data set by I_k , $k = 1, 2, \dots, K$. Also denote the information level that corresponds to the test statistic at an interim stage k_0 by I'_{k_0} , $1 \leq k_0 \leq (K - 1)$. Then for the updated design, the information level at stage k , $k = k_0 + 1, \dots, (K - 1)$, is computed as

$$I'_k = I'_{k_0} + (I_K - I'_{k_0}) \frac{I_k - I_{k_0}}{I_K - I_{k_0}}$$

Note that if $I'_{k_0} \geq I_K$, the information level at stage k_0 reaches the maximum information level in the design, the trial stops at stage k_0 , and no future information levels are derived.

If you specify BOUNDARYKEY=BOTH, the maximum information level for the trial is not necessarily the same as the maximum information level saved in the BOUNDARY= data set. In this case, the INFOADJ=NONE option is not applicable, and the INFOADJ=PROP option is used to proportionally adjust the information levels at future interim stages with the updated maximum information I'_K . That is, with an updated I'_K , the information level at a future interim stage k is computed as

$$I'_k = I'_{k_0} + (I'_K - I'_{k_0}) \frac{I_k - I_{k_0}}{I'_K - I_{k_0}}$$

Boundary Adjustments for Information Levels

In a group sequential clinical trial, if the information level for the observed test statistic does not match the corresponding information level in the BOUNDARY= data set, the INFOADJ=PROP option (which is the default) can be used to modify information levels at future stages to accommodate this observed information level. With the adjusted information levels, the ERRSPENDADJ= option provides various methods to compute error spending values at the current and future interim stages. These error spending values are then used to derive boundary values in the SEQTEST procedure. See the section “Error Spending Methods” in the chapter “The SEQDESIGN Procedure” for a detailed description of how to use these error spending values to derive boundary values.

The ERRSPENDADJ=NONE option keeps the error spending the same at each stage. The ERRSPENDADJ=ERRLINE option uses a linear interpolation on the cumulative error spending in the

design stored in the BOUNDARY= data set to derive the error spending for each unmatched information level (Kittelson and Emerson 1999, p. 882). That is, the cumulative error spending for an information level I is computed as

$$e(I) = \begin{cases} e_1 \left(\frac{I}{I_1} \right) & \text{if } I < I_1 \\ e_j + (\alpha_{j+1} - \alpha_j) \left(\frac{I - I_j}{I_{j+1} - I_j} \right) & \text{if } I_j \leq I < I_{j+1} \\ e_K & \text{if } I \geq I_K \end{cases}$$

where e_1, e_2, \dots, e_K are the cumulative errors at the K stages of the design that is stored in the BOUNDARY= data set.

The ERRSPENDADJ=ERRFUNCPOC option uses Pocock-type cumulative error spending function (Lan and DeMets 1983):

$$E(t) = \begin{cases} 1 & \text{if } t \geq 1 \\ \log(1 + (e - 1)t) & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

With an error level of α or β , the cumulative error spending for an information level I is $e(I) = \alpha E(I/I_K)$ or $e(I) = \beta E(I/I_K)$.

The ERRSPENDADJ=ERRFUNCOBF option uses O'Brien-Fleming-type cumulative error spending function (Lan and DeMets 1983):

$$E(t; a) = \begin{cases} 1 & \text{if } t \geq 1 \\ \frac{1}{a} 2 (1 - \Phi(\frac{z(1-a/2)}{\sqrt{t}})) & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

where a is either α for the α spending function or β for the β spending function, and Φ is the cumulative distribution function of the standardized Z statistic. That is, with an error level of α or β , the cumulative error spending for an information level I is $e(I) = \alpha E(I/I_K; \alpha)$ or $e(I) = \beta E(I/I_K; \beta)$.

The ERRSPENDADJ=ERRFUNCGAMMA option uses gamma cumulative error spending function (Hwang, Shih, and DeCani 1990):

$$E(t; \gamma) = \begin{cases} 1 & \text{if } t \geq 1 \\ \frac{1 - e^{-\gamma t}}{1 - e^{-\gamma}} & \text{if } 0 < t < 1, \gamma \neq 0 \\ t & \text{if } 0 < t < 1, \gamma = 0 \\ 0 & \text{otherwise} \end{cases}$$

where γ is the parameter γ specified in the GAMMA= option. That is, with an error level of α or β , the cumulative error spending for an information level I is $e(I) = \alpha E(I/I_K; \gamma)$ or $e(I) = \beta E(I/I_K; \gamma)$.

The ERRSPENDADJ=ERRFUNCPOW option uses power cumulative error spending function (Jennison and Turnbull 2000, p. 148):

$$E(t; \rho) = \begin{cases} 1 & \text{if } t \geq 1 \\ t^\rho & \text{if } 0 < t < 1 \\ 0 & \text{otherwise} \end{cases}$$

where ρ is the power parameter specified in the RHO= suboption. With an error level of α or β , the cumulative error spending for an information level I is $e(I) = \alpha E(I/I_K; \rho)$ or $e(I) = \beta E(I/I_K; \rho)$.

If the BOUNDARYKEY=BOTH option is specified, the maximum information required for the trial might not be the same as the maximum information level stored in the BOUNDARY= data set. In this case, the information levels at future stages are adjusted proportionally, and the same error spending values that were computed based on the maximum information level stored in the BOUNDARY= data set are used to derive boundary values for the trial.

If an error spending function is used to create boundaries for the design in the SEQDESIGN procedure, then in order to better maintain the design features throughout the group sequential trial, the same error spending function to create boundaries for the design in the SEQDESIGN procedure should be used to modify boundaries in the SEQTEST procedure at each subsequent stage.

Boundary Adjustments for Minimum Error Spending

In a group sequential clinical trial, boundary values created from a design such as an O'Brien-Fleming design might be too conservative in early stages. Thus the trial is unlikely to stop in early stages. Lan and DeMets (1983, p. 662) suggest truncating boundary values to a number such as 3.5 for the trial to have a reasonable probability of stopping at early stages. Instead of truncating boundary values by a specified number, the ERRSPENDMIN= option provides individual minimum error spending at each interim stage to stop the trial early.

For a K -stage trial, denote the derived cumulative error spending at stage k after adjusting for information levels by $e_k, k = 1, 2, \dots, K$. Also denote the specified minimum error spending at interim stage k by $\epsilon_k, k = 1, 2, \dots, K - 1$. Then the cumulative error spending at stage 1 is $e'_1 = \max(e_1, \epsilon_1)$. If $e_1 < e'_1$, the error spending values at subsequent interim stages are adjusted proportionally by

$$e'_j = e'_1 + \frac{e_j - e_1}{e_K - e_1} (e_K - e'_1)$$

for $j = 2, \dots, K - 1$.

The process is repeated at each subsequent interim stage. That is, at stage $k, k = 2, \dots, K - 1$, denote the updated cumulative β spending at stage j by $e_j, j = k, k + 1, \dots, K$. Then the cumulative error spending at stage k is $e'_k = \max(e_k, e'_{k-1} + \epsilon_k)$. If $e_k < e'_k$, the error spending values at subsequent interim stages are adjusted proportionally by

$$e'_j = e'_k + \frac{e_j - e_k}{e_K - e_k} (e_K - e'_k)$$

for $j = k + 1, \dots, K - 1$.

Note that the ERRSPENDMIN= option is applicable only to the boundaries specified in the BOUNDARYKEY= option. That is, the ERRSPENDMIN= option is applicable to the α boundaries with BOUNDARYKEY=ALPHA or BOUNDARYKEY=BOTH, and it is applicable to the β boundaries with BOUNDARYKEY=BETA or BOUNDARYKEY=BOTH.

Boundary Adjustments for Overlapping Lower and Upper β Boundaries

In the SEQTEST procedure, the α and β spending values at the stages are used to derive the boundary values for the trial. For a two-sided design with early stopping to accept H_0 , or to either reject or accept

H_0 , a zero β spending at an interim stage sets the β boundary values to missing. A small β spending at the current or subsequent interim stage might result in overlapping of the lower and upper β boundaries for the two corresponding one-sided tests. Specifically, this form of overlapping occurs at an interim stage k if the upper β boundary value that is derived from the one-sided test for the upper alternative is less than the lower β boundary value that is derived from the one-sided test for the lower alternative (Kittelsohn and Emerson 1999, pp. 881–882; Rudser and Emerson 2007, p. 6). You can use the BETAOVERLAP= option to specify how this type of overlapping is to be handled.

If BETAOVERLAP=ADJUST (which is the default) is specified, the procedure derives the boundary values for the two-sided design and then checks for overlapping of the two one-sided β boundaries at the current and subsequent interim stages. If overlapping occurs at a particular stage, the β boundary values for the two-sided design are set to missing (so the trial does not stop to accept the null hypothesis at this stage), and the β spending values at subsequent stages are adjusted proportionally as follows.

If the β boundary values are set to missing at stage k in a K -stage trial, the adjusted β spending value at stage k , e'_k , is updated for these missing β boundary values, and then the β spending values at subsequent stages are adjusted proportionally by

$$e'_j = e'_k + \frac{e_j - e_k}{e_K - e_k} (e_K - e'_k)$$

for $j = k + 1, \dots, K$, where e_j and e'_j are cumulative β spending values at stage j before and after the adjustment, respectively.

After all these adjusted β spending values are computed, the boundary values are then further modified for these adjusted β spending values.

If you specify BETAOVERLAP=NOADJUST, no adjustment is made when overlapping of one-sided β boundaries occurs.

Stochastic Curtailment

Lan, Simon, and Halperin (1982) introduce stochastic curtailment to stop a trial if, given current data, it is likely to predict the outcome of the trial with high probability. That is, a trial can be stopped to reject the null hypothesis H_0 if, given current data in the analyses, the conditional probability of rejecting H_0 under H_0 at the end of the trial is greater than γ , where the constant γ should be between 0.5 and 1 and values of 0.8 or 0.9 are recommended (Jennison and Turnbull 2000, p. 206). Similarly, a trial can be stopped to accept the null hypothesis H_0 if, given current data in the analyses, the conditional probability of rejecting H_0 under the alternative hypothesis H_1 at the end of the trial is less than γ .

The following two approaches for stochastic curtailment are available in the SEQTEST procedures: conditional power approach and predictive power approach. For each approach, the derived group sequential test is used as the reference test for rejection.

Conditional Power Approach

In the SEQTEST procedure, you can compute two types of conditional power as described in the following sections:

TYPE=ALLSTAGES

The default TYPE=ALLSTAGES suboption in the CONDPOWER and PLOT=CONDPOWER options computes the conditional power at an interim stage k as the total probability of rejecting the null hypothesis at all future stages given the observed statistic (Zhu, Ni, and Yao 2011, pp. 131–132).

For a one-sided test with an upper alternative, the conditional power at an interim stage k is given by

$$\begin{aligned} p_{ku}(\theta) &= P_{\theta}(z_{k+1} > a_{k+1} | z_k, \theta) \\ &+ P_{\theta}(b_{k+1} \leq z_{k+1} < a_{k+1}, z_{k+2} > a_{k+2} | z_k, \theta) \\ &+ \dots \\ &+ P_{\theta}(b_j \leq z_j < a_j, j = k+1, \dots, K-1, z_K > a_K | z_k, \theta) \end{aligned}$$

where z_k is the observed statistic and θ is the hypothetical reference. The conditional power for a one-sided test with a lower alternative is similarly derived.

For a two-sided test, the conditional power for the upper alternative is given by

$$\begin{aligned} p_{ku}(\theta) &= P_{\theta}(z_{k+1} > a_{k+1} | z_k, \theta) \\ &+ P_{\theta}(-a_{k+1} < z_{k+1} \leq -b_{k+1} \text{ or } b_{k+1} \leq z_{k+1} < a_{k+1}, z_{k+2} > a_{k+2} | z_k, \theta) \\ &+ \dots \\ &+ P_{\theta}(-a_j < z_j \leq -b_j \text{ or } b_j \leq z_j < a_j, j = k+1, \dots, K-1, z_K > a_K | z_k, \theta) \end{aligned}$$

The conditional power for the lower alternative is similarly derived.

TYPE=FINALSTAGE

The TYPE=FINALSTAGE suboption in the CONDPOWER and PLOT=CONDPOWER options computes the conditional power at an interim stage k as the probability that the test statistic at the final stage (stage K) would exceed the rejection critical value given the observed statistic (Jennison and Turnbull 2000, p. 207).

The conditional distribution of Z_K given the observed statistic z_k at the k th stage and the hypothetical reference θ is

$$Z_K | (z_k, \theta) \sim N \left(z_k \Pi_k^{\frac{1}{2}} + \theta I_X^{\frac{1}{2}} (1 - \Pi_k), 1 - \Pi_k \right)$$

where $\Pi_k = I_k / I_X$ is the fraction of information at the k th stage.

The power for the upper alternative, $\text{prob}(Z_K > a_K | z_k, \theta)$, is then given by

$$p_{ku}(\theta) = \Phi \left((1 - \Pi_k)^{-\frac{1}{2}} (z_k \Pi_k^{\frac{1}{2}} - a_K) + \theta I_X^{\frac{1}{2}} (1 - \Pi_k)^{\frac{1}{2}} \right)$$

where Φ is the cumulative distribution function of the standardized Z statistic and a_K is the upper critical value at the final stage.

Similarly, the power for the lower alternative, $\text{prob}(Z_K < a_{-K} | z_k, \theta)$, is

$$p_{kl}(\theta) = 1 - \Phi \left((1 - \Pi_k)^{-\frac{1}{2}} (z_k \Pi_k^{\frac{1}{2}} - a_{-K}) + \theta I_X^{\frac{1}{2}} (1 - \Pi_k)^{\frac{1}{2}} \right)$$

where a_{-K} is the lower critical value at the final stage.

If $\theta = \hat{\theta}_k = z_k I_k^{-\frac{1}{2}}$, the maximum likelihood estimate at stage k , the powers for the upper and lower alternatives can be simplified:

$$p_{ku}(\theta) = \Phi \left((1 - \Pi_k)^{-\frac{1}{2}} (z_k \Pi_k^{-\frac{1}{2}} - a_K) \right)$$

$$p_{kl}(\theta) = 1 - \Phi \left((1 - \Pi_k)^{-\frac{1}{2}} (z_k \Pi_k^{-\frac{1}{2}} - a_{-K}) \right)$$

If there exist interim stages between the k th stage and the final stage, $k < K - 1$, the conditional power computed with TYPE=FINALSTAGE is not the conditional probability to reject the null hypothesis H_0 . In this case, you can set the next stage as the final stage, and the conditional power is the conditional probability of rejecting H_0 .

A special case of the conditional power is the futility index (Ware, Muller, and Braunwald 1985). It is 1 minus the conditional power under $H_1 : \theta = \theta_1$:

$$1 - p_{ku}(\theta_1) \text{ or } 1 - p_{kl}(\theta_1)$$

That is, it is the probability of accepting the null hypothesis under the alternative hypothesis given current data. A high futility index indicates a small probability of success (rejecting H_0) given the current data.

Predictive Power Approach

The conditional power depends on the specified reference θ , which might be supported by the current data (Jennison and Turnbull 2000, p. 210). An alternative is to use the predictive power (Herson 1979), which is a weighted average of the conditional power over values of θ . Without prior knowledge about θ , then with $\hat{\theta} = z_k / \sqrt{I_k}$, the maximum likelihood estimate at stage k , the posterior distribution for θ (Jennison and Turnbull 2000, p. 211) is

$$\theta | Z_K \sim N \left(\frac{z_k}{\sqrt{I_k}}, \frac{1}{I_k} \right)$$

Thus, the predictive power at stage k for the upper and lower alternatives can be derived as

$$p_{ku} = 1 - \Phi \left((1 - \Pi_k)^{-\frac{1}{2}} (a_K \Pi_k^{\frac{1}{2}} - z_k) \right)$$

$$p_{kl} = \Phi \left((1 - \Pi_k)^{-\frac{1}{2}} (a_{-K} \Pi_k^{\frac{1}{2}} - z_k) \right)$$

where a_K and a_{-K} are the upper and lower critical values at the final stage.

Repeated Confidence Intervals

In a group sequential test, repeated confidence intervals for a parameter θ are defined as a sequence of intervals $(\hat{\theta}_{kl}, \hat{\theta}_{ku})$, $k = 1, 2, \dots, K$, for which a simultaneous coverage probability is maintained (Jennison and Turnbull 2000, p. 189). That is, a $(1 - \alpha)$ sequence of repeated confidence intervals has

$$\text{Prob}(\hat{\theta}_{kl} \leq \theta \leq \hat{\theta}_{ku}) = 1 - \alpha$$

These confidence limits $\hat{\theta}_{kl}$ and $\hat{\theta}_{ku}$ can be created from observed statistic and boundary values at each stage.

Two-Sided Repeated Confidence Intervals

Two sequences of repeated confidence intervals can be derived for a two-sided test. One is a $(1 - \alpha_l - \alpha_u)$ rejection repeated confidence intervals $(\hat{\theta}_{kl}(\alpha), \hat{\theta}_{ku}(\alpha))$, $k = 1, 2, \dots, K$, and the other is a $(1 - \beta_l - \beta_u)$ acceptance repeated confidence intervals $(\hat{\theta}_{kl}(\beta), \hat{\theta}_{ku}(\beta))$, $k = 1, 2, \dots, K$, where α_l and α_u are the lower and upper Type I error probabilities for the test and β_l and β_u are the lower and upper Type II error probabilities for the test (Jennison and Turnbull 2000, p. 196).

The rejection lower and upper repeated confidence limits at stage k are

$$\hat{\theta}_{kl}(\alpha) = \hat{\theta}_k - \frac{a_k}{\sqrt{I_k}} \quad \hat{\theta}_{ku}(\alpha) = \hat{\theta}_k - \frac{a_k}{\sqrt{I_k}}$$

The hypothesis is rejected for upper alternative if the lower limit $\hat{\theta}_{kl}(\alpha) > \theta_{0u}$ and is rejected for lower alternative if the upper limit $\hat{\theta}_{ku}(\alpha) < \theta_{0l}$. That is, the hypothesis is rejected if both θ_{0l} and θ_{0u} are not in a rejection repeated confidence interval $(\hat{\theta}_{kl}(\alpha), \hat{\theta}_{ku}(\alpha))$.

The acceptance lower and upper repeated confidence limits at stage k are

$$\hat{\theta}_{kl}(\beta) = \hat{\theta}_k + \left(\theta_{1l} - \frac{b_k}{\sqrt{I_k}} \right) \quad \hat{\theta}_{ku}(\beta) = \hat{\theta}_k + \left(\theta_{1u} - \frac{b_k}{\sqrt{I_k}} \right)$$

The hypothesis is accepted if the lower limit $\hat{\theta}_{kl}(\beta) > \theta_{1l}$ and the upper limit $\hat{\theta}_{ku}(\beta) < \theta_{1u}$. That is, a repeated confidence interval is contained in the interval $(\theta_{1l}, \theta_{1u})$.

One-Sided Repeated Confidence Intervals

Like the two-sided repeated confidence intervals, two sequences of repeated confidence intervals can be derived for a one-sided test. Suppose the one-sided test has an upper alternative θ_{1u} . Then one sequence of repeated confidence intervals is a $(1 - \alpha_u)$ rejection repeated confidence intervals $(\hat{\theta}_{kl}(\alpha), \infty)$, $k = 1, 2, \dots, K$, and the other is a $(1 - \beta_u)$ acceptance repeated confidence intervals $(-\infty, \hat{\theta}_{ku}(\beta))$, $k = 1, 2, \dots, K$, where α_u and β_u are the upper Type I and Type II error probabilities for the test. Thus, a sequence of repeated confidence intervals with confidence level greater than or equal to $(1 - \alpha_u - \beta_u)$ is given by $(\hat{\theta}_{kl}(\alpha), \hat{\theta}_{ku}(\beta))$.

The rejection lower repeated confidence limit and the acceptance upper repeated confidence limit at stage k are

$$\hat{\theta}_{kl}(\alpha) = \hat{\theta}_k - \left(\frac{a_k}{\sqrt{I_k}} - \theta_{0u} \right) \quad \hat{\theta}_{ku}(\beta) = \hat{\theta}_k + \left(\theta_{1u} - \frac{b_k}{\sqrt{I_k}} \right)$$

The hypothesis is rejected if the lower limit $\hat{\theta}_{kl}(\alpha) > \theta_{0u}$. and it is accepted if the upper limit $\hat{\theta}_{ku}(\beta) < \theta_{1u}$.

Analysis after a Sequential Test

At the end of a trial, the hypothesis is either rejected or accepted. But the p -value, median, and confidence limits depend on the ordering the sample space (k, z) , where k is the stage number and z is the standardized Z statistic.

Following the notations used in Jennison and Turnbull (2000, pp. 179–180), $(k', z') \succ (k, z)$ if (k', z') has a higher order or more extreme than (k, z) . Then for a given ordering, the p -value, median, and confidence limits associated with the observed statistics (k, z) can be derived.

***p*-value**

With the observed pair of statistics (k_0, z_0) when the trial is stopped, a one-sided upper *p*-value is computed as

$$\text{Prob}\{ (k, z) \succeq (k_0, z_0) \}$$

A one-sided lower *p*-value is computed as

$$\text{Prob}\{ (k, z) \preceq (k_0, z_0) \}$$

A two-sided *p*-value is twice the smaller of the lower and upper *p*-values.

Median Unbiased Estimate

With the observed pair (k_0, z_0) , a median unbiased estimate θ_m is computed from

$$\text{Prob}\{ (k, z) \succeq (k_0, z_0) \mid \theta_m \} = 0.50$$

Confidence Limits

With the observed pair (k_0, z_0) , a lower $(1 - \alpha_l)$ confidence limit for θ , θ_l , is computed from

$$\text{Prob}\{ (k, z) \succeq (k_0, z_0) \mid \theta_l \} = \alpha_l$$

Similarly, an upper $(1 - \alpha_u)$ confidence limit for θ , θ_u , is computed from

$$\text{Prob}\{ (k, z) \preceq (k_0, z_0) \mid \theta_u \} = \alpha_u$$

Available Sample Space Orderings in a Sequential Test

At the end of a trial, the hypothesis is either rejected or accepted. Denote the stage number and the statistic at the end of a trial by a pair of statistics (k, z) , where k is the stage number and z is the standardized Z statistic. Then an ordering on the sample space (k, z) is needed to derive the *p*-value, median, and confidence limits associated with the observed statistics (k^*, z^*) .

The SEQTEST procedure provides the stagewise, LR, and MLE orderings. See Jennison and Turnbull (2000, pp. 179–187) for a detailed description and comparison of these orderings.

Stagewise Ordering

If the continuation regions of a design are intervals, the stagewise ordering (Fairbanks and Madsen 1982; Tsiatis, Rosner, and Mehta 1984; Jennison and Turnbull 2000, pp. 179–180) uses counter-clockwise ordering around the continuation region to compute the *p*-value, unbiased median estimate, and confidence limits. This ordering depends on the stopping region, stopping stage, and standardized statistic at the stopping stage. But it does not depend on information levels beyond the observed stage. For a one-sided design with an upper alternative, $(k', z') \succ (k, z)$ if one of the following criteria holds:

- $k' = k$ and $z' > z$
- $k' < k$ and $z' \geq a_{k'}$, the upper α boundary at stage k'
- $k' > k$ and $z < b_k$, the upper β boundary at stage k

Similar criteria can be derived for a one-sided design with a lower alternative.

For a two-sided design with early stopping to reject the null hypothesis, $(k', z') \succ (k, z)$ if one of the following criteria holds:

- $k' = k$ and $z' > z$
- $k' < k$ and $z' \geq a_{k'}$, the upper α boundary at stage k'
- $k' > k$ and $z \leq -a_k$, the lower α boundary at stage k

Note that the stagewise ordering is not applicable for two-sided designs with early stopping to accept H_0 or to either accept or reject H_0 , which might have two disjoint continuous intervals at each interim stage.

For a two-sided design with early stopping either to reject or to accept the null hypothesis, $(k', z') \succ (k, z)$ if one of the following criteria holds:

- $z' \geq a_{k'}$ and $z < b_k$
- $z' > -b_{k'}$ and $z \leq -a_k$

That is, each value in the continuation region is less extreme than each value in the upper rejection region and more extreme than each value in the lower rejection region. Then, combining with the ordering defined for a two-sided design with early stopping to reject the null hypothesis, the p -value, median, and confidence limits can be derived for the observed statistics in the lower or upper rejection region.

Thus, if the stagewise ordering is specified in the SEQTEST procedure for a two-sided design with early stopping to either reject or accept the null hypothesis, the stagewise ordering is used to derive these statistics only if the observed statistics is in the lower or upper rejection region. Otherwise, the LR ordering is used.

LR Ordering

The LR ordering (Chang 1989) depends on the observed standardized Z statistic z , information levels, and a specified hypothetical reference. For the LR ordering under a given hypothesis $H : \theta = \theta_g$, $(k', z') \succ (k, z)$ if

$$(z' - \theta_g \sqrt{I_{k'}}) > (z - \theta_g \sqrt{I_k})$$

Under the null hypothesis $H_0 : \theta = 0$, it reduces to

$$z' > z$$

and can be used to derive statistics under H_0 , such as p -values.

The LR ordering is applicable to all designs if all information levels are available. But depending on the boundary shape, some observed statistics (k, z) in the rejection region might be less extreme than the statistics in the acceptance region. That is, the p -value for observed statistics in the rejection region might be greater than the significance level.

MLE Ordering

The MLE ordering (Emerson and Fleming 1990) depends only on the observed maximum likelihood estimate. $(k', z') \succ (k, z)$ if

$$\frac{z'}{\sqrt{I_{k'}}} > \frac{z}{\sqrt{I_k}}$$

The MLE ordering is applicable to all designs if all information levels are available.

Applicable Tests and Sample Size Computation

The SEQDESIGN procedure assumes that the data are from a multivariate normal distribution and the sequence of the standardized test statistics $\{Z_1, Z_2, \dots, Z_K\}$ have the following canonical joint distribution:

- $Z_k \sim N(\theta\sqrt{I_k}, 1)$
- $\text{Cov}(Z_{k_1}, Z_{k_2}) = \sqrt{I_{k_1}/I_{k_2}}, 1 \leq k_1 \leq k_2 \leq K$

where K is the total number of stages and I_k is the information available at stage k .

If the data are not from a normal distribution such as binomial distribution, then it is assumed that the test statistic is computed from a large sample such that the statistic has an approximately normal distribution.

In a clinical trial, the sample size required depends on the Type I error probability α , reference improvement θ_1 , power $1 - \beta$, and variance of the response variable. Given a null hypothesis $H_0 : \theta = 0$ with an upper alternative hypothesis $H_1 : \theta = \theta_1$, the information required for a fixed-sample test is given by

$$I_0 = \frac{(\Phi^{-1}(1 - \alpha) + \Phi^{-1}(1 - \beta))^2}{\theta_1^2}$$

where the parameter θ depends on the test specified in the clinical trial. For example, if you are comparing two binomial populations $H_0 : \theta = 0$, then $\theta = p_t - p_c$ is the difference between two proportions if the proportion difference statistic is used, and $\theta = \log\left(\frac{p_t(1-p_c)}{p_c(1-p_t)}\right)$, the log odds ratio for the two proportions if the log odds ratio statistic is used.

If the maximum likelihood estimate $\hat{\theta}$ from the likelihood function can be derived, then the asymptotic variance for $\hat{\theta}$ is $\text{Var}(\hat{\theta}) = 1/I$, where I is Fisher's information for θ .

The resulting statistic $\hat{\theta}$ corresponds to the MLE scale as specified in the BOUNDARYSCALE=MLE option in the PROC SEQDESIGN statement, $\hat{\theta}\sqrt{I}$ corresponds to the standardized Z scale (BOUNDARYSCALE=STDZ), and $\hat{\theta}I$ corresponds to the score scale (BOUNDARYSCALE=SCORE).

Alternatively, if the score statistic is derived, it can also be used as the test statistic and its asymptotic variance is given by Fisher's information.

For a group sequential trial, the maximum information I_X is derived in the SEQDESIGN procedure by using the specified α , β , and θ_1 . With the maximum information

$$I_X = \frac{1}{\text{Var}(\hat{\theta})}$$

the sample size required for a specified test statistic in the trial can be evaluated or estimated from the known or estimated variance of the response variable. Note that different designs might produce different maximum information levels for the same hypothesis, and this in turn might require a different number of observations for the trial.

With a specified test statistic, the required sample sizes at the stages can be computed. These tests include commonly used tests for normal means, binomial proportions, and survival distributions. See the section “Sample Size Computation” in “The SEQDESIGN Procedure” for a description of these tests.

Table Output

The SEQTEST procedure displays the “Design Information” and “Test Information” tables by default.

Conditional Power

The “Conditional Power Information” table displays the following information under a hypothetical reference:

- stopping stage
- MLE, observed maximum likelihood estimate
- conditional power under the hypothetical reference

For a one-sided test, the power are derived under hypothetical references $\theta = \hat{\theta}$ and $\theta = c_i\theta_1$, where $\hat{\theta}$ is the observed statistic, θ_1 is the alternative reference, and c_i are the values specified in the CREF= option. For a two-sided test, the power are derived under the hypothetical references $\theta = \hat{\theta}$, $\theta = c_i\theta_{1l}$, and $\theta = c_i\theta_{1u}$, where θ_{1l} is the lower alternative reference and θ_{1u} is the upper alternative reference. The default is CREF= 0 0.5 1.0 1.5.

Design Information

The “Design Information” table displays the design specifications and derived statistics. The derived Max Information (Percent Fixed-Sample) is the maximum information for the sequential design in percentage of the corresponding fixed-sample information.

The Null Ref ASN (Percent Fixed-Sample) is the average sample size required under the null hypothesis for the group sequential design in percentage of the corresponding fixed-sample design. Similarly, the Alt Ref ASN (Percent Fixed-Sample) is the average sample size required under the alternative reference for the group sequential design in percentage of the corresponding fixed-sample design.

Error Spending Information

The “Error Spending Information” table displays the following information at each stage:

- proportion of information
- actual information level, if the maximum information is either specified or derived
- cumulative error spending for each boundary

Parameter Estimates

The “Parameter Estimates” table displays the following information at the conclusion of a sequential trial:

- stopping stage
- parameter estimate
- median and confidence limits based on the specified ordering
- p -value for the hypothesis H_0 based on the specified ordering

Powers and Expected Sample Sizes

The “Powers and Expected Sample Sizes” table displays the following information under each of the specified hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and c_i are values specified in the CREF= option.

- coefficient c_i for the hypothetical references. The value $c_i = 0$ corresponds to the null hypothesis and $c_i = 1$ corresponds to the alternative hypothesis
- power
- expected sample size, as percentage of fixed-sample size

For a one-sided design, the power and expected sample sizes under the hypothetical references $\theta = c_i \theta_1$ are displayed.

For a two-sided symmetric design, the power and expected sample sizes under each of the hypothetical references $\theta = c_i \theta_{1u}$ are displayed, where θ_{1u} is the upper alternative reference.

For a two-sided asymmetric design, the power and expected sample sizes under each of the hypothetical references $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively.

For a two-sided design, the power is the probability of correctly rejecting the null hypothesis for the correct alternative. Thus, under the null hypothesis, the displayed power corresponds to a one-sided Type I error probability level—that is, the lower α level or the upper α level.

The expected sample size as a percentage of the corresponding fixed-sample design is

$$100 \times \frac{\sum_{k=1}^K p_k I_k}{I_0}$$

where p_k is the stopping probability at stage k , $\sum_{k=1}^K p_k I_k$ is the expected information level, and I_0 is the information level for the fixed-sample design.

Predictive Power

The “Predictive Power Information” table displays the following information:

- stopping stage
- MLE, observed maximum likelihood estimate
- predictive power

Repeated Confidence Intervals

The “Repeated Confidence Intervals” table displays the following information for the observed statistic at each stage:

- information level
- parameter estimate
- rejection confidence limits. The null hypothesis is rejected for the upper alternative if the lower rejection confidence limit is greater than the null parameter value. Similarly, the null hypothesis is rejected for the lower alternative if the upper rejection confidence limit is less than the null parameter value.
- acceptance confidence limits. The upper alternative hypothesis is rejected if the upper acceptance confidence limit is less than the upper alternative value. Similarly, the lower alternative hypothesis is rejected if the lower acceptance confidence limit is greater than the upper alternative value. For a two-sided design, if both upper and lower alternative hypothesis are rejected, the null hypothesis is accepted.

Stopping Probabilities

The “Expected Cumulative Stopping Probabilities” table displays the following information under each of the specified hypothetical references $\theta = c_i \theta_1$, where c_i are values specified in the CREF= option, and θ_1 is the alternative reference:

- coefficient c_i for the hypothetical references. The value $c_i = 0$ corresponds to the null hypothesis, and $c_i = 1$ corresponds to the alternative hypothesis
- expected stopping stage
- source of the stopping probability: reject H_0 (with STOP=REJECT or STOP=BOTH), accept H_0 (with STOP=ACCEPT or STOP=BOTH), or either reject or accept H_0 (with STOP=BOTH)
- expected cumulative stopping probabilities at each stage

For a one-sided design, the expected cumulative stopping probabilities under the hypothetical references $\theta = c_i \theta_1$ are displayed.

For a two-sided design, the expected cumulative stopping probabilities under each of the hypothetical references $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively.

Note that for a symmetric two-sided design, only the expected cumulative stopping probabilities under the hypothetical references $\theta = c_i \theta_{1u}$ are derived.

The expected stopping stage is given by $k_0 + d$ and is derived from the expected information level

$$\sum_{k=1}^K p_k I_k = I_{k_0} + d (I_{(k_0+1)} - I_{k_0})$$

where p_k is the stopping probability at stage k and $0 \leq d < 1$.

For equally spaced information levels, the expected stopping stage is reduced to the weighted average

$$\sum_{k=1}^K p_k k$$

Test Information

The “Test Information” table displays the following information at each stage:

- proportion of information
- actual information level, if the maximum information is available from the input BOUNDARY= data set
- alternative references with the specified statistic scale. If a p -value scale is specified, the standardized Z scale is used.
- boundary values with the specified statistic scale to reject or accept the null hypothesis

Note that implicitly, the test information table also contains variables for the boundary scale, stopping criterion, and type of alternative hypothesis. That is, if an ODS statement is used to save the table, the data set also contains the variables `_Scale_` for the boundary scale, `_Stop_` for the stopping criterion, and `_ALT_` for the type of alternative hypothesis.

If the test variable is specified, the table also displays the following:

- test statistic
- resulting action of test statistic: continue to the next stage, accept the null hypothesis H_0 , or reject H_0

ODS Table Names

PROC SEQTEST assigns a name to each table it creates. You must use these names to reference tables when using the Output Delivery System (ODS). These names are listed in [Table 84.3](#). For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

Table 84.3 ODS Tables Produced by PROC SEQTEST

ODS Table Name	Description	Option
CondPower	Conditional power	CONDPOWER
Design	Design information	
ErrSpend	Error spending	ERRSPEND
ParameterEstimates	Parameter estimates	DATA(TESTVAR=) or PARMS(TESTVAR=)
PowerSampleSize	Power and expected sample sizes	PSS
PredPower	Predictive power	PREDPOWER
RepeatedCI	Repeated confidence intervals	RCI
StopProb	Stopping probabilities	STOPPROB
Test	Test statistics and boundary values	

Graphics Output

This section describes the use of ODS for creating graphics with the SEQTEST procedure. To request these graphs, ODS Graphics must be enabled and you must specify the associated graphics options in the PROC SEQTEST statement. For more information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).”

Sequential ASN Plot

The PLOTS=ASN option displays the average sample numbers (expected sample sizes for nonsurvival data or expected numbers of events for survival data) under various hypothetical references. The average sample numbers are connected for each design, and these connected curves for all designs are displayed in the “Sequential ASN Plot” graph.

For a one-sided design, average sample numbers under the hypothetical references $\theta = c_i \theta_1$ are displayed, where c_i are the values specified in the CREF= option and θ_1 is the alternative reference. The horizontal axis displays the c_i values of these hypothetical references.

For a two-sided design, average sample numbers under each of the hypothetical references $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The horizontal axis displays $-c_i$ values for lower hypothetical references $\theta = c_i \theta_{1l}$ and c_i values for upper hypothetical references $\theta = c_i \theta_{1u}$. Note that for a symmetric two-sided design, only average sample numbers under the hypothetical references $\theta = c_i \theta_{1u}$ are derived.

If the trial stops after the sequential test, the hypothetical reference corresponding to the test statistic is also indicated in the plot.

Conditional Power Plot

The PLOTS=CONDPOWER option displays the conditional powers given the observed statistic under various hypothetical references. These powers are connected and are displayed in the “Conditional Power Plot” graph.

For a one-sided test, the power are derived under the hypothetical references $\theta = \hat{\theta}$ and $\theta = c_i \theta_1$, where $\hat{\theta}$ is the observed statistic, θ_1 is the alternative reference, and c_i are the values specified in the CREF= option. The horizontal axis displays these c_i values for hypothetical references.

For a two-sided test, the power are derived under hypothetical references $\theta = \hat{\theta}$, $\theta = c_i \theta_{1l}$, and $\theta = c_i \theta_{1u}$, where θ_{1l} is the lower alternative reference and θ_{1u} is the upper alternative reference. The horizontal axis displays $-c_i$ values for hypothetical references $\theta = c_i \theta_{1l}$ and c_i values for hypothetical references $\theta = c_i \theta_{1u}$.

If the trial stops after the sequential test, the hypothetical reference corresponding to the test statistic is also indicated in the plot.

Sequential Error Spending Plot

The PLOTS=ERRSPEND option displays the cumulative error spending at each stage on each boundary in the “Sequential Error Spending Plot” graph. A legend table uses the design labels to identify the curves for the corresponding design in the plot.

Sequential Power Plot

The PLOTS=POWER option displays the powers under various hypothetical references. The powers are connected for each design, and these connected curves for all designs are displayed in the “Sequential Power Plot” graph.

For a one-sided design, powers under hypothetical references $\theta = c_i \theta_1$ are displayed, where c_i are the values specified in the CREF= option and θ_1 is the alternative reference. The horizontal axis displays the c_i values of these hypothetical references.

For a two-sided design, powers under hypothetical references $\theta = c_i \theta_{1l}$ and $\theta = c_i \theta_{1u}$ are displayed, where θ_{1l} and θ_{1u} are the lower and upper alternative references, respectively. The horizontal axis displays $-c_i$ values for lower hypothetical references $\theta = c_i \theta_{1l}$ and c_i values for upper hypothetical references $\theta = c_i \theta_{1u}$. Note that for a symmetric two-sided design, only powers under hypothetical references $\theta = c_i \theta_{1u}$ are derived.

If the trial stops after the sequential test, the hypothetical reference corresponding to the test statistic is also indicated in the plot.

Repeated Confidence Intervals Plot

The PLOTS=RCI option displays repeated confidence intervals at each stage given the observed statistic at that stage. These repeated confidence intervals are displayed in the “Repeated Confidence Intervals Plot” graph.

Sequential Test Plot

The PLOTS=TEST option displays boundary values and test statistics in the “Test Plot” graph. The boundary values are connected for each boundary, and both the stage number and the information level at each stage are displayed. The legend table identifies the acceptance and rejection regions in the plot.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS.](#)”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

PROC SEQTEST assigns a name to each graph it creates. You can use these names to reference the graphs when using ODS. To request these graphs, ODS Graphics must be enabled and you must specify the options indicated in [Table 84.4](#).

Table 84.4 Graphs Produced by PROC SEQTEST

ODS Graph Name	Plot Description	Option
AsnPlot	Average sample numbers	PLOTS=ASN
CondPowerPlot	Conditional power curves	PLOTS=CONDPower
ErrSpendPlot	Error spending	PLOTS=ERRSPEND
PowerPlot	Power curves	PLOTS=POWER
RepeatedCIPlot	Repeated confidence intervals	PLOTS=RCI
TestPlot	Boundary values and test statistics	PLOTS=TEST

Examples: SEQTEST Procedure

The following examples perform group sequential tests with various designs and test statistics.

Four statistic scales are available for the input boundary values, the input test statistic, and the displayed test information in the SEQTEST procedure. These are the maximum likelihood estimator scale, score statistic scale, standardized normal Z scale, and p -value scale. There is a unique one-to-one transformation between any two of the scales, and you can use different scales for the input boundary values and input test statistic. These boundary values and test statistic are displayed with the scale specified in the BOUNDARYSCALE= option in the SEQTEST procedure.

Example 84.1: Testing the Difference between Two Proportions

This example demonstrates group sequential tests that use an O'Brien-Fleming group sequential design. A clinic is studying the effect of vitamin C supplements in treating flu symptoms. The study consists of patients in the clinic who have exhibited the first sign of flu symptoms within the last 24 hours. These patients are randomly assigned to either the control group (which receives placebo pills) or the treatment group (which receives large doses of vitamin C supplements). At the end of a five-day period, the flu symptoms of each patient are recorded.

Suppose that you know from past experience that flu symptoms disappear in five days for 60% of patients who experience flu symptoms. The clinic would like to detect a 75% symptom disappearance with a high probability. A test that compares the proportions directly specifies the null hypothesis $H_0 : \theta = p_t - p_c = 0$ with a one-sided alternative $H_1 : \theta > 0$ and a power of 0.90 at $H_1 : \theta = 0.15$, where p_t and p_c are the proportions of symptom disappearance in the treatment group and control group, respectively.

The following statements invoke the SEQDESIGN procedure and request a four-stage group sequential design by using an O'Brien-Fleming method for normally distributed data. The design uses a one-sided alternative hypothesis with early stopping either to accept or reject the null hypothesis H_0 . The BOUNDARYSCALE=MLE option uses the MLE scale to display statistics in the boundary table and boundary plots.

```
ods graphics on;
proc seqdesign altref=0.15
    boundaryscale=mle
    ;
    OBrienFleming: design method=obf
                        nstages=4
                        alt=upper
                        stop=both
                        alpha=0.025
    ;
    samplesize model=twosamplefreq(nullprop=0.6 test=prop);
    ods output Boundary=Bnd_Count;
run;
ods graphics off;
```

The ODS OUTPUT statement with the BOUNDARY=BND_COUNT option creates an output data set named BND_COUNT which contains the resulting boundary information for the subsequent sequential tests.

The “Design Information” table in [Output 84.1.1](#) displays design specifications. With the specified alternative hypothesis $H_1 : \theta = 0.15$, the maximum information is derived to achieve a power of 0.90 at H_1 . The derived fixed-sample information ratio 1.0767 is the maximum information needed for a group sequential design relative to its corresponding fixed-sample design.

Output 84.1.1 O'Brien-Fleming Design Information

The SEQDESIGN Procedure	
Design: OBrienFleming	
Design Information	
Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	0.15
Number of Stages	4
Alpha	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	107.6741
Max Information	502.8343
Null Ref ASN (Percent of Fixed Sample)	61.12891
Alt Ref ASN (Percent of Fixed Sample)	75.89782

The “Boundary Information” table in [Output 84.1.2](#) displays the information level, alternative reference, and boundary values at each stage. With the BOUNDARYSCALE=MLE option, the SEQDESIGN procedure displays the output boundaries with the maximum likelihood estimator scale.

Output 84.1.2 O'Brien-Fleming Boundary Information

Boundary Information (MLE Scale)						
Null Reference = 0						
Stage	-----Information Level-----			-Alternative-	----Boundary Values----	
	Proportion	Actual	N	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2500	125.7086	107.4808	0.15000	-0.09709	0.35291
2	0.5000	251.4171	214.9617	0.15000	0.02645	0.17645
3	0.7500	377.1257	322.4425	0.15000	0.06764	0.11764
4	1.0000	502.8343	429.9233	0.15000	0.08823	0.08823

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 84.1.3](#). The horizontal axis indicates the information levels for the design. The stages are indicated by vertical lines with accompanying stage numbers. If the test statistic at a stage is in a rejection region, the trial stops and the hypothesis is rejected. If the test statistic is in an acceptance region, then the trial also stops and the hypothesis is accepted. If the statistic is not in a rejection or an acceptance region, the trial continues to the next stage.

Output 84.1.3 O'Brien-Fleming Boundary Plot

The boundary plot also displays the information level and critical value for the corresponding fixed-sample design. The solid and dashed lines at the fixed-sample information level correspond to the rejection and acceptance lines, respectively.

With the SAMPLESIZE statement, the maximum information is used to derive the required sample size for the study. The “Sample Size Summary” table in [Output 84.1.4](#) displays parameters for the sample size computation.

Output 84.1.4 Required Sample Size Summary

Sample Size Summary	
Test	Two-Sample Proportions
Null Proportion	0.6
Proportion (Group A)	0.75
Test Statistic	Z for Proportion
Reference Proportions	Alt Ref
Max Sample Size	429.9233
Expected Sample Size (Null Ref)	244.0768
Expected Sample Size (Alt Ref)	303.0464

With the derived maximum information and the specified MODEL= option in the SAMPLESIZE statement, the total sample size in each group for testing the difference between two proportions under the alternative hypothesis is

$$N_1 = N_2 = (p_{1c}(1 - p_{1c}) + p_{1t}(1 - p_{1t})) I_X$$

where $p_{1c} = 0.6$ and $p_{1t} = p_{1c} + \theta_1 = 0.75$. By default (or equivalently if you specify REF=PROP in the MODEL=TWOSAMPLEFREQ option), the required sample sizes are computed under the alternative hypothesis. See the section “Test for the Difference between Two Binomial Proportions” in the chapter “The SEQDESIGN Procedure” for a description of these parameters.

The “Sample Sizes (N)” table in [Output 84.1.5](#) displays the required sample sizes at each stage, in both fractional and integer numbers. The derived sample sizes under the heading Fractional N which correspond to the design are not integers. These sample sizes are rounded up to integers under the heading Ceiling N. In practice, integer sample sizes are used, and the information levels increase slightly. Thus, 54, 108, 162, and 215 patients are needed in each group for the four stages, respectively.

Output 84.1.5 Required Sample Sizes

Sample Sizes (N)				
Two-Sample Z Test for Proportion Difference				
-----Fractional N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	107.48	53.74	53.74	125.7
2	214.96	107.48	107.48	251.4
3	322.44	161.22	161.22	377.1
4	429.92	214.96	214.96	502.8
Sample Sizes (N)				
Two-Sample Z Test for Proportion Difference				
-----Ceiling N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	108	54	54	126.3
2	216	108	108	252.6
3	324	162	162	378.9
4	430	215	215	502.9

Suppose the trial follows the study plan, and 54 patients are available in each group at stage 1. The data set `count_1` contains these 108 patients. [Output 84.1.6](#) lists the first 10 observations of the data set.

Output 84.1.6 Clinical Trial Data

First 10 Obs in the Trial Data		
Obs	Trt	Resp
1	0	0
2	1	1
3	0	1
4	1	0
5	0	0
6	1	0
7	0	0
8	1	1
9	0	1
10	1	0

The Trt variable is a grouping variable with value 0 for a patient in the placebo control group and value 1 for a patient in the treatment group who is given vitamin C supplements. The Resp variable is an indicator variable with value 1 for a patient without flu symptoms after five days and value 0 for a patient with flu symptoms after five days.

The following statements use the GENMOD procedure to estimate the treatment effect at stage 1:

```
proc genmod data=count_1;
  model Resp= Trt;
  ods output ParameterEstimates=Parms_Count1;
run;
```

Output 84.1.7 displays the treatment effect at stage 1.

Output 84.1.7 Stage 1 Treatment Difference

The GENMOD Procedure							
Analysis Of Maximum Likelihood Parameter Estimates							
Parameter	DF	Estimate	Standard Error	Wald 95% Confidence Limits	Wald Chi-Square	Pr > ChiSq	
Intercept	1	0.6296	0.0627	0.5066 0.7526	100.68	<.0001	
Trt	1	0.1111	0.0887	-0.0628 0.2850	1.57	0.2105	
Scale	1	0.4611	0.0314	0.4035 0.5269			
NOTE: The scale parameter was estimated by maximum likelihood.							

The test statistic is $\hat{\theta}_1 = \hat{p}_t - \hat{p}_c = 0.1111$, and its associated standard error is

$$\sqrt{\text{Var}(\hat{\theta}_1)} = \sqrt{\frac{\hat{p}_c(1 - \hat{p}_c)}{54} + \frac{\hat{p}_t(1 - \hat{p}_t)}{54}} = 0.0887$$

The following statements create and display (in [Output 84.1.8](#)) the data set that contains the parameter estimate at stage 1, $\hat{\theta}_1 = 0.1111$, and its associated standard error $\sqrt{\text{Var}(\hat{\theta}_1)} = 0.0887$ which are used in the SEQTEST procedure:

```
data Parms_Count1;
  set Parms_Count1;
  if Parameter='Trt';
  _Scale_='MLE';
  _Stage_= 1;
  keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;

proc print data=Parms_Count1;
  title 'Statistics Computed at Stage 1';
run;
```

Output 84.1.8 Statistics Computed at Stage 1

Statistics Computed at Stage 1					
Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	Trt	0.1111	0.0887	MLE	1

The initial required sample sizes are derived with the proportions $p_c = 0.6$ and $p_t = 0.75$. If the observed proportions are different from these assumed values, or if the number of available patients is different from the study plan in one of the stages, then the information level that corresponds to the test statistic is estimated from

$$I_k = \frac{1}{\text{Var}(\hat{\theta}_k)}$$

The following statements invoke the SEQTEST procedure and test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Count
  Parms (Testvar=Trt)=Parms_Count1
  infoadj=none
  errspendmin=0.001
  boundaryscale=mle
  errspend
  plots=errspend
;
  ods output Test=Test_Count1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_COUNT1 option specifies the input data set PARMS_COUNT1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRT option identifies the test variable TRT in the data set. The INFOADJ=NONE option maintains the information levels at future interim stages (2 and 3) as provided in the

BOUNDARY= data set. The BOUNDARYSCALE=MLE option displays the output boundaries in terms of the MLE scale.

The O'Brien-Fleming design is conservative in early stages and might not be desirable in a clinical trial. The ERRSPENDMIN=0.001 option specifies the minimum error spending at each stage to be 0.001, and it might increase the corresponding nominal p -value in early stages for the trial. The BOUNDARYSCALE=MLE option uses the MLE scale to display test statistics in the boundary table and boundary plots.

The ODS OUTPUT statement with the TEST=TEST_COUNT1 option creates an output data set named TEST_COUNT1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Design Information” table in [Output 84.1.9](#) displays design specifications. The derived statistics, such as the overall α and β levels, are derived from the specified maximum information and boundary values in the BOUNDARY= data set. Note that with a minor change in the information level at stage 1, the power also changes slightly from the design provided in the BOUNDARY= data set.

Output 84.1.9 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.BND_COUNT
Data Set	WORK.PARMS_COUNT1
Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Number of Stages	4
Alpha	0.025
Beta	0.10147
Power	0.89853
Max Information (Percent of Fixed Sample)	108.2301
Max Information	502.834283
Null Ref ASN (Percent of Fixed Sample)	61.09917
Alt Ref ASN (Percent of Fixed Sample)	73.9745

With the ERRSPEND option, the “Error Spending Information” table in [Output 84.1.10](#) displays cumulative error spending at each stage for each boundary. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the Type I error level $\alpha = 0.025$ is maintained. Furthermore, with the ERRSPENDMIN=0.001 option, the α spending at each stage is greater than or equal to 0.001.

Output 84.1.10 Error Spending Information

Error Spending Information				
Stage	---Information Level---		-Cumulative Error Spending-	
	Proportion	Actual	Beta	Alpha
1	0.2525	126.9871	0.00308	0.00100
2	0.5000	251.4171	0.02653	0.00343
3	0.7500	377.1257	0.06456	0.01254
4	1.0000	502.8343	0.10147	0.02500

With the PLOTS=ERRSPEND option, the procedure displays a plot of error spending for each boundary, as shown in [Output 84.1.11](#). The error spending values in the “Error Spending Information” table in [Output 84.1.10](#) are displayed in the plot.

Output 84.1.11 Error Spending Plot

The “Test Information” table in [Output 84.1.12](#) displays the boundary values for the design, test statistic, and resulting action at each stage. With the BOUNDARYSCALE=MLE option, the maximum likelihood

estimator scale is used for the test statistic and boundary values. The table shows that the test statistic 0.1111 is between the upper α and β boundaries, so the trial continues to the next stage.

Output 84.1.12 Sequential Test

Test Information (MLE Scale)					
Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values-----	
	Proportion	Actual	--Reference-- Upper	-----Upper----- Beta	Alpha

2	0.5000	251.4171	0.15000	0.02674	0.17527
3	0.7500	377.1257	0.15000	0.06805	0.11792
4	1.0000	502.8343	0.15000	0.08875	0.08875

Test Information (MLE Scale)		
Null Reference = 0		
Stage	-----Test-----	
	Estimate	Action
1	0.11111	Continue
2	.	
3	.	
4	.	

The information level at stage 1 is derived from the standard error,

$$I_1 = \frac{1}{\text{Var}(\hat{\theta}_1)} = \frac{1}{(\text{s.e.}(\hat{\theta}_1))^2} = 126.987$$

By default (or equivalently if you specify PLOTS=TEST), the “Test Plot” graph displays boundary values of the design and the test statistic at stage 1, as shown in [Output 84.1.13](#). It also shows that the observed statistic is in the continuation region.

Output 84.1.13 Sequential Test Plot

The observed information level at stage 1, $I_1 = 126.987$, is slightly larger than the target information level at the design. If an observed information level in the study is substantially different from its target level in the design, then the sample sizes should be adjusted in the subsequent stages to achieve the target information levels.

Suppose the trial continues to the next stage, and 108 patients are available in each group at stage 2. The data set COUNT_2 contains these 216 patients.

The following statements use the GENMOD procedure to estimate the treatment effect at stage 2:

```
proc genmod data=Count_2;
  model Resp= Trt;
  ods output ParameterEstimates=Parms_Count2;
run;
```

The following statements create the parameter estimate at stage 2, $\hat{\theta}_2 = \hat{p}_2 - \hat{p}_1 = 0.1759$, and its associated standard error $\sqrt{\text{Var}(\hat{\theta}_2)} = 0.0623$ into a test data set:

```
data Parms_Count2;
  set Parms_Count2;
  if Parameter='Trt';
  _Scale_='MLE';
  _Stage_= 2;
  keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;

proc print data=Parms_Count2;
  title 'Statistics Computed at Stage 2';
run;
```

Output 84.1.14 displays the test statistics at stage 2.

Output 84.1.14 Statistics Computed at Stage 2

Statistics Computed at Stage 2					
Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	Trt	0.1759	0.0623	MLE	2

The following statements invoke the SEQTEST procedure and test for early stopping at stage 2:

```
ods graphics on;
proc seqtest Boundary=Test_Count1
  Parms(Testvar=Trt)=Parms_Count2
  infoadj=none
  boundaryscale=mle
  ;
  ods output Test=Test_Count2;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_COUNT2 option creates an output data set named TEST_COUNT2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Test Information” table in Output 84.1.15 displays the boundary values, test statistic, and resulting action at each stage. The table shows that the test statistic 0.17593 is larger than the corresponding upper alpha boundary value, so the trial stops to reject the hypothesis.

Output 84.1.15 Sequential Test

The SEQTEST Procedure					
Test Information (MLE Scale)					
Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values-----	
	Proportion	Actual	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2525	126.9871	0.15000	-0.09306	0.27423
2	0.5122	257.5571	0.15000	0.03019	0.17001
3	0.7500	377.1257	0.15000	0.06783	0.11826

2	0.17593	Reject Null			
3	.				
4	.				

With ODS Graphics enabled, the “Test Plot” is displayed, as shown in [Output 84.1.16](#). The plot displays boundary values of the design and the test statistics at the first two stages. As expected, the test statistic at stage 2 is in the “Upper Rejection Region” above the upper alpha boundary.

Output 84.1.16 Sequential Test Plot

After a trial is stopped, the “Parameter Estimates” table in [Output 84.1.17](#) displays the stopping stage and the maximum likelihood estimate of the parameter. It also displays the p -value, median estimate, and confidence limits for the parameter that correspond to the observed statistic by using the specified sample space ordering.

Output 84.1.17 Parameter Estimates

Parameter Estimates Stagewise Ordering					
Parameter	Stopping Stage	MLE	p-Value for H0:Parm=0	Median Estimate	Lower 95% CL
Trt	2	0.175926	0.0031	0.174462	0.07059

The MLE statistic at the stopping stage is the maximum likelihood estimate of the parameter and is biased. The computation of p -value, unbiased median estimate, and confidence limits depends on the ordering of the sample space (k, z) , where k is the stage number and z is the observed standardized Z statistic. By default

(or equivalently if you specify ORDER=STAGewise), the stagewise ordering that uses counterclockwise ordering around the continuation region is used to compute the p -value, unbiased median estimate, and confidence limits. As expected, the p -value is less than 0.025, and the confidence interval does not contain the null reference zero. With the stagewise ordering, the p -value is computed as

$$P_{\theta=0}(Z_1 > a_1) + P_{\theta=0}(Z_2 > z_2 \mid b_1 < Z_1 < a_1)$$

where z_2 is the observed standardized Z statistic at stage 2, Z_1 is the standardized normal variate at stage 1, Z_2 is the standardized normal variate at stage 2, and a_1 and b_1 are the stage 1 upper rejection and acceptance boundary values, respectively.

See the section “Available Sample Space Orderings in a Sequential Test” on page 7230 for a detailed description of the stagewise ordering.

Example 84.2: Testing an Effect in a Regression Model

This example demonstrates a two-sided group sequential test that uses an error spending design with early stopping to reject the null hypothesis. A study is conducted to examine the effects of Age (years), Weight (kg), RunTime (time in minutes to run 1.5 miles), RunPulse (heart rate while running), and MaxPulse (maximum heart rate recorded while running) on Oxygen (oxygen intake rate, ml per kg body weight per minute). The primary interest is whether oxygen intake rate is associated with weight.

The hypothesis is tested using the following linear model:

$$\text{Oxygen} = \text{Age} + \text{Weight} + \text{RunTime} + \text{RunPulse} + \text{MaxPulse}$$

The null hypothesis is $H_0 : \beta_w = 0$, where β_w is the regression parameter for the variable Weight. Suppose that $\beta_w = 0.10$ is the reference improvement that should be detected at a 0.90 level. Then the maximum information I_X can be derived in the SEQDESIGN procedure.

Following the derivations in the section “Test for a Parameter in the Regression Model” in the chapter “The SEQDESIGN Procedure,” the required sample size can be derived from

$$N = I_X \frac{\sigma_y^2}{(1 - r_x^2) \sigma_x^2}$$

where σ_y^2 is the variance of the response variable in the regression model, r_x^2 is the proportion of variance of Weight explained by other covariates, and σ_x^2 is the variance of Weight.

Further suppose that from past experience, $\sigma_y^2 = 5$, $r_x^2 = 0.10$, and $\sigma_x^2 = 64$. Then the required sample size can be derived using the SAMPLESIZE statement in the SEQDESIGN procedure.

The following statements invoke the SEQDESIGN procedure and request a three-stage group sequential design for normally distributed data to test the null hypothesis of a regression parameter $H_0 : \beta_w = 0$ against the alternative $H_1 : \beta_w \neq 0$:

```
ods graphics on;
proc seqdesign altref=0.10;
  OBFErrorFunction: design method=errfuncobf
                      nstages=3
                      info=cum(2 3 4)
                      ;
  samplesize model=reg(variance=5 xvariance=64 xrsquare=0.10);
  ods output Boundary=Bnd_Fit;
run;
ods graphics off;
```

By default (or equivalently if you specify ALPHA=0.05 and BETA=0.10), the procedure uses a Type I error probability 0.05 and a Type II error probability 0.10. The ALTREF=0.10 option specifies a power of $1 - \beta = 0.90$ at the alternative hypothesis $H_1 : \beta_w = \pm 0.10$. The INFO=CUM(2 3 4) option specifies that the study perform the first interim analysis with information proportion $2/4 = 0.5$ —that is, after half of the total observations are collected.

The ODS OUTPUT statement with the BOUNDARY=BND_FIT option creates an output data set named BND_FIT which contains the resulting boundary information for the subsequent sequential tests.

The “Design Information” table in [Output 84.2.1](#) displays design specifications and derived statistics. Since the alternative reference is specified, the maximum information is derived.

Output 84.2.1 Design Information

The SEQDESIGN Procedure	
Design: OBFErrorFunction	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	Error Spending
Boundary Key	Both
Alternative Reference	0.1
Number of Stages	3
Alpha	0.05
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	101.8276
Max Information	1069.948
Null Ref ASN (Percent of Fixed Sample)	101.2587
Alt Ref ASN (Percent of Fixed Sample)	77.81586

The “Boundary Information” table in [Output 84.2.2](#) displays information level, alternative reference, and boundary values at each stage.

Output 84.2.2 Boundary Information

Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-----Alternative-----	
	Proportion	Actual	N	-----Reference-----	
				Lower	Upper
1	0.5000	534.9738	46.43869	-2.31295	2.31295
2	0.7500	802.4606	69.65804	-2.83277	2.83277
3	1.0000	1069.948	92.87739	-3.27101	3.27101
Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Boundary Values-----				
	---Lower---	---Upper---			
	Alpha	Alpha			
1	-2.96259	2.96259			
2	-2.35902	2.35902			
3	-2.01409	2.01409			

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 84.2.3](#). The boundary plot also displays the information level and critical value for the corresponding fixed-sample design. This design has characteristics of an O’Brien-Fleming design; the probability for early stopping is low, and the maximum information and critical values at the final stage are similar to those of the corresponding fixed-sample design.

Output 84.2.3 Boundary Plot

With the MODEL=REG option in the SAMPLESIZE statement, the “Sample Size Summary” table in [Output 84.2.4](#) displays the parameters for the sample size computation.

Output 84.2.4 Required Sample Size Summary

Sample Size Summary	
Test	Reg Parameter
Parameter	0.1
Variance	5
X Variance	64
R Square (X)	0.1
Max Sample Size	92.87739
Expected Sample Size (Null Ref)	92.35845
Expected Sample Size (Alt Ref)	70.97617

The “Sample Sizes” table in [Output 84.2.5](#) displays the required sample sizes for the group sequential clinical trial.

Output 84.2.5 Required Sample Sizes

Sample Sizes (N)				
Z Test for Regression Parameter				
Stage	-----Fractional N-----		-----Ceiling N-----	
	N	Information	N	Information
1	46.44	535.0	47	541.4
2	69.66	802.5	70	806.4
3	92.88	1069.9	93	1071.4

Thus, 47, 70, and 93 individuals are needed in stages 1, 2, and 3, respectively. Since the sample sizes are derived from estimated values of σ_y^2 , r_x^2 , and σ_x^2 , the actual information levels might not achieve the target information levels. Thus, instead of specifying sample sizes in the protocol, you can specify the maximum information levels. Then if an actual information level is much less than the target level, you can increase the sample sizes for the remaining stages to achieve the desired information levels and power.

Suppose that 47 individuals are available at stage 1. [Output 84.2.6](#) lists the first 10 observations of the trial data.

Output 84.2.6 Clinical Trial Data

First 10 Obs in the Trial Data						
Obs	Oxygen	Age	Weight	RunTime	Run Pulse	Max Pulse
1	54.5521	44	87.7676	11.6949	178.435	181.607
2	52.2821	40	75.4853	9.8872	184.433	183.667
3	62.1871	44	89.0638	8.7950	155.540	167.108
4	65.3269	42	67.7310	8.4577	162.926	173.877
5	59.9809	37	93.1902	9.3228	179.033	180.144
6	52.5588	47	75.9044	12.0385	177.753	175.033
7	51.7838	40	73.5422	11.6607	175.838	178.140
8	57.0024	43	81.2861	11.2219	160.963	171.770
9	48.0775	44	85.2290	13.1789	173.722	176.548
10	68.3357	38	80.2490	8.5066	171.824	184.011

The following statements use the REG procedure to estimate the slope β_w and its associated standard error at stage 1:

```
proc reg data=Fit_1;
  model Oxygen=Age Weight RunTime RunPulse MaxPulse;
  ods output ParameterEstimates=Parms_Fit1;
run;
```

The following statements create and display (in [Output 84.2.7](#)) the input data set that contains slope β_w and its associated standard error for the SEQTEST procedure:

```
data Parms_Fit1;
  set Parms_Fit1;
  if Variable='Weight';
  _Scale_='MLE';
  _Stage_= 1;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_Fit1;
  title 'Statistics Computed at Stage 1';
run;
```

Output 84.2.7 Statistics Computed at Stage 1

Statistics Computed at Stage 1					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Weight	0.03772	0.04345	MLE	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Fit
  Parms(Testvar=Weight)=Parms_Fit1
  infoadj=prop
  errspendadj=errfuncobf
  order=lr
  stopprob
  ;
  ods output Test=Test_Fit1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1 (this data set was generated in the SEQDESIGN procedure). Recall that these boundary values were derived for the information levels specified with the INFO=CUM(2 3 4) option in the SEQDESIGN procedure. The PARMS=PARMS_FIT1 option specifies the input data set PARMS_FIT1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=WEIGHT option identifies the test variable WEIGHT in the data set.

If the computed information level for stage 1 is not the same as the value provided in the BOUNDARY= data set, the INFOADJ=PROP option (which is the default) proportionally adjusts the information levels at future interim stages from the levels provided in the BOUNDARY= data set. The ORDER=LR option uses the LR ordering to derive the p -value, the unbiased median estimate, and the confidence limits for the regression slope estimate. The ERRSPENDADJ=ERRFUNCBOBF option adjusts the boundaries with the updated error spending values generated from an O'Brien-Fleming-type cumulative error spending function.

The ODS OUTPUT statement with the TEST=TEST_FIT1 option creates an output data set named TEST_FIT1 which contains the updated boundary information for the test at stage 1. The adjustment is needed because the observed information level is different from the information level in the BOUNDARY= data set. The data set TEST_FIT1 also provides the boundary information that is needed for the group sequential test at the next stage.

The “Design Information” table in [Output 84.2.8](#) displays the design specifications. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the boundary values are modified for the new information levels to maintain the Type I α level. The maximum information remains the same as in the BOUNDARY= data set, but the derived Type II error probability β and power $1 - \beta$ are different because of the new information level.

Output 84.2.8 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.BND_FIT
Data Set	WORK.PARMS_FIT1
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Number of Stages	3
Alpha	0.05
Beta	0.09994
Power	0.90006
Max Information (Percent of Fixed Sample)	101.8057
Max Information	1069.94751
Null Ref ASN (Percent of Fixed Sample)	101.2416
Alt Ref ASN (Percent of Fixed Sample)	77.87607

With the STOPPROB option, the “Expected Cumulative Stopping Probabilities” table in [Output 84.2.9](#) displays the expected stopping stage and cumulative stopping probability to reject the null hypothesis at each stage under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ by default. You can specify other values for c_i with the CREF= option.

Output 84.2.9 Stopping Probabilities

Expected Cumulative Stopping Probabilities						
Reference = CRef * (Alt Reference)						
CRef	Expected Stopping Stage	Source	----Stopping Probabilities----			
			Stage_1	Stage_2	Stage_3	
0.0000	2.978	Reject Null	0.00289	0.01906	0.05000	
0.5000	2.792	Reject Null	0.03373	0.17443	0.36566	
1.0000	2.069	Reject Null	0.24884	0.68206	0.90006	
1.5000	1.348	Reject Null	0.68172	0.97032	0.99820	

The “Test Information” table in [Output 84.2.10](#) displays the boundary values for the test statistic. By default (or equivalently if you specify `BOUNDARYSCALE=STDZ`), these statistics are displayed with the standardized Z scale. The information level at stage 1 is derived from the standard error s_1 in the `PARMS=` data set,

$$I_1 = \frac{1}{s_1^2} = \frac{1}{0.043453^2} = 529.62$$

Output 84.2.10 Sequential Tests

Test Information (Standardized Z Scale)						
Null Reference = 0						
	--Information Level--		-----Alternative-----		----Boundary Values----	
Stage	Proportion	Actual	-----Reference-----		---Lower--	---Upper--
			Lower	Upper	Alpha	Alpha
1	0.4950	529.6232	-2.30135	2.30135	-2.97951	2.97951
2	0.7475	799.7853	-2.82805	2.82805	-2.36291	2.36291
3	1.0000	1069.948	-3.27101	3.27101	-2.01336	2.01336

Test Information (Standardized Z Scale)			
Null Reference = 0			
	-----Test-----		
	-----Weight-----		
Stage	Estimate	Action	
1	0.86798	Continue	
2	.		
3	.		

With the `INFOADJ=PROP` option (which is the default), the information level at stage 2 is derived proportionally from the observed information at stage 1 and the information levels in the `BOUNDARY=` data set. See the section “[Boundary Adjustments for Information Levels](#)” on page 7223 for details about how the adjusted information levels are computed.

At stage 1, the standardized Z statistic 0.86798 is between the lower α boundary -2.97951 and the upper α boundary 2.97951 , so the trial continues to the next stage.

With ODS Graphics enabled, a boundary plot with test statistics is displayed, as shown in [Output 84.2.11](#). As expected, the test statistic is in the continuation region between the lower and upper α boundaries.

Output 84.2.11 Sequential Test Plot

The following statements use the REG procedure to estimate the slope β_w and its associated standard error at stage 2:

```
proc reg data=Fit_2;
  model Oxygen=Age Weight RunTime RunPulse MaxPulse;
  ods output ParameterEstimates=Parms_Fit2;
run;
```

Note that the data set Fit_2 contains both the data from stage 1 and the data from stage 2.

The following statements create and display (in [Output 84.2.12](#)) the input data set that contains slope β_w and its associated standard error at stage 2 for the SEQTEST procedure:

```
data Parms_Fit2;
  set Parms_Fit2;
  if Variable='Weight';
  _Scale_='MLE';
  _Stage_= 2;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;
```

```
proc print data=Parms_Fit2;
  title 'Statistics Computed at Stage 2';
run;
```

Output 84.2.12 Statistics Computed at Stage 2

Statistics Computed at Stage 2					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Weight	0.02932	0.03520	MLE	2

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
proc seqtest Boundary=Test_Fit1
  Parms(Testvar=Weight)=Parms_Fit2
  infoadj=prop
  errspendadj=errfuncobf
  order=lr
;
ods output Test=Test_Fit2;
run;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_FIT2 option creates an output data set named TEST_FIT2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

Since the data set PARMS_FIT2 does not contain the test information at stage 1, the information level at stage 1 in the TEST_FIT1 data set is used to generate boundary values for the test at stage 2.

Following the process at stage 1, the slope estimate is also between its corresponding lower and upper α boundary values, so the trial continues to the next stage.

The following statements use the REG procedure to estimate the slope β_w and its associated standard error at the final stage:

```
proc reg data=Fit_3;
  model Oxygen=Age Weight RunTime RunPulse MaxPulse;
  ods output ParameterEstimates=Parms_Fit3;
run;
```

The following statements create the input data set that contains slope β_w and its associated standard error at stage 3 for the SEQTEST procedure:

```
data Parms_Fit3;
  set Parms_Fit3;
  if Variable='Weight';
  _Scale_='MLE';
  _Stage_= 3;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;
```

The following statements print (in [Output 84.2.13](#)) the test statistics at stage 3:

```
proc print data=Parms_Fit3;
  title 'Statistics Computed at Stage 3';
run;
```

Output 84.2.13 Statistics Computed at Stage 3

Statistics Computed at Stage 3					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Weight	0.02189	0.03028	MLE	3

The following statements invoke the SEQTEST procedure to test the hypothesis:

```
ods graphics on;
proc seqtest Boundary=Test_Fit2
  Parms(testvar=Weight)=Parms_Fit3
  errspendadj=errfuncobf
  order=1r
  pss
  plots=(asn power)
  ;
  ods output Test=Test_Fit3;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 3, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 3, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_FIT3 option creates an output data set named TEST_FIT3 which contains the updated boundary information for the test at stage 3.

The “Design Information” table in [Output 84.2.14](#) displays design specifications. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the boundary values are modified for the new information levels to maintain the Type I α level.

Output 84.2.14 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.TEST_FIT2
Data Set	WORK.PARMS_FIT3
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Number of Stages	3
Alpha	0.05
Beta	0.09514
Power	0.90486
Max Information (Percent of Fixed Sample)	102.0102
Max Information	1090.63724
Null Ref ASN (Percent of Fixed Sample)	101.4122
Alt Ref ASN (Percent of Fixed Sample)	77.22139

The maximum information is derived from the standard error associated with the slope estimate at the final stage and is larger than the target level. The derived Type II error probability β and power $1 - \beta$ are different because of the new information levels.

With the PSS option, the “Power and Expected Sample Sizes” table in [Output 84.2.15](#) displays powers and expected mean sample sizes under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ by default. You can specify the c_i values with the CREF= option.

Output 84.2.15 Power and Expected Sample Size Information

Powers and Expected Sample Sizes		
Reference = CRef * (Alt Reference)		
CRef	Power	-Sample Size- Percent Fixed-Sample
0.0000	0.02500	101.4122
0.5000	0.37046	96.3754
1.0000	0.90486	77.2214
1.5000	0.99844	58.5301

With the PLOTS=ASN option, the procedure displays a plot of expected sample sizes under various hypothetical references, as shown in [Output 84.2.16](#). By default, expected sample sizes under the hypotheses $\theta = c_i \theta_1$, $c_i = 0, 0.01, 0.02, \dots, 1.50$, are displayed, where θ_1 is the alternative reference.

Output 84.2.16 ASN Plot

With the PLOTS=POWER option, the procedure displays a plot of powers under various hypothetical references, as shown in [Output 84.2.17](#). By default, powers under hypothetical references $\theta = c_i \theta_1$ are displayed, where $c_i = 0, 0.01, 0.02, \dots, 1.50$ by default. You can specify c_i values with the CREF= option. The c_i values are displayed on the horizontal axis.

Output 84.2.17 Power Plot

Under the null hypothesis, $c_i = 0$, the power is 0.025, which is the upper Type I error probability. Under the alternative hypothesis, $c_i = 1$, the power is 0.90486, which is one minus the Type II error probability.

The “Test Information” table in [Output 84.2.18](#) displays the boundary values for the test statistic with the default standardized Z scale. The information level at the current stage is derived from the standard error for the current stage in the PARMS= data set. At stage 3, the standardized slope estimate 0.72284 is still between the lower and upper α boundary values. Since it is the final stage, the trial stops to accept the null hypothesis that the variable Weight has no effect on the oxygen intake rate after adjusting for other covariates.

Output 84.2.18 Sequential Tests

Test Information (Standardized Z Scale)						
Null Reference = 0						
Stage	--Information Level--		-----Alternative-----		----Boundary Values----	
	Proportion	Actual	-----Reference-----		---Lower--	---Upper--
			Lower	Upper	Alpha	Alpha
1	0.4856	529.6232	-2.30135	2.30135	-2.97951	2.97951
2	0.7401	807.1954	-2.84112	2.84112	-2.34945	2.34945
3	1.0000	1090.637	-3.30248	3.30248	-2.01885	2.01885

Test Information (Standardized Z Scale)		
Null Reference = 0		
Stage	-----Test-----	
	-----Weight-----	
	Estimate	Action
1	0.86798	Continue
2	0.83305	Continue
3	0.72284	Accept Null

Since the data set FIT_3 contains the test information only at stage 3, the information levels at previous stages in the TEST_FIT2 data set are used to generate boundary values for the test.

With ODS Graphics enabled, a boundary plot with test statistics is displayed, as shown in [Output 84.2.19](#). As expected, the test statistic is in the acceptance region between the lower and upper α boundaries at the final stage.

Output 84.2.19 Sequential Test Plot

After a trial is stopped, the “Parameter Estimates” table in [Output 84.2.20](#) displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and the p -value under the null hypothesis $H_0 : \beta_w = 0$.

Output 84.2.20 Parameter Estimates

Parameter Estimates LR Ordering				
Parameter	Stopping Stage	MLE	p-Value for $H_0 : \text{Parm}=0$	Median Estimate
Weight	3	0.021888	0.4699	0.021884
Parameter Estimates LR Ordering				
Parameter	95% Confidence Limits			
Weight	-0.03747	0.08123		

As expected, the p -value 0.4699 is not significant at the $\alpha = 0.05$ level, and the confidence interval does contain the value zero. The p -value, unbiased median estimate, and confidence limits depend on the ordering of the sample space (k, z) , where k is the stage number and z is the standardized Z statistic. With the specified LR ordering, the p -values are computed with the ordering $(k', z') \succ (k, z)$ if $z' > z$. See the section “Available Sample Space Orderings in a Sequential Test” on page 7230 for a detailed description of the LR ordering.

Example 84.3: Testing an Effect with Early Stopping to Accept H_0

This example demonstrates a two-sided group sequential test that uses an error spending design with early stopping to accept the null hypothesis H_0 . The example is similar to [Example 84.2](#) but with early stopping to accept H_0 .

A study is conducted to examine the effects of Age (years), Weight (kg), RunTime (time in minutes to run 1.5 miles), RunPulse (heart rate while running), and MaxPulse (maximum heart rate recorded while running) on Oxygen (oxygen intake rate, ml per kg body weight per minute). The primary interest is whether oxygen intake rate is associated with weight.

The hypothesis is tested using the following linear model:

$$\text{Oxygen} = \text{Age} + \text{Weight} + \text{RunTime} + \text{RunPulse} + \text{MaxPulse}$$

The null hypothesis is $H_0 : \beta_w = 0$, where β_w is the regression parameter for the variable Weight. Suppose that $\beta_w = 0.10$ is the reference improvement that should be detected at a 0.90 level. Then the maximum information I_X can be derived in the SEQDESIGN procedure.

Following the derivations in the section “Test for a Parameter in the Regression Model” in the chapter “The SEQDESIGN Procedure,” the required sample size can be derived from

$$N = I_X \frac{\sigma_y^2}{(1 - r_x^2) \sigma_x^2}$$

where σ_y^2 is the variance of the response variable in the regression model, r_x^2 is the proportion of variance of Weight explained by other covariates, and σ_x^2 is the variance of Weight.

Further suppose that from past experience, $\sigma_y^2 = 5$, $r_x^2 = 0.10$, and $\sigma_x^2 = 64$. Then the required sample size can be derived using the SAMPLESIZE statement in the SEQDESIGN procedure.

The following statements invoke the SEQDESIGN procedure and request a three-stage group sequential design for normally distributed data to test the null hypothesis of a regression parameter $H_0 : \beta_w = 0$ against the alternative $H_1 : \beta_w \neq 0$:

```
ods graphics on;
proc seqdesign altref=0.10;
  OBFErrorFunction: design method=errfuncgamma
                      stop=accept
                      nstages=3
                      info=cum(2 3 4);

  samplesize model=reg( variance=5 xvariance=64 xrsquare=0.10);
```

```
ods output Boundary=Bnd_Fit;
run;
ods graphics off;
```

By default (or equivalently if you specify ALPHA=0.05 and BETA=0.10), the procedure uses a Type I error probability 0.05 and a Type II error probability 0.10. The ALTREF=0.10 option specifies a power of $1 - \beta = 0.90$ at the alternative hypothesis $H_1 : \beta_w = \pm 0.10$. The INFO=CUM(2 3 4) option specifies that the study perform the first interim analysis with information proportion $2/4 = 0.5$ —that is, after half of the total observations are collected.

The ODS OUTPUT statement with the BOUNDARY=BND_FIT option creates an output data set named BND_FIT which contains the resulting boundary information for the subsequent sequential tests.

The “Design Information” table in [Output 84.3.1](#) displays design specifications and derived statistics. Since the alternative reference is specified, the maximum information is derived.

Output 84.3.1 Error Spending Design Information

The SEQDESIGN Procedure	
Design: OBFErrorFunction	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Accept Null
Method	Error Spending
Boundary Key	Both
Alternative Reference	0.1
Number of Stages	3

Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	103.9245
Max Information	1091.972
Null Ref ASN (Percent of Fixed Sample)	75.00521
Alt Ref ASN (Percent of Fixed Sample)	101.8099

The “Boundary Information” table in [Output 84.3.2](#) displays information level, alternative reference, and boundary values at each stage.

Output 84.3.2 Boundary Information

Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-----Alternative-----	
	Proportion	Actual	N	-----Reference-----	
				Lower	Upper
1	0.5000	545.9862	47.39463	-2.33663	2.33663
2	0.7500	818.9792	71.09195	-2.86178	2.86178
3	1.0000	1091.972	94.78926	-3.30450	3.30450
Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Boundary Values-----				
	---Lower---	---Upper---			
	Beta	Beta			
1	-0.44937	0.44937			
2	-1.13583	1.13583			
3	-1.91428	1.91428			

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 84.3.3](#). The boundary plot also displays the information level and critical value for the corresponding fixed-sample design.

Output 84.3.3 Boundary Plot

With the `MODEL=REG` option in the `SAMPLESIZE` statement, the “Sample Size Summary” table in [Output 84.3.4](#) displays the parameters for the sample size computation.

Output 84.3.4 Required Sample Size Summary

Sample Size Summary	
Test	Reg Parameter
Parameter	0.1
Variance	5
X Variance	64
R Square (X)	0.1
Max Sample Size	94.78926
Expected Sample Size (Null Ref)	68.41207
Expected Sample Size (Alt Ref)	92.86057

The “Sample Sizes” table in [Output 84.3.5](#) displays the required sample sizes for the group sequential clinical trial.

Output 84.3.5 Required Sample Sizes

Sample Sizes (N)				
Z Test for Regression Parameter				
Stage	-----Fractional N-----		-----Ceiling N-----	
	N	Information	N	Information
1	47.39	546.0	48	553.0
2	71.09	819.0	72	829.4
3	94.79	1092.0	95	1094.4

Thus, 48, 72, and 95 individuals are needed in stages 1, 2, and 3, respectively. Since the sample sizes are derived from estimated values of σ_y^2 , r_x^2 , and σ_x^2 , the actual information levels might not achieve the target information levels. Thus, instead of specifying sample sizes in the protocol, you can specify the maximum information levels. Then if an actual information level is much less than the target level, you can increase the sample sizes for the remaining stages to achieve the desired information levels and power.

Suppose that 48 individuals are available at stage 1. [Output 84.3.6](#) lists the first 10 observations of the trial data.

Output 84.3.6 Clinical Trial Data

First 10 Obs in the Trial Data						
Obs	Oxygen	Age	Weight	RunTime	Run Pulse	Max Pulse
1	54.5521	44	87.7676	11.6949	178.435	181.607
2	52.2821	40	75.4853	9.8872	184.433	183.667
3	62.1871	44	89.0638	8.7950	155.540	167.108
4	65.3269	42	67.7310	8.4577	162.926	173.877
5	59.9809	37	93.1902	9.3228	179.033	180.144
6	52.5588	47	75.9044	12.0385	177.753	175.033
7	51.7838	40	73.5422	11.6607	175.838	178.140
8	57.0024	43	81.2861	11.2219	160.963	171.770
9	48.0775	44	85.2290	13.1789	173.722	176.548
10	68.3357	38	80.2490	8.5066	171.824	184.011

The following statements use the REG procedure to estimate the slope β_w and its associated standard error at stage 1:

```
proc reg data=Fit_1;
  model Oxygen=Age Weight RunTime RunPulse MaxPulse;
  ods output ParameterEstimates=Parms_Fit1;
run;
```

The following statements create and display (in [Output 84.3.7](#)) the input data set that contains slope β_w and its associated standard error for the SEQTEST procedure:

```
data Parms_Fit1;
  set Parms_Fit1;
  if Variable='Weight';
  _Scale_='MLE';
  _Stage_= 1;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_Fit1;
  title 'Statistics Computed at Stage 1';
run;
```

Output 84.3.7 Statistics Computed at Stage 1

Statistics Computed at Stage 1					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Weight	0.04660	0.04308	MLE	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Fit
  Parms(testvar=Weight)=Parms_Fit1
  infoadj=none
  errspendadj=errfuncgamma
  stopprob
  order=lr
  ;
  ods output Test=Test_Fit1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_FIT1 option specifies the input data set PARMS_FIT1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=WEIGHT option identifies the test variable WEIGHT in the data set. The INFOADJ=NONE option maintains the information level for stage 2 at the value provided in the BOUNDARY= data set.

The ORDER=LR option uses the LR ordering to derive the p -value, the unbiased median estimate, and the confidence limits for the regression slope estimate. The ERRSPENDADJ=ERRFUNC GAMMA option adjusts the boundaries with the updated error spending values generated from a gamma cumulative error spending function.

The ODS OUTPUT statement with the TEST=TEST_FIT1 option creates an output data set named TEST_FIT1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Design Information” table in [Output 84.3.8](#) displays the design specifications. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the boundary values are modified for the new information levels to maintain the Type I α level. The maximum information remains the same as in the BOUNDARY= data set, but the derived Type II error probability β and power $1 - \beta$ are different because of the new information level.

Output 84.3.8 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.BND_FIT
Data Set	WORK.PARMS_FIT1
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Accept Null
Number of Stages	3
Alpha	0.05
Beta	0.10007
Power	0.89993
Max Information (Percent of Fixed Sample)	103.9498
Max Information	1091.97232
Null Ref ASN (Percent of Fixed Sample)	75.15846
Alt Ref ASN (Percent of Fixed Sample)	101.8296

With the STOPPROB option, the “Expected Cumulative Stopping Probabilities” table in [Output 84.3.9](#) displays the expected stopping stage and the cumulative stopping probability of accepting the null hypothesis at each stage under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ by default. You can specify other values for c_i with the CREF= option.

Output 84.3.9 Stopping Probabilities

Expected Cumulative Stopping Probabilities						
Reference = CRef * (Alt Reference)						
CRef	Expected Stopping Stage	Source	----Stopping Probabilities----			
			Stage_1	Stage_2	Stage_3	
0.0000	1.895	Accept Null	0.33304	0.76607	0.95000	
0.5000	2.409	Accept Null	0.17680	0.40947	0.62828	
1.0000	2.918	Accept Null	0.02636	0.05453	0.10007	
1.5000	2.997	Accept Null	0.00109	0.00166	0.00242	

The “Test Information” table in [Output 84.3.10](#) displays the boundary values for the test statistic. By default (or equivalently if you specify BOUNDARYSCALE=STDZ), these statistics are displayed with the standardized Z scale. The information level at stage 1 is derived from the standard error s_1 in the PARMS= data set,

$$I_1 = \frac{1}{s_1^2} = \frac{1}{0.04308^2} = 538.8$$

Output 84.3.10 Sequential Tests

Test Information (Standardized Z Scale)				
Null Reference = 0				
Stage	---Information Level---		-----Alternative-----	
	Proportion	Actual	-----Reference-----	
			Lower	Upper
1	0.4934	538.7887	-2.32118	2.32118
2	0.7500	818.9792	-2.86178	2.86178
3	1.0000	1091.972	-3.30450	3.30450
Test Information (Standardized Z Scale)				
Null Reference = 0				
Stage	-----Boundary Values-----		-----Test-----	
	---Lower--- Beta	---Upper--- Beta	-----Weight-----	
			Estimate	Action
1	-0.43033	0.43033	1.08174	Continue
2	-1.13623	1.13623	.	
3	-1.91431	1.91431	.	

At stage 1, the standardized Z statistic 1.08174 is greater than the upper β boundary 0.43033, so the trial continues to the next stage.

With ODS Graphics enabled, a boundary plot with test statistics is displayed, as shown in [Output 84.3.11](#). As expected, the test statistic is in the continuation region.

Output 84.3.11 Sequential Test Plot

The following statements use the REG procedure to estimate the slope β_w and its associated standard error at stage 2:

```
proc reg data=Fit_2;
  model Oxygen=Age Weight RunTime RunPulse MaxPulse;
  ods output ParameterEstimates=Parms_Fit2;
run;
```

Note that the data set Fit_2 contains both the data from stage 1 and the data from stage 2,

The following statements create and display (in [Output 84.3.12](#)) the input data set that contains slope β_w and its associated standard error at stage 2 for the SEQTEST procedure:

```
data Parms_Fit2;
  set Parms_Fit2;
  if Variable='Weight';
  _Scale_='MLE';
  _Stage_= 2;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;
```

```
proc print data=Parms_Fit2;
  title 'Statistics Computed at Stage 2';
run;
```

Output 84.3.12 Statistics Computed at Stage 2

Statistics Computed at Stage 2					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	Weight	0.02925	0.03490	MLE	2

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
ods graphics on;
proc seqtest Boundary=Test_Fit1
  Parms(testvar=Weight)=Parms_Fit2
  errspendadj=errfuncgamma
  order=lr
  pss
  plots=(asn power)
;
ods output Test=Test_Fit2;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

Since the data set PARMS_FIT2 does not contain the test information at stage 1, the information level at stage 1 in the TEST_FIT1 data set is used to generate boundary values for the test.

The ORDER=LR option uses the LR ordering to derive the p -value, unbiased median estimate, and confidence limits for the regression slope estimate.

The ODS OUTPUT statement with the TEST=TEST_FIT2 option creates an output data set named TEST_FIT2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Design Information” table in [Output 84.3.13](#) displays design specifications. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the boundary values are modified for the new information levels to maintain the Type I α level.

Output 84.3.13 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.TEST_FIT1
Data Set	WORK.PARMS_FIT2
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Accept Null
Number of Stages	3
Alpha	0.05
Beta	0.10009
Power	0.89991
Max Information (Percent of Fixed Sample)	103.9566
Max Information	1091.97232
Null Ref ASN (Percent of Fixed Sample)	75.18254
Alt Ref ASN (Percent of Fixed Sample)	101.8349

The derived Type II error probability β and power $1 - \beta$ are different because of the new information levels.

With the PSS option, the “Power and Expected Sample Sizes” table in [Output 84.3.14](#) displays powers and expected mean sample sizes under various hypothetical references $\theta = c_i \theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.5, 1, 1.5$ are the default values in the CREF= option.

Output 84.3.14 Power and Expected Sample Size Information

Powers and Expected Sample Sizes		
Reference = CRef * (Alt Reference)		
CRef	Power	-Sample Size- Percent Fixed-Sample
0.0000	0.02500	75.1825
0.5000	0.37154	88.5975
1.0000	0.89991	101.8349
1.5000	0.99758	103.8843

With the PLOTS=ASN option, the procedure displays a plot of expected sample sizes under various hypothetical references, as shown in [Output 84.3.15](#). By default, expected sample sizes under the hypotheses $\theta = c_i \theta_1$, $c_i = 0, 0.01, 0.02, \dots, 1.50$, are displayed, where θ_1 is the alternative reference.

Output 84.3.15 ASN Plot

With the PLOTS=POWER option, the procedure displays a plot of the power curves under various hypothetical references for all designs simultaneously, as shown in [Output 84.3.16](#). By default, powers under hypothetical references $\theta = c_i \theta_1$ are displayed, where $c_i = 0, 0.01, 0.02, \dots, 1.50$ by default. You can specify c_i values with the CREF= option. The c_i values are displayed on the horizontal axis.

Output 84.3.16 Power Plot

Under the null hypothesis, $c_i = 0$, the power is 0.025, which is the upper Type I error probability. Under the alternative hypothesis, $c_i = 1$, the power is 0.89991, which is one minus the Type II error probability, as displayed in the “Design Information” table in [Output 84.3.13](#).

The “Test Information” table in [Output 84.3.17](#) displays the boundary values for the test statistic with the default standardized Z scale. At stage 2, the standardized slope estimate 0.83805 is between the lower and upper β boundary values. The trial stops to accept the null hypothesis that the variable Weight has no effect on the oxygen intake rate after adjusting for other covariates.

Output 84.3.17 Sequential Tests

Test Information (Standardized Z Scale)				
Null Reference = 0				
Stage	---Information Level---		-----Alternative-----	
	Proportion	Actual	-----Reference-----	
			Lower	Upper
1	0.4934	538.7887	-2.32118	2.32118
2	0.7517	820.8509	-2.86505	2.86505
3	1.0000	1091.972	-3.30450	3.30450
Test Information (Standardized Z Scale)				
Null Reference = 0				
Stage	-----Boundary Values-----		-----Test-----	
	---Lower--- Beta	---Upper--- Beta	-----Weight-----	
			Estimate	Action
1	-0.43033	0.43033	1.08174	Continue
2	-1.14239	1.14239	0.83805	Accept Null
3	-1.91408	1.91408	.	

Since the data set PARMS_FIT2 contains the test information only at stage 2, the information level at stage 1 in the TEST_FIT1 data set is used to generate boundary values for the test.

With ODS Graphics enabled, a boundary plot with test statistics is displayed, as shown in [Output 84.3.18](#). As expected, the test statistic is in the acceptance region between the lower and upper α boundaries at the final stage.

Output 84.3.18 Sequential Test Plot

After a trial is stopped, the “Parameter Estimates” table in [Output 84.3.19](#) displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and the p -value under the null hypothesis $H_0 : \beta_w = 0$. As expected, the p -value 0.3056 is not significant at the $\alpha = 0.05$ level, and the confidence interval does contain the value zero. The p -value, unbiased median estimate, and confidence limits depend on the ordering of the sample space (k, z) , where k is the stage number and z is the standardized Z statistic. With the specified LR ordering, the p -values are computed with the ordering $(k', z') > (k, z)$ if $z' > z$. See the section “[Available Sample Space Orderings in a Sequential Test](#)” on page 7230 for a detailed description of the LR ordering.

Output 84.3.19 Parameter Estimates

Parameter Estimates LR Ordering				
Parameter	Stopping Stage	MLE	p-Value for H0:Parm=0	Median Estimate
Weight	2	0.029251	0.3056	0.037080
Parameter Estimates LR Ordering				
Parameter	95% Confidence Limits			
Weight	-0.03368 0.10532			

Example 84.4: Testing a Binomial Proportion

This example tests a binomial proportion by using a four-stage group sequential design. Suppose a supermarket is developing a new store-brand coffee. From past studies, the positive response for the current store-brand coffee from customers is around 60%. The store is interested in whether the new brand has a better positive response than the current brand.

A power family method is used for the group sequential trial with the null hypothesis $H_0 : p = p_0 = 0.60$ and a one-sided upper alternative with a power of 0.80 at $H_1 : p = 0.70$. To accommodate the zero null reference that is assumed in the SEQDESIGN procedure, an equivalent hypothesis $H_0 : \theta = 0$ with $H_1 : \theta = 0.10$ is used, where $\theta = p - p_0$. The following statements request a power family method with early stopping to reject the null hypothesis:

```
ods graphics on;
proc seqdesign altref=0.10
    boundaryscale=mle
    ;
    PowerFamily: design method=pow
        nstages=4
        alt=upper
        beta=0.20
    ;
    samplesize model=onesamplefreq( nullprop=0.6);
    ods output Boundary=Bnd_Prop;
run;
ods graphics off;
```

The NULLPROP= option in the SAMPLESIZE statement specifies $p_0 = 0.60$ for the sample size computation. The ODS OUTPUT statement with the BOUNDARY=BND_PROP option creates an output data set named BND_PROP which contains the resulting boundary information for the subsequent sequential tests.

With the BOUNDARYSCALE=MLE option, the procedure displays the output boundaries in terms of the maximum likelihood estimates. The “Design Information” table in [Output 84.4.1](#) displays design specifica-

tions and derived statistics. With the specified alternative reference $\theta_1 = p_1 - p_0 = 0.7 - 0.6 = 0.1$, the maximum information 670.38 is also derived.

Output 84.4.1 Design Information

The SEQDESIGN Procedure	
Design: PowerFamily	
Design Information	
Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Upper
Early Stop	Reject Null
Method	Power Family
Boundary Key	Both

Max Information	670.3782
Null Ref ASN (Percent of Fixed Sample)	106.9276
Alt Ref ASN (Percent of Fixed Sample)	78.51072

The “Boundary Information” table in [Output 84.4.2](#) displays the information level, alternative reference, and boundary values at each stage. With the STOP=REJECT option, only the rejection boundary values are displayed.

Output 84.4.2 Boundary Information

Boundary Information (MLE Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-Alternative-	-Boundary Values-
	Proportion	Actual	N	--Reference-- Upper	-----Upper----- Alpha
1	0.2500	167.5945	35.19485	0.10000	0.20018
2	0.5000	335.1891	70.38971	0.10000	0.11903
3	0.7500	502.7836	105.5846	0.10000	0.08782
4	1.0000	670.3782	140.7794	0.10000	0.07077

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 84.4.3](#).

Output 84.4.3 Boundary Plot

With the `MODEL=ONESAMPLEFREQ` option in the `SAMPLESIZE` statement, the “Sample Size Summary” table in [Output 84.4.4](#) displays the parameters for the sample size computation.

Output 84.4.4 Required Sample Size Summary

Sample Size Summary	
Test	One-Sample Proportion
Null Proportion	0.6
Proportion	0.7
Test Statistic	Z for Proportion
Reference Proportion	Alt Ref
Max Sample Size	140.7794
Expected Sample Size (Null Ref)	138.828
Expected Sample Size (Alt Ref)	101.9333

The “Sample Sizes” table in [Output 84.4.5](#) displays the required sample sizes for the group sequential clinical trial.

Output 84.4.5 Required Sample Sizes

Sample Sizes (N) One-Sample Z Test for Proportion				
Stage	-----Fractional N-----		-----Ceiling N-----	
	N	Information	N	Information
1	35.19	167.6	36	171.4
2	70.39	335.2	71	338.1
3	105.58	502.8	106	504.8
4	140.78	670.4	141	671.4

Thus, 36 customers are needed at stage 1, and 35 new customers are needed at each of the remaining stages. Suppose that 36 customers are available at stage 1. [Output 84.4.6](#) lists the 10 observations in the data set `count_1`.

Output 84.4.6 Clinical Trial Data

First 10 Obs in the Trial Data		
	Obs	Resp
	1	1
	2	1
	3	0
	4	0
	5	1
	6	1
	7	0
	8	1
	9	1
	10	1

The `Resp` variable is an indicator variable with a value of 1 for a customer with a positive response and a value of 0 for a customer without a positive response.

The following statements use the MEANS procedure to compute the mean response at stage 1:

```
proc means data=Prop_1;
  var Resp;
  ods output Summary=Data_Prop1;
run;
```

The following statements create and display (in [Output 84.4.7](#)) the data set for the centered mean positive response, $\hat{p} - p_0$:

```
data Data_Prop1;
  set Data_Prop1;
  _Scale_='MLE';
  _Stage_= 1;
  NObs= Resp_N;
  PDiff= Resp_Mean - 0.6;
  keep _Scale_ _Stage_ NObs PDiff;
run;
proc print data=Data_Prop1;
  title 'Statistics Computed at Stage 1';
run;
```

Output 84.4.7 Statistics Computed at Stage 1

Statistics Computed at Stage 1				
Obs	_Scale_	_Stage_	NObs	PDiff
1	MLE	1	36	-0.016667

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Prop
  Data(Testvar=PDiff)=Data_Prop1
  infoadj=prop
  boundarykey=both
  boundaryscale=mle
  ;
  ods output Test=Test_Prop1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The DATA=DATA_PROP1 option specifies the input data set DATA_PROP1 that contains the test statistic and its associated sample size at stage 1, and the TESTVAR=PDIFF option identifies the test variable PDIFF in the data set.

If the computed information level for stage 1 is not the same as the value provided in the BOUNDARY= data set, the INFOADJ=PROP option (which is the default) proportionally adjusts the information levels at future interim stages from the levels provided in the BOUNDARY= data set. The BOUNDARYKEY=BOTH option maintains both the α and β levels. The BOUNDARYSCALE=MLE option displays the output boundaries in terms of the MLE scale.

The ODS OUTPUT statement with the TEST=TEST_PROP1 option creates an output data set named TEST_PROP1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Design Information” table in [Output 84.4.8](#) displays design specifications. With the specified BOUNDARYKEY=BOTH option, the information levels and boundary values at future stages are modified to maintain both the α and β levels.

Output 84.4.8 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.BND_PROP

Test Information (MLE Scale)					
Null Reference = 0					
Stage	-----Test-----		-----PDiff-----		
	Estimate	Action			
1	-0.01667	Continue			
2	.				
3	.				
4	.				

The information level at stage 1 is computed as $I_1^* = I_1 \times (n_1^*/n_1)$, where I_1 and n_1 are the information level and sample size at stage 1 in the BOUNDARY= data set, and $n_1^* = 36$ is the available sample size at stage 1.

With the INFOADJ=PROP option (which is the default), the information levels at interim stages 2 and 3 are derived proportionally from the information levels in the BOUNDARY= data set. At stage 1, the statistic $\hat{\theta} = \hat{p} - p_0 = 0.58333 - 0.6 = -0.01667$ is less than the upper α boundary value 0.19638, so the trial continues to the next stage.

With ODS Graphics enabled, a boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 84.4.10](#). As expected, the test statistic is in the continuation region.

Output 84.4.10 Sequential Test Plot

The following statements use the MEANS procedure to compute the mean response at stage 2:

```
proc means data=Prop_2;
  var Resp;
  ods output Summary=Data_Prop2;
run;
```

The following statements create and display (in [Output 84.4.11](#)) the data set for the centered mean positive response ($\hat{p} - p_0$) at stage 2:

```
data Data_Prop2;
  set Data_Prop2;
  _Scale_='MLE';
  _Stage_= 2;
  NObs= Resp_N;
  PDiff= Resp_Mean - 0.6;
  keep _Scale_ _Stage_ NObs PDiff;
run;

proc print data=Data_Prop2;
  title 'Statistics Computed at Stage 2';
run;
```

Output 84.4.11 Statistics Computed at Stage 2

Statistics Computed at Stage 2				
Obs	_Scale_	_Stage_	NObs	PDiff
1	MLE	2	71	-0.064789

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
ods graphics on;
proc seqtest Boundary=Test_Prop1
  Data(Testvar=PDiff)=Data_Prop2
  infoadj=prop
  boundarykey=both
  boundaryscale=mle
  condpower(cref=1)
  predpower
  plots=condpower
  ;
  ods output test=Test_Prop2;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The DATA= option specifies the input data set that contains the test statistic and its associated sample size at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_PROP2 option creates an output data set named TEST_PROP2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The CONDPower(CREF=1) option requests the conditional power with the observed statistic under the alternative hypothesis, in addition to the conditional power under the hypothetical reference $\theta = \hat{\theta}$, the MLE estimate. The PREDPOWER option requests the noninformative predictive power with the observed statistic.

The “Test Information” table in [Output 84.4.12](#) displays the boundary values for the test statistic with the specified MLE scale. The test statistic $\hat{\theta} = -0.06479$ is less than the corresponding upper α boundary 0.11831, so the sequential test does not stop at stage 2 to reject the null hypothesis.

Output 84.4.12 Sequential Tests

The SEQTEST Procedure					
Test Information (MLE Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-Alternative- --Reference--	-Boundary Values- -----Upper-----
	Proportion	Actual	N	Upper	Alpha
1	0.2556	171.4286	35.98223	0.10000	0.19638
2	0.5043	338.2478	70.99698	0.10000	0.11831
3	0.7522	504.4785	105.8882	0.10000	0.08767
4	1.0000	670.7092	140.7794	0.10000	0.07081
Test Information (MLE Scale)					
Null Reference = 0					
Stage	-----Test-----		-----PDiff-----		
	Estimate	Action			
1	-0.01667	Continue			
2	-0.06479	Continue			
3	.				
4	.				

With ODS Graphics enabled, the “Test Plot” displays boundary values of the design and the test statistic, as shown in [Output 84.4.13](#). It also shows that the test statistic is in the “Continuation Region” below the upper α boundary value at stage 2.

Output 84.4.13 Sequential Test Plot

The “Conditional Power Information” table in [Output 84.4.14](#) displays conditional powers given the observed statistic under hypothetical references $\theta = \hat{\theta}$, the maximum likelihood estimate, and $\theta = \theta_1$. The constant c under CRef for the MLE is derived from $\hat{\theta} = c\theta_1$; that is, $c = \hat{\theta}/\theta_1 = -0.06479/0.1 = -0.6479$.

Output 84.4.14 Conditional Power

Conditional Power Information				
Reference = CRef * (Alt Reference)				
Stopping Stage	MLE	-----Reference----- Ref	CRef	Conditional Power
2	-0.06479	MLE	-0.6479	0.00000
2	-0.06479	Alternative	1.0000	0.02369

The conditional power is the probability of rejecting the null hypothesis under these hypothetical references given the observed statistic $\hat{\theta} = -0.06479$. The table in [Output 84.4.14](#) shows a weak conditional power of 0.02369 under the alternative hypothesis.

With the default TYPE=ALLSTAGES suboption in the CONDPOWER option, the conditional power at the interim stage 2 is the probability that the test statistic would exceed the rejection critical value at all future stages given the observed statistic $\hat{\theta} = -0.06479$.

The “Conditional Power Plot” displays conditional powers given the observed statistic under various hypothetical references, as shown in [Output 84.4.15](#). These references include $\theta = \hat{\theta}$, the maximum likelihood estimate, and $\theta = c_i \theta_1$, where θ_1 is the alternative reference and $c_i = 0, 0.01, \dots, 1.50$ are constants that are specified in the CREF= option. [Output 84.4.16](#) shows that the conditional power increases as c_i increases.

Output 84.4.15 Conditional Power Plot

The predictive power is the probability to reject the null hypothesis under the posterior distribution with a noninformative prior given the observed statistic $\hat{\theta} = -0.06479$. The “Predictive Power Information” table in [Output 84.4.16](#) indicates that the predictive power at $\hat{\theta} = -0.06479$ is 0.0002.

Output 84.4.16 Predictive Power

Predictive Power Information		
Stopping Stage	MLE	Predictive Power
2	-0.06479	0.00020

With a predictive power 0.0002 and a conditional power of 0.02369 under H_1 , the supermarket decides to stop the trial and accept the null hypothesis. That is, the positive response for the new store-brand coffee is not better than that for the current store-brand coffee.

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2. The NSTAGES=3 option sets the next stage as the final stage (stage 3), and the BOUNDARYKEY=BOTH option derives the information level at stage 3 that maintain both Type I and Type II error probability levels. The CONDPower(CREF=1) option requests the conditional power with the observed statistic under the alternative hypothesis, in addition to the conditional power under the hypothetical reference $\theta = \hat{\theta}$, the MLE estimate.

```
proc seqtest Boundary=Test_Prop1
              Data(Testvar=PDiff)=Data_Prop2
              nstages=3
              boundarykey=both
              boundaryscale=mle
              condpower(cref=1)
              ;
run;
```

The “Test Information” table in [Output 84.4.17](#) displays the boundary values for the test statistic with the specified MLE scale, assuming that the next stage is the final stage.

Output 84.4.17 Sequential Tests

The SEQTEST Procedure					
Test Information (MLE Scale)					
Null Reference = 0

2	-0.06479	Continue			
3	.				

The “Conditional Power Information” table in [Output 84.4.18](#) displays conditional powers given the observed statistic, assuming that the next stage is the final stage.

Output 84.4.18 Conditional Power

Conditional Power Information				
Reference = CRef * (Alt Reference)				
Stopping Stage	MLE	-----Reference----- Ref	CRef	Conditional Power
2	-0.06479	MLE	-0.6479	0.00000
2	-0.06479	Alternative	1.0000	0.02278

The conditional power is the probability of rejecting the null hypothesis under these hypothetical references given the observed statistic $\hat{\theta} = -0.06479$. The table in [Output 84.4.18](#) also shows a weak conditional power of 0.02278 under the alternative hypothesis.

Example 84.5: Comparing Two Proportions with a Log Odds Ratio Test

This example compares two binomial proportions by using a log odds ratio statistic in a five-stage group sequential test. A clinic is studying the effect of vitamin C supplements in treating flu symptoms. The study consists of patients in the clinic who exhibit the first sign of flu symptoms within the last 24 hours. These patients are randomly assigned to either the control group (which receives placebo pills) or the treatment group (which receives large doses of vitamin C supplements). At the end of a five-day period, the flu symptoms of each patient are recorded.

Suppose that you know from past experience that flu symptoms disappear in five days for 60% of patients who experience flu symptoms. The clinic would like to detect a 70% symptom disappearance with a high probability. A test that compares the proportions directly specifies the null hypothesis $H_0 : \theta = p_t - p_c = 0$ with a one-sided alternative $H_1 : \theta > 0$ and a power of 0.90 at $H_1 : \theta = 0.10$, where p_t and p_c are the proportions of symptom disappearance in the treatment group and control group, respectively. An alternative trial tests an equivalent hypothesis by using the log odds ratio statistics:

$$\theta = \log \left(\frac{\left(\frac{p_t}{1-p_t} \right)}{\left(\frac{p_c}{1-p_c} \right)} \right)$$

Then the null hypothesis is $H_0 : \theta = \theta_0 = 0$ and the alternative hypothesis is

$$H_1 : \theta = \theta_1 = \log \left(\frac{\left(\frac{0.70}{0.30} \right)}{\left(\frac{0.6}{0.4} \right)} \right) = 0.441833$$

The following statements invoke the SEQDESIGN procedure and request a five-stage group sequential design by using an error spending function method for normally distributed statistics. The design uses a two-sided alternative hypothesis with early stopping to reject the null hypothesis H_0 .

```
ods graphics on;
proc seqdesign altref=0.441833
    boundaryscale=mle
    ;
    OneSidedErrorSpending: design method=errfuncpow
                            nstages=5
                            alt=upper
                            stop=accept
                            alpha=0.025;
    samplesize model=twosamplefreq( nullprop=0.6 test=logor);
    ods output Boundary=Bnd_CSUP;
run;
ods graphics off;
```

The ODS OUTPUT statement with the BOUNDARY=BND_CSUP option creates an output data set named BND_CSUP which contains the resulting boundary information for the subsequent sequential tests.

The “Design Information” table in [Output 84.5.1](#) displays design specifications and derived statistics. With the specified alternative reference, the maximum information 56.30934 is derived.

Output 84.5.1 Design Information

The SEQDESIGN Procedure	
Design: OneSidedErrorSpending	
Design Information	
Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Upper
Early Stop	Accept Null

4	0.8000	45.04747	804.4192	0.44183	0.19708
5	1.0000	56.30934	1005.524	0.44183	0.25345

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 84.5.3](#).

Output 84.5.3 Boundary Plot

With the SAMPLESIZE statement, the “Sample Size Summary” table in [Output 84.5.4](#) displays the parameters for the sample size computation.

Output 84.5.4 Sample Size Summary

Sample Size Summary		
Test	Two-Sample Proportions	
Null Proportion		0.6
Proportion (Group A)		0.7
Test Statistic	Log Odds Ratio	
Reference Proportions	Alt	Ref
Max Sample Size		1005.524
Expected Sample Size (Null Ref)		549.9132
Expected Sample Size (Alt Ref)		981.3914

The “Sample Sizes” table in [Output 84.5.5](#) displays the required sample sizes for the group sequential clinical trial.

Output 84.5.5 Required Sample Sizes

Sample Sizes (N)				
Two-Sample Log Odds Ratio Test for Proportion Difference				
-----Fractional N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	201.10	100.55	100.55	11.2619
2	402.21	201.10	201.10	22.5237
3	603.31	301.66	301.66	33.7856
4	804.42	402.21	402.21	45.0475
5	1005.52	502.76	502.76	56.3093

Sample Sizes (N)				
Two-Sample Log Odds Ratio Test for Proportion Difference				
-----Ceiling N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	202	101	101	11.3120
2	404	202	202	22.6240
3	604	302	302	33.8240
4	806	403	403	45.1360
5	1006	503	503	56.3360

Thus, 101 new patients are needed in each group at stages 1, 2, and 4, and 100 new patients are needed in each group at stages 3 and 5. Suppose that 101 patients are available in each group at stage 1. [Output 84.5.6](#) lists the 10 observations in the data set `count_1`.

Output 84.5.6 Clinical Trial Data

First 10 Obs in the Trial Data		
Obs	TrtGrp	Resp
1	Control	1
2	C_Sup	0
3	Control	0
4	C_Sup	1
5	Control	1
6	C_Sup	1
7	Control	1
8	C_Sup	0
9	Control	0
10	C_Sup	1

The `TrtGrp` variable is a grouping variable with the value `Control` for a patient in the placebo control group and the value `C_Sup` for a patient in the treatment group who receives vitamin C supplements. The `Resp` variable is an indicator variable with the value 1 for a patient without flu symptoms after five days and the value 0 for a patient with flu symptoms after five days.

The following statements use the LOGISTIC procedure to compute the log odds ratio statistic and its associated standard error at stage 1:

```
proc logistic data=CSup_1 descending;
  class TrtGrp / param=ref;
  model Resp= TrtGrp;
  ods output ParameterEstimates=Parms_CSup1;
run;
```

The DESCENDING option is used to reverse the order for the response levels, so the LOGISTIC procedure is modeling the probability that Resp = 1.

The following statements create and display (in [Output 84.5.7](#)) the data set for the log odds ratio statistic and its associated standard error:

```
data Parms_CSup1;
  set Parms_CSup1;
  if Variable='TrtGrp' and ClassVal0='C_Sup';
  _Scale_='MLE';
  _Stage_= 1;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_CSup1;
  title 'Statistics Computed at Stage 1';
run;
```

Output 84.5.7 Statistics Computed at Stage 1

Statistics Computed at Stage 1					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	TrtGrp	0.3247	0.2856	MLE	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_CSup
  Parms(Testvar=TrtGrp)=Parms_CSup1
  infoadj=prop
  errspendadj=errfuncpow
  boundarykey=both
  boundaryscale=mle
  ;
  ods output test=Test_CSup1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_CSUP1 option specifies the input data set PARMS_CSUP1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRTGRP option identifies the test variable TRTGRP in the data set.

If the computed information level for stage 1 is not the same as the value provided in the BOUNDARY= data set, the INFOADJ=PROP option (which is the default) proportionally adjusts the information levels at future interim stages from the levels provided in the BOUNDARY= data set. The ERRSPENDADJ=ERRFUNCPOW option adjusts the boundaries with the updated error spending values generated from the power error spending function. The BOUNDARYKEY=BOTH option maintains both the α and β levels. The BOUNDARYSCALE=MLE option displays the output boundaries in terms of the MLE scale.

The ODS OUTPUT statement with the TEST=TEST_CSUP1 option creates an output data set named TEST_CSUP1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Design Information” table in [Output 84.5.8](#) displays design specifications. With the specified BOUNDARYKEY=BOTH option, the information levels and boundary values at future stages are modified to maintain both the α and β levels.

Output 84.5.8 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.BND_CSUP
Data Set	WORK.PARMS_CSUP1
Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Upper
Early Stop	Accept Null
Number of Stages	5
Alpha	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	104.6673
Max Information	56.3361718
Null Ref ASN (Percent of Fixed Sample)	57.02894
Alt Ref ASN (Percent of Fixed Sample)	102.1369

The “Test Information” table in [Output 84.5.9](#) displays the boundary values for the test statistic with the specified MLE scale. With the INFOADJ=PROP option (which is the default), the information levels at future interim stages are derived proportionally from the observed information at stage 1 and the information levels in the BOUNDARY= data set.

Since the information level at stage 1 is derived from the PARMS= data set and other information levels are not specified, equal increments are used at remaining stages. At stage 1, the MLE statistic 0.32474 is greater than the corresponding upper β boundary value -0.29906 , so the sequential test continues to the next stage.

Output 84.5.9 Sequential Tests

Test Information (MLE Scale)			
Null Reference = 0			
Stage	---Information Level---		-Alternative-
	Proportion	Actual	--Reference-- Upper

	Beta	Estimate	Action
1	-0.29906	0.32474	Continue
2	-0.01067	.	
3	0.11942	.	
4	0.19829	.	
5	0.25325	.	

With ODS Graphics enabled, a boundary plot with the boundary values and test statistics is displayed, as shown in [Output 84.5.10](#). As expected, the test statistic is in the continuation region.

Output 84.5.10 Sequential Test Plot

The following statements use the LOGISTIC procedure to compute the log odds ratio statistic and its associated standard error at stage 2:

```
proc logistic data=CSup_2 descending;
  class TrtGrp / param=ref;
  model Resp= TrtGrp;
  ods output ParameterEstimates=Parms_CSup2;
run;
```

The following statements create and display (in [Output 84.5.11](#)) the data set for the mean positive response and its associated standard error at stage 2:

```
data Parms_CSup2;
  set Parms_CSup2;
  if Variable='TrtGrp' and ClassVal0='C_Sup';
  _Scale_='MLE';
  _Stage_= 2;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;
proc print data=Parms_CSup2;
  title 'Statistics Computed at Stage 2';
run;
```

Output 84.5.11 Statistics Computed at Stage 2

Statistics Computed at Stage 2					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	TrtGrp	0.2356	0.2073	MLE	2

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
proc seqtest Boundary=Test_CSup1
              Parms( testvar=TrtGrp)=Parms_CSup2
              infoadj=prop
              errspendadj=errfuncpow
              boundarykey=both
              boundaryscale=mle
              ;
ods output Test=Test_CSup2;
run;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=CSUP_LDL2 option creates an output data set named CSUP_LDL2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Test Information” table in [Output 84.5.12](#) displays the boundary values for the test statistic with the specified MLE scale. The test statistic 0.2356 is greater than the corresponding upper β boundary value -0.01068 , so the sequential test continues to the next stage.

Output 84.5.12 Sequential Tests

The SEQTEST Procedure				
Test Information (MLE Scale)				
Null Reference = 0				
Stage	---Information Level---		-Alternative-	
	Proportion	Actual	--Reference--	Upper

2		-0.01068	0.23560	Continue
3		0.11942	.	
4		0.19829	.	
5		0.25325	.	

Similar results are found at stages 3 and stage 4, so the trial continues to the final stage. The following statements use the LOGISTIC procedure to compute the log odds ratio statistic and its associated standard error at stage 5:

```
proc logistic data=CSup_5 descending;
  class TrtGrp / param=ref;
  model Resp= TrtGrp;
  ods output ParameterEstimates=Parms_CSup5;
run;
```

The following statements create and display (in [Output 84.5.13](#)) the data set for the log odds ratio statistic and its associated standard error at stage 5:

```
data Parms_CSup5;
  set Parms_CSup5;
  if Variable='TrtGrp' and ClassVal0='C_Sup';
  _Scale_='MLE';
  _Stage_= 5;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_CSup5;
  title 'Statistics Computed at Stage 5';
run;
```

Output 84.5.13 Statistics Computed at Stage 5

Statistics Computed at Stage 5					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	TrtGrp	0.2043	0.1334	MLE	5

The following statements invoke the SEQTEST procedure to test for the hypothesis at stage 5:

```
ods graphics on;
proc seqtest Boundary=Test_CSup4
              Parms( testvar=TrtGrp)=Parms_CSup5
              errspendadj=errfuncpow
              boundaryscale=mle
              cialpha=.025
              rci
              plots=rci
              ;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 5, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 5, and the TESTVAR= option identifies the test variable in the data set. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the boundary value at stage 5 is derived to maintain the α level.

The “Test Information” table in [Output 84.5.14](#) displays the boundary values for the test statistic with the specified MLE scale. The test statistic 0.2043 is less than the corresponding upper β boundary 0.25375, so the sequential test stops to accept the null hypothesis. That is, there is no reduction in duration of symptoms for the group receiving vitamin C supplements.

Output 84.5.14 Sequential Tests

The SEQTEST Procedure				
Test Information (MLE Scale)				
Null Reference = 0				
Stage	---Information Level---		-Alternative-	
	Proportion	Actual	--Reference--	Upper
1	0.2183	12.26014		0.44183
2	0.4145	23.27916		0.44183
3	0.6141	34.48793		0.44183
4	0.8092	45.44685		0.44183
5	1.0000	56.16068		0.44183
Test Information (MLE Scale)				
Null Reference = 0				
Stage	-Boundary Values-		-----Test-----	
	-----Upper-----	Beta	-----TrtGrp-----	Action
1		-0.29906	0.32474	Continue
2		-0.01068	0.23560	Continue
3		0.12134	0.14482	Continue
4		0.19899	0.20855	Continue
5		0.25375	0.20430	Accept Null

The “Test Plot” displays boundary values of the design and the test statistics, as shown in [Output 84.5.15](#). It also shows that the test statistic is in the “Acceptance Region” at the final stage.

Output 84.5.15 Sequential Test Plot

After a trial is stopped, the “Parameter Estimates” table in [Output 84.5.16](#) displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and the p -value under the null hypothesis $H_0 : \theta = 0$. As expected, the p -value 0.0456 is not significant at $\alpha = 0.025$ level and the lower 97.5% confidence limit is less than the value $\theta_0 = 0$. The p -value, unbiased median estimate, and confidence limits depend on the ordering of the sample space (k, z) , where k is the stage number and z is the standardized Z statistic.

Output 84.5.16 Parameter Estimates

Parameter Estimates Stagewise Ordering					
Parameter	Stopping Stage	MLE	p-Value for $H_0: \text{Parm}=0$	Median Estimate	Lower 97.5% CL
TrtGrp	5	0.204303	0.0456	0.234494	-0.03712

Since the test is accepted at stage 5, the p -value computed by using the default stagewise ordering can be expressed as

$$\alpha_u = P_{\theta=0}(z_5 < Z_5 \mid b_k < Z_k, k < 5)$$

where $z_5 = 1.53105$ is the test statistic at stage 5, Z_k is a standardized normal variate at stage k , and b_k is the upper β boundary value in the standardized Z scale at stage k , $k = 1, 2, \dots, 5$.

With the RCI option, the “Repeated Confidence Intervals” table in [Output 84.5.17](#) displays repeated confidence intervals for the parameter. For a one-sided test with an upper alternative hypothesis, since the upper acceptance repeated confidence limit 0.3924 at the final stage is less than the alternative reference 0.441833, the null hypothesis is accepted.

Output 84.5.17 Repeated Confidence Intervals

Repeated Confidence Intervals			
<u>_Stage_</u>	Information Level	Parameter Estimate	-Acceptance Boundary- Upper 89.94% CL
1	12.2601	0.32474	1.0656
2	23.2792	0.23560	0.6881
3	34.4879	0.14482	0.4653
4	45.4468	0.20855	0.4514
5	56.1607	0.20430	0.3924

With the PLOTS=RCI option, the “Repeated Confidence Intervals Plot” displays repeated confidence intervals for the parameter, as shown in [Output 84.5.18](#). It shows that the upper acceptance repeated confidence limit at the final stage is less than the alternative reference 0.441833. This implies that the study accepts the null hypothesis at the final stage.

Output 84.5.18 Repeated Confidence Intervals Plot

Example 84.6: Comparing Two Survival Distributions with a Log-Rank Test

This example requests a log-rank test that compares two survival distributions for the treatment effect (Jenkinson and Turnbull 2000, pp. 77–79; Whitehead 1997, pp. 36–39).

A clinic is studying the effect of a new cancer treatment. The study consists of mice exposed to a carcinogen and randomized to either the control group or the treatment group. The event of interest is the death from cancer induced by the carcinogen, and the response is the time from randomization to death.

Following the derivations in the section “Test for Two Survival Distributions with a Log-Rank Test” in the chapter “The SEQDESIGN Procedure,” the hypothesis $H_0 : \theta = -\log(\lambda) = 0$ with an alternative hypothesis $H_1 : \theta = \theta_1 > 0$ can be used, where λ is the hazard ratio between the treatment group and control group.

Suppose that from past experience, the median survival time for the control group is $t_0 = 20$ weeks, and the study would like to detect a $t_1 = 40$ weeks median survival time with a 80% power in the trial. Assuming exponential survival functions for the two groups, the hazard rates can be computed from

$$S_j(t_j) = e^{-h_j t_j} = \frac{1}{2}$$

where $j = 0, 1$.

Thus, with $h_0 = 0.03466$ and $h_1 = 0.01733$, the hazard ratio $\lambda_1 = h_1/h_0 = 1/2$ and the alternative hypothesis is

$$\theta_1 = -\log(\lambda_1) = -\log\left(\frac{1}{2}\right) = 0.69315$$

The following statements invoke the SEQDESIGN procedure and request a four-stage group sequential design for normally distributed data. The design uses a one-sided alternative hypothesis with early stopping to reject and to accept the null hypothesis H_0 . Whitehead's triangular method is used to derive the boundaries.

```
ods graphics on;
proc seqdesign altref=0.69315
    boundaryscale=score
    ;
    OneSidedWhitehead: design method=whitehead
                        nstages=4
                        boundarykey=alpha
                        alt=upper stop=both
                        beta=0.20;
    samplesize model=twosamplesurvival
                ( nullhazard=0.03466
                  accrate=10);
run;
ods graphics off;
```

A Whitehead method creates boundaries that approximately satisfy the Type I and Type II error probability level specification. The BOUNDARYKEY=ALPHA option is used to adjust the boundary value at the last stage and to meet the specified Type I probability level.

The specified ACCRATE=10 option indicates that 10 mice will be accrued each week and the resulting minimum and maximum accrual times are displayed. With the BOUNDARYSCALE=SCORE option, the procedure displays the output boundaries with the score statistics.

The “Design Information” table in [Output 84.6.1](#) displays design specifications and derived statistics.

Output 84.6.1 Design Information

The SEQDESIGN Procedure	
Design: OneSidedWhitehead	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Score
Alternative Hypothesis	Upper
Early Stop	Accept/Reject Null
Method	Whitehead
Boundary Key	Alpha
Alternative Reference	0.69315
Number of Stages	4
Alpha	0.05
Beta	0.20044
Power	0.79956
Max Information (Percent of Fixed Sample)	129.9894
Max Information	16.70624
Null Ref ASN (Percent of Fixed Sample)	62.6302
Alt Ref ASN (Percent of Fixed Sample)	74.00064

The “Boundary Information” table in [Output 84.6.2](#) displays the information level, alternative reference, and boundary values at each stage.

Output 84.6.2 Boundary Information

Boundary Information (Score Scale)						
Null Reference = 0						
Stage	-----Information Level-----			-Alternative-	----Boundary Values----	
	Proportion	Actual	Events	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2500	4.176561	16.70624	2.89498	-0.95755	4.78773
2	0.5000	8.353122	33.41249	5.78997	1.91509	5.74527
3	0.7500	12.52968	50.11873	8.68495	4.78773	6.70282
4	1.0000	16.70624	66.82498	11.57993	7.81296	7.81296

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 84.6.3](#).

Output 84.6.3 Boundary Plot

With the MODEL=TWOSAMPLESURVIVAL option in the SAMPLESIZE statement, the “Sample Size Summary” table in [Output 84.6.4](#) displays the parameters for the sample size computation.

Output 84.6.4 Required Sample Size Summary

Sample Size Summary		
Test	Two-Sample Survival	
Null Hazard Rate		0.03466
Hazard Rate (Group A)		0.01733
Hazard Rate (Group B)		0.03466
Hazard Ratio		0.499999
log(Hazard Ratio)		-0.69315
Reference Hazards		Alt Ref
Accrual		Uniform
Accrual Rate		10
Min Accrual Time		6.682498
Min Sample Size		66.82498
Max Accrual Time		25.401
Max Sample Size		254.01
Max Number of Events		66.82498

With a minimum accrual time of 6.6825 weeks and a maximum accrual time of 25.401 weeks, an accrual time of 20 weeks is used in the study.

The “Numbers of Events” table in [Output 84.6.5](#) displays the required number of events for the group sequential clinical trial.

Output 84.6.5 Required Numbers of Events

Numbers of Events (D) Two-Sample Log-Rank Test		
Stage	D	Information
1	16.71	4.1766
2	33.41	8.3531
3	50.12	12.5297
4	66.82	16.7062

The following statements invoke the SEQDESIGN procedure and provide more detailed sample size information:

```
proc seqdesign altref=0.69315
    boundaryscale=score
    ;
    OneSidedWhitehead: design method=whitehead
                        nstages=4
                        boundarykey=alpha
                        alt=upper
                        stop=both
                        beta=0.20;
    samplesize model=twosamplesurvival
                ( nullhazard=0.03466
                  accrate=10 acctime=20);
    ods output Boundary=Bnd_Surv;
run;
```

The ODS OUTPUT statement with the BOUNDARY=BND_SURV option creates an output data set named BND_SURV which contains the resulting boundary information for the subsequent sequential tests.

With an accrual time of 20 weeks, the “Sample Size Summary” table in [Output 84.6.6](#) displays the follow-up time for the trial.

Output 84.6.6 Required Sample Size Summary

The SEQDESIGN Procedure	
Design: OneSidedWhitehead	
Sample Size Summary	
Test	Two-Sample Survival
Null Hazard Rate	0.03466
Hazard Rate (Group A)	0.01733
Hazard Rate (Group B)	0.03466
Hazard Ratio	0.499999
log(Hazard Ratio)	-0.69315
Reference Hazards	Alt Ref
Accrual	Uniform
Accrual Rate	10
Accrual Time	20
Follow-up Time	6.47422
Total Time	26.47422
Max Number of Events	66.82498
Max Sample Size	200
Expected Sample Size (Null Ref)	161.5937
Expected Sample Size (Alt Ref)	172.4689

The “Numbers of Events and Sample Sizes” table in [Output 84.6.7](#) displays the required sample sizes for the group sequential clinical trial.

Output 84.6.7 Numbers of Events and Sample Sizes

Numbers of Events (D) and Sample Sizes (N) Two-Sample Log-Rank Test							
-----Fractional Time-----							
Stage	D	D(Grp 1)	D(Grp 2)	Time	N	N(Grp 1)	N(Grp 2)
1	16.71	5.82	10.89	11.9866	119.87	59.93	59.93
2	33.41	11.84	21.57	17.3584	173.58	86.79	86.79
3	50.12	18.01	32.11	21.7479	200.00	100.00	100.00
4	66.82	24.46	42.37	26.4742	200.00	100.00	100.00

Numbers of Events (D) and Sample Sizes (N) Two-Sample Log-Rank Test							
-Fractional Time-----							
-----Ceiling Time-----							
Stage	Information	D	D(Grp 1)	D(Grp 2)	Time	N	N(Grp 1)
1	4.1766	16.74	5.83	10.91	12	120.00	60.00
2	8.3531	35.73	12.68	23.04	18	180.00	90.00
3	12.5297	51.07	18.37	32.70	22	200.00	100.00
4	16.7062	68.55	25.14	43.41	27	200.00	100.00

Numbers of Events (D) and Sample Sizes (N) Two-Sample Log-Rank Test							
-----Ceiling Time-----							
Stage	N(Grp 2)	Information					
1	60.00	4.1854					
2	90.00	8.9322					
3	100.00	12.7667					
4	100.00	17.1377					

Thus the study will perform three interim analyses after 12, 18, and 22 weeks and a final analysis after 27 weeks if the study does not stop at any of the interim analyses.

Note that the SEQDESIGN procedure does not compute numbers of events or sample sizes for all statistical models. If the number of events or sample size for a fixed-sample design is available, then the MODEL=INPUTNEVENTS or MODEL=INPUTNOBS option can be used to input fixed-sample information. For example, with a required fixed-sample number of events 51.4073, the following SAMPLESIZE statement can be used to produce the same sample size results:

```
samplesize model=inputnevents
  ( d=51.47 sample=two
    hazard=0.03466 0.01733
    accrate=10 acctime=20);
```

Suppose that 120 mice are available after week 12 for the first interim analysis. [Output 84.6.8](#) lists the 10 observations in the data set weeks_1.

Output 84.6.8 Clinical Trial Data

First 10 Obs in the Trial Data				
Obs	Trt Gp	Event	Weeks	
1	0	0	11	
2	1	0	11	
3	0	0	11	
4	1	0	11	
5	0	1	6	
6	1	0	11	
7	0	0	11	
8	1	0	11	
9	0	1	9	
10	1	0	11	

The TrtGp variable is a grouping variable with the value 0 for a mouse in the placebo control group and the value 1 for a mouse in the treatment group. The Weeks variable is the survival time variable measured in weeks and the Event variable is the censoring variable with the value 0 indicating censoring. That is, the values of Weeks are considered censored if the corresponding values of Event are 0; otherwise, they are considered as event times.

The following statements use the LIFETEST procedure to estimate the log-rank statistic at stage 1:

```
proc lifetest data=Surv_1;
  time Weeks*Event(0);
  test TrtGp;
  ods output logunichisq=Parms_Surv1;
run;
```

The following statements create and display (in [Output 84.6.9](#)) the data set for the log-rank statistic and its associated standard error:

```
data Parms_Surv1;
  set Parms_Surv1(rename=(Statistic=Estimate));
  if Variable='TrtGp';
  _Scale_='Score';
  _Stage_= 1;
  keep Variable _Scale_ _Stage_ StdErr Estimate;
run;

proc print data=Parms_Surv1;
  title 'Statistics Computed at Stage 1';
run;
```

Output 84.6.9 Statistics Computed at Stage 1

Statistics Computed at Stage 1					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	TrtGp	3.2004	1.9979	Score	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Surv
              Parms(Testvar=TrtGp)=Parms_Surv1
              infoadj=none
              boundaryscale=score
              ;
  ods output Test=Test_Surv1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_SURV1 option specifies the input data set PARMS_SURV1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRTGP option identifies the test variable TRTGP in the data set. The INFOADJ=NONE option maintains the information levels for future interim stages (2 and 3) at the values provided in the BOUNDARY= data set.

The ODS OUTPUT statement with the TEST=TEST_SURV1 option creates an output data set named TEST_SURV1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Design Information” table in [Output 84.6.10](#) displays design specifications. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the maximum information and the Type I error level α are preserved. Since the computed information level at stage 1 is not the same as the value provided in the BOUNDARY= data set, the power has been modified.

Output 84.6.10 Design Information

The SEQTEST Procedure		
Design Information		
BOUNDARY Data Set		WORK.BND_SURV
Data Set		WORK.PARMS_SURV1
Statistic Distribution		Normal
Boundary Scale		Score
Alternative Hypothesis		Upper
Early Stop	Accept/Reject	Null
Number of Stages		4
Alpha		0.05
Beta		0.20055
Power		0.79945
Max Information (Percent of Fixed Sample)		130.0335
Max Information		16.7062448
Null Ref ASN (Percent of Fixed Sample)		62.80855
Alt Ref ASN (Percent of Fixed Sample)		74.19155

The “Test Information” table in [Output 84.6.11](#) displays the boundary values for the test statistic with the SCORE statistic scale. Since only the information level at stage 1 is specified in the DATA= data set, the information levels at subsequent stages are derived proportionally from the corresponding information levels provided in the BOUNDARY= data set. At stage 1, the score statistic 3.2004 is between the upper β boundary value -1.0386 and the upper α boundary value 4.7142 , so the trial continues to the next stage.

Output 84.6.11 Sequential Tests

Test Information (Score Scale)					
Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values----

Test Information (Score Scale)		
Null Reference = 0		
Stage	-----Test-----	
	-----TrtGp-----	
	Estimate	Action
1	3.20040	Continue
2	.	
3	.	
4	.	

Note that the observed information level 3.9917 corresponds to a proportion of 0.2389 in information level. If the observed information level is much smaller than the target proportion of 0.25, then you need to increase the accrual rate, accrual time, or follow-up time to achieve the target maximum information level for the trial. Scharfstein and Tsiatis (1998) use the simulation and bootstrap methods to modify the trial at interim stages to achieve the target maximum information level. These modifications should be specified in the study protocol or study plan before the study starts.

With ODS Graphics enabled, a boundary plot with test statistics is displayed, as shown in [Output 84.6.12](#). As expected, the test statistic is in the continuation region between the upper β and α boundary values.

Output 84.6.12 Sequential Test Plot

Note that the input DATA= option can also be used for the test statistics. For example, the following statements create and display (in [Output 84.6.13](#)) the data set for the log-rank statistic and its associated standard error after the LIFETEST procedure. Since the log-rank statistic is a score statistic, the corresponding information level is the variance of the statistic.

```
proc lifetest data=Surv_1;
  time Weeks*Event(0);
  test TrtGp;
  ods output logunichisq=Parms_Surv1a;
run;
```

```

data Parms_Surv1a;
  set Parms_Surv1a(rename=(Statistic=TrtGp));
  keep _Scale_ _Stage_ _Info_ TrtGp;
  _Scale_='Score';
  _Stage_= 1;
  _Info_= StdErr * StdErr;
  if Variable='TrtGp';
run;

proc print data=Parms_Surv1a;
  title 'Statistics Computed at Stage 1';
run;

```

Output 84.6.13 Statistics Computed at Stage 1

Statistics Computed at Stage 1				
Obs	TrtGp	_Scale_	_Stage_	_Info_
1	3.2004	Score	1	3.99170

The following statements can be used to invoke the SEQTEST procedure to test for early stopping at stage 1:

```

ods graphics on;
proc seqtest Boundary=Bnd_Surv
  Data(Testvar=TrtGp)=Parms_Surv1a
  infoadj=none
  boundaryscale=score
  ;
  ods output Test=Test_Surv1;
run;
ods graphics off;

```

The following statements use the LIFETEST procedure to compute the log-rank statistic and its associated standard error at stage 2:

```

proc lifetest data=Surv_2;
  time Weeks*Event(0);
  test TrtGp;
  ods output logunichisq=Parms_Surv2;
run;

```

The following statements create and display (in [Output 84.6.14](#)) the data set for the log-rank statistic and its associated standard error for each of the first two stages:

```

data Parms_Surv2;
  set Parms_Surv2 (rename=(Statistic=Estimate));
  if Variable='TrtGp';
  _Scale_='Score';
  _Stage_= 2;
  keep Variable _Scale_ _Stage_ StdErr Estimate;
run;

```

```
proc print data=Parms_Surv2;
  title 'Statistics Computed at Stage 2';
run;
```

Output 84.6.14 Statistics Computed at Stage 2

Statistics Computed at Stage 2					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	TrtGp	7.3136	2.9489	Score	2

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
ods graphics on;
proc seqtest Boundary=Test_Surv1
  Parms (Testvar=TrtGp) =Parms_Surv2
  infoadj=none
  boundaryscale=score
  cotype=lower
;
ods output Test=Test_Surv2;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set. The INFOADJ=NONE option maintains the information level for stage 3 at the value provided in the BOUNDARY= data set.

The ODS OUTPUT statement with the TEST=TEST_SURV2 option creates an output data set named TEST_SURV2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage if the trial does not stop at the current stage.

The “Test Information” table in [Output 84.6.15](#) displays the boundary values for the test statistic. The test statistic 7.31365 is larger than the corresponding upper α boundary 5.79886, so the study stops and rejects the null hypothesis. That is, there is evidence of reduction in hazard rate for the new treatment.

Output 84.6.15 Sequential Tests

The SEQTEST Procedure					
Test Information (Score Scale)					
Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values-----	
	Proportion	Actual	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2389	3.991698	2.76685	-1.03860	4.71422
2	0.5205	8.696125	6.02772	2.17045	5.79332
3	0.7500	12.52968	8.68495	4.76306	6.72915
4	1.0000	16.70624	11.57993	7.81287	7.81287
Test Information (Score Scale)					
Null Reference = 0					
Stage	-----Test-----		-----TrtGp-----		
	Estimate	Action			
1	3.20040	Continue			
2	7.31365	Reject Null			
3	.				
4	.				

With ODS Graphics enabled, the “Test Plot” displays boundary values of the design and the test statistic at the first two stages, as shown in [Output 84.6.16](#). It also shows that the test statistic is in the “Rejection Region” above the upper α boundary value at stage 2.

Output 84.6.16 Sequential Test Plot

After the stopping of a trial, the “Parameter Estimates” table in [Output 84.6.17](#) displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and p -value under the null hypothesis $H_0 : \theta = 0$.

Output 84.6.17 Parameter Estimates

Parameter Estimates Stagewise Ordering					
Parameter	Stopping Stage	MLE	p-Value for $H_0: \text{Parm}=0$	Median Estimate	Lower 95% CL
TrtGp	2	0.841024	0.0139	0.810329	0.21615

As expected, the p -value 0.0139 is significant at the $\alpha = 0.05$ level and the lower 95% confidence limit is larger than $\theta_0 = 0$. The p -value, unbiased median estimate, and lower confidence limit depend on the ordering of the sample space (k, z) , where k is the stage number and z is the standardized Z statistic. With

the specified stagewise ordering, the p -value is $p_1 + p_2$, where p_1 is the α spending at stage 1,

$$p_1 = P_{\theta=0}(Z_1 \sqrt{I_1} \geq 4.71422) = 0.00915$$

$$p_2 = P_{\theta=0}(Z_2 \sqrt{I_2} \geq 7.31365 \mid -1.04069 < Z_1 \sqrt{I_1} < 4.71422)$$

where Z_k is a standardized normal variate and I_k is the information level at stage k for $k = 1, 2$.

Example 84.7: Testing an Effect in a Proportional Hazards Regression Model

This example compares two survival distributions for the treatment effect. The example uses a power family method to generate two-sided asymmetric boundaries and then uses a proportional hazards regression model to test the hypothesis with a covariate.

A clinic is conducting a clinical study for the effect of a new cancer treatment. The study consists of mice exposed to a carcinogen and randomized to either the control group or the treatment group. The event of interest is the death from cancer induced by the carcinogen, and the response is the time from randomization to death.

Consider the proportional hazards regression model

$$h(t; \text{TrtGp}, \text{Wgt}) = h_0(t) \exp(\beta_g \text{TrtGp} + \beta_w \text{Wgt})$$

where $h_0(t)$ is an arbitrary and unspecified baseline hazard function, TrtGp is the grouping variable for the two groups, Wgt is the initial weight of the mice, and β_g and β_w are the regression parameters associated with the variables TrtGp and Wgt , respectively. The grouping variable has the value 0 for each mouse in the control group and the value 1 for each mouse in the treatment group.

The hypothesis $H_0 : \beta_g = 0$ with an alternative hypothesis $H_1 : \beta_g \neq 0$ is used for the study.

Suppose that from past experience, the median survival time for the control group is $t_0 = 20$ weeks. The study would like to detect a $t_1 = 40$ weeks median survival time with a 80% power in the trial. Assuming exponential survival functions for the two groups, the hazard rates can be computed from

$$S_j(t_j) = e^{-h_j t_j} = \frac{1}{2}$$

where $j = 0, 1$.

Thus, with the hazard rates $h_0 = 0.03466$ and $h_1 = 0.01733$, the hazard ratio $\exp(\beta_g) = h_1/h_0 = 1/2$ and the alternative hypothesis

$$\beta_{g1} = \log\left(\frac{1}{2}\right) = -0.69315$$

Following the derivations in the section “Test for a Parameter in the Proportional Hazards Regression Model” in the chapter “The SEQDESIGN Procedure,” the required number of events for testing a parameter in β is given by

$$D_X = I_X \frac{1}{(1 - r_x^2) \sigma_x^2}$$

where σ_x^2 is the variance of TrtGp and r_x^2 is the proportion of variance of TrtGp explained by the variable Wgt.

If the two groups have the same number of mice in the study, then the MLE of the variance is $\hat{\sigma}_x^2 = 0.25$. Further, if $r_x^2 = 0.10$, then you can specify the MODEL=PHREG(XVARIANCE=0.25 XRSQUARE=0.10) option in the SAMPLESIZE statement in the SEQDESIGN procedure to compute the required number of events and the individual number of events at each stage.

The following statements invoke the SEQDESIGN procedure and request a four-stage group sequential design for normally distributed data. The design uses a two-sided alternative hypothesis with early stopping to reject the null hypothesis H_0 . A power family method is used to derive the boundaries.

```
ods graphics on;
proc seqdesign altref=0.69315;
    TwoSidedPowerFamily: design method=pow
                           nstages=4
                           alpha=0.075 (lower=0.025)
                           beta=0.20;
    samplesize model=phreg( xvariance=0.25 xrsquare=0.10
                           hazard=0.02451 accrate=10);
run;
ods graphics off;
```

The ALPHA=0.075(LOWER=0.025) option specifies a lower α level 0.025 for the lower rejection boundary and an upper α level $0.05 = 0.075 - 0.025$ for the upper rejection boundary. The geometric average hazard $\sqrt{h_0 \times h_1} = \sqrt{0.03466 \times 0.01733} = 0.02451$ is used in the HAZARD= option in the SAMPLESIZE statement to compute the required sample size. The specified ACCRATE=10 option indicates that 10 mice will be accrued each week and the resulting minimum and maximum accrual times will be displayed.

The “Design Information” table in [Output 84.7.1](#) displays the design specifications and the derived statistics.

Output 84.7.1 Design Information

The SEQDESIGN Procedure	
Design: TwoSidedPowerFamily	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Two-Sided
Early Stop	Reject Null
Method	Power Family
Boundary Key	Both

Max Information	17.39288
Null Ref ASN (Percent of Fixed Sample)	104.3691
Lower Alt Ref ASN (Number of Events)	58.04014
Upper Alt Ref ASN (Number of Events)	52.05395

The “Boundary Information” table in [Output 84.7.2](#) displays the information level, alternative reference, and boundary values at each stage. By default (or equivalently if you specify `BOUNDARYSCALE=STDZ`), the procedure displays the output boundaries with the standardized Z statistic.

Output 84.7.2 Boundary Information

Boundary Information (Standardized Z Scale)					
Null Reference = 0					
Stage	-----Information Level-----			-----Alternative-----	
	Proportion	Actual	Events	-----Reference-----	
				Lower	Upper
1	0.2500	4.348221	19.32543	-1.44538	1.44538
2	0.5000	8.696441	38.65085	-2.04408	2.04408
3	0.7500	13.04466	57.97628	-2.50348	2.50348
4	1.0000	17.39288	77.3017	-2.89077	2.89077

Boundary Information (Standardized Z Scale)			
Null Reference = 0			
Stage	-----Boundary Values-----		
	---Lower---		---Upper---
	Alpha		Alpha
1	-2.98871		2.59149
2	-2.51320		2.17917
3	-2.27093		1.96910
4	-2.11334		1.83246

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 84.7.3](#).

Output 84.7.3 Boundary Plot

With the MODEL=PHREG option in the SAMPLESIZE statement, the “Sample Size Summary” table in [Output 84.7.4](#) displays the parameters used in the sample size computation for the proportional hazards regression model.

Output 84.7.4 Required Sample Size Summary

Sample Size Summary	
Test	PH Reg Parameter
Parameter	0.69315
X Variance	0.25
R Square (X)	0.1
Hazard Rate	0.02451
Accrual	Uniform
Accrual Rate	10
Min Accrual Time	7.73017
Min Sample Size	77.3017
Max Accrual Time	27.97872
Max Sample Size	279.7872
Max Number of Events	77.3017

With a minimum accrual time of 7.73 weeks and maximum accrual time of 27.98 weeks, an accrual time of 20 weeks is used in the study. The “Numbers of Events” table in [Output 84.7.5](#) displays the required numbers of events for the group sequential clinical trial.

Output 84.7.5 Required Sample Sizes

Numbers of Events (D)		
Z Test for PH Regression Parameter		
Stage	D	Information
1	19.33	4.3482
2	38.65	8.6964
3	57.98	13.0447
4	77.30	17.3929

The following statements invoke the SEQDESIGN procedure and provide more detailed sample size information with a 20-week accrual time:

```
proc seqdesign altref=0.69315;
  TwoSidedPowerFamily: design method=pow
                        nstages=4
                        alpha=0.075(lower=0.025)
                        beta=0.20;
  samplesize model=phreg( xvariance=0.25 xrsquare=0.10
                        hazard=0.02451
                        accrate=10 acctime=20);
  ods output Boundary=Bnd_Time;
run;
```

The ODS OUTPUT statement with the BOUNDARY=BND_TIME option creates an output data set named BND_TIME which contains the resulting boundary information for the subsequent sequential tests.

With an accrual time of 20 weeks, the “Sample Size Summary” table in [Output 84.7.6](#) displays the follow-up time for the trial.

Output 84.7.6 Sample Size Summary

The SEQDESIGN Procedure	
Design: TwoSidedPowerFamily	
Sample Size Summary	
Test	PH Reg Parameter
Parameter	0.69315
X Variance	0.25
R Square (X)	0.1
Hazard Rate	0.02451
Accrual	Uniform
Accrual Rate	10
Accrual Time	20
Follow-up Time	10.34195
Total Time	30.34195
Max Number of Events	77.3017
Max Sample Size	200
Expected Sample Size (Null Ref)	199.4282
Expected Sample Size (Alt Ref)	188.6561

The “Numbers of Events and Sample Sizes” table in [Output 84.7.7](#) displays the required sample sizes for the group sequential clinical trial.

Output 84.7.7 Numbers of Events and Sample Sizes

Numbers of Events (D) and Sample Sizes (N)

Numbers of Events (D) and Sample Sizes (N)				
Z Test for PH Regression Parameter				
-----Ceiling Time-----				
Stage	D	Time	N	Information
1	21.49	14	140.00	4.8359
2	41.90	20	200.00	9.4281
3	60.14	25	200.00	13.5309
4	79.26	31	200.00	17.8346

Thus, the study will perform three interim analyses after 14, 20, and 25 weeks and a final analysis after 31 weeks if the study does not stop at any of the interim analyses.

Suppose 140 mice are available for the first interim analysis after week 14. [Output 84.7.8](#) lists the first 10 observations in the data set `weeks_1`.

Output 84.7.8 Clinical Trial Data

First 10 Obs in the Trial Data					
Obs	Trt Gp	Event	Wgt	Weeks	
1	0	0	22.1659	12	
2	1	0	28.4458	12	
3	0	0	26.2857	12	
4	1	0	25.0283	12	
5	0	0	21.5114	12	
6	1	0	23.2240	12	
7	0	1	22.6845	6	
8	1	0	27.9292	12	
9	0	0	22.5514	12	
10	1	1	27.3793	11	

The `TrtGp` variable is a grouping variable with the value 0 for a mouse in the placebo control group and the value 1 for a mouse in the treatment group.

The `Weeks` variable is the survival time variable measured in weeks and the `Event` variable is the censoring variable with the value 0 indicating censoring. That is, the values of `Weeks` are considered censored if the corresponding values of `Event` are 0; otherwise, they are considered as event times.

The following statements use the PHREG procedure to estimate the treatment effect after adjusting for the `Wgt` variable at stage 1:

```
proc phreg data=Time_1;
  model Weeks*Event(0)= TrtGp Wgt;
  ods output parameterestimates=Parms_Time1;
run;
```

The following statements create and display (in [Output 84.7.9](#)) the data set for the treatment effect MLE statistic and its associated standard error. Note that for a MLE statistic, the inverse of the variance of the statistic is the information.

```
data Parms_Time1;
  set Parms_Time1;
  if Parameter='TrtGp';
  _Scale_='MLE';
  _Stage_= 1;
  keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;

proc print data=Parms_Time1;
  title 'Statistics Computed at Stage 1';
run;
```

Output 84.7.9 Statistics Computed at Stage 1

Statistics Computed at Stage 1					
Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	TrtGp	0.00836	0.46588	MLE	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Time
              Parms(Testvar=TrtGp)=Parms_Time1
              infoadj=prop
              order=lr
              ;
  ods output Test=Test_Time1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_TIME1 option specifies the input data set PARMS_TIME1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRTGP option identifies the test variable TRTGP in the data set.

If the computed information level for stage 1 is not the same as the value provided in the BOUNDARY= data set, the INFOADJ=PROP option (which is the default) proportionally adjusts the information levels at future interim stages from the levels provided in the BOUNDARY= data set. The ORDER=LR option uses the LR ordering to derive the p -value, the unbiased median estimate, and the confidence limits for the regression slope estimate.

The ODS OUTPUT statement with the TEST=TEST_TIME1 option creates an output data set named TEST_TIME1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Design Information” table in [Output 84.7.10](#) displays design specifications. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the boundary values are modified for the new information levels to maintain the Type I α level. The maximum information and the power have been modified for the new information levels.

Output 84.7.10 Design Information

The SEQTEST Procedure

4	.	

With the INFOADJ=PROP option (which is the default), the information levels at interim stages 2 and 3 are derived proportionally from the information levels in the BOUNDARY= data set. At stage 1, the standardized Z statistic 0.01795 is between the lower and upper α boundary values of -2.92457 and 2.54086 , so the trial continues to the next stage.

Note that the observed information level 4.6073 corresponds to a proportion of 0.2649 in the information level. If the observed information level is much larger than the target proportion of 0.25, then you can decrease the accrual rate, accrual time, or follow-up time to achieve target information levels for subsequent stages. These modifications should be specified in the study plan before the study begins.

With ODS Graphics enabled, a boundary plot with test statistics is displayed, as shown in [Output 84.7.12](#). As expected, the test statistic is in the continuation region between the lower and upper α boundary values.

Output 84.7.12 Sequential Test Plot

The following statements use the PHREG procedure to compute the MLE statistic and its associated standard error at stage 2:

```
proc phreg data=Time_2;
  model Weeks*Event(0) = TrtGp Wgt;
  ods output parameterestimates = ParmTime2;
run;
```

The following statements create the data set for the MLE statistic and its associated standard error at stage 2:

```
data Parms_Time2;
  set Parms_Time2;
  if Parameter='TrtGp';
  _Scale_='MLE';
  _Stage_= 2;
  keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;
```

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
proc seqtest Boundary=Test_Time1
  Parms(Testvar=TrtGp)=Parms_Time2
  infoadj=prop
  order=lr
  ;
  ods output Test=Test_Time2;
run;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_TIME2 option creates an output data set named TEST_TIME2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Test Information” table in [Output 84.7.13](#) displays the boundary values for the test statistic with the MLE statistic scale. At stage 2, the standardized Z statistic -0.43552 is between the lower α and upper boundary values, -2.47689 and 2.14819 , respectively, so the trial continues to the next stage.

Output 84.7.13 Sequential Tests

The SEQTEST Procedure						
Test Information (Standardized Z Scale)						
Null Reference = 0

4	.					

Since the data set PARMS_Time2 contains the test information only at stage 2, the information level at stage 1 in the TEST_Time1 data set is used to generate boundary values for the test.

Similarly, the test statistic at stage 3 is also between its corresponding lower and upper α boundary values. The trial continues to the next stage.

The following statements use the PHREG procedure to compute the MLE statistic and its associated standard error at the final stage:

```
proc phreg data=Time_4;
  model Weeks*Event(0)= TrtGp Wgt;
  ods output parameterestimates= Parms_Time4;
run;
```

The following statements create and display (in Output 84.7.14) the data set for the MLE statistic and its associated standard error at each stage of the study:

```
data Parms_Time4;
  set Parms_Time4;
  if Parameter='TrtGp';
  _Scale_='MLE';
  _Stage_= 4;
  keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;

proc print data=Parms_Time4;
  title 'Statistics Computed at Stage 4';
run;
```

Output 84.7.14 Statistics Computed at Stage 4

Statistics Computed at Stage 4					
Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	TrtGp	-0.04451	0.23971	MLE	4

The following statements invoke the SEQTEST procedure to test the hypothesis at stage 4:

```
ods graphics on;
proc seqtest Boundary=Test_Time3
              Parms (Testvar=TrtGp)=Parms_Time4
              order=lr
              ;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 4, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 4, and the TESTVAR= option identifies the test variable in the data set.

The “Test Information” table in [Output 84.7.15](#) displays the boundary values for the test statistic. The standardized test statistic -0.1857 is between the lower and upper α boundary values of -2.10447 and 1.82112 , respectively, so the study stops and accepts the null hypothesis. That is, there is no evidence of reduction in hazard rate for the new treatment.

Output 84.7.15 Sequential Tests

The SEQTEST Procedure						
Test Information (Standardized Z Scale)						
Null Reference = 0						
Stage	--Information Level--		-----Alternative-----		----Boundary Values----	
	Proportion	Actual	-----Reference-----		---Lower--	---Upper--
			Lower	Upper	Alpha	Alpha

4	-0.18570	Accept Null				

The “Test Plot” displays boundary values of the design and the test statistic at the first two stages, as shown in [Output 84.7.16](#). It also shows that the test statistic is in the “Acceptance Region” between the lower and upper α boundary values at stage 4.

Output 84.7.16 Sequential Test Plot

After the stopping of a trial, the “Parameter Estimates” table in [Output 84.7.17](#) displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and p -value under the null hypothesis $H_0 : \theta = 0$.

Output 84.7.17 Parameter Estimates

Parameter Estimates LR Ordering				
Parameter	Stopping Stage	MLE	p-Value for $H_0: \text{Parm}=0$	Median Estimate
TrtGp	4	-0.044514	0.8525	-0.044577
Parameter Estimates LR Ordering				
Parameter	95% Confidence Limits			
TrtGp	-0.51461	0.42538		

As expected, the two-sided p -value 0.8525 is not significant at the lower $\alpha = 0.025$ level and the upper $\alpha = 0.05$ level, and the two-sided 95% confidence interval contains the null value zero. The p -value, unbiased median estimate, and lower confidence limit depend on the ordering of the sample space (k, z) , where k is the stage number and z is the standardized Z statistic. With the specified LR ordering, the two-sided p -value is derived from the one-sided p -value

$$p_u = \sum_{k=1}^4 P_{\theta=0} (Z_k \geq z_4 \mid _a_{k'} < Z_{k'} < a_{k'}, k' < k)$$

where $z_4 = -0.1857$ is the observed test statistic at stage 4, Z_k is a standardized normal variate at stage k , and $_a_{k'}$ and $a_{k'}$ are the stage k lower and upper rejection boundary values, respectively.

Thus,

$$p_u = \alpha_u + P_{\theta=0} (z_4 \leq Z_4 < a_4 \mid _a_{k'} < Z_{k'} < a_{k'}, k' < 4)$$

where $\alpha_u = 0.05$ is the upper α level and $a_4 = 1.82112$.

Since $P_{\theta=0} (z_4 \leq Z_4 \leq a_4 \mid _a_{k'} < Z_{k'} < a_{k'}, k' < 4) = 0.52374$, $p_u = 0.05 + 0.52374 = 0.57374$, which is greater than 0.50. Thus, the two-sided p -value is given by $2 \times (1.0 - p_u) = 0.8525$.

Example 84.8: Testing an Effect in a Logistic Regression Model

This example requests a two-sided test for the dose effect in a dose-response model (Whitehead 1997, pp. 262–263). Consider the logistic regression model

$$\text{logit}(p) = \log\left(\frac{p}{1-p}\right) = \beta_0 + \beta_1 \text{LDose}$$

where $p = \text{Prob}(\text{Resp} = 1 \mid \text{LDose})$ is the response probability to be modeled for the binary response Resp and $\text{LDose} = \log(\text{Dose} + 1)$ is the covariate. The dose levels are 0 for the control group, and they are 1, 3, and 6 for the three treatment groups.

Following the derivations in the section “Test for a Parameter in the Logistic Regression Model” in the chapter “The SEQDESIGN Procedure,” the required sample size can be derived from

$$N = I_X \frac{\sigma_y^2}{(1 - r_x^2) \sigma_x^2}$$

where σ_y^2 is the variance of the response variable in the logistic regression model, r_x^2 is the proportion of variance of LDose explained by other covariates, and σ_x^2 is the variance of LDose .

Since LDose is the only covariate in the model, $r_x^2 = 0$. For a logistic model, the variance σ^2 can be estimated by

$$\sigma_y^2 = \frac{1}{\hat{p}(1 - \hat{p})}$$

where \hat{p} is the estimated probability of the response variable Resp . Thus, the sample size can be computed as

$$N = I_X \frac{1}{p(1 - p)} \frac{1}{\sigma_x^2}$$

The null hypothesis $H_0 : \beta_1 = 0$ corresponds to no treatment effect. Suppose that the alternative hypothesis $H_1 : \beta_1 = 0.5$ is the reference improvement that should be detected at a 0.90 level.

Note that $\beta_1 = 0.5$ corresponds to an odds ratio of 2 between the treatment group with dose level 3 and the control group. The log odds ratio between the two groups is

$$\log \left(\frac{p_t(1-p_c)}{(1-p_t)p_0} \right) = \log \left(\frac{p_t}{1-p_t} \right) - \log \left(\frac{p_c}{1-p_c} \right)$$

which corresponds to

$$(\beta_0 + \beta_1 \log(3+1)) - (\beta_0 + \beta_1 \log(1)) = \beta_1 \log(4) = \log(2)$$

If the same number of patients are assigned in each of the four groups, then the MLE of the variance of LDose is $\hat{\sigma}_x^2 = 0.5345$. Further, if the response rate is 0.40, then the required sample size can be derived using the SAMPLESIZE statement in the SEQDESIGN procedure.

The following statements invoke the SEQDESIGN procedure and request a three-stage group sequential design for normally distributed data. The design has a null hypothesis of no treatment effect $H_0 : \beta_1 = 0$ with early stopping to reject the null hypothesis with a two-sided alternative hypothesis $H_1 : \beta_1 = \pm 0.5$.

```
ods graphics on;
proc seqdesign altref=0.5;
    TwoSidedErrorSpending: design method=errfuncpow
                                method(loweralpha)=errfuncpow(rho=1)
                                method(upperalpha)=errfuncpow(rho=3)
                                nstages=3
                                stop=both;
    samplesize model=logistic( prop=0.4 xvariance=0.5345);
    ods output Boundary=Bnd_Dose;
run;
ods graphics off;
```

The ODS OUTPUT statement with the BOUNDARY=BND_DOSE option creates an output data set named BND_DOSE which contains the resulting boundary information for the subsequent sequential tests.

The “Design Information” table in [Output 84.8.1](#) displays design specifications and derived statistics. Since the alternative reference is specified, the maximum information 47.22445 is derived.

Output 84.8.1 Error Spending Design Information

The SEQDESIGN Procedure	
Design: TwoSidedErrorSpending

9	0	0	0.00000	
10	0	1	0.69315	

The following statements use the LOGISTIC procedure to estimate the slope β_1 and its associated standard error at stage 1:

```
proc logistic data=Dose_1;
  model Resp(event='1')= LDose;
  ods output ParameterEstimates=Parms_Dose1;
run;
```

The following statements create and display (in [Output 84.8.7](#)) the input data set that contains slope β_1 and its associated standard error for the SEQTEST procedure:

```
data Parms_Dose1;
  set Parms_Dose1;
  if Variable='LDose';
  _Scale_='MLE';
  _Stage_= 1;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_Dose1;
  title 'Statistics Computed at Stage 1';
run;
```

Output 84.8.7 Statistics Computed at Stage 1

Statistics Computed at Stage 1					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	LDose	0.5741	0.2544	MLE	1

The following statements invoke the SEQTEST procedure to test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Dose
  Parms(testvar=LDose)=Parms_Dose1
  infoadj=prop
  order=mle
  boundaryscale=mle
  ;
  ods output Test=Test_Dose1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_DOSE1 option specifies the input data set PARMS_DOSE1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=LDLOSE option identifies the test variable LDLOSE in the data set.

If the computed information level for stage 1 is not the same as the value provided in the BOUNDARY= data set, the INFOADJ=PROP option (which is the default) proportionally adjusts the information levels at future interim stages from the levels provided in the BOUNDARY= data set. The ORDER=MLE option uses the MLE ordering to derive the p -value, the unbiased median estimate, and the confidence limits for the regression slope estimate.

The ODS OUTPUT statement with the TEST=TEST_DOSE1 option creates an output data set named TEST_DOSE1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Design Information” table in [Output 84.8.8](#) displays design specifications. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the boundary values are modified for the new information

levels to maintain the Type I α level. The maximum information remains the same as the design stored in the BOUNDARY= data set, but the derived Type II error probability β and power $1 - \beta$ are different because of the new information levels.

Output 84.8.8 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.BND_DOSE
Data Set	WORK.PARMS_DOSE1
Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Two-Sided
Early Stop	Accept/Reject Null

	Alpha	Beta	Beta	Alpha	Estimate	Action
1	-0.61078	.	.	0.79337	0.57409	Continue
2	-0.40974	-0.18169	0.16222	0.44033	.	
3	-0.31633	-0.31633	0.28860	0.28860	.	

The information level at stage 1 is derived from the standard error s_1 in the PARMS= data set,

$$I_1 = \frac{1}{s_1^2} = \frac{1}{0.2544^2} = 15.45$$

With the INFOADJ=PROP option (which is the default), the information level at stage 2 is derived proportionally from the observed information at stage 1 and the information levels in the BOUNDARY= data set. At stage 1, the β boundary values are missing and there is no early stopping to accept H_0 . The MLE statistic 0.57409 is between the lower and upper α boundaries, so the trial continues to the next stage.

With ODS Graphics enabled, a boundary plot with the boundary values and test statistics is displayed, as shown in [Output 84.8.10](#). As expected, the test statistic is in the continuation region below the upper alpha boundary.

Output 84.8.10 Sequential Test Plot

The following statements use the LOGISTIC procedure to estimate the slope β_1 and its associated standard error at stage 2:

```
proc logistic data=dose_2;
  model Resp(event='1')=LDose;
  ods output ParameterEstimates=Parms_Dose2;
run;
```

The following statements create and display (in [Output 84.8.11](#)) the input data set that contains slope β_1 and its associated standard error at stage 2 for the SEQTEST procedure:

```
data Parms_Dose2;
  set Parms_Dose2;
  if Variable='LDose';
  _Scale_='MLE';
  _Stage_= 2;
  keep _Scale_ _Stage_ Variable Estimate StdErr;
run;

proc print data=Parms_Dose2;
  title 'Statistics Computed at Stage 2';
run;
```

Output 84.8.11 Statistics Computed at Stage 2

Statistics Computed at Stage 2					
Obs	Variable	Estimate	StdErr	_Scale_	_Stage_
1	LDose	0.5213	0.1788	MLE	2

The following statements invoke the SEQTEST procedure to test for early stopping at stage 2:

```
ods graphics on;
proc seqtest Boundary=Test_Dose1
  Parms (Testvar=LDose)=Parms_Dose2
  infoadj=prop
  order=mle
  boundaryscale=mle
  rci
  plots=rci
  ;
  ods output Test=Test_Dose2;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ORDER=MLE option uses the MLE ordering to derive the p -value, unbiased median estimate, and confidence limits for the regression slope estimate.

The ODS OUTPUT statement with the TEST=TEST_DOSE2 option creates an output data set named TEST_DOSE2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Design Information” table in [Output 84.8.12](#) displays design specifications. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the boundary values are modified for the new information levels to maintain the Type I α level.

Output 84.8.12 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.TEST_DOSE1
Data Set	WORK.PARMS_DOSE2
Statistic Distribution	Normal
Boundary Scale	MLE
Alternative Hypothesis	Two-Sided
Early Stop	Accept/Reject Null
Number of Stages	3
Alpha	0.05
Beta (Lower)	0.0999
Beta (Upper)	0.07871
Power (Lower)	0.9001
Power (Upper)	0.92129
Max Information (Percent of Fixed Sample)	103.7227
Max Information	47.2244524
Null Ref ASN (Percent of Fixed Sample)	79.44086
Lower Alt Ref ASN (Percent of Fixed Sample)	66.04641
Upper Alt Ref ASN (Percent of Fixed Sample)	76.22739

The information is derived from the standard error associated with the slope estimate at the final stage and is larger than the target level. The derived Type II error probability β and power $1 - \beta$ are different because of the new information levels.

The “Test Information” table in [Output 84.8.13](#) displays the boundary values for the test statistic with the specified MLE scale. The information levels are derived from the standard errors in the PARMS= data set. At stage 2, the slope estimate 0.52128 is larger than 0.44091, the upper α boundary value, the trial stops to reject the null hypothesis of no treatment effect.

Output 84.8.13 Sequential Tests

Test Information (MLE Scale)						
Null Reference = 0						
Stage	---Information Level---		-----Alternative-----			
	Proportion	Actual	-----Reference-----			
			Lower		Upper	
1	0.3272	15.45062	-0.50000		0.50000	
2	0.6624	31.28346	-0.50000		0.50000	
3	1.0000	47.22445	-0.50000		0.50000	
Test Information (MLE Scale)						
Null Reference = 0						
Stage	-----Boundary Values-----				-----Test-----	
	-----Lower-----		-----Upper-----		-----LDose-----	
	Alpha	Beta	Beta	Alpha	Estimate	Action
1	-0.61078	.	.	0.79337	0.57409	Continue
2	-0.41028	-0.18112	0.16166	0.44091	0.52128	Reject Null
3	-0.31628	-0.31628	0.28861	0.28861	.	

With ODS Graphics enabled, a boundary plot with the boundary values and test statistics is displayed, as shown in [Output 84.8.14](#). As expected, the test statistic is above the upper α boundary in the upper rejection region at stage 2.

Output 84.8.14 Sequential Test Plot

After a trial is stopped, the “Parameter Estimates” table in [Output 84.8.15](#) displays the stopping stage, parameter estimate, unbiased median estimate, confidence limits, and the p -value under the null hypothesis $H_0 : \beta_1 = 0$.

Output 84.8.15 Parameter Estimates

Parameter Estimates MLE Ordering				
Parameter	Stopping Stage	MLE	p-Value for $H_0 : \text{Parm}=0$	Median Estimate
LDose	2	0.521275	0.0050	0.502647
Parameter Estimates MLE Ordering				
Parameter	95% Confidence Limits			
LDose	0.15745	0.85154		

With the ORDER=MLE option, the MLE ordering is used to compute the p -value, unbiased median estimate, and confidence limits. As expected, the p -value 0.005 is significant at the $\alpha = 0.05$ level and the confidence interval does not contain the null reference zero.

With the RCI option, the “Repeated Confidence Intervals” table in [Output 84.8.16](#) displays repeated confidence intervals for the parameter. For a two-sided test, since the rejection lower repeated confidence limit 0.0804 is greater than the null reference zero, the trial is stopped to reject the hypothesis.

Output 84.8.16 Repeated Confidence Intervals

Repeated Confidence Intervals						
Stage	Information Level	Parameter Estimate	-Rejection Boundary- Lower 97.5% Repeated CL	Boundary- Upper 97.5% Repeated CL	-Acceptance Boundary- Lower 90.01% Repeated CL	Boundary- Upper 92.13% Repeated CL
1	15.4506	0.57409	-0.2193	1.1849	.	.
2	31.2835	0.52128	0.0804	0.9316	0.2024	0.8596

With the PLOTS=RCI option, the “Repeated Confidence Intervals Plot” displays repeated confidence intervals for the parameter, as shown in [Output 84.8.17](#). It shows that the null reference zero is inside the rejection repeated confidence interval at stage 1 but outside the rejection repeated confidence interval at stage 2. This implies that the study stops at stage 2 to reject the hypothesis.

Output 84.8.17 Repeated Confidence Intervals Plot

Note that the hypothesis is accepted if at any stage, the acceptance repeated confidence interval falls within the interval $(-0.5, 0.5)$ of the alternative references.

Example 84.9: Conducting a Trial with a Nonbinding Acceptance Boundary

This example demonstrates a trial with a nonbinding acceptance boundary. The design is similar to the design in [Example 84.1](#), but has a nonbinding beta boundary.

A clinic is studying the effect of vitamin C supplements in treating flu symptoms. The study consists of patients in the clinic who have exhibited the first sign of flu symptoms within the last 24 hours. These patients are randomly assigned to either the control group (which receives placebo pills) or the treatment group (which receives large doses of vitamin C supplements). At the end of a five-day period, the flu symptoms of each patient are recorded.

Suppose that you know from past experience that flu symptoms disappear in five days for 60% of patients who experience flu symptoms. The clinic would like to detect a 75% symptom disappearance with a high probability. A test that compares the proportions directly specifies the null hypothesis $H_0 : \theta = p_t - p_c = 0$

with a one-sided alternative $H_1 : \theta > 0$ and a power of 0.90 at $H_1 : \theta = 0.15$, where p_t and p_c are the proportions of symptom disappearance in the treatment group and control group, respectively.

The following statements invoke the SEQDESIGN procedure and request a four-stage group sequential design by using an O'Brien-Fleming method for normally distributed data.

```
ods graphics on;
proc seqdesign altref=0.15 errspend
    ;
    NonbindingDesign: design nstages=4
                        method=obf
                        alt=upper
                        stop=both(betaboundary=nonbinding)
                        alpha=0.025
    ;
    samplesize model=twosamplefreq(nullprop=0.6 test=prop);
ods output Boundary=Bnd_Count;
run;
ods graphics off;
```

The ALT=UPPER option specifies a one-sided alternative hypothesis, and the STOP=BOTH option specifies early stopping to reject or accept the null hypothesis H_0 . The BETABOUNDARY=NONBINDING suboption requests nonbinding beta boundary to have the flexibility to continue the trial when a test statistic falls in the acceptance region at interim stages (Zhu, Ni, and Yao 2011, pp. 132–133). The ODS OUTPUT statement with the BOUNDARY=BND_COUNT option creates an output data set named BND_COUNT which contains the resulting boundary information for the subsequent sequential tests.

The “Design Information” table in [Output 84.9.1](#) displays design specifications. With the specified alternative hypothesis $H_1 : \theta = 0.15$, the maximum information is derived to achieve a power of 0.90 at H_1 . The derived fixed-sample information ratio 1.107 is the maximum information needed for a group sequential design relative to its corresponding fixed-sample design. Compare to the default BETABOUNDARY=BINDING option, the BETABOUNDARY=NONBINDING option requires a larger sample size for the design.

Output 84.9.1 O'Brien-Fleming Design Information

The SEQDESIGN Procedure	
Design: NonbindingDesign	
Design Information	
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Accept (Nonbinding) / Reject Null
Method	O'Brien-Fleming
Boundary Key	Both
Alternative Reference	0.15
Number of Stages	4
Alpha (Binding Beta Boundary)	0.02228
Alpha (Nonbinding Beta Boundary)	0.025
Beta	0.1
Power	0.9
Max Information (Percent of Fixed Sample)	110.7138
Max Information	517.0296
Null Ref ASN (Percent of Fixed Sample)	62.29796
Alt Ref ASN (Percent of Fixed Sample)	78.5392

The “Boundary Information” table in [Output 84.9.2](#) displays the information level, alternative reference, and boundary values at each stage. With the default BOUNDARYSCALE=STDZ option, the SEQDESIGN procedure displays the output boundaries with the standardized normal Z scale.

Output 84.9.2 O'Brien-Fleming Boundary Information

Boundary Information (Standardized Z Scale)						
Nonbinding Beta Boundary, Null Reference = 0						
Stage	-----Information Level-----			-Alternative-	----Boundary Values----	
	Proportion	Actual	N	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2500	129.2574	110.5151	1.70537	-1.06752	4.04859
2	0.5000	258.5148	221.0302	2.41176	0.45103	2.86279
3	0.7500	387.7722	331.5452	2.95379	1.35286	2.33746
4	1.0000	517.0296	442.0603	3.41074	2.02430	2.02430

With ODS Graphics enabled, a detailed boundary plot with the rejection and acceptance regions is displayed, as shown in [Output 84.1.3](#). The horizontal axis indicates the information levels for the design. The stages are indicated by vertical lines with accompanying stage numbers. If the test statistic at a stage is in a rejection region, the trial stops and the hypothesis is rejected. If the test statistic is in an acceptance region, then the trial either stops to accept the hypothesis or continues to the next stage. If the statistic is not in a rejection or an acceptance region, the trial continues to the next stage.

Output 84.9.3 O'Brien-Fleming Boundary Plot

The boundary plot also displays the information level and critical value for the corresponding fixed-sample design. The solid and dashed lines at the fixed-sample information level correspond to the rejection and acceptance lines, respectively.

The “Error Spending Information (Nonbinding Beta Boundary)” in [Output 84.9.4](#) displays cumulative error spending at each stage for each boundary. With a nonbinding beta boundary, the α spending at each stage is computed by using the α boundary only.

Output 84.9.4 Error Spending Information

Error Spending Information (Nonbinding Beta Boundary)			
Stage	-Information Level- Proportion	-Cumulative Error Spending- -----Upper-----	
		Beta	Alpha
1	0.2500	0.00278	0.00003
2	0.5000	0.02603	0.00211
3	0.7500	0.06343	0.01046
4	1.0000	0.10000	0.02500

With the SAMPLESIZE statement, the maximum information is used to derive the required sample size for the study. The “Sample Size Summary” table in [Output 84.9.5](#) displays parameters for the sample size computation.

Output 84.9.5 Required Sample Size Summary

Sample Size Summary		
Test	Two-Sample Proportions	
Null Proportion		0.6
Proportion (Group A)		0.75
Test Statistic	Z for Proportion	
Reference Proportions	Alt	Ref
Max Sample Size		442.0603
Expected Sample Size (Null Ref)		248.7446
Expected Sample Size (Alt Ref)		313.5929

With the derived maximum information and the specified MODEL= option in the SAMPLESIZE statement, the total sample size in each group for testing the difference between two proportions under the alternative hypothesis is

$$N_1 = N_2 = (p_{1c}(1 - p_{1c}) + p_{1t}(1 - p_{1t})) I_X$$

where $p_{1c} = 0.6$ and $p_{1t} = p_{1c} + \theta_1 = 0.75$. By default (or equivalently if you specify REF=PROP in the MODEL=TWOSAMPLEFREQ option), the required sample sizes are computed under the alternative hypothesis. See the section “Test for the Difference between Two Binomial Proportions” in the chapter “The SEQDESIGN Procedure” for a description of these parameters.

The “Sample Sizes (N)” table in [Output 84.9.6](#) displays the required sample sizes at each stage, in both fractional and integer numbers. The derived sample sizes under the heading Fractional N which correspond to the design are not integers. These sample sizes are rounded up to integers under the heading Ceiling N. In practice, integer sample sizes are used, and the information levels increase slightly. Thus, 56, 111, 166, and 222 patients are needed in each group for the four stages, respectively.

Output 84.9.6 Required Sample Sizes

Sample Sizes (N) Two-Sample Z Test for Proportion Difference				
-----Fractional N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	110.52	55.26	55.26	129.3
2	221.03	110.52	110.52	258.5
3	331.55	165.77	165.77	387.8
4	442.06	221.03	221.03	517.0

Sample Sizes (N) Two-Sample Z Test for Proportion Difference				
-----Ceiling N-----				
Stage	N	N(Grp 1)	N(Grp 2)	Information
1	112	56	56	131.0
2	222	111	111	259.6
3	332	166	166	388.3
4	444	222	222	519.3

Suppose the trial follows the study plan, and 56 patients are available in each group at stage 1. The data set `count_1` contains these 108 patients. [Output 84.9.7](#) lists the first 10 observations of the data set.

Output 84.9.7 Clinical Trial Data

First 10 Obs in the Trial Data			
	Obs	Trt	Resp
	1	0	0
	2	1	1
	3	0	1
	4	1	1
	5	0	1
	6	1	0
	7	0	0
	8	1	1
	9	0	1
	10	1	0

The `Trt` variable is a grouping variable with value 0 for a patient in the placebo control group and value 1 for a patient in the treatment group who is given vitamin C supplements. The `Resp` variable is an indicator variable with value 1 for a patient without flu symptoms after five days and value 0 for a patient with flu symptoms after five days.

The following statements use the GENMOD procedure to estimate the treatment effect at stage 1:

```
proc genmod data=count_1;
  model Resp= Trt;
  ods output ParameterEstimates=Parms_Count1;
run;
```

Output 84.9.8 displays the treatment effect at stage 1.

Output 84.9.8 Stage 1 Treatment Difference

The GENMOD Procedure							
Analysis Of Maximum Likelihood Parameter Estimates							
Parameter	DF	Estimate	Standard Error	Wald 95% Confidence Limits	Wald Chi-Square	Pr >	ChiSq
Intercept	1	0.6786	0.0619	0.5572 0.7999	120.07		<.0001
Trt	1	0.0179	0.0876	-0.1538 0.1895	0.04		0.8384
Scale	1	0.4634	0.0310	0.4065 0.5283			
NOTE: The scale parameter was estimated by maximum likelihood.							

The test statistic is $\hat{\theta}_1 = \hat{p}_t - \hat{p}_c = 0.0179$, and its associated standard error is

$$\sqrt{\text{Var}(\hat{\theta}_1)} = \sqrt{\frac{\hat{p}_c(1 - \hat{p}_c)}{56} + \frac{\hat{p}_t(1 - \hat{p}_t)}{56}} = 0.0876$$

The following statements create and display (in [Output 84.9.9](#)) the data set that contains the parameter estimate at stage 1, $\hat{\theta}_1 = 0.0179$, and its associated standard error $\sqrt{\text{Var}(\hat{\theta}_1)} = 0.0876$ which are used in the SEQTEST procedure:

```
data Parms_Count1;
  set Parms_Count1;
  if Parameter='Trt';
  _Scale_='MLE';
  _Stage_= 1;
  keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;

proc print data=Parms_Count1;
  title 'Statistics Computed at Stage 1';
run;
```

Output 84.9.9 Statistics Computed at Stage 1

Statistics Computed at Stage 1					
Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	Trt	0.0179	0.0876	MLE	1

The initial required sample sizes are derived with the proportions $p_c = 0.6$ and $p_t = 0.75$. If the observed proportions are different from these assumed values, or if the number of available patients is different from the study plan in one of the stages, then the information level that corresponds to the test statistic is estimated from

$$I_k = \frac{1}{\text{Var}(\hat{\theta}_k)}$$

The following statements invoke the SEQTEST procedure and test for early stopping at stage 1:

```
ods graphics on;
proc seqtest Boundary=Bnd_Count
              Parms (Testvar=Trt)=Parms_Count1
              betaboundary=nonbinding
              infoadj=none
              errspendmin=0.001
              errspend
              ;
ods output Test=Test_Count1;
run;
ods graphics off;
```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 1, which was generated in the SEQDESIGN procedure. The PARMS=PARMS_COUNT1 option specifies the input data set PARMS_COUNT1 that contains the test statistic and its associated standard error at stage 1, and the TESTVAR=TRT option identifies the test variable TRT in the data set.

The BETABOUNDARY=NONBINDING option requests nonbinding beta boundary to have the flexibility to continue the trial when the test statistic falls in the acceptance region at stage 1. The INFOADJ=NONE option maintains the information levels at future interim stages (2 and 3) as provided in the BOUNDARY= data set. The default BOUNDARYSCALE=STDZ option displays the output boundaries in terms of the standardized normal Z scale.

The O'Brien-Fleming design is conservative in early stages and might not be desirable in a clinical trial. The ERRSPENDMIN=0.001 option specifies the minimum error spending at each stage to be 0.001, and it might increase the corresponding nominal p -value in early stages for the trial. The default BOUNDARYSCALE=STDZ option uses the standardized normal Z scale to display test statistics in the boundary table and boundary plots.

The ODS OUTPUT statement with the TEST=TEST_COUNT1 option creates an output data set named TEST_COUNT1 which contains the updated boundary information for the test at stage 1. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The "Design Information" table in [Output 84.9.10](#) displays design specifications. The derived statistics, such as the overall α and β levels, are derived from the specified maximum information and boundary values in the BOUNDARY= data set. Note that with a minor change in the information level at stage 1, the power also changes slightly from the design provided in the BOUNDARY= data set.

Output 84.9.10 Design Information

The SEQTEST Procedure	
Design Information	
BOUNDARY Data Set	WORK.BND_COUNT
Data Set	WORK.PARMS_COUNT1
Statistic Distribution	Normal
Boundary Scale	Standardized Z
Alternative Hypothesis	Upper
Early Stop	Accept (Nonbinding) /Reject Null
Number of Stages	4
Alpha (Binding Beta Boundary)	0.02237
Alpha (Nonbinding Beta Boundary)	0.025
Beta	0.10142
Power	0.89858
Max Information (Percent of Fixed Sample)	111.2654
Max Information	517.029617
Null Ref ASN (Percent of Fixed Sample)	62.27694
Alt Ref ASN (Percent of Fixed Sample)	76.31328

With the ERRSPEND option, the “Error Spending Information” table in [Output 84.9.11](#) displays cumulative error spending at each stage for each boundary. By default (or equivalently if you specify BOUNDARYKEY=ALPHA), the Type I error level with nonbinding beta boundary $\alpha = 0.025$ is maintained. Furthermore, with the ERRSPENDMIN=0.001 option, the α spending at each stage is greater than or equal to 0.001.

Output 84.9.11 Error Spending Information

Error Spending Information (Nonbinding Beta Boundary)				
Stage	---Information Level---		-Cumulative Error Spending-	
	Proportion	Actual	Beta	Alpha
1	0.2522	130.3756	0.00302	0.00100
2	0.5000	258.5148	0.02640	0.00299
3	0.7500	387.7722	0.06433	0.01101
4	1.0000	517.0296	0.10142	0.02500

The “Test Information” table in [Output 84.9.12](#) displays the boundary values for the design, test statistic, and resulting action at each stage. With the default BOUNDARYSCALE=STDZ option, the standardized normal Z scale is used for the test statistic and boundary values. The table shows that the test statistic 0.2039 is between the upper α and β boundaries, so the trial continues to the next stage.

Output 84.9.12 Sequential Test

Test Information (Standardized Z Scale)					
Nonbinding Beta Boundary, Null Reference = 0					
Stage	---Information Level---		-Alternative- --Reference-- Upper	-----Boundary Values-----	
	Proportion	Actual		-----Upper----- Beta	Alpha
1	0.2522	130.3756	1.71273	-1.03271	3.09023
2	0.5000	258.5148	2.41176	0.45564	2.84016
3	0.7500	387.7722	2.95379	1.36069	2.34211
4	1.0000	517.0296	3.41074	2.03599	2.03599

Test Information (Standardized Z Scale)			
Nonbinding Beta Boundary, Null Reference = 0			
Stage	-----Test-----		
	-----Trt-----		
	Estimate	Action	
1	0.20390	Continue	
2	.		
3	.		
4	.		

The information level at stage 1 is derived from the standard error,

$$I_1 = \frac{1}{\text{Var}(\hat{\theta}_1)} = \frac{1}{(\text{s.e.}(\hat{\theta}_1))^2} = 130.376$$

By default (or equivalently if you specify PLOTS=TEST), the “Test Plot” graph displays boundary values of the design and the test statistic at stage 1, as shown in [Output 84.9.13](#). It also shows that the observed statistic is in the continuation region.

Output 84.9.13 Sequential Test Plot

The observed information level at stage 1, $I_1 = 130.376$, is slightly larger than the target information level at the design. If an observed information level in the study is substantially different from its target level in the design, then the sample sizes should be adjusted in the subsequent stages to achieve the target information levels.

Suppose the trial continues to the next stage, and 111 patients are available in each group at stage 2. The data set COUNT_2 contains these 222 patients.

The following statements use the GENMOD procedure to estimate the treatment effect at stage 2:

```
proc genmod data=Count_2;
  model Resp= Trt;
  ods output ParameterEstimates=Parms_Count2;
run;
```

The following statements create the parameter estimate at stage 2, $\hat{\theta}_2 = \hat{p}_2 - \hat{p}_1 = 0.027$, and its associated standard error $\sqrt{\text{Var}(\hat{\theta}_2)} = 0.0621$ into a test data set:

```

data Parms_Count2;
  set Parms_Count2;
  if Parameter='Trt';
  _Scale_='MLE';
  _Stage_= 2;
  keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;

proc print data=Parms_Count2;
  title 'Statistics Computed at Stage 2';
run;

```

Output 84.9.14 displays the test statistics at stage 2.

Output 84.9.14 Statistics Computed at Stage 2

Statistics Computed at Stage 2					
Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	Trt	0.0270	0.0621	MLE	2

The following statements invoke the SEQTEST procedure and test for early stopping at stage 2:

```

ods graphics on;
proc seqtest Boundary=Test_Count1
  Parms(Testvar=Trt)=Parms_Count2
  betaboundary=nonbinding
  infoadj=none
  ;
ods output Test=Test_Count2;
run;
ods graphics off;

```

The BOUNDARY= option specifies the input data set that provides the boundary information for the trial at stage 2, which was generated by the SEQTEST procedure at the previous stage. The PARMS= option specifies the input data set that contains the test statistic and its associated standard error at stage 2, and the TESTVAR= option identifies the test variable in the data set.

The ODS OUTPUT statement with the TEST=TEST_COUNT2 option creates an output data set named TEST_COUNT2 which contains the updated boundary information for the test at stage 2. The data set also provides the boundary information that is needed for the group sequential test at the next stage.

The “Test Information” table in [Output 84.9.15](#) displays the boundary values, test statistic, and resulting action at each stage. The table shows that the test statistic 0.43522 is less than the corresponding upper beta boundary value, so the trial can be stopped to accept the hypothesis. With the BETABOUNDARY=NONBINDING option, The clinic has the option to continue the trial while still maintaining the Type I error level.

Output 84.9.15 Sequential Test

The SEQTEST Procedure					
Test Information (Standardized Z Scale)					
Nonbinding Beta Boundary, Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values----	
	Proportion	Actual	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2522	130.3756	1.71273	-1.03271	3.09023
2	0.5015	259.3157	2.41549	0.46349	2.83297
3	0.7500	387.7722	2.95379	1.36018	2.34294
4	1.0000	517.0296	3.41074	2.03610	2.03610
Test Information (Standardized Z Scale)					
Nonbinding Beta Boundary, Null Reference = 0					
Stage	-----Test-----		-----Trt-----		
	Estimate	Action			
1	0.20390	Continue			
2	0.43522	Accept Null (Nonbinding)			
3	.				
4	.				

With ODS Graphics enabled, the “Test Plot” is displayed, as shown in [Output 84.9.16](#). The plot displays boundary values of the design and the test statistics at the first two stages. As expected, the test statistic at stage 2 is in the “Upper Acceptance Region” below the upper beta boundary.

Output 84.9.16 Sequential Test Plot

Suppose the clinic decides to continue the trial, and at the next stage, 108 patients are available in each group at stage 3. The data set COUNT_3 contains these 332 patients.

The following statements use the GENMOD procedure to estimate the treatment effect at stage 3:

```
proc genmod data=Count_3;
  model Resp= Trt;
  ods output ParameterEstimates=Parms_Count3;
run;
```

The following statements create the parameter estimate at stage 2, $\hat{\theta}_2 = \hat{p}_2 - \hat{p}_1 = 0.1205$, and its associated standard error $\sqrt{\text{Var}(\hat{\theta}_2)} = 0.0507$ into a test data set:

```
data Parms_Count3;
  set Parms_Count3;
  if Parameter='Trt';
  _Scale_='MLE';
  _Stage_= 3;
  keep _Scale_ _Stage_ Parameter Estimate StdErr;
run;
```

```
proc print data=Parms_Count3;
  title 'Statistics Computed at Stage 3';
run;
```

Output 84.9.17 displays the test statistics at stage 3.

Output 84.9.17 Statistics Computed at Stage 3

Statistics Computed at Stage 3					
Obs	Parameter	Estimate	StdErr	_Scale_	_Stage_
1	Trt	0.1205	0.0507	MLE	3

The following statements invoke the SEQTEST procedure and test for early stopping at stage 3:

```
ods graphics on;
proc seqtest Boundary=Test_Count2
 Parms (Testvar=Trt)=Parms_Count3
  betaboundary=nonbinding
;
ods output Test=Test_Count3;
run;
ods graphics off;
```

The “Test Information” table in [Output 84.9.18](#) displays the boundary values, test statistic, and resulting action at each stage. The table shows that the test statistic 2.37437 is greater than the corresponding upper alpha boundary value, so the trial stops to reject the hypothesis.

Output 84.9.18 Sequential Test

The SEQTEST Procedure					
Test Information (Standardized Z Scale)					
Nonbinding Beta Boundary, Null Reference = 0					
Stage	---Information Level---		-Alternative-	-----Boundary Values----	
	Proportion	Actual	--Reference-- Upper	-----Upper----- Beta	Alpha
1	0.2522	130.3756	1.71273	-1.03271	3.09023
2	0.5015	259.3157	2.41549	0.46349	2.83297
3	0.7512	388.3763	2.95609	1.36434	2.34036
4	1.0000	517.0296	3.41074	2.03658	2.03658
Test Information (Standardized Z Scale)					
Nonbinding Beta Boundary, Null Reference = 0					
Stage	-----Test-----		-----Trt-----		
	Estimate	Action			
1	0.20390	Continue			
2	0.43522	Accept Null (Nonbinding)			
3	2.37437	Reject Null			
4	.				

With ODS Graphics enabled, the “Test Plot” is displayed, as shown in [Output 84.9.19](#). The plot displays boundary values of the design and the test statistics at the first two stages. As expected, the test statistic at stage 3 is in the “Upper Rejection Region” above the upper alpha boundary.

Output 84.9.19 Sequential Test Plot

After a trial is stopped, the “Parameter Estimates” table in [Output 84.9.20](#) displays the stopping stage and the maximum likelihood estimate of the parameter. It also displays the p -value, median estimate, and confidence limits for the parameter that correspond to the observed statistic by using the specified sample space ordering.

Output 84.9.20 Parameter Estimates

Parameter Estimates Stagewise Ordering					
Parameter	Stopping Stage	MLE	p-Value for H0:Parm=0	Median Estimate	Lower 95% CL
Trt	3	0.120482	0.0103	0.119371	0.03494

The MLE statistic at the stopping stage is the maximum likelihood estimate of the parameter and is biased. The computation of p -value, unbiased median estimate, and confidence limits depends on the ordering of the sample space (k, z) , where k is the stage number and z is the observed standardized Z statistic. By default

(or equivalently if you specify ORDER=STAGewise), the stagewise ordering that uses counterclockwise ordering around the continuation region is used to compute the p -value, unbiased median estimate, and confidence limits. As expected, the p -value is less than 0.025, and the confidence interval does not contain the null reference zero.

See the section “[Available Sample Space Orderings in a Sequential Test](#)” on page 7230 for a detailed description of the stagewise ordering.

Overview: SIM2D Procedure

The SIM2D procedure uses an LU decomposition technique to produce a spatial simulation for a Gaussian random field with a specified mean and covariance structure in two dimensions.

The simulation can be conditional or unconditional. If it is conditional, a set of coordinates and associated field values are read from a SAS data set. The resulting simulation honors these data values.

You can specify the mean structure as a quadratic function in the coordinates. Specify the semivariance by naming the form and supplying the associated parameters, or by using the contents of an item store file that was previously created by PROC VARIOGRAM.

PROC SIM2D can handle anisotropic and nested semivariogram models. Seven covariance models are supported: Gaussian, exponential, spherical, cubic, pentaspherical, sine hole effect, and Matérn. A single nugget effect is also supported.

You can specify the locations of simulation points in a **GRID** statement, or they can be read from a SAS data set. The grid specification is most suitable for a regular grid; the data set specification can handle any irregular pattern of points.

The SIM2D procedure writes the simulated values for each grid point to an output data set. The SIM2D procedure uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For more information about the graphics available in PROC SIM2D, see the section “[ODS Graphics](#)” on page 7413.

Introduction to Spatial Simulation

The purpose of spatial simulation is to produce a set of partial realizations of a spatial random field (SRF) $Z(s), s \in D \subset \mathcal{R}^2$ in a way that preserves a specified mean $\mu(s) = E[Z(s)]$ and covariance structure $C_z(s_1 - s_2) = \text{Cov}(Z(s_1), Z(s_2))$. The realizations are partial in the sense that they occur only at a finite set of locations (s_1, s_2, \dots, s_n) . These locations are typically on a regular grid, but they can be arbitrary locations in the plane.

PROC SIM2D produces simulations for continuous processes in two dimensions by using the lower-upper (LU) decomposition method. In these simulations the possible values of the measured quantity $Z(s_0)$ at location $s_0 = (x_0, y_0)$ can vary continuously over a certain range. An additional assumption, needed for computational purposes, is that the spatial random field $Z(s)$ is Gaussian. The section “[Details: SIM2D Procedure](#)” on page 7408 provides more information about different types of spatial simulation and associated computational methods.

Spatial simulation is different from spatial prediction, where the emphasis is on predicting a point value at a given grid location. In this sense, spatial prediction is local. In contrast, spatial simulation is global; the emphasis is on the entire realization $(Z(s_1), Z(s_2), \dots, Z(s_n))$.

Given the correct mean $\mu(s)$ and covariance structure $C_z(s_1 - s_2)$, SRF quantities that are difficult or impossible to calculate in a spatial prediction context can easily be approximated by functions of multiple simulations.

Getting Started: SIM2D Procedure

Spatial simulation, just like spatial prediction, requires a model of spatial dependence, usually in terms of the covariance $C_z(\mathbf{h})$. For a given set of spatial data $Z(s_i), i = 1, \dots, n$, the covariance structure (both the form and parameter values) can be found by the VARIOGRAM procedure. This example uses the coal seam thickness data that are also used in the section “[Getting Started: VARIOGRAM Procedure](#)” on page 8561.

In this example, the data consist of coal seam thickness measurements (in feet) taken over an area of 100×100 (10^6 ft²). The coordinates are offsets from a point in the southwest corner of the measurement area, with the north and east distances in units of thousands of feet.

Preliminary Spatial Data Analysis

A semivariance analysis of the coal seam thickness data set is performed in “[Getting Started: VARIOGRAM Procedure](#)” on page 8561 of the VARIOGRAM procedure. The analysis considers the spatial random field (SRF) $Z(s)$ of the Thick variable to be free of surface trends. The expected value $E[Z(s)]$ is then a constant $\mu(s) = \mu$, which suggests that you can work with the original thickness data rather than residuals from a trend surface fit. In fact, a reasonable approximation of the spatial process generating the coal seam data is given by

$$Z(s) = \mu + \varepsilon(s)$$

where $\varepsilon(s)$ is a Gaussian SRF with Gaussian covariance structure

$$C_z(\mathbf{h}) = c_0 \exp\left(-\frac{h^2}{a_0^2}\right)$$

Of note, the term “Gaussian” is used in two ways in this description. For a set of locations s_1, s_2, \dots, s_n , the random vector

$$\mathbf{Z}(s) = \begin{bmatrix} Z(s_1) \\ Z(s_2) \\ \vdots \\ Z(s_n) \end{bmatrix}$$

has a multivariate Gaussian or normal distribution $N_n(\mu, \Sigma)$. The (i,j) element of Σ is computed by $C_z(s_i - s_j)$, which happens to be a Gaussian functional form.

Any functional form for $C_z(\mathbf{h})$ that yields a valid covariance matrix Σ can be used. Both the functional form of $C_z(\mathbf{h})$ and the parameter values

$$\mu = 40.1173$$

$$c_0 = 7.4599$$

$$a_0 = 30.1111$$

are estimated by using PROC VARIOGRAM in section “[Theoretical Semivariogram Model Fitting](#)” on page 8571 in the VARIOGRAM procedure. Specifically, the expected value μ is reported in the VARIOGRAM procedure OUTV output data set, and the parameters c_0 and a_0 are estimates derived from a weighted least squares fit.

The choice of a Gaussian functional form for $C_z(\mathbf{h})$ is simply based on the data, and it is not at all crucial to the simulation. However, it *is* crucial to the simulation method used in PROC SIM2D that $Z(s)$ be a Gaussian SRF. For details, see the section “[Computational and Theoretical Details of Spatial Simulation](#)” on page 7408.

Investigating Variability by Simulation

The variability of $Z(s)$, as modeled by

$$Z(s) = \mu + \varepsilon(s)$$

with the Gaussian covariance structure $C_z(\mathbf{h})$ found previously, is not obvious from the covariance model form and parameters. The variation around the mean of the surface is relatively small, making it difficult visually to pick up differences in surface plots of simulated realizations.

Instead, you can compute the mean for each location on a grid from a series of realizations in a simulation. Then, the standard deviation of all the simulated values at each grid location provides you with a measure of the variability of $Z(s)$ for the given covariance structure. You can also investigate variations at selected grid points in more detail, as shown in the “[Example 85.2: Variability at Selected Locations](#)” on page 7419.

The present example shows how to use ODS Graphics with PROC SIM2D to investigate the mean and standard deviation of simulated values. You use the thick data set which is available from the SasHELP library. In the data set, the Thick variable represents simulated observations of coal seam thickness. For your goal, you produce 5,000 realizations of a simulation with PROC SIM2D, where you specify the Gaussian model with the parameters found previously. You want the simulated data to pass through the simulated values, so first you define the data with the following data step:

```

```

Since this is a conditional simulation, you can specify the **OBSERV** option in the **PLOTS** option in PROC SIM2D to see the locations and values of the measured points in the area where you want to perform spatial simulations.

Furthermore, the **SIM** suboption in the **PLOTS** option specifies that you want to create a plot that shows the means of the simulated values across the region. The **SIM** suboption with no other arguments produces a plot that shows the contours of the simulated means in the foreground and the gradient of the simulated standard deviations in the background.

You obtain these PROC SIM2D results at the nodes of an output grid that you specify according to your application needs. In the present analysis, a convenient area that encompasses all the Thick data points is a square with a side length of 100,000 feet. You define a regular grid for your simulation in this area. Assume a distance of 2,500 feet between grid nodes in both directions for a smooth contour plot. Based on this choice, your square grid has 41 nodes on each side. This means that PROC SIM2D computes the simulated values at a total of 1,681 grid points. You use the **GRID** statement of the PROC SIM2D to specify this grid.

The **SIMULATE** statement specifies the parameters of your simulation across the output grid. In particular, the **VAR=** option specifies the conditional simulation variable. The number of realizations in the simulation is specified with the **NUMREAL=** option. The **SEED=** option specifies the seed for the simulation random number generator.

The spatial correlation model for the simulation is also specified in the **SIMULATE** statement. You specify the model type by using the **FORM=** option. The options **SCALE=** and **RANGE=** specify the covariance structure sill c_0 and range a_0 parameters, respectively, as discussed in the previous section.

Although it is not included in the original spatial structure, note that a minimal nugget effect is specified with the **NUGGET=** option to avoid singularity issues. Singularity can appear in the present example as a result of the combined use of the Gaussian covariance model and relatively short distances between nodes, data, or nodes and data in the simulation area.

These steps are implemented using the following DATA step and statements:

```
ods graphics on;

proc sim2d data=thick outsim=sim plot=(observ sim);
  coordinates xc=East yc=North;
  simulate var=Thick numreal=5000 seed=79931
    scale=7.4599 range=30.1111 nugget=1e-8 form=gauss;
  mean 40.1173;
  grid x=0 to 100 by 2.5 y=0 to 100 by 2.5;
run;
```

The table in [Figure 85.1](#) shows the number of observations read and used in the conditional simulation. This table can provide you with useful information in case you have missing values in the input data.

Figure 85.1 Number of Observations for the thick Data Set

Using PROC SIM2D for Spatial Simulation	
The SIM2D Procedure	
Simulation: SIM1, Dependent Variable: Thick	
Number of Observations Read	75
Number of Observations Used	75

The sample locations are then plotted in [Figure 85.2](#). The figure clearly shows some small-scale variation that is typical of spatial data.

Figure 85.2 Scatter Plot of the Observations Spatial Distribution

PROC SIM2D also produces the table shown in Figure 85.3, which contains information about the type of simulation you run and the number of realizations requested.

Figure 85.3 Simulation Analysis Information

Simulation Information	
Simulation Grid Points	1681
Type	Conditional
Number of Realizations	5000

The table in Figure 85.4 displays the spatial correlation model information that is used by PROC SIM2D for the current simulation. If applicable, the table also provides the effective range. This is the distance r_ϵ at which the covariance is 5% of its value at zero. Here you specified the Gaussian model, for which the effective range r_ϵ is $\sqrt{3}a_0$.

Figure 85.4 Simulation Covariance Model Information

Covariance Model Information	
Type	Gaussian
Sill	7.4599
Range	30.1111
Effective Range	52.153955
Nugget Effect	1E-8

Eventually, the SIM2D procedure produces the requested simulation plot shown in Figure 85.5. The contours of the mean of the simulated values show the average of the simulated realizations at each grid node; the average is based on the given spatial structure characteristics. In this case, these means are also conditioned by the Thick observations across the region.

Figure 85.5 Contour Plot of Conditionally Simulated Coal Seam Thickness

Observe also the gradient that shows the standard deviation of the simulated values at each grid node. This gradient appears to be generally small throughout the region. A few exceptions are evident close to the region borders. In these areas the simulated realizations depend on a limited amount of neighboring data. The simulation at these locations relies mainly on the underlying spatial structure.

In addition to the simulation analysis, you can use the PROC SIM2D output to obtain statistical information about the simulated values at selected locations. Assume that you would like some basic statistics for the extreme southwest point at (East=0, North=0) and the point (East=75, North=75) toward the northeast corner of the region. You use the following DATA step to select the realizations for these points from the OUTSIM= output data set:

```
data selected;
  set sim(where=((gxc=0 and gyc=0) or (gxc=75 and gyc=75)));
  label gxc = "X-coord";
  label gyc = "Y-coord";
run;
```

Then, you use PROC SORT to sort the selected data set entries and PROC MEANS to produce the simulation statistics for the selected points. The following statements yield the mean, standard deviation, and maximum values of the 5,000 realizations of the Thick values at each one of the selected locations:

```
proc sort data=selected;
  by gxc gyc;
run;
proc means data=selected Mean Std Max;
  class gxc gyc;
  ways 2;
  where ( ((gxc = 0) & (gyc = 0))
        | ((gxc = 75) & (gyc = 75)));
  var SValue;
run;

ods graphics off;
```

The requested statistics for the grid points (East=0, North=0) and (East=75, North=75) are shown in Figure 85.6.

Figure 85.6 Simulation Statistics at Grid Points (East=0, North=0) and (East=75, North=75)

Using PROC SIM2D for Spatial Simulation						
The MEANS Procedure						
Analysis Variable : SVALUE Simulated Value at Grid Point						
X-coord	Y-coord	N Obs	Mean	Std Dev	Maximum	
0	0	5000	40.6968472	0.5328597	42.6616357	
75	75	5000	40.1090845	0.0024556	40.1197239	

“[Example 85.2: Variability at Selected Locations](#)” on page 7419 shows you how to perform a simulation at a set of selected locations rather than on a domain-wide grid, and how to obtain more detailed statistics from the simulation.

Syntax: SIM2D Procedure

The following statements are available in the SIM2D procedure:

```

PROC SIM2D options ;
  BY variables ;
  COORDINATES coordinate-variables ;
  GRID grid-options ;
  ID variable ;
  RESTORE store-options ;
  SIMULATE simulate-options ;
  MEAN mean-options ;

```

The **SIMULATE** and **MEAN** statements are hierarchical; you can specify any number of **SIMULATE** statements, but you must specify at least one. If you specify a **MEAN** statement, it refers to the preceding **SIMULATE** statement. If you omit the **MEAN** statement, a zero-mean model is simulated.

You must specify a single **COORDINATES** statement to identify the x and y coordinate variables in the input data set when you perform a conditional simulation. You must also specify a single **GRID** statement to specify the grid information.

Table 85.1 outlines the options available in PROC SIM2D classified by function.

Table 85.1 Options Available in the SIM2D Procedure

Task	Statement	Option
Data Set Options		
Specify an input data set	PROC SIM2D	DATA=
Specify a grid data set	GRID	GDATA=
Specify labels for individual grid points or in 1-D	GRID	LABEL
Specify correlation model and parameters	SIMULATE	MDATA=

Specify model and parameters from an item store	SIMULATE	STORESELECT

PROC SIM2D Statement

PROC SIM2D *options* ;

The PROC SIM2D statement invokes the SIM2D procedure. Table 85.2 summarizes the options available in the PROC SIM2D statement.

Table 85.2 PROC SIM2D Statement Options

Option	Description
DATA=	Specifies an input data set
IDGLOBAL	Uses ascending observation numbers across BY groups
IDNUM	Uses the observation number for the observation labels
NARROW	Restricts the variables included in the OUTSIM= data set
NOPRINT	Suppresses the normal display of results
OUTSIM=	Writes simulated values to a SAS data set
PLOTS	Specifies plot display and options

You can specify the following options with the PROC SIM2D statement.

DATA=SAS-data-set

specifies a SAS data set that contains the x and y coordinate variables and the **VAR=** variables that are used in the **SIMULATE** statements. This data set is required if you specify the **BY** statement or the **COORDINATES** statement or if any of the **SIMULATE** statements are conditional—that is, if you specify the **VAR=** option in any of those. Otherwise, you do not need the **DATA=** option, and this option is ignored if you specify it.

IDGLOBAL

specifies that ascending observation numbers be used across BY groups for the observation labels in the appropriate output data sets and the **OBSERVATIONS** plot, instead of resetting the observation number in the beginning of each BY group. The **IDGLOBAL** option is ignored if no BY variables are specified. Also, if you specify the **ID** statement, then the **IDGLOBAL** option is ignored unless you also specify the **IDNUM** option in the **PROC SIM2D** statement.

IDNUM

specifies that the observation number be used for the observation labels in the appropriate output data sets and the **OBSERVATIONS** plot. The **IDNUM** option takes effect when you specify the **ID** statement; otherwise, it is ignored.

NARROW

restricts the variables included in the **OUTSIM=** data set. When you specify the **NARROW** option, only four variables are included. This option is useful when a large number of simulations are produced. Including only four variables reduces the memory required for the **OUTSIM=** data set. For details about the variables that are excluded with the **NARROW** option, see the section “[Output Data Set](#)” on page 7411.

NOPRINT

suppresses the normal display of results. The NOPRINT option is useful when you want only to create one or more output data sets with the procedure. **NOTE:** This option temporarily disables the Output Delivery System (ODS); see the section “[ODS Graphics](#)” on page 7413 for more information.

OUTSIM=SAS-data-set

specifies a SAS data set in which to store the simulation values, iteration number, simulate statement label, variable name, and grid location. For details, see the section “[Output Data Set](#)” on page 7411.

PLOTS < (*global-plot-option*) > < = *plot-request* < (*options*) > >**PLOTS** < (*global-plot-option*) > < = (*plot-request* < (*options*) > < ... *plot-request* < (*options*) > > >

controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses around the plot request. Here are some examples:

```
plots=none
plots=observ
plots=(observ(out1) sim)
plots=(sim(fill=mean line=sd obs=grad) sim(fill=sd))
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;

proc sim2d data=thick outsim=sim;
  coordinates xc=East yc=North;
  simulate var=Thick numreal=5000 seed=79931
    scale=7.4599 range=30.1111 form=gauss;
  mean 40.1173;
  grid x=0 to 100 by 2.5 y=0 to 100 by 2.5;
run;

ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

By default, no graphs are created; you must specify the PLOTS= option to make graphs.

The following *global-plot-option* is available:

ONLY

produces only plots that are specifically requested.

The following individual *plot-requests* and plot *options* are available:

ALL

produces all appropriate plots. You can specify other *options* with ALL. For example, to request all appropriate plots and an additional simulation plot, specify PLOTS=(ALL SIM).

EQUATE

specifies that all appropriate plots be produced in a way in which the axes coordinates have equal size units.

NONE

suppresses all plots.

OBSERVATIONS < (*observations-plot-options*) >**OBSERV** < (*observations-plot-options*) >**OBS** < (*observations-plot-options*) >

produces the observed data plot in conditional simulations. Only one observations plot is created if you specify the OBSERVATIONS option more than once within a PLOTS option.

The OBSERVATIONS option has the following suboptions:

GRADIENT

specifies that observations be displayed as circles colored by the observed measurement.

LABEL < (*label-option*) >

labels the observations. The label is the ID variable if the **ID** statement is specified; otherwise, it is the observation number. The *label-option* can be one of the following:

EQ=number

specifies that labels show for any observation whose value is equal to the specified *number*.

MAX=number

specifies that labels show for observations with values smaller than or equal to the specified *number*.

MIN=number

specifies that labels show for observations with values equal to or greater than the specified *number*.

If you specify multiple instances of the OBSERVATIONS option and you specify the LABEL suboption in any of those, then the resulting observations plot displays the observations labels. If more than one *label-option* is specified in multiple LABEL suboptions, then the prevailing *label-option* in the resulting OBSERVATIONS plot emerges by adhering to the choosing order: MIN, MAX, EQ.

OUTLINE

specifies that observations be displayed as circles with a border but with a completely transparent fill.

OUTLINEGRADIENT

is the same as OBSERVATIONS(GRADIENT) except that a border is shown around each observation.

SHOWMISSING

specifies that observations with missing values be displayed in addition to the observations with nonmissing values. By default, missing values locations are not shown on the

plot. If you specify multiple instances of the OBSERVATIONS option and you specify the SHOWMISSING suboption in any of those, then the resulting observations plot displays the observations with missing values.

If you omit any of the GRADIENT, OUTLINE, and OUTLINEGRADIENT suboptions, the OUTLINEGRADIENT is the default suboption. If you specify multiple instances of the OBSERVATIONS option or multiple suboptions for OBSERVATIONS, then the resulting observations plot honors the last specified GRADIENT, OUTLINE, or OUTLINEGRADIENT suboption.

SIMULATION < (*sim-plot-options*) >

SIM < (*sim-plot-options*) >

specifies that simulation plots be produced. You can specify the SIM option multiple times in the same PLOTS option to request instances of plots with the following *sim-plot-options*:

ALPHA=number

specifies a parameter to obtain the confidence level for constructing confidence limits based on the simulation standard deviation. The value of *number* must be between 0 and 1, and the confidence level is $1 - \text{number}$. The default is ALPHA=0.05; this corresponds to the confidence level of 95%. The ALPHA= suboption is used only for simulation plots in one dimension, and it is incompatible with the FILL and LINE suboptions.

CLONLY

specifies that only the confidence limits be shown in a simulation plot without the simulation mean. This suboption can be useful for identifying confidence limits when the simulation standard deviation is small at the simulation locations. CLONLY is used only for simulation band plots of simulations on a linear grid, and it is incompatible with the FILL and LINE suboptions.

CONN

specifies that grid points that you provide as individual simulation locations be connected with a line on the area map. This suboption is ignored when you have a single grid point, a prediction grid in two dimensions, or when you also specify the NOMAP suboption. The CONNP suboption is incompatible with the FILL and LINE suboptions.

FILL=NONE | MEAN | SD

produces a surface plot for either the values of the means or the standard deviations. FILL=SD is the default. However, if you omit the FILL suboption the behavior depends on the LINE suboption as follows: If you specify LINE=NONE or entirely omit the LINE suboption, then the FILL suboption is set to its default value. If LINE=PRED or LINE=SE, then the FILL suboption is set to the same value as the LINE suboption.

LINE=NONE | MEAN | SD

produces a contour line plot for either the values of the means or the standard deviations. LINE=MEAN is the default. However, if you omit the LINE suboption the behavior depends on the FILL suboption as follows: If you specify FILL=NONE or entirely omit the FILL suboption, then the LINE suboption is set to its default value. If FILL=PRED or FILL=SE, then the LINE suboption is set to the same value as the FILL suboption.

NOMAP

specifies that the simulation plot be produced without a map of the domain where you have observations. The NOMAP suboption is used in the case of simulation in one dimension or at individual points. It is ignored in the case of unconditional simulation, and it is incompatible with the FILL and LINE suboptions.

OBS=obs-options

produces an overlaid scatter plot of the observations in addition to the specified contour plots. The following *obs-options* are available:

GRAD

specifies that observations be displayed as circles colored by the observed measurement. The same color gradient displays the means surface and the observations. The conditional simulation honors the observed values, so the means surface at the observation locations has the same color as the corresponding observations.

LINEGRAD

is the same as OBS=GRAD except that a border is shown around each observation. This option is useful for identifying the location of observations where the standard deviations are small, because at these points the color of the observations and the color of the surface are indistinguishable.

NONE

specifies that no observations be displayed.

OUTL

specifies that observations be displayed as circles with a border but with a completely transparent fill.

OBS=NONE is the default when you have a grid in two dimensions, and OBS=LINEGRAD is the default used in the area map when you specify a conditional simulation in one dimension.

SHOWD

specifies that the horizontal axis in scatter plots of linear simulation grids show the distance between grid points instead of the grid points' coordinates. When the area map is displayed, the simulation locations are also connected with a line. In all other grid configurations the SHOWD suboption is ignored, and it is incompatible with the FILL and LINE suboptions.

SHOWP

specifies that the grid points in band plots of linear simulation grids be shown as marks on the band plot. In all other grid configurations the SHOWP suboption is ignored, and it is incompatible with the FILL and LINE suboptions.

TYPE=BAND | BOX

requests a particular type of plot when you have a linear grid, regardless of the default SIM plot behavior in this case. The TYPE suboption is incompatible with the FILL and LINE suboptions.

If you specify multiple instances of the ALPHA, FILL, LINE, OBS, or TYPE suboptions in the same SIM option, then the resulting simulation plot honors the last value specified for any

of the suboptions. Any combination where you specify FILL=NONE and LINE=NONE is not available. When the simulation grid is in two dimensions, only the FILL, LINE, and OBS suboptions apply. If you specify incompatible suboptions in the same SIM plot, then the plot instance is skipped.

The SIM option produces a surface or contour line plot for grids in two dimensions and a band plot or box plot for grids in one dimension or individual points. In two dimensions the plot illustrates the means and standard deviations of the simulation realizations at each grid point. By default, when you specify a linear grid with fewer than 10 points, PROC SIM2D produces a SIM box plot that depicts the simulation distribution at each point. For 10 or more points in a linear grid, the SIM plot is a band plot of the simulation means and the confidence limits at the 95% confidence level. You can override the default behavior in linear grids with the TYPE suboption. Simulation at individual locations always produces a SIM box plot.

In cases of conditional simulation in one dimension or at individual points an area map is produced that shows the observations and the grid points. Band plots of linear grids display the grid points as a line on the map. When you specify individual simulation locations, the grid points are indicated with marks on the area map. The area map appears on the side of conditional simulation band plots or box plots, unless you specify the NOMAP suboption. You can also label individual grid points or the ends of linear grid segments with the LABEL option of the GRID statement.

SEMIVARIOGRAM <(semivar-plot-option)>

SEMIVAR <(semivar-plot-option)>

specifies that the semivariogram used for the simulation be produced. You can use the following *semivar-plot-option*:

MAXD=number

specifies a positive value for the upper limit of the semivariogram horizontal axis of distance. The SEMIVARIOGRAM plot extends by default to a distance that depends on the correlation model range. You can use the MAXD= option to adjust the default maximum distance value for the plot.

The SEMIVARIOGRAM option produces a plot for each correlation model that you specify for your simulation tasks. In an anisotropic case, the plot is not produced if you assign different anisotropy angles for different model components. The only exception is when you specify zonal components at right angles with the nonzonal model components. Also, the SEMIVARIOGRAM option is ignored for models that consist of purely zonal components.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC SIM2D to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the SIM2D procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

In PROC SIM2D it makes sense to use the BY statement only in conditional simulations where observations are involved. In particular, using the BY statement assumes that you have specified an input data set with the **DATA=** option in the **PROC SIM2D** statement. In PROC SIM2D if you omit the **VAR=** option in the **SIMULATE** statement, then this is a request for unconditional simulation even if you have specified the **DATA=** option in the **PROC SIM2D** statement. Therefore, it is possible to specify the BY statement and request mixed types of simulations by specifying multiple **SIMULATE** statements in the same PROC SIM2D step.

A special case occurs when you omit the **DATA=** option in the **PROC SIM2D** statement, your unconditional simulation correlation model input comes from an item store in the **RESTORE** statement, and this store has its own BY groups. The SIM2D procedure exhibits then a BY-like behavior, even though you specified no BY statement. This behavior enables you to distinguish the simulation tasks that depend on models in the different store BY groups.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

COORDINATES Statement

COORDINATES *coordinate-variables* ;

The two options in the COORDINATES statement give the name of the variables in the **DATA=** data set that contains the values of the x and y coordinates of the conditioning data. You must specify the COORDINATES statement when you specify an input data set with the **DATA=** option in the **PROC SIM2D** statement.

Only one COORDINATES statement is allowed, and it is applied to all **SIMULATE** statements that have the **VAR=** specification. In other words, it is assumed that all the **VAR=** variables in all **SIMULATE** statements have the same x and y coordinates.

You can abbreviate the COORDINATES statement as **COORD**.

XCOORD=(*variable-name*)

XC=(*variable-name*)

gives the name of the variable that contains the x coordinate of the data in the **DATA=** data set.

YCOORD=(*variable-name*)

YC=(*variable-name*)

gives the name of the variable that contains the y coordinate of the data locations in the **DATA=** data set.

GRID Statement

GRID *grid-options* < / *option* > ;

The GRID statement specifies the grid of spatial locations at which to perform the simulations. A single GRID statement is required and is applied to all **SIMULATE** statements. Specify the grid in one of the following three ways:

- Specify the x and y coordinates explicitly for a grid in two dimensions.
- Specify the **NPTS=** option in addition to the x and y coordinates to define a grid of individual points or in one dimension.
- Specify the coordinates by using a SAS data set for a grid of individual points or in one dimension.

The GRID statement has the following *grid-options*:

NPTS=*number*

NPTS=ALL

controls specification of a grid in one dimension or a grid of individual simulation locations.

When you specify the **NPTS=***number* option and the coordinates of two points in the **GRIDDATA=** data set or in both the **X=** and **Y=** options, you request a linear simulation grid. Its direction is across the line defined by the specified points. The grid size is equal to the *number* of points that you specify in the **NPTS=** option, where $number \geq 2$.

When you specify the **NPTS=ALL** option and the coordinates for any number of points in the **GRIDDATA=** data set or in each of the **X=** and **Y=** options, the **SIM2D** procedure performs simulation only at the specified individual locations. Use the **NPTS=ALL** option to examine a set of individual points anywhere on the **XY** plane or to specify a custom grid in one dimension.

If the number of x coordinates and the number of y coordinates in the **X=** and **Y=** options, respectively, are different, then the **NPTS=** option is ignored; in that case, a two-dimensional grid is used according to the specified **X=** and **Y=** options.

If you specify a simulation grid with any number of points other than two in the **GRIDDATA=** data set, then the option **NPTS=ALL** has the same effect as omitting the **NPTS=** option.

X=*number*

X= x_1, \dots, x_m

X= x_1 to x_m

X= x_1 to x_m by δx

specifies the x coordinate of the grid locations.

Y=number

Y=y₁, . . . , y_m

Y=y₁ to y_m

Y=y₁ to y_m by δy

specifies the y coordinate of the grid locations.

Use the X= and Y= options of the GRID statement to specify a grid in one or two dimensions, or a grid of individual simulation locations.

For example, the following two GRID statements are equivalent:

```
GRID X=1, 2, 3, 4, 5 Y=0, 2, 4, 6, 8, 10;
```

```
GRID X=1 TO 5 Y=0 to 10 by 2;
```

In the following example, the first GRID statement produces a grid in two dimensions. The second statement produces simulation output only for the four individual points at the locations (1,0), (2,5), (3,7), and (4,10) on the XY plane.

```
GRID X=1 TO 4 Y=0, 5, 7, 10;
```

```
GRID X=1 TO 4 Y=0, 5, 7, 10 NPTS=ALL;
```

In the next example, the first GRID statement specifies a 2-by-2 grid in two dimensions. The second GRID statement specifies a linear grid of eight points. The grid is in the direction of the line defined by the specified points (2,8) and (3,5) on the XY plane and it extends between these two points.

```
GRID X=2, 3 Y=8, 5;
```

```
GRID x=2, 3 Y=8, 5 NPTS=8;
```

The last example shows a GRID statement that specifies a linear grid made of seven points across the Y axis. In this case, the syntax is sufficient to fully define a linear grid without the NPTS= option.

```
GRID X=5 Y=3 TO 9;
```

To specify grid locations from a SAS data set, you must provide the name of the data set and the variables that contain the values of the x and y coordinates.

GRIDDATA=SAS-data-set

GDATA=SAS-data-set

specifies a SAS data set that contains the x and y grid coordinates. Use the GRIDDATA= option of the GRID statement to specify a grid in one dimension or a grid of individual simulation locations.

XCOORD=(*variable-name*)

XC=(*variable-name*)

gives the name of the variable that contains the *x* coordinate of the grid locations in the **GRIDDATA**= data set.

YCOORD=(*variable-name*)

YC=(*variable-name*)

gives the name of the variable that contains the *y* coordinate of the grid locations in the **GRIDDATA**= data set.

You can specify the following option in the **GRID** statement after a slash (/):

LABEL <(*suboption*)> = (*character-list*)

specifies labels to tag grid points in simulation plots when you use grids in one dimension. You can specify one or more such labels as quoted strings in the *character-list*.

When the number of labels in the *character-list* exceeds the number of points in your grid, the labels in the list are used sequentially and any labels in excess are ignored. When the number of labels in the *character-list* is smaller than the number of points in your grid, the behavior is as follows:

- If an area map is included in the simulation plot, then blank labels are assigned to the remaining nonlabeled grid points on the map.
- For the simulation band and box plots, the coordinates of nonlabeled grid points are automatically assigned as their labels.

If the grid points are collinear and the horizontal axis displays distance, then two labels appear by default in the simulation plot. These are assigned to the first and the last points of the grid to help identify the ends of the linear grid segment on the plot map. This label pair is shown only when the plot includes an area map. Specifically, the two labels appear when you request simulation band plots, or simulation box plots for which you specify the **SIM(SHOWD)** suboption, if applicable. The two labels do not appear if you specify explicitly the **NOMAP** suboption in the **PLOTS=SIM** option.

The two labels have default values, unless you choose to specify your own labels with the **LABEL**= option. If you specify more than two labels in the *character-list* under these conditions, then only the first and last labels in the list are used; any additional labels in between are ignored.

The **LABEL**= option has the following *suboption*:

ALL

specifies that all individual points in the grid are assigned sequentially the labels you specify in the **LABEL(ALL)**= option when the **SIM(SHOWD)** suboption is applicable and specified in a simulation box plot. In all other cases, the **ALL** suboption is ignored.

The **ALL** suboption enables you to override the default behavior when the **SIM(SHOWD)** suboption is specified (the default behavior is to display labels only for the first and last grid points). As a result, you can use the **ALL** suboption to label grid grid points in both conditional and unconditional simulation tasks regardless of whether you specify the **NOMAP** suboption in the **PLOTS=SIM** option.

The **LABEL**= option is ignored when you produce simulation plots of grids in two dimensions.

ID Statement

ID *variable* ;

The ID statement specifies which variable to include for identification of the observations in the labels and tool tips of the **OBSERVATIONS** plot and the tool tips of the **SIM** plot. The ID statement has an effect only when you perform conditional simulation.

In the SIM2D procedure you can specify only one ID variable in the ID statement. If no ID statement is given, then PROC SIM2D uses the observation number in the plots.

RESTORE Statement

RESTORE **IN=***store-name* **</ option>** ;

The RESTORE statement specifies an item store that provides spatial correlation model input for the PROC SIM2D simulation tasks. An item store is a binary file defined by the SAS System. You cannot modify the contents of an item store. The SIM2D procedure can use only item stores created by PROC VARIOGRAM.

Item stores enable you to use saved correlation models without having to repeat specification of these models in the **SIMULATE** statement. In principle, an item store contains the chosen model from a model fitting process in PROC VARIOGRAM. If more than one model form is fitted, then all successful fits are included in the item store. In this case, you can choose any of the available models to use for simulation with the **STORESELECT(MODEL=)** option in the **SIMULATE** statement. Successfully fitted models might include questionable fits, which are so flagged when you specify the **INFO** option to display model names.

The *store-name* is a usual one- or two-level SAS name, as for SAS data sets. If you specify a one-level name, then the item store resides in the WORK library and is deleted at the end of the SAS session. Since item stores are often used for postprocessing tasks, typical usage specifies a two-level name of the form *libname.membername*.

When you specify the RESTORE statement, the default output contains some general information about the input item store. This information includes the store name, label (if assigned), the data set that was used to create the store, BY group information, the procedure that created the store, and the creation date.

You can specify the following option in the RESTORE statement after a slash (/):

INFO **<(info-options)>**

specifies that additional information about the input item store be printed. This information is provided in two ODS tables. One table displays the variables in the item store, in addition to the mean and standard deviation for each of them. These statistics are based on the observations that were used to produce the store results. The second table shows the model on top of the list of all fitted models for each direction angle in the item store. The INFO option has the following *info-options*:

DETAILS

DET

specifies that more detailed information be displayed about the input item store. This option produces the full list of models for each direction angle in the item store, in addition to the model equivalence class. For more information about classes of equivalence, see the section

“Classes of Equivalence” on page 8634 in the VARIOGRAM procedure. The DETAILS option is ignored if the input item store contains information about a single fitted model.

ONLY

specifies that only information about the input item store without any simulation tasks be displayed.

Each variable in an item store has a mean value that is passed to PROC SIM2D and used in simulations. If the mean in the item store is a missing value, then a zero mean is used by default. Specify the “[MEAN Statement](#)” on page 7406 to override the mean information in the item store. For example, if you want to use only the correlation model in the item store and exclude the accompanying mean, then explicitly specify a zero mean in the “[MEAN Statement](#)” on page 7406.

When you specify an input item store with the RESTORE statement in PROC SIM2D, all the [DATA=](#) input data set variables must match input item store variables. If there are BY groups in the input [DATA=](#) set or in the input RESTORE variables, then PROC SIM2D handles the different cases as follows:

- If both PROC SIM2D has BY groups and the RESTORE statement has BY groups, then the analysis variables must match. This matching assumes implicitly that in each BY group of PROC SIM2D and the item store, the corresponding set of observations and correlation model comes from the same random field. This assumption is valid if you use the same data set, first in PROC VARIOGRAM to fit a model and save it in the item store, and then in PROC SIM2D to run simulations with the resulting correlation models.
- If PROC SIM2D has BY groups but the item store does not, then the item store is accepted only if the procedure and the item store analysis variables match. In this case, the same item store model choice iterates across the BY groups of the input data. You are advised to proceed with caution: each BY group in the input [DATA=](#) set corresponds to a different realization of a random field. Hence, by using the same correlation model for simulation purposes, you implicitly assume that all these different realizations are instances of the same random field.
- If PROC SIM2D has an input [DATA=](#) set and no BY groups but the item store has BY groups, then the item store is rejected
- If PROC SIM2D has no input [DATA=](#) set and the item store has BY groups, then PROC SIM2D runs unconditional simulations for the models in the store BY groups. See also the [BY](#) statement for more about the behavior in this case.

SIMULATE Statement

SIMULATE *simulate-options* ;

The SIMULATE statement specifies details on the simulation and the covariance model used in the simulation. You can specify the following *simulate-options* with a SIMULATE statement, which can be abbreviated by SIM.

Table 85.3 summarizes the options available in the SIMULATE statement.

Table 85.3 SIMULATE Statement Options

Option	Description
Simulate-Options	
NUMREAL=	Specifies the number of realizations to produce
VAR=	Specifies the conditioning variable
Covariance Model Specification	
ANGLE=	Specifies the angle of the major axis
FORM=	Specifies the functional form
MDATA=	Specifies the input data set containing parameter values
NUGGET=	Specifies the nugget effect for the model
RANGE=	Specifies the range parameter
RATIO=	Specifies the ratio of the minor axis to the major axis
SCALE=	Specifies the scale (or <i>sill</i>) parameter
SEED=	Specifies the seed to use for the random number generator
SINGULAR=	Gives the singularity criterion
SMOOTH=	Specifies the smoothness parameter
STORESELECT	Uses information from an input item store for prediction

NUMREAL=*number*

NUMR=*number*

NR=*number*

specifies the number of realizations to produce for the spatial process specified by the covariance model. As a result, the number of observations in the **OUTSIM=** data set contributed by a given **SIMULATE** statement is the product of the **NUMREAL=** value and the number of grid points. This can cause the **OUTSIM=** data set to become large even for moderate values of the **NUMREAL=** option.

VAR=(*variable-name*)

specifies the single numeric variable used as the conditioning variable in the simulation. In other words, the simulation is conditional on the values of the **VAR=** variable found in the **DATA=** data set. If you omit the **VAR=** option or if all observations of the **VAR=** variable are missing values, then the simulation is *unconditional*. Since multiple **SIMULATE** statements are allowed, you can perform both unconditional and conditional simulations with a single **PROC SIM2D** statement.

Covariance Model Specification

You can specify a semivariogram or covariance model in three ways:

- You specify the required parameters **SCALE**, **RANGE**, **FORM**, and **SMOOTH** (if you specify the MATERN form), and possibly the optional parameters **NUGGET**, **ANGLE**, and **RATIO**, explicitly in the **SIMULATE** statement.
- You specify an **MDATA=** data set. This data set contains variables that correspond to the required parameters **SCALE**, **RANGE**, **FORM**, and **SMOOTH** (if you specify the MATERN form), and, optionally, variables for the **NUGGET**, **ANGLE**, and **RATIO** parameters.

- You can specify an input item store in the **RESTORE** statement. The item store contains one or more correlation models for one or more direction angles. You can specify these models in the **STORESELECT** option of the **SIMULATE** statement to run a simulation.

The three methods are mutually exclusive: you specify all parameters explicitly, they are all read from the **MDATA=** data set, or you select a model and its parameters from an input item store. The following *simulate-options* are related to model specification:

ANGLE=*angle*

ANGLE=(*angle1*, ..., *anglek*)

specifies the angle of the major axis for anisotropic models, measured in degrees clockwise from the N–S axis. The default is **ANGLE=0**.

In the case of a nested semivariogram model with k nestings, you have the following two ways to specify the anisotropy major axis: you can specify only one *angle* which is then applied to all nested forms, or you can specify one angle for each of the k nestings.

NOTE: The syntax makes it possible to specify different angles for different forms of the nested model, but this practice is rarely used.

FORM=*form*

FORM=(*form1*, ..., *formk*)

specifies the functional form (type) of the semivariogram model. Use the syntax with the single *form* to specify a non-nested model. Use the syntax with forms *formi*, $i = 1, \dots, k$, to specify a nested model with k structures. Each of the forms can be any of the following:

**CUBIC | EXPONENTIAL | GAUSSIAN | MATERN |
PENTASPHERICAL | SINEHOLEEFFECT | SPHERICAL**

CUB | EXP | GAU | MAT | PEN | SHE | SPH

specify the functional form (type).

For example, the syntax

FORM=GAU

specifies a model with a single Gaussian structure. Also, the syntax

FORM= (EXP, SHE, MAT)

specifies a nested model with an exponential, a sine hole effect, and a Matérn structure. Finally

FORM= (EXP, EXP)

specifies a nested model with two structures both of which are exponential.

NOTE: In the documentation, models are named either by using their full names or by using the first three letters of their structures. Also, the names of different structures in a nested model are separated by a hyphen (-). According to this convention, the previous examples illustrate how to specify a GAU, an EXP-SHE-MAT, and an EXP-EXP model, respectively, with the **FORM=** option.

All the supported model forms have two parameters specified by the **SCALE=** and **RANGE=** options, except for the MATERN model which has a third parameter specified by the **SMOOTH=** option. A **FORM=** value is required, unless you specify the **MDATA=** option or the **STORESELECT** option.

Computation of the MATERN covariance is numerically demanding. As a result, simulations that use Matérn covariance structures can be time-consuming.

MDATA=SAS-data-set

specifies the input data set that contains parameter values for the covariance or semivariogram model. The **MDATA=** option cannot be combined with any of the **FORM=** or **STORESELECT** options.

The **MDATA=** data set must contain variables named **SCALE**, **RANGE**, and **FORM**, and it can optionally contain variables **NUGGET**, **ANGLE**, and **RATIO**. If you specify the MATERN form, then you must also include a variable named **SMOOTH** in the **MDATA=** data set.

The **FORM** variable must be a character variable, and it can assume only the values allowed in the explicit **FORM=** syntax described previously. The **RANGE**, **SCALE** and **SMOOTH** variables must be numeric. The optional variables **ANGLE**, **RATIO**, and **NUGGET** must also be numeric if present.

The number of observations present in the **MDATA=** data set corresponds to the level of nesting of the covariance or semivariogram model. For example, to specify a non-nested model that uses a spherical covariance, an **MDATA=** data set might contain the following statements:

```
data mdl;
  input scale range form $;
  datalines;
  25 10 SPH
  ;
```

The PROC SIM2D statement to use the **MDATA=** specification is of the form shown in the following:

```
proc sim2d data=...;
  sim var=... mdata=mdl;
run;
```

This is equivalent to the following explicit specification of the covariance model parameters:

```
proc sim2d data=...;
  sim var=... scale=25 range=10 form=sph;
run;
```

The following **MDATA=** data set is an example of an anisotropic nested model:

```
data md2;
  input scale range form $ nugget angle ratio smooth;
  datalines;
  20 8 SPH 5 35 .7 .
  12 3 MAT 5 0 .8 2.8
  4 1 GAU 5 45 .5 .
  ;
```

```
proc sim2d data=...;
  sim var=.... mdata=md2;
run;
```

This is equivalent to the following explicit specification of the covariance model parameters:

```
proc sim2d data=...;
  sim var=.... scale=(20,12,4) range=(8,3,1) form=(SPH,MAT,GAU)
    angle=(35,0,45) ratio=(.7,.8,.5) nugget=5 smooth=2.8;
run;
```

This example is somewhat artificial in that it is usually hard to detect different anisotropy directions and ratios for different nestings by using an experimental semivariogram. **NOTE:** The NUGGET variable value is the same for all nestings. This is always the case; the nugget effect is a single additive term for all models. For further details, see the section “[The Nugget Effect](#)” on page 3830 in the KRIGE2D procedure.

The example also shows that if you specify a MATERN form in the nested model, then the SMOOTH variable must be specified for all nestings in the MDATA= data set. You simply specify the SMOOTH value as missing for nestings other than MATERN.

The **SIMULATE** statement can be given a label. This is useful for identification in the **OUTSIM=** data set when multiple **SIMULATE** statements are specified. For example:

```
proc sim2d data=...;
  gauss1: sim var=.... form=gau;
  mean ....;
  gauss2: sim var=.... form gau;
  mean ....;
  exp1: sim var=.... form=exp;
  mean ....;
  exp2: sim var=.... form=exp;
  mean ....;
run;
```

In the **OUTSIM=** data set, the values “GAUSS1,” “GAUSS2,” “EXP1,” and “EXP2” for the LABEL variable help to identify the realizations that correspond to the four **SIMULATE** statements. If you do not provide a label for a **SIMULATE** statement, a default label of SIM n is given, where n is the number of unlabeled **SIMULATE** statements seen so far.

NUGGET=*number*

specifies the nugget effect for the model. This effect is due to a discontinuity in the semivariogram as determined by plotting the sample semivariogram (see the section “[The Nugget Effect](#)” on page 3830 in the KRIGE2D procedure for details). For models without any nugget effect, the NUGGET= option is left out. The default is NUGGET=0.

RANGE=*range*

RANGE=(*range1*, ..., *rangek*)

specifies the range parameter in the semivariogram models. In the case of a nested semivariogram model with k nestings, you must specify a range for each nesting.

The range parameter is the divisor in the exponent in all supported models. It has the units of distance or distance squared for these models, and it is related to the correlation scale for the underlying spatial process.

See the section “[Theoretical Semivariogram Models](#)” on page 3823 in the KRIGE2D procedure for details about how the RANGE= values are determined.

RATIO=*ratio*

RATIO=(*ratio1*, ..., *ratio**k*)

specifies the ratio of the length of the minor axis to the length of the major axis for anisotropic models. The value of the RATIO= option must be between 0 and 1. In the case of a nested semivariogram model with *k* nestings, you can specify a ratio for each nesting. The default is RATIO=1.

SCALE=*scale*

SCALE=(*scale1*, ..., *scale**k*)

specifies the scale (or *sill*) parameter in semivariogram models. In the case of a nested semivariogram model with *k* nestings, you must specify a scale for each nesting. The scale parameter is the multiplicative factor in all supported models; it has the same units as the variance of the VAR= variable.

See the section “[Theoretical Semivariogram Models](#)” on page 3823 in the KRIGE2D procedure for details about how the SCALE= values are determined.

SEED=*seed-value*

specifies the seed to use for the random number generator. The SEED= option *seed-value* has to be an integer.

SINGULAR=*number*

gives the singularity criterion for solving the set of linear equations involved in the computation of the mean and covariance of the conditional distribution associated with a given SIMULATE statement. The larger the value of the SINGULAR= option, the easier it is for the covariance matrix system to be declared singular. The default is SINGULAR=1E-8.

For more details about the use of the SINGULAR= option, see the section “[Computational and Theoretical Details of Spatial Simulation](#)” on page 7408.

SMOOTH=*smooth*

SMOOTH=(*smooth1*, ..., *smooth**m*)

specifies the smoothness parameter $\nu > 0$ in the Matérn type of semivariance structures. The special case $\nu = 0.5$ is equivalent to the exponential model, whereas $\nu \rightarrow \infty$ gives the Gaussian model.

When you specify *m* different MATERN forms in the FORM= option, you must also provide *m* smoothness values in the SMOOTH option. If you must specify more than one smoothness value, the values are assigned sequentially to the MATERN nestings in the order the nestings are specified. If you specify more smoothness values than necessary, then values in excess are ignored.

STORESELECT(*ssel-options*)

SSSEL(*ssel-options*)

specifies that information from an input item store be used for the prediction. You cannot combine the STORESELECT option with any of the FORM= or MDATA= options. The STORESELECT option has the following *ssel-options*:

TYPE=*field-type*

specifies whether to perform isotropic or anisotropic simulation. You can choose the *field-type* from one of the following:

ISO

specifies isotropic field for the simulation.

ANIGEO | GEO

specifies a field with geometric anisotropy for the simulation.

ANIZON(*zonal-form1*, ..., *zonal-formn*)**ZON**(*zonal-form1*, ..., *zonal-formn*)

specifies a field with zonal anisotropy for the simulation. Each *zonal-formi*, $i = 1, \dots, n$, can be any of the following:

CUB | EXP | GAU | MAT | PEN | SHE | SPH

specify a form for the simulation.

Each *zonal-formi*, $i = 1, \dots, n$, is a structure in the purely zonal component of the correlation model in the direction angle of the minor anisotropy axis. For this reason, when you specify the TYPE=ANIZON suboption you must also specify the nonzonal component of the correlation model in the **MODEL=** suboption of the STORESELECT option. Assume the nonzonal component has k structures; these are common across all directions and each one has the same scale in all directions. In that sense, you use the TYPE=ANIZON suboption to specify only the n zonal anisotropy structures of an input store ($k + n$)-structure nested model in the direction angle of the minor anisotropy axis.

Given this specification, $k + n$ must be up to the maximum number of nested model structures that is supported by the item store. See also the **MODEL=** suboption of the STORESELECT option.

In conclusion, you can use an input item store for prediction with zonal anisotropy if you know that every structure in the nonzonal model component has the same scale across all directions. When this condition does not apply for the item store models, specify the model parameters explicitly in the **SIMULATE** statement.

Computation of the MATERN covariance is numerically demanding. As a result, predictions that use Matérn covariance structures can be time-consuming.

If you omit the TYPE= option, the default behavior is TYPE=ISO when the input item store contains information for only one angle or for the omnidirectional case. If you specify an item store with information for more than one direction, then the default behavior is TYPE=ANIGEO.

When you specify TYPE=ISO to request isotropic analysis in the presence of an item store with information for multiple directions, you must specify the **ANGLEID=** suboption of the STORESELECT option with one argument. This argument specifies which of the direction angles information to use for the isotropic analysis.

When you indicate the presence of anisotropy with the TYPE=ANIGEO or TYPE=ANIZON suboptions of the STORESELECT option, the following conditions apply:

- You must specify the **ANGLEID=** suboption of the STORESELECT option to designate the major and minor anisotropy axes. See the **ANGLEID=** suboption of the STORESELECT option for details.

- – For TYPE=ANIGEO, ensure that you have the same scale in all anisotropy directions.
- – For TYPE=ANIZON, ensure that the nonzonal component scale is the same in all anisotropy directions.

If you import a nested model, these rules also apply to each one of the nested structures.

- Model ranges in the major anisotropy axis must be longer than ranges in the minor anisotropy axis.
- Any Matérn covariance structure must maintain its smoothness parameter value in all anisotropy directions.

ANGLEID=*angleid1*

ANGLEID=(*angleid1*, *angleid2*)

specifies which direction angles in the input item store be used for simulation. The angles are identified by the corresponding number in the AngleID column of the “Store Models Information” table, or by the AngleID parameter in the table title when you specify the [INFO\(DETAILS\)](#) option in the [RESTORE](#) statement.

If you request isotropic prediction in the [TYPE=](#) suboption of the STORESELECT option and the item store has omnidirectional contents or information about only one angle, then the ANGLEID= option is ignored. The simulation input comes from the omnidirectional information. In the case of a single angle, you still perform isotropic simulation and the model parameters are provided by the model in the single direction angle in the item store. However, if the item store contains information for more than one angle, then you must specify one angle ID in *angleid1*. The model information from the corresponding angle is then used in your isotropic simulation.

When you specify an anisotropic simulation in the [TYPE=](#) option of the STORESELECT option, you need to have information about two perpendicular direction angles. One of them is the major and the other is the minor anisotropy axis. You must always specify the major anisotropy axis angle ID in *angleid1* and the minor anisotropy axis angle ID in *angleid2*. This means that the range parameters of the model forms in the angle designated by the *angleid1* need to be larger than the corresponding ranges of the forms in the angle designated by the *angleid2*. Conveniently, if the item store has only two angles, then you only need to specify the ID *angleid1* of the major anisotropy axis angle. If the item store has only one angle, then you cannot perform anisotropic simulation with input from the item store.

NOTE: You can perform geometric anisotropic analysis even if the item store does not contain information about a direction that is perpendicular to the one specified by *angleid1*. This is possible due to the geometry of the ellipse. In particular, when you specify the major axis with *angleid1* and an angle ID for a second direction with a corresponding smaller range, then PROC SIM2D automatically computes the minor anisotropy axis range and the necessary range ratio parameter.

Anisotropic analysis is not possible when you specify instances of the same angle in the input item store. It is possible that PROC VARIOGRAM produces an item store where two or more directions can be the same if their corresponding correlation models were obtained for different angle tolerances or bandwidths in the VARIOGRAM procedure. Consequently, you cannot specify anisotropic simulation if the input store contains only two angles that are the same or if you specify *angleid1* and *angleid2* that correspond to equal angles.

MODEL=*form*

MODEL=(*form1*, ..., *formk*)

specifies the theoretical semivariogram model selection to use for the simulation. Use any combination of one, two, or three forms to describe a model in the input item store because up to three nested structures are supported. Each *formi*, $i = 1, \dots, k$, can be any of the following:

CUB | EXP | GAU | MAT | PEN | SHE | SPH

specify the selection model.

Computation of the MATERN covariance is numerically demanding. As a result, simulations that use Matérn covariance structures can be time-consuming.

All fitted models that are stored in the input item store contain information about their component parameters and also about the nugget effect if any. The SIM2D procedure retrieves this information when you make a model selection in the MODEL= option, and you do not need to individually specify a nugget effect or any other parameter of the model.

By default, the model that is ranked first among the models for a given angle in the item store is used for the simulation task. If more than one model is available in the item store, then you can specify the MODEL= option to use a different model for the simulation.

In an anisotropic simulation, the default selection is the model that is ranked first in the direction angle of the major anisotropy axis. If you specify the **TYPE=ANIGEO** option, then a model that consists of identical structures needs to be present in the selected minor anisotropy axis angle in the item store. If you specify the **TYPE=ANIZON** option, then a model with the exact same first k structures must be present in the selected minor anisotropy axis angle, and it must feature at least one more structure as a zonal component. The zonal component is specified separately in the **TYPE=ANIZON** suboption of the STORESELECT option. Consequently, remember that in zonal anisotropy the MODEL= suboption designates only the nonzonal component of the correlation model in the minor anisotropy axis direction. In all, if there are k common structures and n structures in the purely zonal component, then $k + n$ must be up to the maximum number of nested model structures that is supported by the item store.

SVAR=*store-var*

SVAR=(*store-varlist*)

specifies one *store-var* item store variable or a list *store-varlist* of variables that are present in the item store. This option selects one or more item store variables whose correlation models you want to use in the current simulation task.

If you are performing a conditional simulation, then PROC SIM2D searches the input item store for the variable that is specified in the **VAR=** option of the **SIMULATE** statement. Then, the procedure selects the appropriate correlation model for the task. In this case, if you specify the SVAR= option, it is ignored. However, when you request an unconditional simulation and specify input from an item store, then you must also use SVAR= to specify a source for your correlation model.

In comparison to the other two ways of specifying a correlation model in PROC SIM2D, the STORESELECT option is quite different because you can avoid explicit specification of all parameter values of a model. When you specify the STORESELECT option, then the corresponding scale, range, nugget effect, and smoothness (if appropriate) parameter values are invoked as saved attributes of the model that you select from the item store.

In the case of anisotropy, you specify the angles indirectly with the **ANGLEID=** option of the **STORESELECT** option, and the ratios are computed implicitly by using the selected model ranges. Explore how to specify valid anisotropic models imported from an input item store with the two examples that follow.

In the first example, assume the input item store **lnStoreGeo** contains exponential models in the angles $\theta_1 = 0^\circ$, $\theta_2 = 45^\circ$, and $\theta_3 = 90^\circ$. You know in advance that all models have the same scale $c_1 = c_2 = c_3$ across these directions and that the respective ranges are $a_1 = 15$, $a_2 = 20$, and $a_3 = 25$ in distance units. Hence, you have a case of geometric anisotropy where the major anisotropy axis is in the direction of angle θ_3 and the minor anisotropy axis is in the direction of angle θ_1 . The following statements in PROC SIM2D use the information in the item store **lnStoreGeo** to perform simulation under the assumption of geometric anisotropy:

```
proc sim2d data=...;
  restore in=lnStoreGeo;
  simulate storeselect(model=exp type=anigeo angleid=(3,1));
run;
```

For the second example, assume a case of zonal anisotropy. Consider the input item store **lnStoreZon**, which contains models in the two angles, $\theta_1 = 30^\circ$ and $\theta_2 = 120^\circ$. Specifically, in θ_1 you have an exponential-spherical model: the exponential structure has scale $c_{1E} = 3$ and range $a_{1E} = 10$; the spherical structure has scale $c_{1S} = 1$ and range $a_{1S} = 6$. In direction θ_2 you have an exponential model with scale $c_{1E} = 3$ and range $a_{1E} = 12$. Hence, the zonal anisotropy major axis is in the direction of the lowest total variance, which is in angle θ_2 ; then, the minor axis is in the direction of angle θ_1 . The following statements in PROC SIM2D use the information in the store **lnStoreZon** to perform simulation under the assumption of zonal anisotropy:

```
proc sim2d data=...;
  restore in=lnStoreZon;
  simulate storeselect(model=exp type=anizon(sph) angleid=(2,1));
run;
```

MEAN Statement

MEAN *spec1, ..., spec6* ;

MEAN QDATA=SAS-data-set **CONST=var1** **CX=var2** **CY=var3**
CXX=var4 **CYY=var5** **CXY=var6** ;

MEAN QDATA=SAS-data-set ;

A mean function $\mu(s)$ that is a quadratic in the coordinates can be written as

$$\mu(s) = \mu(x, y) = \beta_0 + \beta_1 x + \beta_2 y + \beta_3 x^2 + \beta_4 y^2 + \beta_5 xy$$

The **MEAN** statement specifies the quadratic surface to use as the mean function for the simulated SRF. There are two ways to specify the **MEAN** statement. The **MEAN** statement allows the specification of the coefficients β_0, \dots, β_5 either explicitly or through a **QDATA=** data set.

An example of an explicit specification is the following:

```
mean 1.4 + 2.5*x + 3.6*y + 0.47*x*x + 0.58*y*y + 0.69*x*y;
```

In this example, all terms have a nonzero coefficient. Any term with a zero coefficient is simply left out of the specification. For example,

```
mean 1.4;
```

is a valid quadratic form with all terms having zero coefficients except the constant term.

An equivalent way of specifying the mean function is through the QDATA= data set. For example, the MEAN statement

```
mean 1.4 + 2.5*x + 3.6*y + 0.47*x*x + 0.58*y*y + 0.69*x*y;
```

can be alternatively specified by the following DATA step and MEAN statement:

```
data q1;
  input c1 c2 c3 c4 c5 c6;
  datalines;
  1.4 2.5 3.6 0.47 0.58 0.69
  ;

proc sim2d data=....;
  simulate ...;
  mean qdata=q1 const=c1 cx=c2 cy=c3 cxx=c4 cyy=c5 cxy=c6;
run;
```

The QDATA= data set specifies the data set containing the coefficients. The parameters CONST=, CX=, CY=, CXX=, CYY=, and CYX= specify the variables in the QDATA= data set that correspond to the constant, linear x, linear y, and so on. For any coefficient not specified in this list, the QDATA= data set is checked for the presence of variables with default names of CONST, CX, CY, CXX, CYY, and CXY. If these variables are present, their values are taken as the corresponding coefficients. Hence, you can rewrite the previous example as follows:

```
data q1;
  input const cx cy cxx cyy cxy;
  datalines;
  1.4 2.5 3.6 0.47 0.58 0.69
  ;

proc sim2d data=....;
  simulate ...;
  mean qdata=q1;
run;
```

If a given coefficient does not appear in the list or in the data set with the default name, a value of zero is assumed.

If you run a simulation task with input from a [RESTORE](#) statement, then by default the simulation uses the mean of the item store variable in the simulation. You can override this default behavior if you explicitly specify the MEAN statement with a different mean function.

Details: SIM2D Procedure

Computational and Theoretical Details of Spatial Simulation

Introduction

There are a number of approaches to simulating spatial random fields or, more generally, simulating sets of dependent random variables. These include sequential indicator methods, turning bands, and the Karhunen-Loeve expansion. See Christakos (1992, Chapter 8) and Deutsch and Journel (1992, Chapter V) for details.

A particularly simple method available for Gaussian spatial random fields is the LU decomposition method. This method is computationally efficient. For a given covariance matrix, the $LU = \mathbf{LL}'$ decomposition is computed once, and the simulation proceeds by repeatedly generating a vector of independent $N(0, 1)$ random variables and multiplying by the \mathbf{L} matrix.

One problem with this technique is memory requirements; memory is required to hold the full data and grid covariance matrix in core. While this is especially limiting in the three-dimensional case, you can use PROC SIM2D, which handles only two-dimensional data, for moderately sized simulation problems.

Theoretical Development

It is a simple matter to produce an $N(0, 1)$ random number, and by stacking k $N(0, 1)$ random numbers in a column vector, you can obtain a vector with independent standard normal components $\mathbf{W} \sim N_k(\mathbf{0}, \mathbf{I})$. The meaning of the terms *independence* and *randomness* in the context of a deterministic algorithm required for the generation of these numbers is subtle; see Knuth (1981, Chapter 3) for details.

Rather than $\mathbf{W} \sim N_k(\mathbf{0}, \mathbf{I})$, what is required is the generation of a vector $\mathbf{Z} \sim N_k(\mathbf{0}, \mathbf{C})$ —that is,

$$\mathbf{Z} = \begin{bmatrix} Z_1 \\ Z_2 \\ \vdots \\ Z_k \end{bmatrix}$$

with covariance matrix

$$\mathbf{C} = \begin{pmatrix} C_{11} & C_{12} & \cdots & C_{1k} \\ C_{21} & C_{22} & \cdots & C_{2k} \\ & \ddots & & \\ C_{k1} & C_{k2} & \cdots & C_{kk} \end{pmatrix}$$

If the covariance matrix is symmetric and positive definite, it has a Cholesky root \mathbf{L} such that \mathbf{C} can be factored as

$$\mathbf{C} = \mathbf{LL}'$$

where \mathbf{L} is lower triangular. See Ralston and Rabinowitz (1978, Chapter 9, Section 3-3) for details. This vector \mathbf{Z} can be generated by the transformation $\mathbf{Z} = \mathbf{LW}$. Here is where the assumption of a Gaussian SRF is crucial. When $\mathbf{W} \sim N_k(\mathbf{0}, \mathbf{I})$, then $\mathbf{Z} = \mathbf{LW}$ is also Gaussian. The mean of \mathbf{Z} is

$$E(\mathbf{Z}) = \mathbf{L}(E(\mathbf{W})) = \mathbf{0}$$

and the variance is

$$\text{Var}(\mathbf{Z}) = \text{Var}(\mathbf{LW}) = E(\mathbf{LWW}'\mathbf{L}') = \mathbf{L}E(\mathbf{WW}')\mathbf{L}' = \mathbf{LL}' = \mathbf{C}$$

Consider now an SRF $Z(s), s \in D \subset \mathcal{R}^2$, with spatial covariance function $C(\mathbf{h})$. Fix locations s_1, s_2, \dots, s_k , and let \mathbf{Z} denote the random vector

$$\mathbf{Z} = \begin{bmatrix} Z(s_1) \\ Z(s_2) \\ \vdots \\ Z(s_k) \end{bmatrix}$$

with corresponding covariance matrix

$$\mathbf{C}_Z = \begin{pmatrix} C(\mathbf{0}) & C(s_1 - s_2) & \cdots & C(s_1 - s_k) \\ C(s_2 - s_1) & C(\mathbf{0}) & \cdots & C(s_2 - s_k) \\ & & \ddots & \\ C(s_k - s_1) & C(s_k - s_2) & \cdots & C(\mathbf{0}) \end{pmatrix}$$

Since this covariance matrix is symmetric and positive definite, it has a Cholesky root, and the $Z(s_i), i = 1, \dots, k$, can be simulated as described previously. This is how the SIM2D procedure implements unconditional simulation in the zero-mean case. More generally,

$$Z(s) = \mu(s) + \varepsilon(s)$$

where $\mu(s)$ is a quadratic form in the coordinates $s = (x, y)$ and the $\varepsilon(s)$ is an SRF that has the same covariance matrix \mathbf{C}_Z as previously. In this case, the $\mu(s_i), i = 1, \dots, k$, is computed once and added to the simulated vector $\varepsilon(s_i), i = 1, \dots, k$, for each realization.

For a conditional simulation, this distribution of

$$\mathbf{Z} = \begin{bmatrix} Z(s_1) \\ Z(s_2) \\ \vdots \\ Z(s_k) \end{bmatrix}$$

must be conditioned on the observed data. The relevant general result concerning conditional distributions of multivariate normal random variables is the following. Let $\mathbf{X} \sim N_m(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, where

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \end{bmatrix}$$

$$\boldsymbol{\mu} = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix}$$

$$\boldsymbol{\Sigma} = \begin{pmatrix} \boldsymbol{\Sigma}_{11} & \boldsymbol{\Sigma}_{12} \\ \boldsymbol{\Sigma}_{21} & \boldsymbol{\Sigma}_{22} \end{pmatrix}$$

The subvector \mathbf{X}_1 is $k \times 1$, \mathbf{X}_2 is $n \times 1$, $\boldsymbol{\Sigma}_{11}$ is $k \times k$, $\boldsymbol{\Sigma}_{22}$ is $n \times n$, and $\boldsymbol{\Sigma}_{12} = \boldsymbol{\Sigma}'_{21}$ is $k \times n$, with $k + n = m$. The full vector \mathbf{X} is partitioned into two subvectors, \mathbf{X}_1 and \mathbf{X}_2 , and $\boldsymbol{\Sigma}$ is similarly partitioned into covariances and cross covariances.

With this notation, the distribution of \mathbf{X}_1 conditioned on $\mathbf{X}_2 = \mathbf{x}_2$ is $N_k(\tilde{\boldsymbol{\mu}}, \tilde{\boldsymbol{\Sigma}})$, with

$$\tilde{\boldsymbol{\mu}} = \boldsymbol{\mu}_1 + \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}(\mathbf{x}_2 - \boldsymbol{\mu}_2)$$

and

$$\tilde{\boldsymbol{\Sigma}} = \boldsymbol{\Sigma}_{11} - \boldsymbol{\Sigma}_{12}\boldsymbol{\Sigma}_{22}^{-1}\boldsymbol{\Sigma}_{21}$$

See Searle (1971, pp. 46–47) for details. The correspondence with the conditional spatial simulation problem is as follows. Let the coordinates of the observed data points be denoted $\tilde{s}_1, \tilde{s}_2, \dots, \tilde{s}_n$, with values $\tilde{z}_1, \tilde{z}_2, \dots, \tilde{z}_n$. Let $\tilde{\mathbf{Z}}$ denote the random vector

$$\tilde{\mathbf{Z}} = \begin{bmatrix} Z(\tilde{s}_1) \\ Z(\tilde{s}_2) \\ \vdots \\ Z(\tilde{s}_n) \end{bmatrix}$$

The random vector $\tilde{\mathbf{Z}}$ corresponds to \mathbf{X}_2 , while \mathbf{Z} corresponds to \mathbf{X}_1 . Then $(\mathbf{Z} \mid \tilde{\mathbf{Z}} = \tilde{\mathbf{z}}) \sim N_k(\tilde{\boldsymbol{\mu}}, \tilde{\mathbf{C}})$ as in the previous distribution. The matrix

$$\tilde{\mathbf{C}} = \mathbf{C}_{11} - \mathbf{C}_{12}\mathbf{C}_{22}^{-1}\mathbf{C}_{21}$$

is again positive definite, so a Cholesky factorization can be performed.

The dimension n for $\tilde{\mathbf{Z}}$ is simply the number of nonmissing observations for the **VAR=** variable; the values $\tilde{z}_1, \tilde{z}_2, \dots, \tilde{z}_n$ are the values of this variable. The coordinates $\tilde{s}_1, \tilde{s}_2, \dots, \tilde{s}_n$ are also found in the **DATA=** data set, with the variables that correspond to the x and y coordinates identified in the **COORDINATES** statement. **NOTE:** All **VAR=** variables use the same set of conditioning coordinates; this fixes the matrix \mathbf{C}_{22} for all simulations.

The dimension k for \mathbf{Z} is the number of grid points specified in the **GRID** statement. Since there is a single **GRID** statement, this fixes the matrix \mathbf{C}_{11} for all simulations. Similarly, \mathbf{C}_{12} is fixed.

The Cholesky factorization $\tilde{\mathbf{C}} = \mathbf{L}\mathbf{L}'$ is computed once, as is the mean correction

$$\tilde{\boldsymbol{\mu}} = \boldsymbol{\mu}_1 + \mathbf{C}_{12}\mathbf{C}_{22}^{-1}(\mathbf{x}_2 - \boldsymbol{\mu}_2)$$

The means $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ are computed using the grid coordinates s_1, s_2, \dots, s_k , the data coordinates $\tilde{s}_1, \tilde{s}_2, \dots, \tilde{s}_n$, and the quadratic form specification from the **MEAN** statement. The simulation is now performed exactly as in the unconditional case. A $k \times 1$ vector of independent standard $N(0, 1)$ random variables is generated and multiplied by \mathbf{L} , and $\tilde{\boldsymbol{\mu}}$ is added to the transformed vector. This is repeated N times, where N is the value specified for the **NR=** option.

Computational Details

In the computation of $\tilde{\boldsymbol{\mu}}$ and $\boldsymbol{\Sigma}$ described in the previous section, the inverse $\boldsymbol{\Sigma}_{22}^{-1}$ is never actually computed; an equation of the form

$$\boldsymbol{\Sigma}_{22}\mathbf{A} = \mathbf{B}$$

is solved for \mathbf{A} by using a modified Gaussian elimination algorithm that takes advantage of the fact that $\boldsymbol{\Sigma}_{22}$ is symmetric with constant diagonal $C_z(0)$ that is larger than all off-diagonal elements. The **SINGULAR=** option pertains to this algorithm. The value specified for the **SINGULAR=** option is scaled by $C_z(0)$ before comparison with the pivot element.

Memory Usage

For conditional simulations, the largest matrix held in core memory at any one time depends on the number of grid points and data points. Using the previous notation, the data-data covariance matrix \mathbf{C}_{22} is $n \times n$, where n is the number of nonmissing observations for the **VAR=** variable in the **DATA=** data set. The grid-data cross covariance \mathbf{C}_{12} is $n \times k$, where k is the number of grid points. The grid-grid covariance \mathbf{C}_{11} is $k \times k$. The maximum memory required at any one time for storing these matrices is

$$\max(k(k+1), n(n+1) + 2(n \times k)) \times \text{sizeof(double)}$$

There are additional memory requirements that add to the total memory usage, but usually these matrix calculations dominate, especially when the number of grid points is large.

Output Data Set

The **SIM2D** procedure produces a single output data set: the **OUTSIM=SAS-data-set**. The **OUTSIM=** data set contains all the needed information to uniquely identify the simulated values.

The **OUTSIM=** data set contains the following variables:

- **LABEL**, which is the label for the current **SIMULATE** statement
- **VARNAME**, which is the name of the conditioning variable for the current **SIMULATE** statement
- **MODSVAR**, which is the name of the input item store variable associated with the current correlation model in an unconditional simulation

- `_ITER_`, which is the iteration number within the current `SIMULATE` statement
- `GXC`, which is the x coordinate for the current grid point
- `GYC`, which is the y coordinate for the current grid point
- `SVALUE`, which is the value of the simulated variable

If you specify the `NARROW` option in the `PROC SIM2D` statement, the `LABEL` and `VARNAME` variables are not included in the `OUTSIM=` data set. This option is useful in the case where the number of data points, grid points, and realizations are such that they generate a very large `OUTSIM=` data set. The size of the `OUTSIM=` data set is reduced when these variables are not included.

In unconditional simulation tasks where no input data set is specified, the `VARNAME` variable is excluded from the `OUTSIM=` data set. In unconditional simulation tasks where you have specified an input data set, the `VARNAME` variable is included but given a missing value. In the case of mixed conditional and unconditional simulations (that is, when multiple `SIMULATE` statements are specified, among which one or more contain a `VAR=` specification and one or more have no `VAR=` specification), the `VARNAME` variable is included but is given a missing value for those observations that correspond to an unconditional simulation.

The `MODSVAR` variable is included in the `OUTSIM=` data set only when you specify an input item store with the `RESTORE` statement, and it indicates the presence of that store. This variable helps you identify the output of different unconditional simulations when the model input comes from an item store; it is not suggesting that a simulation task is conditioned upon it.

Specifically, the `MODSVAR` variable has a missing value for conditional simulation tasks. The variable also has a missing value for unconditional simulations for which you specify a correlation model explicitly, either with the `FORM=` option or with the `MDATA=` data set in the `SIMULATE` statement. In all other cases, the `MODSVAR` variable indicates the input item store variable that is associated with the store model used for the current unconditional simulation task.

Displayed Output

In addition to the output data set, the `SIM2D` procedure produces output objects as well. The `SIM2D` procedure output objects are the following:

- a default “Number of Observations” table that displays the number of observations read from the input data set and the number of observations used in the analysis.
- a map that shows the spatial distribution of the observations of the current `VAR` variable in the `SIMULATE` statement, in the case of conditional simulations. The observations are displayed by default with circled markers whose color indicates the `VAR` value at the corresponding location.
- a default table for each `SIMULATE` statement that summarizes the simulation specifications.
- a default table for each `SIMULATE` statement that shows the covariance model parameters for the corresponding simulation.
- plots of simulation outcome at each point of the specified output grid or at specified individual locations. You can produce more than one of these plots for every `SIMULATE` statement with styles that you can specify by using the available suboptions of the `PLOTS=SIM` option.

- a “Store Info” table with basic information about the input item store. This table is produced by default when you specify the **RESTORE** statement.
- a “Store Variables Information” table that describes the analysis variables of an input item store. The table is produced by default when you specify an item store with the **RESTORE** statement.
- a “Store Models Information” table with detailed information about the models and direction angles that are contained in an input item store. The table is produced by default when you specify an item store with the **RESTORE** statement.

ODS Table Names

Each table created by PROC SIM2D has a name associated with it, and you must use this name to reference the table when using ODS Graphics. These names are listed in [Table 85.4](#).

Table 85.4 ODS Tables Produced by PROC SIM2D

ODS Table Name	Description	Statement	Option
ModelInfo	Parameters of the covariance model used in current simulation	PROC	Default output
NObs	Number of observations read and used	PROC	Default output
SimuInfo	General information about the simulation	PROC	Default output
StoreInfo	Input item store identity information	RESTORE	Default output
StoreModelInfo	Input item store direction angles and models information	RESTORE	INFO
StoreVarInfo	Input item store variables and their statistics	RESTORE	INFO

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

For additional control of the graphics that are displayed, see the **PLOTS** option in the section “[PROC SIM2D Statement](#)” on page 7386.

ODS Graph Names

PROC SIM2D assigns a name to each graph it creates by using ODS Graphics. You can use these names to reference the graphs when using ODS Graphics. You must also specify the PLOTS= option indicated in Table 85.5.

Table 85.5 Graphs Produced by PROC SIM2D

ODS Graph Name	Plot Description	Statement	Option
SimulationPlot	Outlines of the observation locations, and either a contour plot of the simulated means and surface of the standard deviation in areal grids, or a band plot of the simulated means or box plot of the simulation distribution in linear grids or individual locations	PROC	PLOTS=SIM
ObservationsPlot	Scatter plot of observed data and colored markers indicating observed values	PROC	PLOTS=OBSERV
Semivariogram	Plots of the semivariogram models used for all simulation tasks	PROC	PLOTS=SEMIVAR

Examples: SIM2D Procedure

Example 85.1: Simulation and Economic Feasibility

You can use simulations to investigate the expected behavior of a stochastic process. Simulations with PROC SIM2D can indicate spatial characteristics in your study that might be important for decision making or general assessment. The present example and the one in section “[Example 85.3: Risk Analysis with Simulation](#)” on page 7423 are two instances of this type of analysis in different fields.

Continuing with the coal seam thickness example from the section “[Getting Started: SIM2D Procedure](#)” on page 7377, this example asks a rather complicated question of economic nature. For illustration, an (approximate) answer is provided, which requires the use of simulation.

Simulating a Subregion for Economic Feasibility

The coal seam must be of a minimum thickness, called a *cutoff value*, for a mining operation to be profitable. Suppose that, for a subregion of the measured area, the cost of mining is higher than in the remaining areas due to the geology of the overburden. This higher cost results in a higher thickness cutoff value for the subregion. Suppose also that it is determined from a detailed cost analysis that at least 60% of the subregion must exceed a seam thickness of 39.7 feet for profitability.

How can you use the SRF model (μ and $C_z(s)$) and the measured seam thickness values $Z(s_i), i = 1, \dots, 75$, to determine, in some approximate way, whether at least 60% of the subregion exceeds this minimum?

Spatial prediction does not appear to be helpful in answering this question. Although it is easy to determine whether a predicted value at a location in the subregion is above the 39.7-foot cutoff value, it is not clear how to incorporate the standard error associated with the predicted value. The standard error is what characterizes the stochastic nature of the prediction (and the underlying SRF). It is clear that it must be included in any realistic approach to the problem.

A conditional simulation, on the other hand, seems to be a natural way of obtaining an approximate answer. By simulating the SRF on a sufficiently fine grid in the subregion, you can determine the proportion of grid points in which the mean value over realizations exceeds the 39.7-foot cutoff and compare it with the 60% value needed for profitability.

It is desirable in any simulation study that the quantity being estimated (in this case, the proportion that exceeds the 39.7-foot cutoff) not depend on the number of simulations performed. For example, suppose that the maximum seam thickness is simulated. It is likely that the maximum value increases as the number of simulations performed increases. Hence, a simulation is not useful for such an estimate. A simulation is useful for determining the *distribution* of the maximum, but there are general theoretical results for such distributions, making such a simulation unnecessary. See Leadbetter, Lindgren, and Rootzen (1983) for details.

In the case of simulating the proportion that exceeds the 39.7-foot cutoff, it is expected that this quantity will settle down to a fixed value as the number of realizations increases. At a fixed grid point, the quantity being compared with the cutoff value is the mean over all simulated realizations; this mean value settles down to a fixed number as the number of realizations increases. In the same manner, the proportion of the grid where the mean values exceed the cutoff also becomes constant. This can be tested using PROC SIM2D.

A crucial, nonprovable assumption in applying SRF theory to the coal seam thickness data is that the values $Z(s_i), i = 1, \dots, 75$, represent a *single* realization from the set of all possible realizations consistent with the SRF model (μ and $C_z(\mathbf{h})$). A conditional simulation repeatedly produces other possible simulated realizations consistent with the model and data. However, the only concern of the mining company is this single unique realization. It is not concerned about similar coal fields to be mined sometime in the future; it might never see another coal field remotely similar to this one, or it might not be in business in the future.

Hence the proportion found by generating repeated simulated realizations must somehow relate back to the unique realization that is the coal field (seam thickness). This is done by interpreting the proportion found from a simulation to the spatial mean proportion for the unique realization. The term “spatial mean” is simply an appropriate integral over the fixed (but unknown) spatial function $z(\mathbf{s})$. (The SRF is denoted $Z(\mathbf{s})$; a particular realization, a deterministic function of the spatial coordinates, is denoted $z(\mathbf{s})$.)

This interpretation requires an ergodic assumption, which is also needed in the original estimation of $C_z(\mathbf{s})$. See Cressie (1993, pp. 53–58) for a discussion of ergodicity and Gaussian SRFs.

Implementation Using PROC SIM2D

The subregion to be considered is the southeast corner of the field, which is a square region with a length of 40 distance units (in thousands of feet). First, you input the thickness data as the following DATA step shows:

```
title 'Simulating a Subregion for Economic Feasibility';

data thick;
  input East North Thick @@;
  label Thick='Coal Seam Thickness';
```

;

```

PROC SIM2D is run on the entire data set for conditioning, while the simulation grid covers only this subregion. It is convenient to be able to vary the seed, the grid increment, and the number of simulations performed. The following macro implements the computation of the percent area that exceeds the cutoff value by using the seed, the grid increment, and the number of simulated realizations as macro arguments.

Within the macro, the data set produced by PROC SIM2D is transposed with PROC TRANSPOSE so that each grid location is a separate variable. The MEANS procedure averages then the simulated value at each grid point over all realizations. It is this average that is compared to the cutoff value. The last DATA step does the comparison, uses an appropriate loop to determine the percent of the grid locations that exceed this cutoff value, and writes the results to the listing file in the form of a report. This sequence is implemented with the following statements:

```

/* Construct macro for conditional simulation -----*/
%let cc0=7.4599;
%let aa0=30.1111;
%let ng1=1e-8;
%let form=gauss;
%let cut=39.7;

%macro area_sim(seed=,nr=,ginc=);
  %let ngrid=%eval(40/%ginc+1);
  %let tgrid=%eval(&ngrid*&ngrid);

  proc sim2d data=thick outsim=sim1;
    coordinates xc=east yc=north;
    simulate var=thick numreal=&nr seed=&seed

```

```

        scale=&cc0 range=&aa0 nugget=&ngt form=&form;
mean 40.1173;
grid x=60 to 100 by &ginc
      y= 0 to 40 by &ginc;
run;

proc transpose data=sim1 out=sim2 prefix=sims;
  by _iter_;
  var svalue;
run;

proc means data=sim2 noprint n mean;
  var sims1-sims&tgrid;
  output out=msim n=numsim mean=ms1-ms&tgrid;
run;

data _null_;
  file print;
  array simss ms1-ms&tgrid;
  set msim;
  cflag=0;
  do ss=1 to &tgrid;
    tempv=simss[ss];
    if simss[ss] > &cut then do;
      cflag + 1;
    end;
  end;
  end;

  area_per=100*(cflag/&tgrid);
  put // +5 'Conditional Simulation of Coal Seam'
      ' Thickness for Subregion';
  put / +5 'Subregion is South-East Corner 40 by 40 distance units';
  put / +5 "Seed:&seed" +2 "Grid Increment:&ginc";
  put / +5 "Total Number of Grid Points:&tgrid" +2
      "Number of Simulations:&nr";
  put / +5 "Percent of Subregion Exceeding Cutoff of %left(&cut) ft.:"
      +2 area_per 5.2;

run;
%mend area_sim;

```

In the following statement, you invoke the macro three times. Each time, the macro is invoked with a different seed and combination of the grid increment and number of simulations. The macro is first invoked with a relatively coarse grid (grid increment of 10 distance units) and a small number of realizations (5). The output of this conditional simulation is shown in [Output 85.1.1](#).

```

/* Execute macro for coarse grid -----*/
%area_sim(seed=12345,nr=5,ginc=10);

```

Output 85.1.1 Conditional Simulation of Coal Seam Thickness on a Coarse Grid

```

      Simulating a Subregion for Economic Feasibility

      Conditional Simulation of Coal Seam Thickness for Subregion

      Subregion is South-East Corner 40 by 40 distance units

      Seed:12345   Grid Increment:10

      Total Number of Grid Points:25   Number of Simulations:5

      Percent of Subregion Exceeding Cutoff of 39.7 ft.:  76.00

```

The next invocation, in the following statement, uses a finer grid and 50 realizations. The output of the second conditional simulation is shown in [Output 85.1.2](#).

```

/* Execute macro for fine grid and fewer simulations -----*/
%area_sim(seed=54321,nr=50,ginc=1);

```

Output 85.1.2 Conditional Simulation of Coal Seam Thickness on a Fine Grid

```

      Simulating a Subregion for Economic Feasibility

      Conditional Simulation of Coal Seam Thickness for Subregion

      Subregion is South-East Corner 40 by 40 distance units

      Seed:54321   Grid Increment:1

      Total Number of Grid Points:1681   Number of Simulations:50

      Percent of Subregion Exceeding Cutoff of 39.7 ft.:  76.09

```

The final invocation, in the following statement, uses the same grid increment and 500 realizations. The output of this conditional simulation is shown in [Output 85.1.3](#).

```

/* Execute macro for fine grid and more simulations -----*/
%area_sim(seed=655311,nr=500,ginc=1);

```

Output 85.1.3 Conditional Simulation of Coal Seam Thickness on a Fine Grid**Simulating a Subregion for Economic Feasibility****Conditional Simulation of Coal Seam Thickness for Subregion****Subregion is South-East Corner 40 by 40 distance units****Seed:655311 Grid Increment:1****Total Number of Grid Points:1681 Number of Simulations:500****Percent of Subregion Exceeding Cutoff of 39.7 ft.: 76.09**

The results from the preceding simulations indicate that about 76% of the subregion exceeds the cutoff value.

NOTE: The number of grid points in the simulation increases with the square of the decrease in the grid increment, leading to long CPU processing times. Increasing the number of realizations results in a linear increase in processing times. Hence, using as coarse a grid as possible allows for more realizations and experimentation with different seeds.

Example 85.2: Variability at Selected Locations

This example exhibits a more detailed investigation of the variation of simulated Thick variable values. You use the same thick data set from the section “[Getting Started: SIM2D Procedure](#)” on page 7377, and you are interested in the simulated values statistics at two selected grid points.

Specifically, you perform a simulation asking for 5,000 realizations (iterations) at two points of the region defined in the section “[Preliminary Spatial Data Analysis](#)” on page 7377. These are the extreme southwest point and a point toward the northeast corner of the region. Since you want to avoid performing the simulation across the whole region, you need to produce a `GDATA=` data set to specify the coordinates of the selected points. These steps are implemented using the following DATA step and statements:

```

title 'Investigation of Random Field Variability';

data thick;
  input East North Thick @@;
  label Thick='Coal Seam Thickness';
  datalines;
    0.7 59.6 34.1 2.1 82.7 42.2 4.7 75.1 39.5

  ;

data grid;
  input xc yc;
  datalines;
    0 0
    75 75
  ;

```

Then, you run PROC SIM2D with the same parameters and characteristics as those shown in the section “[Preliminary Spatial Data Analysis](#)” on page 7377. This time, however, you ask for simulated values only at the two locations you specified in the previous DATA step. The following statements execute the requested simulation:

```

proc sim2d data=thick outsim=sim1;
  coordinates xc=East yc=North;
  simulate var=Thick numreal=5000 seed=79931
    scale=7.4599 range=30.1111 form=gauss;
  mean 40.1173;
  grid gdata=grid xc=xc yc=yc;
run;

```

After the simulation is performed, summary statistics are computed for each of the specified grid points. In particular, you use PROC UNIVARIATE and a BY statement to request the quantiles and the extreme observations at these locations, as the following statements show:

```
proc sort data=sim1;
  by gxc gyc;
run;

proc univariate data=sim1;
  var svalue;
  by gxc gyc;
  ods select Quantiles ExtremeObs;
  title 'Simulation Statistics at Selected Grid Points';
run;
```

The summary statistics for the first grid point (East=0, North=0) are presented in [Output 85.2.1](#).

Output 85.2.1 Simulation Statistics at Grid Point (East=0, North=0)

```

For each simulation location, a single realization might result in values that differ significantly from the random field mean at that location. However, the averages of progressively larger numbers of realizations tend to shorten this gap and reduce the simulation variability, as exhibited in the results for the two example locations in [Output 85.2.1](#) and [Output 85.2.2](#). At the limit of an infinite number of realizations, the simulation mean recovers the mean and covariance structure of the random field.

Example 85.3: Risk Analysis with Simulation

This example is in the field of environmental risk assessment. A square region of size $500 \text{ km} \times 500 \text{ km}$ has been sampled for arsenic in drinking water. The `logAsData` data set consists of 138 simulated arsenic logarithm concentration observations represented by the `logAs` variable. Section “[Example 102.1: Aspects of Semivariogram Model Fitting](#)” on page 8648 in the VARIOGRAM procedure treats these observations as actual data in order to determine the spatial continuity structure for illustration in the examples.

A preliminary analysis indicates that the population exposure to the pollutant is currently at a relatively low level, as shown in the section “[Example 49.1: Spatial Prediction of Pollutant Concentration](#)” on page 3846 in the KRIGE2D procedure. In particular, spatial prediction with kriging suggests that less than 1% of the region is affected by arsenic concentration in water that exceeds the World Health Organization (WHO) standard of $10 \mu\text{g/l}$.

You want to simulate the random field of the arsenic logarithm concentration so that you can gain insight into the characteristics of this field. Your objective is to assess whether the occurrence of above-threshold arsenic concentrations is a localized phenomenon, and whether you might expect more such occurrences across the region. For the simulation you need the outcome of the spatial continuity analysis in section “[Example 102.1: Aspects of Semivariogram Model Fitting](#)” on page 8648 in the VARIOGRAM procedure. These results are the fitted semivariance models that are stored in the `SemivAsStore` item store by PROC VARIOGRAM.

Based on the discussion in the section “[Example 85.1: Simulation and Economic Feasibility](#)” on page 7414, you simulate the arsenic logarithm concentration on the premise of the ergodicity assumption. In brief, this assumption relates the mean and covariances of each individual realization to the corresponding values of the random field; see also the section “[Ergodicity](#)” on page 8615 in the VARIOGRAM procedure. In the present case you are interested in the average of a large size of realizations, rather than individual ones. A single realization could suggest possible locations where the WHO regulatory standard might be violated. The average of multiple realizations has a smoothing effect on individual excessive-concentration episodes in single realizations. The smoothing enables you to see general characteristics of the arsenic concentration field behavior on the basis of its spatial correlation description.

For illustration, assume a rectangular grid of nodes with an equal spacing of 10 km between neighboring nodes in the north and east directions. Then, simulated values are produced at a total of $51 \times 51 = 2601$ locations.

You begin by reading the `logAsData` data set with the following DATA step:

```

;

```

For this simulation you use the spatial correlation information that is saved in the SemivAsStore item store in the section “[Example 102.1: Aspects of Semivariogram Model Fitting](#)” on page 8648 in the VARIOGRAM procedure with the following statements:

```
ods graphics on;

proc variogram data=logAsData plots=none;
  store out=SemivAsStore / label='LogAs Concentration Models';
  compute lagd=5 maxlag=40;
  coord xc=East yc=North;
  model form=auto(mlist=(exp,gau,mat) nest=1 to 2);
  var logAs;
run;
```

In PROC SIM2D you specify the container item store with the **IN=** option of the **RESTORE** statement. You request correlation input from an item store by specifying the **STORESELECT** option in the **SIMULATE** statement. You request 5,000 realizations for this simulation by specifying the number in the **NUMREAL=** option of the **SIMULATE** statement.

Assume that you first want to review the saved models in the item store. Use the **INFO** option of the **RESTORE** statement to produce a table with information about the top-ranking fitted model in the item store. Use the **DET** and **ONLY** suboptions of the **INFO** option to request details about all fitted models included in the item store. The **ONLY** suboption suppresses the simulation tasks and produces only the tables about the item store. You specify the following statements:

```
proc sim2d data=logAsData outsim=Outsim plots=none;
  restore in=SemivAsStore / info(det only);
  coordinates xc=East yc=North;
  simulate var=logAs numreal=5000 storeselect seed=39841;
  grid x=0 to 500 by 10 y=0 to 500 by 10;
run;
```

PROC SIM2D produces a table with general information about the input item store identity, as shown in [Output 85.3.1](#).

Output 85.3.1 PROC SIM2D and Input Item Store General Information

Risk Assessment with Simulation	
The SIM2D Procedure	
Correlation Model Item Store Information	
Input Item Store	WORK.SEMIVASSTORE
Item Store Label	LogAs Concentration Models
Data Set Created From	WORK.LOGASDATA
By-group Information	No By-groups Present
Created By	PROC VARIOGRAM
Date Created	07JUN12:14:11:33

Output 85.3.2 displays the item store variables, in addition to the mean and standard deviation of their data set of origin. In this case, the logAs values come from the logAsData data set. By default, the SIM2D procedure uses the variable mean in the item store for the simulation, unless you explicitly specify the **MEAN** statement.

Output 85.3.2 Variables in the Input Item Store

Item Store Variables		
Variable	Mean	Std Deviation
logAs	0.084309	1.527707

The models in the SemivAsStore item store that have been fitted to the arsenic logarithm logAs empirical semivariance are shown in Output 85.3.3. The default item store model selection is the model on top of the list in Output 85.3.3.

Output 85.3.3 Angle and Models Information in the Input Item Store

Item Store Models For logAs	
Class	Model
1	Gau-Gau Gau-Mat
2	Exp-Gau
3	Exp-Mat
4	Mat
5	Gau
6	Exp Exp-Exp Mat-Exp Gau-Exp

You run again the SIM2D procedure without the **INFO** option in the **RESTORE** statement. This action prompts PROC SIM2D to run the simulation tasks that you specify with the **SIMULATE** statement. You specify the **STORESELECT** option in the **SIMULATE** statement without any suboptions, so that the simulation uses the default model selection in the SemivAsStore item store. You save the simulation output in the Outsim output data set. You also specify the **SIM** and the **SEMIVAR** suboptions in the **PLOTS** option of the **PROC SIM2D** statement to obtain output plots. You use the following statements:

```
proc sim2d data=logAsData outsim=Outsim plots=(sim semivar);
  restore in=SemivAsStore;
  coordinates xc=East yc=North;
  simulate var=logAs numreal=5000 storeselect seed=89702;
  grid x=0 to 500 by 10 y=0 to 500 by 10;
run;
```

NOTE: This step can take several minutes to run, and it produces a data set with over 10 million observations. When you run these statements, PROC SIM2D again produces a table about the input item store identity. This output is followed by a number of observations table and information about the simulation task, as shown in [Output 85.3.4](#).

Output 85.3.4 Number of Observations and Simulation Information Tables

Risk Assessment with Simulation	
The SIM2D Procedure	
Simulation: SIM1, Dependent Variable: logAs	
Number of Observations Read	138
Number of Observations Used	138
Simulation Information	
Simulation Grid Points	2601
Type	Conditional
Number of Realizations	5000

The SIM2D procedure uses the selected fitted Gaussian-Gaussian model in the SemivAsStore item store. [Output 85.3.5](#) shows the saved parameter values of the model that are used in the simulation.

Output 85.3.5 Information about the Gaussian-Gaussian Model

Covariance Model Information	
Nested Structure 1 Type	Gaussian
Nested Structure 1 Sill	0.3276646
Nested Structure 1 Range	62.312728
Nested Structure 1 Effective Range	107.92881
Nested Structure 2 Type	Gaussian
Nested Structure 2 Sill	1.261545
Nested Structure 2 Range	21.459563
Nested Structure 2 Effective Range	37.169053
Nugget Effect	0.0830758

[Output 85.3.6](#) shows a plot of the correlation model used in the simulation. Its parameters come from the stored information in the SemivAsStore item store.

Output 85.3.6 Gaussian-Gaussian Semivariogram Model Used in Simulation

The PLOTS=SIM option produces contours of the mean value of the 5,000 realizations for each one of the output grid locations, and a surface of the associated standard deviation. The resulting plot is shown in [Output 85.3.7](#). The mean value contours exhibit reduced variation compared to a SIM plot of one single realization. In fact, [Output 85.3.7](#) is very similar to the prediction plot of the same Gaussian model in the section “[Example 49.1: Spatial Prediction of Pollutant Concentration](#)” on page 3846 in the KRIGE2D procedure.

Clearly, there appears to be a small area of increased arsenic concentration values, which is located in the central-eastern part of the domain. The WHO threshold of $10 \mu\text{g/l}$ for the maximum allowed arsenic concentration in water translates into about 2.3 in the log scale. The indicated area is the only one within the region where the simulated means exceed the value 3. In addition, there appear to be two smaller areas of simulated means values at or above 2 in the southern part of the region.

Output 85.3.7 Simulated Arsenic Logarithm Values with Gaussian-Gaussian Covariance

The simulation plot indicates that arsenic concentration values in excess of the WHO health standard is a rather localized phenomenon. If it were not so, then the plot would suggest that increased arsenic concentrations extend across larger areas. In turn, this means that individual realizations would tend to produce systematically higher arsenic concentrations at different neighboring locations, and their average would appear as higher logAs values in the **SIM** plot. Instead, you conclude that the Gaussian-Gaussian correlation that describes the spatial continuity for the arsenic logarithm observations leads to only localized occurrence of the WHO standard violation.

Now you want to find out whether additional localized occurrences might take place on the basis of the Gaussian-Gaussian spatial continuity behavior. The distribution of the simulation standard deviation values in **Output 85.3.7** offers important feedback about this issue. Observe the areas in the plot where the means gradient indicates increasing values. The means contours create several pools where the values increase to simulated means higher than 1.

With the clear exceptions of the isolated area in the central-eastern part of the domain and the pool in the south-west that exhibit logAs values above 2, the simulation standard deviation seems to be around 1 or less in almost all other pools with logAs values above 1. Due to those relatively low standard deviations, this visual inspection suggests that even in individual realizations you might rarely expect the arsenic logarithm to exceed the threshold value of around 2.3.

However, in the few pools of logAs values above 1, there can be patches of increased standard deviation. In these cases, you suspect that arsenic concentration could exceed occasionally the WHO regulatory standard, even if the plot of the simulated means does not explicitly portray so.

Based on these remarks, you want to quantify the percentage of the region that could be affected by excessive arsenic concentration. You begin with a DATA step that takes as input the simulation Outsim output data set. The DATA step marks the simulated arsenic logarithm means values that are in excess of the WHO concentration threshold of 10 $\mu\text{g/l}$ t, and saves the outcome into an indicator variable OverLimit. At the same time, the arsenic logarithm values are transformed back into arsenic concentration values so that they can be compared to the threshold value. The simulated means in the Outsim data set are stored in the svalue variable. You use the following statements:

```
data AsOverLimit;
    set Outsim;
    OverLimit = (exp(svalue) > 10) * 100;
run;
```

Then, you use the MEANS procedure to express the selected nodes population (where the WHO standard violation occurs) as a percentage of the entire domain area. You invoke PROC MEANS twice. The first time, you average over each realization in the PROC SIM2D output. For that purpose, you use the variable `_ITER_` in the simulation sim1 output data set as a BY variable in PROC MEANS. You save the iteration-averaged indicator values in the PctOverLimit variable. The second time, PROC MEANS averages the PctOverLimit variable to obtain the percentage you want. You also specify the P5 and P95 options in the PROC MEANS statement to request the lower and upper confidence limits, respectively, in this computation. The interval between those limits expresses the 90% interval for the true area percentage based on the stochastic simulation. You use the following statements:

```
proc means data=AsOverLimit noprint;
    by _ITER_;
    var OverLimit;
    output out=OverLimitData mean=PctOverLimit;
run;
proc means data=OverLimitData mean p5 p95;
    var PctOverLimit;
    label PctOverLimit="Percent above threshold";
run;
```

The result is shown in [Output 85.3.8](#). PROC MEANS accounts for all individual occurrences throughout the simulation where the WHO arsenic concentration threshold is exceeded. This happens at about 3.9% of the total area in 5,000 realizations. Compare this value to the less than 1% percentage in the PROC KRIGE2D prediction, as reported in the beginning of this section. On one hand, the prediction outcome tells you what goes on currently across the region within a degree of certainty given by the prediction error. On the other hand, the simulation provides you with an indicator that under the given spatial continuity estimate a relatively larger area is in potential danger of being affected by above-threshold arsenic concentration.

In fact, the 5% and 95% confidence limits in [Output 85.3.8](#) show the area percentage limits within which you can expect excessive arsenic concentration. Based on the stochastic simulation, at the 90% confidence level the arsenic concentration in drinking water is expected to violate the WHO regulatory standard in anywhere from about 2.6% to 5.4% of the study region.

Output 85.3.8 Violation of Arsenic Concentration Threshold Using Gaussian-Gaussian Model

Risk Assessment with Simulation		
The MEANS Procedure		
Analysis Variable : PctOverLimit Percent above threshold		
Mean	5th Pctl	95th Pctl
3.9308727	2.6143791	5.4209919

You also want to compute the probability that individual areas in the region are expected to violate the WHO arsenic concentration standard. Start by identifying again the simulated arsenic logarithm means values in excess of the WHO concentration threshold of 10 $\mu\text{g}/\text{lt}$. The following DATA step saves the outcome into the variable LocalOverLimit:

```
data LocalAsOverLimit;
  set Outsim;
  LocalOverLimit = (exp(svalue) > 10);
run;
```

Then you use the SORT procedure to sort the information based on location coordinates. This intermediate step is necessary so that you can use the MEANS procedure with the LocalAsOverLimit data set. In the following statements, PROC MEANS computes the expected violations of the WHO standard for each location in the region across all realizations of the simulation:

```
proc sort data=LocalAsOverLimit;
  by gxc gyc;
run;
proc means data=LocalAsOverLimit noprint;
  by gxc gyc;
  var LocalOverLimit;
  output out=OverLimLocl mean=ProbOverLimit;
run;
```

The output is the probability that the WHO standard is violated at each one of the simulation locations across the region. You create a plot of this probability with the help of the TEMPLATE and the SGRENDER procedures. You use the following statements:

```

proc template;
  define statgraph surfacePlot;
    dynamic _VARX _VARY _VAR _TITLE _LEGENDLABEL;
    BeginGraph;
    entrytitle _TITLE;
    layout overlay /
      xaxisopts = (offsetmax=0)
      yaxisopts = (offsetmax=0);
    contourplotparm x=_VARX y=_VARY z=_VAR /
      nhint=10 name='probplot';
    continuouslegend 'probplot' / title=_LEGENDLABEL;
    endlayout;
    EndGraph;
  end;
run;

```

Output 85.3.9 shows the map of probability that the arsenic concentration WHO standard is violated in the region for the selected spatial correlation model of the pollutant. Based on the preceding analysis, the probability is very close to 1 in the area where the simulation mean values are above the standard limit. A few more areas that were indicated earlier in the analysis suggest a violation probability between 20% and 40%. The remaining areas in the region exhibit very low probability, which is notably nonzero at a few scattered locations. These findings suggest that throughout the simulation there have been realizations where the arsenic WHO standard was exceeded at locations whose simulated mean is well below that standard.

From the environmental risk assessment perspective, the preceding analysis can trigger a more detailed investigation into areas in the region where the health standard might be violated. Although the original observations in the logAsData data set indicate no existing problem in some of these areas, the present example illustrates that spatial analysis and simulation can raise flags of caution. This type of analysis can help to focus scientific, management, and policy efforts on these particular areas of the region and to monitor closely the pollutant concentration for potential health risks.

Output 85.3.9 Map of Violation of the Arsenic WHO Standard Probability

Overview: SIMNORMAL Procedure

The SIMNORMAL procedure can perform conditional and unconditional simulation for a set of correlated normal or Gaussian random variables.

The means, variances, and covariances (or correlations) are read from an input TYPE=CORR or TYPE=COV data set. This data set is typically produced by the CORR procedure. Conditional simulations are performed by appending a special observation, identified by the value of 'COND' for the _TYPE_ variable, which contains the conditioning value.

The output data set from PROC SIMNORMAL contains simulated values for each of the analysis variables. Optionally, the output data set also contains the seed stream and the values of the conditioning variables. PROC SIMNORMAL produces no printed output.

Getting Started: SIMNORMAL Procedure

The following example illustrates the use of PROC SIMNORMAL to generate variable values conditioned on a set of related or correlated variables.

Suppose you are given a sample of size 50 from ten normally distributed, correlated random variables, $IN_{1,i}, \dots, IN_{5,i}, OUT_{1,i}, \dots, OUT_{5,i}, i = 1, \dots, 50$. The first five variables represent input variables for a chemical manufacturing process, and the last five are output variables.

First, the data are input and the correlation structure is determined by using PROC CORR, as in the following statements. The results are shown in Figure 86.1.

```
data a ;
  input in1-in5 out1-out5 ;
  datalines ;

After the mean and correlation structure are determined, any subset of these variables can be simulated. Suppose you are interested in a particular function of the output variables for two sets of values of the input variables for the process. In particular, you are interested in the mean and variability of the following function over 500 runs of the process conditioned on each set of input values:

$$f(out_1, \dots, out_5) = \frac{out_1 - out_3}{out_1 + out_2 + out_3 + out_4 + out_5}$$

Although the distribution of these quantities could be determined theoretically, it is simpler to perform a conditional simulation by using PROC SIMNORMAL.

To do this, you first append a `_TYPE_='COND'` observation to the covariance data set produced by PROC CORR for each group of input values:

```
data cond1 ;
  _TYPE_='COND' ;
  in1 = 8 ;
  in2 = 10.5 ;
  in3 = 12 ;
  in4 = 13.5 ;
  in5 = 14.4 ;
  output ;
run ;

data cond2 ;
  _TYPE_='COND' ;
  in1 = 15.4 ;
  in2 = 13.7 ;
  in3 = 11 ;
  in4 = 7.9 ;
  in5 = 5.5 ;
  output ;
run ;
```

Next, each of these conditioning observations is appended to a copy of the `OUTP=OUTCOV` data from the CORR procedure, as in the following statements. A new variable, `INPUT`, is added to distinguish the sets of input values. This variable is used as a `BY` variable in subsequent steps.

```
data outcov1 ;
  input=1 ;
  set outcov cond1 ;
run ;

data outcov2 ;
  input=2 ;
  set outcov cond2 ;
run ;
```

Finally, these two data sets are concatenated:

```
data outcov ;
  set outcov1 outcov2 ;
run ;
proc print data=outcov ;
  where (_type_ ne 'COV') ;
run ;
```

Figure 86.2 shows the added observations.

26	1.2676	0.8983	0.9641	1.3555	0.9126	0.8353	
27	50.0000	50.0000	50.0000	50.0000	50.0000	50.0000	
28	5.5000	

You now run PROC SIMNORMAL, specifying the input data set and the VAR and COND variables. Note that you must specify a TYPE=COV or TYPE=CORR for the input data set. PROC CORR automatically assigns a TYPE=COV or TYPE=CORR attribute for the OUTP= data set. However, since the intermediate DATA steps that appended the _TYPE_='COND' observations turned off this attribute, an explicit TYPE=CORR in the DATA= option in the PROC SIMNORMAL statement is needed.

The specification of PROC SIMNORMAL now follows from the problem description. The condition variables are IN1–IN5, the analysis variables are OUT1–OUT5, and 500 realizations are required. A seed value can be chosen arbitrarily, or the system clock can be used. Note that in the following statements, the simulation is done for each of the values of the BY variable INPUT:

```
proc simnormal data=outcov(type=cov)
    out = osim
    numreal = 500
    seed = 33179
    ;
    by input ;
    var out1-out5 ;
    cond in1-in5 ;
run;

data b;
    set osim ;
    denom = sum(of out1-out5) ;
    if abs(denom) < 1e-8 then ff = . ;
    else ff = (out1-out3)/denom ;
run ;
```

The DATA step that follows the simulation computes the function $f(out_1, \dots, out_5)$; in the following statements the UNIVARIATE procedure computes the simple statistics for this function for each set of conditioning input values. This is shown in Figure 86.3, and Figure 86.4 shows the distribution of the function values for each set of input values by using the SGPanel procedure.

```
proc univariate data=b ;
  by input ;
  var ff ;
run ;
title ;
proc sgpanel data=b ;
  panelby input ;
  REFLINE 0 / axis= x ;
  density ff ;
run ;
```

Figure 86.4 Frequency Plot for ff for Each Set of Input Values

Syntax: SIMNORMAL Procedure

The following statements are available in the SIMNORMAL procedure:

```
PROC SIMNORMAL DATA=SAS-data-set < options > ;
    VAR variables ;
    BY variables ;
    CONDITION variables ;
```

Both the PROC SIMNORMAL and VAR statements are required. The following statements can be used with the SIMNORMAL procedure:

PROC SIMNORMAL Statement

```
PROC SIMNORMAL DATA=SAS-data-set < options > ;
```

The PROC SIMNORMAL statement invokes the SIMNORMAL procedure. Table 86.1 summarizes the options available in the PROC SIMNORMAL statement.

Table 86.1 Summary of PROC SIMNORMAL Statement Options

Option	Description
Specify Input and Output Data Sets	
DATA=	Specifies input data set (TYPE=CORR, COV, and so on)
OUT=	Creates output data set that contains simulated values
Seed Values	
SEED=	Specifies seed value (integer)
SEEDBY	Requests reinitialization of seed for each BY group
Control Contents of OUT= Data Set	
OUTSEED	Requests seed values written to OUT= data set
OUTCOND	Requests conditioning variable values written to OUT=data set
Control Number of Simulated Values	
NUMREAL=	Specifies the number of realizations for each BY group written to the OUT= data set
Singularity Criteria	
SINGULAR1=	Sets the singularity criterion for Cholesky decomposition
SINGULAR2=	Sets the singularity criterion for covariance matrix sweeping

The following options can be used with the PROC SIMNORMAL statement.

DATA=SAS-data-set

specifies the input data set that must be a specially structured TYPE=CORR, COV, UCORR, UCOV, or SSCP SAS data set. If the DATA= option is omitted, the most recently created SAS data set is used.

SEED=seed-value

specifies the seed to use for the random number generator. If the SEED= value is omitted, the system clock is used. If the system clock is used, a note is written to the log; the note gives the seed value based on the system clock. In addition, the random seed stream is copied to the OUT= data set if the OUTSEED option is specified.

SEEDBY

specifies that the seed stream be reinitialized for each BY group. By default, a single random stream is used over all BY groups. If you specify SEEDBY, the random stream starts again at the initial seed value. This initial value is from the SEED= value that you specify. If you do not specify a SEED=value, the system clock generates this initial seed.

For example, suppose you had a TYPE=CORR data set with BY groups, and the mean, variances, and covariance or correlation values were identical for each BY group. Then if you specified SEEDBY, the simulated values in each BY group in the OUT= data set would be identical.

OUT=SAS-data-set

specifies a SAS data set in which to store the simulated values for the VAR variables. If you omit the OUT=option, the output data set is created and given a default name by using the DATA n convention.

See the section “[OUT= Output Data Set](#)” on page 7446 for details.

NUMREAL= n

specifies the number of realizations to generate. A value of NUMREAL=500 generates 500 observations in the OUT=dataset, or 500 observations within each BY group if a BY statement is given.

NUMREAL can be abbreviated as NUMR or NR.

OUTSEED

requests that the seed values be included in the OUT= data set. The variable Seed is added to the OUT= data set. The first value of Seed is the SEED= value specified in the PROC SIMNORMAL statement (or obtained from the system clock); subsequent values are produced by the random number generator.

OUTCOND

requests that the values of the conditioning variables be included in the OUT= data set. These values are constant for the data set or within a BY group. Note that specifying OUTCOND can greatly increase the size of the OUT= data set. This increase depends on the number of conditioning variables.

SINGULAR1=number

specifies the first singularity criterion, which is applied to the Cholesky decomposition of the covariance matrix. The SINGULAR1= value must be in the range (0, 1). The default value is 10^{-8} . SINGULAR1 can be abbreviated SING1.

SINGULAR2=number

specifies the second singularity criterion, which is applied to the sweeping of the covariance or correlation matrix to obtain the conditional covariance. The SINGULAR2=option is applicable only when a CONDITION statement is given. The SINGULAR2= value must be in the range (0, 1). The default value is 10^{-8} . SINGULAR2 can be abbreviated SING2.

BY Statement

BY variables ;

A BY statement can be used with the SIMNORMAL procedure to obtain separate simulations for each covariance structure defined by the BY variables. When a BY statement appears, the procedure expects the input DATA= data set to be sorted in the order of the BY variables. If a CONDITION statement is used along with a BY statement, there must be a _TYPE_='COND' observation within each BY group. Note that if a BY statement is specified, the number of realizations specified by the NUMREAL= option are produced for each BY group.

CONDITION Statement

CONDITION | COND variables ;

A **CONDITION** statement specifies the conditioning variables. The presence of a **CONDITION** statement requests that a conditional simulation be performed.

The lack of a **CONDITIONAL** statement simply means that an unconditional simulation for the **VAR** variables is to be performed.

If a **CONDITION** statement is given, the variables listed must be numeric variables in the **DATA=** data set. This requires a conditioning value for each of the **CONDITION** variables. This value is supplied by adding a **_TYPE_='COND'** observation for each **CONDITION** variable. Such observations are added to the **DATA=** data set by a **DATA** step.

Note that a data set created by the **CORR** procedure is automatically given the **TYPE=COV**, **UCOV**, **CORR**, or **UCORR** attribute, so you do not have to specify the **TYPE=** option in the **DATA=** option in the **PROC SIMNORMAL** statement. However, when adding the conditioning values by using a **DATA** step with a **SET** statement, you must use the **TYPE=COV**, **UCOV**, **CORR**, or **UCORR** attribute in the new data set. See the section “[Getting Started: SIMNORMAL Procedure](#)” on page 7435 for an example in which the **TYPE** is set.

VAR Statement

VAR *variables* ;

Use the **VAR** statement to specify the analysis variables. Only numeric variables can be specified. If a **VAR** statement is not given, all numeric variables in the **DATA=** data set that are not in the **CONDITION** or **BY** statement are used.

OUT= Output Data Set

The **SIMNORMAL** procedure produces a single output data set: the **OUT=SAS-data-set**.

The **OUT=** data set contains the following variables:

- all variables listed in the **VAR** statement
- all variables listed in the **BY** statement, if one is given
- **Rnum**, which is the realization number within the current **BY** group
- **Seed**, which is current seed value, if the **OUTSEED** option is specified
- all variables listed in the **CONDITION** statement, if a **CONDITION** statement is given and the **OUTCOND** option is specified

The number of observations is determined by the value of the **NUMREAL=** option. If there are no **BY** groups, the number of observations in the **OUT=** data set is equal to the value of the **NUMREAL=** option. If there are **BY** groups, there are number of observations equals the value of the **NUMREAL=** option for each **BY** group.

Computational Details: SIMNORMAL Procedure

Introduction

There are a number of approaches to simulating a set of dependent random variables. In the context of spatial random fields, these include sequential indicator methods, turning bands, and the Karhunen-Loeve expansion. See Christakos (1992, Chapter 8) and Deutsch and Journel (1992, Chapter 5) for details.

In addition, there is the LU decomposition method, a particularly simple and computationally efficient for normal or Gaussian variates. For a given covariance matrix, the $\mathbf{LU} = \mathbf{LL}'$ decomposition is computed once, and the simulation proceeds by repeatedly generating a vector of independent $N(0, 1)$ random variables and multiplying by the \mathbf{L} matrix.

One problem with this technique is that memory is required to hold the covariance matrix of all the analysis and conditioning variables in core.

Unconditional Simulation

It is a simple matter to produce an $N(0, 1)$ random number, and by stacking k such numbers in a column vector you obtain a vector with independent standard normal components $\mathbf{W} \sim N_k(\mathbf{0}, \mathbf{I})$. The meaning of the terms *independence* and *randomness* in the context of a deterministic algorithm required for the generation of these numbers is somewhat subtle; see Knuth (1973, Vol. 2, Chapter 3) for a discussion of these issues.

Rather than $\mathbf{W} \sim N_k(\mathbf{0}, \mathbf{I})$, what is required is the generation of a vector $\mathbf{Z} \sim N_k(\mathbf{0}, \mathbf{V})$ —that is,

$$\mathbf{Z} = \begin{bmatrix} Z_1 \\ Z_2 \\ \vdots \\ Z_k \end{bmatrix}$$

with covariance matrix

$$\mathbf{V} = \begin{pmatrix} \sigma_{11} & \sigma_{12} & \cdots & \sigma_{1k} \\ \sigma_{21} & \sigma_{22} & \cdots & \sigma_{2k} \\ & \ddots & & \\ \sigma_{k1} & \sigma_{k2} & \cdots & \sigma_{kk} \end{pmatrix}$$

where

$$\sigma_{ij} = \text{Cov}(Z_i, Z_j)$$

If the covariance matrix is symmetric and positive definite, it has a Cholesky root \mathbf{L} such that \mathbf{V} can be factored as

$$\mathbf{V} = \mathbf{L}\mathbf{L}'$$

where \mathbf{L} is lower triangular. See Ralston and Rabinowitz (1978, Chapter 9, Section 3-3) for details. This vector \mathbf{Z} can be generated by the transformation $\mathbf{Z} = \mathbf{L}\mathbf{W}$. Note that this is where the assumption of multivariate normality is crucial. If $\mathbf{W} \sim N_k(\mathbf{0}, \mathbf{I}_k)$, then $\mathbf{Z} = \mathbf{L}\mathbf{W}$ is also normal or Gaussian. The mean of \mathbf{Z} is

$$\mathbf{E}(\mathbf{Z}) = \mathbf{L}(\mathbf{E}(\mathbf{W})) = \mathbf{0}$$

and the variance is

$$\text{Var}(\mathbf{Z}) = \text{Var}(\mathbf{L}\mathbf{W}) = \mathbf{E}(\mathbf{L}\mathbf{W}\mathbf{W}'\mathbf{L}') = \mathbf{L} \mathbf{E}(\mathbf{W}\mathbf{W}') \mathbf{L}' = \mathbf{L}\mathbf{L}' = \mathbf{V}$$

Finally, let $Y_k = Z_k + \mu_k$; that is, you add a mean term to each variable Z_k . The covariance structure of the Y_k 's remains the same. Unconditional simulation is done by simply repeatedly generating k $N(0, 1)$ random numbers, stacking them, and performing the transformation

$$\mathbf{W} \mapsto \mathbf{Z} = \mathbf{L}\mathbf{W} \mapsto \mathbf{Y} = \mathbf{Z} + \boldsymbol{\mu}$$

Conditional Simulation

For a conditional simulation, this distribution of

$$\mathbf{Y} = \begin{bmatrix} Y_1 \\ Y_2 \\ \vdots \\ Y_k \end{bmatrix}$$

must be conditioned on the values of the CONDITION variables. The relevant general result concerning conditional distributions of multivariate normal random variables is the following. Let $\mathbf{X} \sim N_m(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, where

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \end{bmatrix}$$

$$\boldsymbol{\mu} = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix}$$

$$\boldsymbol{\Sigma} = \begin{pmatrix} \boldsymbol{\Sigma}_{11} & \boldsymbol{\Sigma}_{12} \\ \boldsymbol{\Sigma}_{21} & \boldsymbol{\Sigma}_{22} \end{pmatrix}$$

and where bX_1 is $k \times 1$, X_2 is $n \times 1$, Σ_{11} is $k \times k$, Σ_{22} is $n \times n$, and $\Sigma_{12} = \Sigma'_{21}$ is $k \times n$, with $k + n = m$. The full vector \mathbf{X} has simply been partitioned into two subvectors, \mathbf{X}_1 and \mathbf{X}_2 , and Σ has been similarly partitioned into covariances and cross covariances.

With this notation, the distribution of \mathbf{X}_1 conditioned on $\mathbf{X}_2 = x_2$ is $N_k(\tilde{\mu}, \tilde{\Sigma})$, with

$$\tilde{\mu} = \mu_1 + \Sigma_{12}\Sigma_{22}^{-1}(x_2 - \mu_2)$$

and

$$\tilde{\Sigma} = \Sigma_{11} - \Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}$$

See Searle (1971, pp. 46–47) for details.

Using the SIMNORMAL procedure corresponds with the conditional simulation as follows. Let Y_1, \dots, Y_k be the VAR variables as before (k is the number of variables in the VAR list). Let the mean vector for \mathbf{Y} be denoted by $\mu_1 = E(\mathbf{Y})$. Let the CONDITION variables be denoted by C_1, \dots, C_n (where n is the number of variables in the COND list). Let the mean vector for \mathbf{C} be denoted by $\mu_2 = E(\mathbf{C})$ and the conditioning values be denoted by

$$\mathbf{c} = \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_n \end{bmatrix}$$

Then stacking

$$\mathbf{X} = \begin{bmatrix} \mathbf{Y} \\ \mathbf{C} \end{bmatrix}$$

the variance of \mathbf{X} is

$$\mathbf{V} = \text{Var}(\mathbf{X}) = \Sigma = \begin{pmatrix} \mathbf{V}_{11} & \mathbf{V}_{12} \\ \mathbf{V}_{21} & \mathbf{V}_{22} \end{pmatrix}$$

where $\mathbf{V}_{11} = \text{Var}(\mathbf{Y})$, $\mathbf{V}_{12} = \text{Cov}(\mathbf{Y}, \mathbf{C})$, and $\mathbf{V}_{22} = \text{Var}(\mathbf{C})$. By using the preceding general result, the relevant covariance matrix is

$$\tilde{\mathbf{V}} = \mathbf{V}_{11} - \mathbf{V}_{12}\mathbf{V}_{22}^{-1}\mathbf{V}_{21}$$

and the mean is

$$\tilde{\mu} = \mu_1 + \mathbf{V}_{12}\mathbf{V}_{22}^{-1}(\mathbf{c} - \mu_2)$$

By using $\tilde{\mathbf{V}}$ and $\tilde{\mu}$, simulating $(\mathbf{Y}|\mathbf{C} = \mathbf{c}) \sim N_k(\tilde{\mu}, \tilde{\mathbf{V}})$ now proceeds as in the unconditional case.

Overview: STDIZE Procedure

The STDIZE procedure standardizes one or more numeric variables in a SAS data set by subtracting a location measure and dividing by a scale measure. A variety of location and scale measures are provided, including estimates that are resistant to outliers and clustering. Some of the well-known standardization methods such as mean, median, standard deviation, range, Huber's estimate, Tukey's biweight estimate, and Andrew's wave estimate are available in the STDIZE procedure.

In addition, you can multiply each standardized value by a constant and add a constant. Thus, the final output value is

$$result = add + multiply \times \frac{original - location}{scale}$$

where

result = final output value
add = constant to add (ADD= option)
multiply = constant to multiply by (MULT= option)
original = original input value
location = location measure
scale = scale measure

PROC STDIZE can also find quantiles in one pass of the data, a capability that is especially useful for very large data sets. With such data sets, the UNIVARIATE procedure might have high or excessive memory or time requirements.

Getting Started: STDIZE Procedure

The following example demonstrates how you can use the STDIZE procedure to obtain location and scale measures of your data.

In the following hypothetical data set, a random sample of grade twelve students is selected from a number of coeducational schools. Each school is classified as one of two types: Urban or Rural. There are 40 observations.

The variables are id (student identification), Type (type of school attended: 'urban'=urban area and 'rural'=rural area), and total (total assessment scores in History, Geometry, and Chemistry).

The following DATA step creates the SAS data set TotalScores.

```
data TotalScores;
  title 'High School Scores Data';
  input id Type $ total @@;
  datalines;
1 rural 135    2 rural 125    3 rural 223    4 rural 224    5 rural 133
6 rural 253    7 rural 144    8 rural 193    9 rural 152   10 rural 178
11 rural 120   12 rural 180   13 rural 154   14 rural 184   15 rural 187
16 rural 111   17 rural 190   18 rural 128   19 rural 110   20 rural 217
21 urban 192   22 urban 186   23 urban  64   24 urban 159   25 urban 133
26 urban 163   27 urban 130   28 urban 163   29 urban 189   30 urban 144
31 urban 154   32 urban 198   33 urban 150   34 urban 151   35 urban 152
36 urban 151   37 urban 127   38 urban 167   39 urban 170   40 urban 123
;
```

Suppose you now want to standardize the total scores in different types of schools prior to any further analysis. Before standardizing the total scores, you can use the box plot from PROC BOXPLOT to summarize the total scores for both types of schools.

```
ods graphics on;  
proc boxplot data=TotalScores;  
  plot total*Type / boxstyle=schematic noserifs;  
run;
```

The PLOT statement in the PROC BOXPLOT statement creates the schematic plots (without the serifs) when you specify **boxstyle=schematic noserifs**. Figure 87.1 displays a box plot for each type of school.

Figure 87.1 Schematic Plots from PROC BOXPLOT

Inspection reveals that one urban score is a low outlier. Also, if you compare the lengths of two box plots, there seems to be twice as much dispersion for the rural scores as for the urban scores.

The following PROC UNIVARIATE statement reports the information about the extreme values of the Score variable for each type of school:

```
proc univariate data=TotalScores;
  var total;
  by Type;
run;
```

Figure 87.2 displays the table from PROC UNIVARIATE for the lowest and highest five total scores for urban schools. The outlier (Obs = 23), marked in Figure 87.2 by the symbol '0', has a score of 64.

Figure 87.2 Table for Extreme Observations When Type=urban

High School Scores Data			
----- Type=urban -----			
The UNIVARIATE Procedure			
Variable: total			
Extreme Observations			
----Lowest----		----Highest---	
Value	Obs	Value	Obs
64	23	170	39
123	40	186	22
127	37	189	29
130	27	192	21
133	25	198	32

The following PROC STDIZE procedure requests the METHOD=STD option for computing the location and scale measures:

```
proc stdize data=totalscores method=std pstat;
  title2 'METHOD=STD';
  var total;
  by Type;
run;
```

Figure 87.3 displays the table of location and scale measures from the PROC STDIZE statement. PROC STDIZE uses the sample mean as the location measure and the sample standard deviation as the scale measure for standardizing. The PSTAT option displays a table containing these two measures.

Figure 87.3 Location and Scale Measures Table When METHOD=STD

High School Scores Data METHOD=STD			
----- Type=rural -----			
The STDIZE Procedure			
Location and Scale Measures			
Location = mean		Scale = standard deviation	
Name	Location	Scale	N
total	167.050000	41.956713	20
High School Scores Data METHOD=STD			
----- Type=urban -----			
The STDIZE Procedure			
Location and Scale Measures			
Location = mean		Scale = standard deviation	
Name	Location	Scale	N
total	153.300000	30.066768	20

The ratio of the scale of rural scores to the scale of urban scores is approximately 1.4 (41.96/30.07). This ratio is smaller than the dispersion ratio observed in the previous schematic plots.

The STDIZE procedure provides several location and scale measures that are resistant to outliers. The following statements invoke three different standardization methods and display the tables for the location and scale measures:

```
proc stdize data=totalscores method=mad pstat;
  title2 'METHOD=MAD';
  var total;
  by Type;
run;

proc stdize data=totalscores method=iqr pstat;
  title2 'METHOD=IQR';
  var total;
  by Type;
run;
```

```

proc stdize data=totalscores method=abw(4) pstat;
  title2 'METHOD=ABW(4)';
  var total;
  by Type;
run;

```

Figure 87.4 displays the table of location and scale measures when the standardization method is median absolute deviation (MAD). The location measure is the median, and the scale measure is the median absolute deviation from the median. The ratio of the scale of rural scores to the scale of urban scores is approximately 2.06 (32.0/15.5) and is close to the dispersion ratio observed in the previous schematic plots.

Figure 87.4 Location and Scale Measures Table When METHOD=MAD

High School Scores Data METHOD=MAD			
----- Type=rural -----			
The STDIZE Procedure			
Location and Scale Measures			
Location = median		Scale = median abs dev from median	
Name	Location	Scale	N
total	166.000000	32.000000	20
High School Scores Data METHOD=MAD			
----- Type=urban -----			
The STDIZE Procedure			
Location and Scale Measures			
Location = median		Scale = median abs dev from median	
Name	Location	Scale	N
total	153.000000	15.500000	20

Figure 87.5 displays the table of location and scale measures when the standardization method is IQR. The location measure is the median, and the scale measure is the interquartile range. The ratio of the scale of rural scores to the scale of urban scores is approximately 2.03 (61/30) and is, in fact, the dispersion ratio observed in the previous schematic plots.

Figure 87.5 Location and Scale Measures Table When METHOD=IQR

High School Scores Data METHOD=IQR			
----- Type=rural -----			
The STDIZE Procedure			
Location and Scale Measures			
Location = median		Scale = interquartile range	
Name	Location	Scale	N
total	166.000000	61.000000	20
High School Scores Data METHOD=IQR			
----- Type=urban -----			
The STDIZE Procedure			
Location and Scale Measures			
Location = median		Scale = interquartile range	
Name	Location	Scale	N
total	153.000000	30.000000	20

Figure 87.6 displays the table of location and scale measures when the standardization method is ABW, for which the location measure is the biweight one-step M-estimate, and the scale measure is the biweight A-estimate. Note that the initial estimate for ABW is MAD. The following steps help to decide the value of the tuning constant:

1. For rural scores, the location estimate for MAD is 166.0, and the scale estimate for MAD is 32.0. The maximum of the rural scores is 253 (not shown), and the minimum is 110 (not shown). Thus, the tuning constant needs to be 3 so that it does not reject any observation that has a score between 110 to 253.
2. For urban scores, the location estimate for MAD is 153.0, and the scale estimate for MAD is 15.5. The maximum of the rural scores is 198, and the minimum (also an outlier) is 64. Thus, the tuning constant needs to be 4 so that it rejects the outlier (64) but includes the maximum (198) as a normal observation.
3. The maximum of the tuning constants, obtained in steps 1 and 2, is 4.

See Goodall (1983, Chapter 11) for details about the tuning constant. The ratio of the scale of rural scores to the scale of urban scores is approximately 2.06 (32.0/15.5). It is also close to the dispersion ratio observed in the previous schematic plots.

Figure 87.6 Location and Scale Measures Table When METHOD=ABW

High School Scores Data METHOD=ABW(4)			
----- Type=rural -----			
The STDIZE Procedure			
Location and Scale Measures			
Location = biweight 1-step M-estimate		Scale = biweight A-estimate	
Name	Location	Scale	N
total	162.889603	56.662855	20
High School Scores Data METHOD=ABW(4)			
----- Type=urban -----			
The STDIZE Procedure			
Location and Scale Measures			
Location = biweight 1-step M-estimate		Scale = biweight A-estimate	
Name	Location	Scale	N
total	156.014608	28.615980	20

The preceding analysis shows that METHOD=MAD, METHOD=IQR, and METHOD=ABW all provide better dispersion ratios than METHOD=STD does.

You can recompute the standard deviation after deleting the outlier from the original data set for comparison. The following statements create a data set NoOutlier that excludes the outlier from the TotalScores data set and invoke PROC STDIZE with METHOD=STD.

```
data NoOutlier;
  set totalscores;
  if (total = 64) then delete;
run;

proc stdize data=NoOutlier method=std pstat;
  title2 'After Removing Outlier, METHOD=STD';
  var total;
  by Type;
run;
```

Figure 87.7 displays the location and scale measures after deleting the outlier. The lack of resistance of the standard deviation to outliers is clearly illustrated: if you delete the outlier, the sample standard deviation of urban scores changes from 30.07 to 22.09. The new ratio of the scale of rural scores to the scale of urban scores is approximately 1.90 (41.96/22.09).

total	158.000000	22.088207	19

Syntax: STDIZE Procedure

The following statements are available in the STDIZE procedure:

```

PROC STDIZE < options > ;
  BY variables ;
  FREQ variable ;
  LOCATION variables ;
  SCALE variables ;
  VAR variables ;
  WEIGHT variable ;

```

The PROC STDIZE statement is required. The BY, LOCATION, FREQ, VAR, SCALE, and WEIGHT statements are described in alphabetical order following the PROC STDIZE statement.

PROC STDIZE Statement

PROC STDIZE < options > ;

The PROC STDIZE statement invokes the STDIZE procedure. You can specify the following options in the PROC STDIZE statement. Table 87.1 summarizes the options available in the PROC STDIZE statement.

Table 87.1 Summary of PROC STDIZE Statement Options

Option	Description
Specify standardization methods	
METHOD=	Specifies the name of the standardization method
INITIAL=	Specifies the method for computing initial estimates for the A estimates
Unstandardize variables	
UNSTD	Unstandardizes variables when you also specify the METHOD=IN option
Process missing values	
NOMISS	Omits observations with any missing values from computation
MISSING=	Specifies the method or a numeric value for replacing missing values
REPLACE	Replaces missing data with zero in the standardized data
REONLY	Replaces missing data with the location measure (does not standardize the data)
Specify data set details	
DATA=	Specifies the input data set
KEEPLN	Specifies that output variables inherit the length of the analysis variable
OUT=	Specifies the output data set
OPREFIX=	Specifies that original variables appear in the OUT= data set
SPREFIX=	Specifies a prefix for the standardized variable names
OUTSTAT=	Specifies the output statistic data set
Specify computational settings	
VARDEF=	Specifies the variances divisor
NMARKERS=	Specifies the number of markers when you also specify PCTLMTD=ONEPASS
MULT=	Specifies the constant to multiply each value by after standardizing
ADD=	Specifies the constant to add to each value after standardizing and multiplying by the value specified in the MULT= option
FUZZ=	Specifies the relative fuzz factor for writing the output
Specify percentiles	
PCTLDEF=	Specifies the definition of percentiles when you also specify the PCTLMTD=ORD_STAT option

Table 87.1 continued

Option	Description
PCTLMTD=	Specifies the method used to estimate percentiles
PCTLPTS=	Writes observations containing percentiles to the data set specified in the OUTSTAT= option
Normalize scale estimators	
NORM	Normalizes the scale estimator to be consistent for the standard deviation of a normal distribution
SNORM	Normalizes the scale estimator to have an expectation of approximately 1 for a standard normal distribution
Specify output	
PSTAT	Displays the location and scale measures

These options and their abbreviations are described (in alphabetical order) in the remainder of this section.

ADD=c

specifies a constant, *c*, to add to each value after standardizing and multiplying by the value you specify in the MULT= option. The default value is 0.

DATA=SAS-data-set

specifies the input data set to be standardized. If you omit the DATA= option, the most recently created data set is used.

FUZZ=c

specifies the relative fuzz factor. The default value is 1E–14. For the OUT= data set, the score is computed as follows:

$$\text{if } |result| < m \times c \text{ then } result = 0$$

where *m* is the constant specified in the MULT= option, or 1 if MULT= option is not specified.

For the OUTSTAT= data set and the location and scale table, the *scale* and *location* values are computed as follows:

$$\text{if } scale < |location| \times c \text{ then } scale = 0$$

Otherwise,

$$\text{if } |location| < m \times c \text{ then } location = 0$$

INITIAL=method

specifies the method for computing initial estimates for the A estimates (ABW, AWAVE, and AHUBER). You cannot specify the following methods for initial estimates: INITIAL=ABW, INITIAL=AHUBER, INITIAL=AWAVE, and INITIAL=IN. The default is INITIAL=MAD.

KEELEN

specifies that the standardized variables inherit the lengths of the analysis variables that PROC STDIZE uses to derive them. PROC STDIZE stores numbers in double-precision without this option.

Caution: The KEELEN option causes the standardized variables to permanently lose numeric precision by truncating or rounding the values. However, the precision of the output variables will match that of the input.

METHOD=*name*

specifies the name of the method for computing location and scale measures. Valid values for *name* are as follows: MEAN, MEDIAN, SUM, EUCLEN, USTD, STD, RANGE, MIDRANGE, MAXABS, IQR, MAD, ABW, AHUBER, AWAVE, AGK, SPACING, L, and IN.

For details about these methods, see the descriptions in the section “[Standardization Methods](#)” on page 7468. The default is METHOD=STD.

MISSING=*method* | *value*

specifies the method (or a numeric value) for replacing missing values. If you omit the MISSING= option, the REPLACE option replaces missing values with the location measure given by the METHOD= option. Specify the MISSING= option when you want to replace missing values with a different value. You can specify any name that is valid in the METHOD= option except the name IN. The corresponding location measure is used to replace missing values.

If a numeric value is given, the value replaces missing values after standardizing the data. However, you can specify the REONLY option with the MISSING= option to suppress standardization for cases in which you want only to replace missing values.

MULT=*c*

specifies a constant, *c*, by which to multiply each value after standardizing. The default value is 1.

NMARKERS=*n*

specifies the number of markers used when you specify the one-pass algorithm (PCTLMTD=ONEPASS). The value *n* must be greater than or equal to 5. The default value is 105.

NOMISS

omits observations with missing values for any of the analyzed variables from calculation of the location and scale measures. If you omit the NOMISS option, all nonmissing values are used.

NORM

normalizes the scale estimator to be consistent for the standard deviation of a normal distribution when you specify the option METHOD=AGK, METHOD=IQR, METHOD=MAD, or METHOD=SPACING.

OPREFIX<=*o-prefix*>

specifies that the original variables should appear in the OUT= data set. You can optionally specify an equal sign and a prefix. For example, if OPREFIX=Original, then the names of the variables are OriginalVAR1, OriginalVAR2, and so on, where VAR1 and VAR2 are the original variable names. The value of OPREFIX= must be different from the value of [SPREFIX=](#). If you specify OPREFIX, without an equal sign and a prefix, then the default prefix is null and you must specify SPREFIX=*s-prefix*.

OUT=SAS-data-set

specifies the name of the SAS data set created by PROC STDIZE. By default, the output data set is a copy of the DATA= data set except that the analyzed variables have been standardized. Analyzed variables are those specified in the VAR statement or, if there is no VAR statement, all numeric variables not listed in any other statement. However, you can use the OPREFIX option to request that both the original and standardized variables be included in the output data set. You can change variable names by specifying prefixes with the OPREFIX= and SPREFIX= options. See the section [“Output Data Sets”](#) on page 7473 for more information.

If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

If you omit the OUT= option, PROC STDIZE creates an output data set named according to the DATA n convention.

OUTSTAT=SAS-data-set

specifies the name of the SAS data set containing the location and scale measures and other computed statistics. See the section [“Output Data Sets”](#) on page 7473 for more information.

PCTLDEF=percentiles

specifies which of five definitions is used to calculate percentiles when you specify the option PCTLMTD=ORD_STAT. By default, PCTLDEF=5. Note that the option PCTLMTD=ONEPASS implies PCTLDEF=5. See the section [“Computational Methods for the PCTLDEF= Option”](#) on page 7471 for details about percentile definition.

You cannot use PCTLDEF= when you compute weighted quantiles.

PCTLMTD=ORD_STAT | ONEPASS | P2

specifies the method used to estimate percentiles. Specify the PCTLMTD=ORD_STAT option to compute the percentiles by the order statistics method.

The PCTLMTD=ONEPASS option modifies an algorithm invented by Jain and Chlamtac (1985). See the section [“Computing Quantiles”](#) on page 7471 for more details about this algorithm.

PCTLPTS= n

writes percentiles to the OUTSTAT= data set. Values of n can be any decimal number between 0 and 100, inclusive.

A requested percentile is identified by the _TYPE_ variable in the OUTSTAT= data set with a value of P n . For example, suppose you specify the option PCTLPTS=10, 30. The corresponding observations in the OUTSTAT= data set that contain the 10th and the 30th percentiles would then have values _TYPE_=P10 and _TYPE_=P30, respectively.

PSTAT

displays the location and scale measures.

REPLACE

replaces missing data with the value 0 in the standardized data (this value corresponds to the location measure before standardizing). To replace missing data by other values, see the preceding description of the MISSING= option. You cannot specify both the REPLACE and REONLY options.

REONLY

replaces missing data only; PROC STDIZE does not standardize the data. Missing values are replaced with the location measure unless you also specify the `MISSING=value` option, in which case missing values are replaced with *value*. You cannot specify both the `REPLACE` and `REONLY` options.

SNORM

normalizes the scale estimator to have an expectation of approximately 1 for a standard normal distribution when you specify the `METHOD=SPACING` option.

SPREFIX=<s-prefix>

specifies a prefix for the standardized variables. For example, if `SPREFIX=Std`, then the names of the standardized variables are `StdVAR1`, `StdVAR2`, and so on, where `VAR1` and `VAR2` are the original variable names. The value of `SPREFIX=` must be different from the value of `OPREFIX=`. The default prefix is null. If you omit the `SPREFIX` option, the standardized variables still appear in the `OUT=` data set by default and the variable names remain the same. If you want to have the variable names changed, you need to specify a prefix with `SPREFIX=s-prefix`.

UNSTD**UNSTDIZE**

unstandardizes variables when you specify the `METHOD=IN(ds)` option. The location and scale measures, along with constants for addition and multiplication that the unstandardization is based on, are identified by the `_TYPE_` variable in the `ds` data set.

The `ds` data set must have a `_TYPE_` variable and contain the following two observations: a `_TYPE_ = 'LOCATION'` observation and a `_TYPE_ = 'SCALE'` observation. The variable `_TYPE_` can also contain the optional observations, `'ADD'` and `'MULT'`; if these observations are not found in the `ds` data set, the constants specified in the `ADD=` and `MULT=` options (or their default values) are used for unstandardization.

See the section “[OUTSTAT= Data Set](#)” on page 7473 for details about the statistics that each value of `_TYPE_` represents. The formula used for unstandardization is as follows: If the final output value from the previous standardization is calculated as

$$result = add + multiply \times \frac{original - location}{scale}$$

The unstandardized variable is computed as

$$original = scale \times \frac{result - add}{multiply} + location$$

VARDEF=DF | N | WDF | WEIGHT | WGT

specifies the divisor to be used in the calculation of variances. By default, `VARDEF=DF`. The values and associated divisors are as follows.

Value	Divisor	Formula
DF	Degrees of freedom	$n - 1$
N	Number of observations	n
WDF	Sum of weights minus 1	$(\sum_i w_i) - 1$
WEIGHT WGT	Sum of weights	$\sum_i w_i$

BY Statement

BY variables ;

You can specify a BY statement with PROC STDIZE to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the STDIZE procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

When you specify the option METHOD=IN(ds), the following rules are applied to BY-group processing:

- If the ds data set does not contain any of the BY variables, the entire DATA= data set is standardized by the location and scale measures (along with the constants for addition and multiplication) in the ds data set.
- If the ds data set contains some, but not all, of the BY variables or if some BY variables do not have the same type or length in the ds data set that they have in the DATA= data set, PROC STDIZE displays an error message and stops.
- If all of the BY variables appear in the ds data set with the same type and length as in the DATA= data set, each BY group in the DATA= data set is standardized using the location and scale measures (along with the constants for addition and multiplication) from the corresponding BY group in the ds data set. The BY groups in the ds data set must be in the same order in which they appear in the DATA= data set. All BY groups in the DATA= data set must also appear in the ds data set. If you do not specify the NOTSORTED option, some BY groups can appear in the ds data set but not in the DATA= data set; such BY groups are not used in standardizing data.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FREQ Statement

FREQ *variable* ;

If one variable in the input data set represents the frequency of occurrence for other values in the observation, specify the variable name in a FREQ statement. PROC STDIZE treats the data set as if each observation appeared n times, where n is the value of the FREQ variable for the observation. Nonintegral values of the FREQ variable are truncated to the largest integer less than the FREQ value. If the FREQ variable has a value that is less than 1 or is missing, the observation is not used in the analysis.

NOTRUNCATE

NOTRUNC

specifies that frequency values are not truncated to integers.

The nonintegral values of the FREQ variable can be used for the following standardization methods: AGK, ABW, AHUBER, AWAVE, EUCLLEN, IQR, L, MAD, MEAN, MEDIAN, SPACING, STD, SUM, and USTD. The nonintegral frequency values are used for the MAD, MEDIAN, or IQR method only when PCTLMTD=ORD_STAT is specified. If PCTLMTD=ONEPASS is specified, the NOTRUNCATE option is ignored.

LOCATION Statement

LOCATION *variables* ;

The LOCATION statement specifies a list of numeric variables that contain location measures in the input data set specified by the METHOD=IN option.

SCALE Statement

SCALE *variables* ;

The SCALE statement specifies the list of numeric variables that contain scale measures in the input data set specified by the METHOD=IN option.

VAR Statement

VAR *variable* ;

The VAR statement lists numeric variables to be standardized. If you omit the VAR statement, all numeric variables not listed in the BY, FREQ, and WEIGHT statements are used.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement specifies a numeric variable in the input data set with values that are used to weight each observation. Only one variable can be specified.

The WEIGHT variable values can be nonintegers. An observation is used in the analysis only if the value of the WEIGHT variable is greater than zero.

The WEIGHT variable applies only when you specify the following standardization methods: AGK, EUCLEN, IQR, L, MAD, MEAN, MEDIAN, STD, SUM, and USTD. Weights are used for the METHOD=MAD, MEDIAN, or IQR only when PCTLMTD=ORD_STAT is specified; if PCTLMTD=ONEPASS is specified, the WEIGHT statement is ignored.

PROC STDIZE uses the value of the WEIGHT variable to calculate the sample mean and sample variances:

$$\bar{x}_w = \sum_i w_i x_i / \sum_i w_i \quad (\text{sample mean})$$

$$us_w^2 = \sum_i w_i x_i^2 / d \quad (\text{uncorrected sample variances})$$

$$s_w^2 = \sum_i w_i (x_i - \bar{x}_w)^2 / d \quad (\text{sample variances})$$

where w_i is the weight value of the i th observation, x_i is the value of the i th observation, and d is the divisor controlled by the VARDEF= option (see the VARDEF= option for details).

The following weighted statistics are defined accordingly:

MEAN	the weighted mean, \bar{x}_w
SUM	the weighted sum, $\sum_i w_i x_i$
USTD	the weighted uncorrected standard deviation, $\sqrt{us_w^2}$
STD	the weighted standard deviation, $\sqrt{s_w^2}$
EUCLEN	the weighted Euclidean length, computed as the square root of the weighted uncorrected sum of squares:

$$\sqrt{\sum_i w_i x_i^2}$$

MEDIAN	the weighted median. See the section “ Weighted Percentiles ” on page 7472 for the formulas and descriptions.
MAD	the weighted median absolute deviation from the weighted median. See the section “ Weighted Percentiles ” on page 7472 for the formulas and descriptions.
IQR	the weighted median, 25th percentile, and the 75th percentile. See the section “ Weighted Percentiles ” on page 7472 for the formulas and descriptions.

- AGK the AGK estimate. This estimate is documented further in the ACECLUS procedure as the METHOD=COUNT option. See the discussion of the WEIGHT statement in Chapter 23, “[The ACECLUS Procedure](#),” for information about how the WEIGHT variable is applied to the AGK estimate.
- L the L_p estimate. This estimate is documented further in the FASTCLUS procedure as the LEAST= option. See the discussion of the WEIGHT statement in Chapter 36, “[The FASTCLUS Procedure](#),” for information about how the WEIGHT variable is used to compute weighted cluster means. The number of clusters is always 1.

Details: STDIZE Procedure

Standardization Methods

The following table lists standardization methods and their corresponding location and scale measures available with the METHOD= option.

Table 87.2 Available Standardization Methods

Method	Location	Scale
MEAN	Mean	1
MEDIAN	Median	1
SUM	0	Sum
EUCLEN	0	Euclidean length
USTD	0	Standard deviation about origin
STD	Mean	Standard deviation
RANGE	Minimum	Range
MIDRANGE	Midrange	Range/2
MAXABS	0	Maximum absolute value
IQR	Median	Interquartile range
MAD	Median	Median absolute deviation from median
ABW(<i>c</i>)	Biweight one-step M-estimate	Biweight A-estimate
AHUBER(<i>c</i>)	Huber one-step M-estimate	Huber A-estimate
AWAVE(<i>c</i>)	Wave one-step M-estimate	Wave A-estimate
AGK(<i>p</i>)	Mean	AGK estimate (ACECLUS)
SPACING(<i>p</i>)	Mid-minimum spacing	Minimum spacing
L(<i>p</i>)	L(<i>p</i>)	L(<i>p</i>)
IN(ds)	Read from data set	Read from data set

For METHOD=ABW(c), METHOD=AHUBER(c), or METHOD=AWAVE(c), c is a positive numeric tuning constant.

For METHOD=AGK(p), p is a numeric constant that gives the proportion of pairs to be included in the estimation of the within-cluster variances.

For METHOD=SPACING(p), p is a numeric constant that gives the proportion of data to be contained in the spacing.

For METHOD=L(p), p is a numeric constant greater than or equal to 1 that specifies the power to which differences are to be raised in computing an L(p) or Minkowski metric.

For METHOD=IN(ds), ds is the name of a SAS data set that meets either of the following two conditions:

- The data set contains a `_TYPE_` variable. The observation that contains the location measure corresponds to the value `_TYPE_ = 'LOCATION'`, and the observation that contains the scale measure corresponds to the value `_TYPE_ = 'SCALE'`. You can also use a data set created by the `OUTSTAT=` option from another PROC STDIZE statement as the ds data set. See the section “[Output Data Sets](#)” on page 7473 for the contents of the `OUTSTAT=` data set.
- The data set contains the location and scale variables specified by the `LOCATION` and `SCALE` statements.

PROC STDIZE reads in the location and scale variables in the ds data set by first looking for the `_TYPE_` variable in the ds data set. If it finds this variable, PROC STDIZE continues to search for all variables specified in the VAR statement. If it does not find the `_TYPE_` variable, PROC STDIZE searches for the location variables specified in the `LOCATION` statement and the scale variables specified in the `SCALE` statement.

The variable `_TYPE_` can also contain the optional observations, ‘ADD’ and ‘MULT’. If these observations are found in the ds data set, the values in the observation of `_TYPE_ = 'MULT'` are the multiplication constants, and the values in the observation of `_TYPE_ = 'ADD'` are the addition constants; otherwise, the constants specified in the `ADD=` and `MULT=` options (or their default values) are used.

For robust estimators, see Goodall (1983) and Iglewicz (1983). The MAD method has the highest breakdown point (50%), but it is somewhat inefficient. The ABW, AHUBER, and AWAVE methods provide a good compromise between breakdown and efficiency. The L(p) location estimates are increasingly robust as p drops from 2 (which corresponds to least squares, or mean estimation) to 1 (which corresponds to least absolute value, or median estimation). However, the L(p) scale estimates are not robust.

The SPACING method is robust to both outliers and clustering (Jannsen et al. 1995) and is, therefore, a good choice for cluster analysis or nonparametric density estimation. The mid-minimum spacing method estimates the mode for small p . The AGK method is also robust to clustering and more efficient than the SPACING method, but it is not as robust to outliers and takes longer to compute. If you expect g clusters, the argument to METHOD=SPACING or METHOD=AGK should be $\frac{1}{g}$ or less. The AGK method is less biased than the SPACING method for small samples. As a general guide, it is reasonable to use AGK for samples of size 100 or less and SPACING for samples of size 1,000 or more, with the treatment of intermediate sample sizes depending on the available computer resources.

Computation of the Statistics

Formulas for statistics of METHOD=MEAN, METHOD=MEDIAN, METHOD=SUM, METHOD=USTD, METHOD=STD, METHOD=RANGE, and METHOD=IQR are given in the chapter “Elementary Statistics Procedures” (*Base SAS Procedures Guide*).

Note that the computations of median and upper and lower quartiles depend on the PCTLMTD= option.

The other statistics listed in Table 87.2, except for METHOD=IN, are described as follows:

EUCLEN	Euclidean length. $\sqrt{\sum_{i=1}^n x_i^2}$, where x_i is the i th observation and n is the total number of observations in the sample.
L(p)	Minkowski metric. This metric is documented as the LEAST= p option in the PROC FASTCLUS statement of the FASTCLUS procedure (see Chapter 36, “ The FASTCLUS Procedure ”). If you specify METHOD=L(p) in the PROC STDIZE statement, your results are similar to those obtained from PROC FASTCLUS if you specify the LEAST= p option with MAXCLUS=1 (and use the default values of the MAXITER= option). The difference between the two types of calculations concerns the maximum number of iterations. In PROC STDIZE, it is a criterion for convergence on all variables; in PROC FASTCLUS, it is a criterion for convergence on a single variable. The location and scale measures for L(p) are output to the OUTSEED= data set in PROC FASTCLUS.
MIDRANGE	$(maximum + minimum)/2$
ABW(c)	Tukey’s biweight. See Goodall (1983, pp. 376–378, p. 385) for the biweight one-step M-estimate. Also see Iglewicz (1983, pp. 416–418) for the biweight A-estimate.
AHUBER(c)	Hubers. See Goodall (1983, pp. 371–374) for the Huber one-step M-estimate. Also see Iglewicz (1983, pp. 416–418) for the Huber A-estimate of scale.
AWAVE(c)	Andrews’ wave. See Goodall (1983, p. 376) for the Wave one-step M-estimate. Also see Iglewicz (1983, pp. 416–418) for the Wave A-estimate of scale.
AGK(p)	The noniterative univariate form of the estimator described by Art, Gnanadesikan, and Kettenring (1982). The AGK estimate is documented in the section on the METHOD= option in the PROC ACECLUS statement of the ACECLUS procedure (also see the section “ Background ” on page 814 in Chapter 23, “ The ACECLUS Procedure ”). Specifying METHOD=AGK(p) in the PROC STDIZE statement is the same as specifying METHOD=COUNT and P= p in the PROC ACECLUS statement.
SPACING(p)	The absolute difference between two data values. The minimum spacing for a proportion p is the minimum absolute difference between two data values that contain a proportion p of the data between them. The mid-minimum spacing is the mean of these two data values.

Computing Quantiles

PROC STDIZE offers two methods for computing quantiles: the one-pass approach and the order-statistics approach (like that used in the UNIVARIATE procedure).

The one-pass approach used in PROC STDIZE modifies the P^2 algorithm for histograms proposed by Jain and Chlamtac (1985). The primary difference comes from the movement of markers. The one-pass method allows a marker to move to the right (or left) by more than one position (to the largest possible integer) as long as it does not result in two markers being in the same position. The modification is necessary in order to incorporate the FREQ variable.

You might obtain inaccurate results if you use the one-pass approach to estimate quantiles beyond the quartiles (that is, when you estimate quantiles $< P25$ or quantiles $> P75$). A large sample size (10,000 or more) is often required if the tail quantiles (quantiles $\leq P10$ or quantiles $\geq P90$) are requested. Note that, for variables with highly skewed or heavy-tailed distributions, tail quantile estimates might be inaccurate.

The order-statistics approach for estimating quantiles is faster than the one-pass method but requires that the entire data set be stored in memory. The accuracy in estimating the quantiles is comparable for both methods when the requested percentiles are between the lower and upper quartiles. The default is PCTLMTD=ORD_STAT if enough memory is available; otherwise, PCTLMTD=ONEPASS.

Computational Methods for the PCTLDEF= Option

You can specify one of five methods for computing quantile statistics when you use the order-statistics approach (PCTLMTD=ORD_STAT); otherwise, the PCTLDEF=5 method is used when you use the one-pass approach (PCTLMTD=ONEPASS).

Percentile Definitions Let n be the number of nonmissing values for a variable, and let x_1, x_2, \dots, x_n represent the ordered values of the variable. For the t th percentile, let $p = t/100$. In the following definitions numbered 1, 2, 3, and 5, let

$$np = j + g$$

where j is the integer part and g is the fractional part of np . For definition 4, let

$$(n + 1)p = j + g$$

Given the preceding definitions, the t th percentile, y , is defined as follows:

PCTLDEF=1 weighted average at x_{np}

$$y = (1 - g)x_j + gx_{j+1}$$

where x_0 is taken to be x_1

PCTLDEF=2 observation numbered closest to np

$$y = x_i$$

where i is the integer part of $np + 1/2$ if $g \neq 1/2$. If $g = 1/2$, then

$y = x_j$ if j is even, or

$y = x_{j+1}$ if j is odd

PCTLDEF=3 empirical distribution function

$$y = x_j \text{ if } g = 0$$

$$y = x_{j+1} \text{ if } g > 0$$

PCTLDEF=4 weighted average aimed at $x_{p(n+1)}$

$$y = (1 - g)x_j + gx_{j+1}$$

where x_{n+1} is taken to be x_n

PCTLDEF=5 empirical distribution function with averaging

$$y = (x_j + x_{j+1})/2 \text{ if } g = 0$$

$$y = x_{j+1} \text{ if } g > 0$$

Weighted Percentiles

When you specify a WEIGHT statement, or specify the NOTRUNCATE option in a FREQ statement, the percentiles are computed differently. The 100 p th weighted percentile y is computed from the empirical distribution function with averaging

$$y = \begin{cases} \frac{1}{2}(x_i + x_{i+1}) & \text{if } \sum_{j=1}^i w_j = pW \\ x_{i+1} & \text{if } \sum_{j=1}^i w_j < pW < \sum_{j=1}^{i+1} w_j \end{cases}$$

where w_i is the weight associated with x_i , and where $W = \sum_{i=1}^n w_i$ is the sum of the weights.

For PCTLMTD= ORD_STAT, the PCTLDEF= option is not applicable when a WEIGHT statement is used, or when a NOTRUNCATE option is specified in a FREQ statement. However, in this case, if all the weights are identical, the weighted percentiles are the same as the percentiles that would be computed without a WEIGHT statement and with PCTLDEF=5.

For PCTLMTD= ONEPASS, the quantile computation currently does not use any weights.

Constant Data

Constant variables are not standardized. The scale value is set to missing when the data are constant.

Missing Values

Missing values can be replaced by the location measure or by any specified constant (see the REPLACE option and the MISSING= option). You can also suppress standardization if you want only to replace missing values (see the REONLY option).

If you specify the NOMISS option, PROC STDIZE omits observations with any missing values in the analyzed variables from computation of the location and scale measures.

Output Data Sets

OUT= Data Set

By default, the output data set is a copy of the DATA= data set except that the analyzed variables have been standardized. Analyzed variables are those specified in the VAR statement or, if there is no VAR statement, all numeric variables not listed in any other statement. However, you can use the OPREFIX option to request that both the original and standardized variables be included in the output data set. You can change variable names by specifying prefixes with the OPREFIX=*o-prefix* and SPREFIX=*s-prefix* options, but keep in mind that the two prefixes must be different. See [OPREFIX](#) and [SPREFIX](#) for more information.

OUTSTAT= Data Set

The new data set contains the following variables:

- the BY variables, if any
- `_TYPE_`, a character variable
- the analyzed variables

Each observation in the new data set contains a type of statistic as indicated by the `_TYPE_` variable. The values of the `_TYPE_` variable are as follows:

LOCATION	location measure of each variable
SCALE	scale measure of each variable
ADD	constant specified in the ADD= option. This value is the same for each variable.
MULT	constant specified in the MULT= option. This value is the same for each variable.
N	total number of nonmissing positive frequencies of each variable
NORM	norm measure of each variable. This observation is produced only when you specify the NORM option with METHOD=AGK, METHOD=IQR, METHOD=MAD, or METHOD=SPACING or when you specify the SNORM option with METHOD=SPACING.
NObsRead	number of physical records read
NObsUsed	number of physical records used in the analysis
NObsMiss	number of physical records containing missing values
P _n	percentiles of each variable, as specified by the PCTLPTS= option. The argument <i>n</i> is any real number such that $0 \leq n \leq 100$
SumFreqsRead	sum of the frequency variable (or the sum of NObsUsed ones when there is no frequency variable) for all observations read
SumFreqsUsed	sum of the frequency variable (or the sum of NObsUsed ones when there is no frequency variable) for all observations used in the analysis
SumWeightsRead	sum of the weight variable (or the sum of NObsUsed ones when there is no weight variable) for all observations read

SumWeightsUsed sum of the weight variable (or the sum of NObsUsed ones when there is no weight variable) for all observations used in the analysis

Displayed Output

If you specify the PSTAT option, PROC STDIZE displays the following statistics for each variable:

- the name of the variable, Name
- the location estimate, Location
- the scale estimate, Scale
- the norm estimate, Norm (when you specify the NORM option with METHOD=AGK, METHOD=IQR, METHOD=MAD, or METHOD=SPACING or when you specify the SNORM option with METHOD=SPACING)
- sum of nonmissing positive frequencies, N
- sum of nonmissing positive weights if the WEIGHT statement is specified, Sum of Weights

ODS Table Names

PROC STDIZE assigns a name to the single table it creates. You can use this name to reference the table when using the Output Delivery System (ODS) to select a table or create an output data set. This name is listed in [Table 87.3](#). For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

Table 87.3 ODS Table Produced by PROC STDIZE

ODS Table Name	Description	Statement	Option
Statistics	Location and Scale Measures	PROC	PSTAT

Example: STDIZE Procedure

Example 87.1: Standardization of Variables in Cluster Analysis

To illustrate the effect of standardization in cluster analysis, this example uses the Fish data set described in the “Getting Started” section of Chapter 36, “The FASTCLUS Procedure.” The numbers are measurements taken on 159 fish caught from the same lake (Laengelmavesi) near Tampere in Finland (Puranen 1917). The fish data set is available from the Sashelp library.

The species (bream, parkki, pike, perch, roach, smelt, and whitefish), weight, three different length measurements (measured from the nose of the fish to the beginning of its tail, the notch of its tail, and the end of its tail), height, and width of each fish are recorded.

A couple of new variables are created in the Fish data set: Weight3 and logLengthRatio. The weight of a fish indicates its size—a heavier pike tends to be larger than a lighter pike. To get a one-dimensional measure of the size of a fish, take the cubic root of the weight (Weight3). The variables Height, Width, Length1, Length2, and Length3 are rescaled in order to adjust for dimensionality. The logLengthRatio variable measures the tail length.

Because the new variables Weight3–logLengthRatio depend on the variable Weight, observations with missing values for Weight are not added to the data set. Consequently, there are 157 observations in the SAS data set Sashelp.Fish.

Before you perform a cluster analysis on coordinate data, it is necessary to consider scaling or transforming the variables since variables with large variances tend to have a larger effect on the resulting clusters than variables with small variances do.

This example uses three different approaches to standardize or transform the data prior to the cluster analysis. The first approach uses several standardization methods provided in the STDIZE procedure. However, since standardization is not always appropriate prior to the clustering (see Milligan and Cooper (1987) for a Monte Carlo study on various methods of variable standardization), the second approach performs the cluster analysis with no standardization. The third approach invokes the ACECLUS procedure to transform the data into a within-cluster covariance matrix.

The clustering is performed by the FASTCLUS procedure to find seven clusters. Note that the variables Length2 and Length3 are eliminated from this analysis since they both are significantly and highly correlated with the variable Length1. The correlation coefficients are 0.9958 and 0.9604, respectively. An output data set is created, and the FREQ procedure is invoked to compare the clusters with the species classification.

The DATA step is as follows:

```

title 'Fish Measurement Data';

data Fish;
  set sashelp.fish;
  if Weight <= 0 or Weight = . then delete;
  Weight3 = Weight ** (1/3);
  Height = Height / Weight3;
  Width = Width / Weight3;
  Length1 = Length1 / Weight3;
  Length2 = Length2 / Weight3;
  Length3 = Length3 / Weight3;
  LogLengthRatio = log(Length3 / Length1);
run;

```

The following macro, Std, standardizes the Fish data. The macro reads a single argument, mtd, which selects the METHOD= specification to be used in PROC STDIZE.

```

/*--- macro for standardization ---*/

%macro Std(mtd);
  title2 "Data are Standardized by PROC STDIZE with METHOD= &mtd";
  proc stdize data=fish out=sdzout method=&mtd;
    var Length1 logLengthRatio Height Width Weight3;
  run;
%mend Std;

```

The following macro, FastFreq, includes a PROC FASTCLUS statement for performing cluster analysis and a PROC FREQ statement for crosstabulating species with the cluster membership information that is derived from the previous PROC FASTCLUS statement. The macro reads a single argument, ds, which selects the input data set to be used in PROC FASTCLUS.

```

/*--- macro for clustering and crosstabulating ---*/
/*--- cluster membership with species ---*/

%macro FastFreq(ds);
  proc fastclus data=&ds out=clust maxclusters=7 maxiter=100 noprint;
    var Length1 logLengthRatio Height Width Weight3;
  run;

  proc freq data=clust;
    tables species*cluster;
  run;
%mend FastFreq;

```

The following analysis (labeled ‘Approach 1’) includes 18 different methods of standardization followed by clustering. Since there is a large amount of output from this approach, only results from METHOD=STD, METHOD=RANGE, METHOD=AGK(0.14), and METHOD=SPACING(0.14) are shown. The following statements produce [Output 87.1.1](#) through [Output 87.1.4](#).

```

/*      Approach 1: data are standardized by PROC STDIZE      */

Table 87.4 displays a table summarizing each classification results. In this table, the first column represents the standardization method, the second column represents the number of clusters that the seven species are classified into, and the third column represents the total number of observations that are misclassified.

Table 87.4 Summary of Clustering Results

Method of Standardization	Number of Clusters	Misclassification
MEAN	5	71
MEDIAN	5	71
SUM	6	51
EUCLEN	6	45
USTD	6	45
STD	5	33
RANGE	7	32
MIDRANGE	7	32
MAXABS	7	26
IQR	5	28
MAD	4	35
ABW(5)	6	34
AWAVE(5)	6	29
AGK(0.14)	7	28
SPACING(0.14)	7	25
L(1)	6	41
L(1.5)	5	33
L(2)	5	33
untransformed	5	71
PROC ACECLUS	5	71

Consider the results displayed in [Output 87.1.1](#). In that analysis, the method of standardization is STD, and the number of clusters and the number of misclassifications are computed as shown in [Table 87.5](#).

Table 87.5 Computations of Numbers of Clusters and Misclassification When Standardization Method Is STD

Species	Cluster Number	Misclassification in Each Species
Bream	6	0
Parkki	5	0
Perch	7	29
Pike	1	0
Roach	7	0
Smelt	3	1
Whitefish	7	3

In [Output 87.1.1](#), the bream species is classified as cluster 6 since all 34 bream are categorized into cluster 6 with no misclassification. A similar pattern is seen with the roach, parkki, pike, and smelt species.

For the whitefish species, two fish are categorized into cluster 2, one fish is categorized into cluster 4, and three fish are categorized into cluster 7. Because the majority of this species is categorized into cluster 7, it is recorded in Table 87.5 as being classified as cluster 7 with 3 misclassifications. A similar pattern is seen with the perch species: it is classified as cluster 7 with 29 misclassifications.

In summary, when the standardization method is STD, seven species of fish are classified into only five clusters and the total number of misclassified observations is 33.

The result of this analysis demonstrates that when variables are standardized by the STDIZE procedure with methods including RANGE, MIDRANGE, MAXABS, AGK(0.14), and SPACING(0.14), the FASTCLUS procedure produces the correct number of clusters and less misclassification than it does when other standardization methods are used. The SPACING method attains the best result, probably because the variables Length1 and Height both exhibit marked groupings (bimodality) in their distributions.

Overview: STD RATE Procedure

Epidemiology is the study of the occurrence and distribution of health-related states or events in specified populations. Epidemiology also includes the study of the determinants that influence these states, and the application of this knowledge to control health problems (Porta 2008). It is a discipline that describes, quantifies, and postulates causal mechanisms for health phenomena in populations (Friss and Sellers 2009).

A common goal is to establish relationships between various factors (such as exposure to a specific chemical) and the event outcomes (such as incidence of disease). But the measure of an association between an exposure and an event outcome can be biased due to confounding. That is, the association of the exposure to some other variables, such as age, influences the occurrence of the event outcome. With confounding, the usual effect between an exposure and an event outcome can be biased because some of the effect might be accounted for by other variables. For example, with an event rate discrepancy among different age groups of a population, the overall crude rate might not provide a useful summary statistic to compare populations.

One strategy to control confounding is stratification. In stratification, a population is divided into several subpopulations according to specific criteria for the confounding variables, such as age and sex groups. The effect of the exposure on the event outcome is estimated within each stratum, and then these stratum-specific effect estimates are combined into an overall estimate.

Two commonly used event frequency measures are rate and risk:

- A rate is a measure of the frequency with which an event occurs in a defined population in a specified period of time. It measures the change in one quantity per unit of another quantity. For example, an event rate measures how fast the events are occurring. That is, an event rate of a population over a specified time period can be defined as the number of new events divided by population-time (Kleinbaum, Kupper, and Morgenstern 1982, p. 100) over the same time period.
- A risk is the probability that an event occurs in a specified time period. It is assumed that only one event can occur in the time period for each subject or item. The overall crude risk of a population over a specified time period is the number of new events in the time period divided by the population size at the beginning of the time period.

Standardized overall rate and risk estimates based on stratum-specific estimates can be derived with the effects of confounding variables removed. These estimates provide useful summary statistics and allow valid comparison of the populations. There are two types of standardization:

- Direct standardization computes the weighted average of stratum-specific estimates in the study population, using the weights from a standard or reference population. This standardization is applicable when the study population is large enough to provide stable stratum-specific estimates. The directly standardized estimate is the overall crude rate in the study population if it has the same strata distribution as the reference population. When standardized estimates for different populations are derived by using the same reference population, the resulting estimates can also be compared by using the estimated difference and estimated ratio statistics.
- Indirect standardization computes the weighted average of stratum-specific estimates in the reference population, using the weights from the study population. The ratio of the overall crude rate or risk in the study population and the corresponding weighted estimate in the reference population is the standardized morbidity ratio (SMR). This ratio is also the standardized mortality ratio if the event is death. SMR is used to compare rates or risks in the study and reference populations. With SMR, the indirectly standardized estimate is then computed as the product of the SMR and the overall crude estimate for the reference population. SMR and indirect standardization are applicable even when the study population is so small that the resulting stratum-specific rates are not stable.

Assuming that an effect, such as the rate difference between two populations, is homogeneous across strata, each stratum provides an estimate of the same effect. A pooled estimate of the effect can then be derived

from these stratum-specific effect estimates. One way to estimate a homogeneous effect is the Mantel-Haenszel method (Greenland and Rothman 2008, p. 271). For a homogeneous rate difference effect between two populations, the Mantel-Haenszel estimate is identical to the difference between two directly standardized rates, but with weights derived from the two populations instead of from an explicitly specified reference population. The Mantel-Haenszel method can also be applied to other homogeneous effects between populations, such as the rate ratio, risk difference, and risk ratio.

The STD RATE procedure computes directly standardized rates and risks for study populations. For two study populations with the same reference population, PROC STD RATE compares directly standardized rates or risks from these two populations. For homogeneous effects across strata, PROC STD RATE computes Mantel-Haenszel estimates. The STD RATE procedure also computes indirectly standardized rates and risks, including SMR.

The attributable fraction measures the excess event rate or risk fraction in the exposed population that can be attributed to the exposure. The rate or risk ratio statistic is required in the attributable fraction computation, and the STD RATE procedure estimates the ratio by using either SMR or the rate ratio statistic in the Mantel-Haenszel estimates.

Although the STD RATE procedure provides useful summary standardized statistics, standardization is not a substitute for individual comparisons of stratum-specific estimates. PROC STD RATE provides summary statistics, such as rate and risk estimates and their confidence limits, in each stratum. In addition, PROC STD RATE also displays these stratum-specific statistics by using ODS Graphics.

Note that the term standardization has different meanings in other statistical applications. For example, the STDIZE procedure standardizes numeric variables in a SAS data set by subtracting a location measure and dividing by a scale measure.

Getting Started: STD RATE Procedure

This example illustrates indirect standardization and uses the standardized mortality ratio to compare the death rate from skin cancer between people who live in the state of Florida and people who live in the United States as a whole.

The Florida_C43 data set contains the stratum-specific mortality information for skin cancer in year 2000 for the state of Florida (Florida Department of Health 2000, 2012). The variable **Age** is a grouping variable that forms the strata in the standardization, and the variables **Event** and **PYear** identify the number of events and total person-years, respectively. The COMMA11. format is specified in the DATA step to input numerical values that contain commas in **PYear**.

```
data Florida_C43;
  input Age $1-5 Event PYear comma11.;
  datalines;
00-04      0      953,785
05-14      0  1,997,935
15-24      4  1,885,014
25-34     14  1,957,573
35-44     43  2,356,649
45-54     72  2,088,000
55-64     70  1,548,371
65-74    126  1,447,432
```

```

75-84  136  1,087,524
85+    73   335,944
;

```

The US_C43 data set contains the corresponding stratum-specific mortality information for the United States in year 2000 (Miniño et al. 2002; U.S. Bureau of Census 2011). The variable **Age** is the grouping variable, and the variables **Event** and **PYear** identify the number of events and the total person-years, respectively.

```

data US_C43;
  input Age $1-5 Event comma7. PYear comma12.;
  datalines;
00-04      0  19,175,798
05-14      1  41,077,577
15-24     41  39,183,891
25-34    186  39,892,024
35-44    626  45,148,527
45-54   1,199  37,677,952
55-64   1,303  24,274,684
65-74   1,637  18,390,986
75-84   1,624  12,361,180
85+      803   4,239,587
;

```

The following statements invoke the STD RATE procedure and request indirect standardization to compare death rates between the state of Florida and the United States:

```

ods graphics on;
proc stdrate data=Florida_C43 refdata=US_C43
  method=indirect
  stat=rate(mult=100000)
  plots=all
  ;
  population event=Event total=PYear;
  reference  event=Event total=PYear;
  strata Age / stats smr;
run;
ods graphics off;

```

The **DATA=** and **REFDATA=** options name the study data set and reference data set, respectively. The **METHOD=INDIRECT** option requests indirect standardization. The **STAT=RATE** option specifies the rate as the frequency measure for standardization, and the **MULT=100000** suboption (which is the default) displays the rates per 100,000 person-years in the table output and graphics output. The **PLOTS=ALL** option requests all appropriate plots with indirect standardization.

The POPULATION statement specifies the options that are related to the study population, and the EVENT= and TOTAL= options specify variables for the number of events and person-years in the study population, respectively.

The REFERENCE statement specifies the options related to the reference population, and the EVENT= and TOTAL= options specify variables for the number of events and person-years in the reference population, respectively.

The STRATA statement lists the variable Age that forms the strata. The STATS option requests a strata information table that contains stratum-specific statistics such as rates, and the SMR option requests a table of stratum-specific SMR estimates.

The “Standardization Information” table in [Figure 88.1](#) displays the standardization information.

Figure 88.1 Standardization Information

The STD RATE Procedure	
Standardization Information	
Data Set	WORK.FLORIDA_C43
Reference Data Set	WORK.US_C43
Method	Indirect Standardization
Statistic	Rate
Number of Strata	10
Rate Multiplier	100000

The STATS option in the STRATA statement requests that the “Indirectly Standardized Strata Statistics” table in [Figure 88.2](#) display the strata information and expected number of events at each stratum. The MULT=100000 suboption in the STAT=RATE option requests that crude rates per 100,000 person-years be displayed. The Expected Events column displays the expected number of events when the stratum-specific rates in the reference data set are applied to the corresponding person-years in the study data set.

Figure 88.2 Strata Information (Indirect Standardization)

10	16.7451	26.7146	4239587	0.0151	18.9405	63.630

With ODS Graphics enabled, the PLOTS=ALL option displays all appropriate plots. With indirect standardization and a rate statistic, these plots include the strata distribution plot, the strata rate plot, and the strata SMR plot. By default, strata levels are displayed on the vertical axis for these plots.

The strata distribution plot displays proportions for stratum-specific person-years in the study and reference populations, as shown in [Figure 88.3](#).

Figure 88.3 Strata Distribution Plot

The strata distribution plot displays the proportions in the “Indirectly Standardized Strata Statistics” table in [Figure 88.2](#). In the plot, the proportions of the study population are identified by the blue lines, and the proportions of the reference population are identified by the red lines. The plot shows that the study population has higher proportions in older age groups and lower proportions in younger age groups than the reference population.

The strata rate plot displays stratum-specific rate estimates in the study and reference populations, as shown in [Figure 88.4](#). This plot displays the rate estimates in the “Indirectly Standardized Strata Statistics” table in [Figure 88.2](#). In addition, the plot displays the confidence limits for the rate estimates in the study population and the overall crude rates for the two populations.

Figure 88.4 Strata Rate Plot

The SMR option in the STRATA statement requests that the “Strata SMR Estimates” table in Figure 88.5 display the strata SMR at each stratum. The MULT=100000 suboption in the STAT=RATE option requests that the reference rates per 100,000 person-years be displayed.

Figure 88.5 Strata SMR Information

Strata SMR Estimates							
Rate Multiplier = 100000							
Stratum Index	Age	---Study Observed Events	Population-- Population-- Time	Reference Crude Rate	Expected Events	SMR	Standard Error
1	00-04	0	953785	0.0000	0.000	.	.
2	05-14	0	1997935	0.0024	0.049	0.0000	.
3	15-24	4	1885014	0.1046	1.972	2.0280	1.0140
4	25-34	14	1957573	0.4663	9.127	1.5339	0.4099
5	35-44	43	2356649	1.3865	32.676	1.3160	0.2007
6	45-54	72	2088000	3.1822	66.445	1.0836	0.1277
7	55-64	70	1548371	5.3677	83.112	0.8422	0.1007
8	65-74	126	1447432	8.9011	128.837	0.9780	0.0871
9	75-84	136	1087524	13.1379	142.878	0.9519	0.0816
10	85+	73	335944	18.9405	63.630	1.1473	0.1343

Strata SMR Estimates		
Rate Multiplier = 100000		
Stratum Index	95% Normal Confidence Limits	
1	.	.
2	.	.
3	0.0406	4.0154
4	0.7304	2.3373
5	0.9226	1.7093
6	0.8333	1.3339
7	0.6449	1.0395
8	0.8072	1.1487
9	0.7919	1.1118
10	0.8841	1.4104

The “Strata SMR Estimates” table shows that although SMR is less than 1 only at three age strata (55–64, 65–74, and 75–84), these three strata contain about 60% of the total events.

The strata SMR plot displays stratum-specific SMR estimates with confidence limits, as shown in [Figure 88.6](#). The plot displays the SMR estimates in the “Strata SMR Estimates” table in [Figure 88.5](#).

Figure 88.6 Strata SMR Plot

The METHOD=INDIRECT option requests that the “Standardized Morbidity/Mortality Ratio” table in Figure 88.7 be displayed. The table displays the SMR, its confidence limits, and the test for the null hypothesis $H_0 : \text{SMR} = 1$. The default ALPHA=0.05 option requests that 95% confidence limits be constructed.

Figure 88.7 Standardized Morbidity/Mortality Ratio

Standardized Morbidity/Mortality Ratio							
Observed Events	Expected Events	SMR	Standard Error	95% Normal Confidence Limits		Z	Pr > Z
538	528.726	1.0175	0.0439	0.9316	1.1035	0.40	0.6893

The 95% normal confidence limits contain the null hypothesis value $\text{SMR} = 1$, and the hypothesis of $\text{SMR} = 1$ is not rejected at the $\alpha = 0.05$ level from the normal test.

The “Indirectly Standardized Rate Estimates” table in Figure 88.8 displays the indirectly standardized rate and related statistics.

Figure 88.8 Standardized Rate Estimates (Indirect Standardization)

Indirectly Standardized Rate Estimates					
Rate Multiplier = 100000					
-----Study Population-----			Reference		
Observed Events	Population- Time	Crude Rate	Crude Rate	Expected Events	SMR
538	15658227	3.4359	2.6366	528.726	1.0175
Indirectly Standardized Rate Estimates					
Rate Multiplier = 100000					
-----Standardized Rate-----					
Estimate		Standard Error	95% Normal Confidence Limits		
2.6829		0.1157	2.4562	2.9096	

The indirectly standardized rate estimate is the product of the SMR and the crude rate estimate for the reference population. The table shows that although the crude rate in the state of Florida (3.4359) is 30% higher than the crude rate in the U.S. (2.6366), the resulting standardized rate (2.6829) is close to the crude rate in the U.S.

Syntax: STD RATE Procedure

The following statements are available in PROC STD RATE:

```

PROC STD RATE < options > ;
  BY variables ;
  POPULATION options ;
  REFERENCE options ;
  STRATA variables < / option > ;

```

The PROC STD RATE statement invokes the procedure, names the data sets, specifies the standardization method, and identifies the statistic for standardization. The BY statement requests separate analyses of groups defined by the BY variables. The required POPULATION statement specifies the rate or risk information in study populations, and the REFERENCE statement specifies the rate or risk information in the reference population. The STRATA statement lists the variables that form the strata.

The following sections describe the PROC STD RATE statement and then describe the other statements in alphabetical order.

PROC STD RATE Statement

PROC STD RATE < options > ;

Table 88.1 summarizes the *options* in the PROC STD RATE statement.

Table 88.1 Summary of PROC STD RATE Options

Option	Description
Input Data Sets	
DATA=	Names the SAS data set that contains the study populations
REFDATA=	Names the SAS data set that contains the reference population
Standardization Methods	
METHOD=	Specifies the method for standardization
STAT=	Specifies the statistic for standardization
EFFECT	Specifies the test to compare study populations for direct standardization and Mantel-Haenszel estimation
Displayed Output	
ALPHA=	Specifies the significance level for confidence intervals
CL=	Requests the confidence limits for the standardized estimates
PLOTS	Requests stratum-specific plots

You can specify the following *options* in the PROC STD RATE statement to compute standardized rates and risks in the procedure. They are listed in alphabetical order.

ALPHA= α

requests that confidence limits be constructed with confidence level $100(1 - \alpha)\%$, where $0 < \alpha < 1$. The default is ALPHA=0.05. These confidence limits include confidence limits for the stratum-specific rates or risks, standardized rate and risk, standardized morbidity/mortality ratio, and population attributable rate and risk.

CL=GAMMA < (TYPE=AVERAGE | CONSERVATIVE) > | LOGNORMAL | NONE | NORMAL | POISSON

specifies the method to construct confidence limits for SMR and standardized rate and risk. You can specify the following values for this option:

GAMMA

requests confidence limits based on a gamma distribution for METHOD=DIRECT and METHOD=MH. This value applies only when STAT=RATE. You can specify the TYPE=CONSERVATIVE suboption to request conservative confidence limits that are based on a gamma distribution and were developed by Fay and Feuer (1997), or you can specify the TYPE=AVERAGE suboption to request modified confidence limits proposed by Tiwari, Clegg, and Zou (2006).

LOGNORMAL

requests confidence limits based on a lognormal distribution.

NONE

suppresses construction of confidence limits.

NORMAL

requests confidence limits based on a normal distribution.

POISSON

requests confidence limits based on a Poisson distribution. This value applies only when METHOD=INDIRECT.

The default is CL=NORMAL.

DATA=SAS-data-set

names the required SAS data set that contains the event information in the study populations.

EFFECT <=DIFF | RATIO>

displays a table of the effect estimate and associated confidence limits. This option applies only when METHOD=DIRECT with two study populations and when METHOD=MH, where two study populations are required.

EFFECT and EFFECT=RATIO display a test on the ratio effect of estimates between the study populations, and the EFFECT=DIFF option displays a test on the difference effect.

METHOD= DIRECT | INDIRECT <(AF)> | MH <(AF)>**M= DIRECT | INDIRECT <(AF)> | MH <(AF)>**

specifies the required method for standardization. METHOD=DIRECT requests direct standardization, METHOD=INDIRECT requests indirect standardization, and METHOD=MH requests Mantel-Haenszel estimation.

The AF suboption requests the attributable fraction that measures the excess event rate or risk fraction in the exposed population that is attributable to the exposure. This suboption also requests the population attributable fraction that measures the excess event rate or risk fraction in the total population that is attributable to the exposure.

PLOTS <(global-options)> <= plot-request>**PLOTS <(global-options)> <= (plot-request <...plot-request>)>**

specifies options that control the details of the plots. The default is PLOTS=RATE for STAT=RATE and PLOTS=RISK for STAT=RISK.

You can specify the following *global-options*:

DISPLAY=INDEX | LEVEL

specifies tick mark values for the strata axis. DISPLAY=LEVEL displays strata levels on the strata axis, and DISPLAY=INDEX displays strata indices of sequential strata identification numbers on the strata axis. The default is DISPLAY=LEVEL.

ONLY

suppresses the default plots and displays only plots that are specifically requested.

STRATUM=HORIZONTAL | VERTICAL

controls the orientation of the plots. STRATUM=VERTICAL places the strata information on the vertical axis, and STRATUM=HORIZONTAL places the strata information on the horizontal axis. The default is STRATUM=VERTICAL.

You can specify the following *plot-requests*:

ALL

produces all appropriate plots.

DIST | DISTRIBUTION

displays a plot of the proportions for stratum-specific exposed time or sample size.

EFFECT

displays a plot of the stratum-specific effect estimates and associated confidence limits. This option applies only when METHOD=DIRECT with two study populations and when METHOD=MH, where two study populations are required. If the EFFECT=DIFF option is specified, the stratum-specific rate or risk difference effects are displayed. Otherwise, the stratum-specific rate or risk ratio effects are displayed.

NONE

suppresses all plots.

RATE

displays a plot of the stratum-specific rates and associated confidence limits. This option applies only when STAT=RATE. If a confidence limits method is specified in the STATS(CL=) option in the STRATA statement, that method is used to compute the confidence limits. Otherwise, the normal approximation is used.

RISK

displays a plot of the stratum-specific risks and associated confidence limits. This option applies only when STAT=RISK. If a confidence limits method is specified in the STATS(CL=) option in the STRATA statement, that method is used to compute the confidence limits. Otherwise, the normal approximation is used.

SMR

displays a plot of the stratum-specific SMR estimates and associated confidence limits. This option applies only when METHOD=INDIRECT. If a method is specified in the SMR(CL=) option in the STRATA statement, that method is used to compute the confidence limits. Otherwise, the normal approximation is used.

REFDATA=SAS-data-set

names the required SAS data set that contains the event information in the reference population.

STAT=RATE < (**MULT** =*c*) >

STAT=RISK

specifies the statistic for standardization. **STAT=RATE** computes standardized rates, and **STAT=RISK** computes standardized risks. The default is **STAT=RATE**.

The **MULT=** suboption in the **STAT=RATE** option specifies a power of 10 constant *c*, and requests that rates per *c* population-time units be displayed in the output tables and graphics. The default is **MULT=100000**, which specifies rates per 100,000 population-time units.

BY Statement

BY *variables* ;

You can specify a **BY** statement with **PROC STDRATE** to obtain separate analyses of observations in groups that are defined by the **BY** variables. When a **BY** statement appears, the procedure expects the input data set to be sorted in order of the **BY** variables. If you specify more than one **BY** statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the **SORT** procedure with a similar **BY** statement.
- Specify the **NOTSORTED** or **DESCENDING** option in the **BY** statement for the **STDRATE** procedure. The **NOTSORTED** option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the **BY** variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the **BY** variables by using the **DATASETS** procedure (in Base SAS software).

For more information about **BY**-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the **DATASETS** procedure, see the discussion in the *Base SAS Procedures Guide*.

POPULATION Statement

POPULATION < *options* > ;

The required **POPULATION** statement specifies the information in the study data set. You can specify the following *options* in the **POPULATION** statement:

EVENT=*variable*

specifies the *variable* for the number of events in the study data set.

GROUP < (**ORDER=DATA** | **FORMATTED** | **INTERNAL**) > =*variable*

specifies the *variable* whose values identify the various populations. This option is required when **METHOD=MH** and also applies when **METHOD=DIRECT** in the **PROC STDRATE** statement.

The optional ORDER= suboption specifies the order in which the values of the *variable* are to be displayed. You can specify the following values for the ORDER= suboption:

DATA	sorts by the order in which the values appear in the input data set.
FORMATTED	sorts by their external formatted values.
INTERNAL	sorts by the unformatted values, which yields the same order that the SORT procedure does.

By default, ORDER=INTERNAL. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent.

POPEVENT=number

specifies the total number of events in the study data set. This option applies only when METHOD=INDIRECT is specified in the PROC STD RATE statement and the total number of events is not available in the study data set.

RATE < (MULT=c) > = variable

specifies the *variable* for the observed rate in the study data set. This option applies only when STAT=RATE is specified in the PROC STD RATE statement. The MULT=c suboption specifies a power of 10 constant *c* and requests that the rates per *c* population-time units be read from the data set. The default is the value of the MULT= suboption used in the STAT=RATE option in the PROC STD RATE statement.

RISK=variable

specifies the *variable* for the observed risk in the study data set. This option applies only when STAT=RISK is specified in the PROC STD RATE statement.

TOTAL=variable

specifies the *variable* for either the population-time (STAT=RATE) or the number of observations (STAT=RISK) in the study data set.

REFERENCE Statement

REFERENCE < options > ;

The REFERENCE statement specifies the information in the reference data set. This statement is required when METHOD=DIRECT or METHOD=INDIRECT is specified in the PROC STD RATE statement.

You can specify the following *options* in the REFERENCE statement:

EVENT=variable

specifies the *variable* for the number of events in the reference data set.

RATE < (MULT=c) > = variable

specifies the *variable* for the observed rate in the reference data set. This option applies only when STAT=RATE is specified in the PROC STD RATE statement. The MULT=c suboption specifies a power of 10 constant *c* and requests that the rates per *c* population-time units be read from the data set. The default is the value of the MULT= suboption used in the STAT=RATE option in the PROC STD RATE statement.

RISK=*variable*

specifies the *variable* for the observed risk in the reference data set. This option applies only when STAT=RISK is specified in the PROC STD RATE statement.

TOTAL=*variable*

specifies the *variable* for either the population-time (STAT=RATE) or the number of observations (STAT=RISK) in the reference data set.

When METHOD=INDIRECT is specified in the PROC STD RATE statement, the overall reference population rate and risk are needed to compute indirect standardized rate and risk, respectively. If the information is not available in the reference data set, you can specify the following *options* for overall reference population rate and risk.

REFEVENT=*number*

specifies the total *number* of events in the reference data set.

REFRATE < (MULT=*c*) > = *number*

specifies the crude rate in the reference data set. This option applies only when STAT=RATE is specified in the PROC STD RATE statement. The MULT=*c* suboption specifies a power of 10 constant *c*, and the *number* is the crude rate per *c* population-time units in the data set. The default is the value of the MULT= suboption in the STAT=RATE option in the PROC STD RATE statement.

REFRISK=*number*

specifies the crude risk in the reference data set. This option applies only when STAT=RISK is specified in the PROC STD RATE statement.

REFTOTAL=*number*

specifies either the total population-time (STAT=RATE) or the total number of observations (STAT=RISK) in the reference data set.

When STAT=RATE, the REFRATE= option specifies the crude reference rate for the indirect standardized rate. If the REFRATE= option is not specified, the REFEVENT= and REFTOTAL options can be used to compute the crude reference rate. Similarly, when STAT=RISK, the REFRISK= option specifies the crude reference risk for the indirect standardized rate. If the REFRISK= option is not specified, the REFEVENT= and REFTOTAL options can be used to compute the crude reference risk.

STRATA Statement

STRATA *variables* </ *options* > ;

The STRATA statement names *variables* that form the strata in the standardization. The combinations of categories of STRATA variables define the strata in the population.

The STRATA variables are one or more variables in all input data sets. These variables can be either character or numeric. The formatted values of the STRATA variables determine the levels. Thus, you can use formats to group values into levels. See the FORMAT procedure in the *Base SAS Procedures Guide* and the FORMAT statement and SAS formats in *SAS Language Reference: Dictionary* for more information.

When the STRATA statement is not specified or the statement is specified without variables, all observations in a data set are treated as though they are from a single stratum.

You can specify the following *options* in the STRATA statement after a slash (/):

EFFECT

displays a table of the stratum-specific effect estimates and associated confidence limits. This option applies only when METHOD=DIRECT with two study populations and when METHOD=MH, where two study populations are required. If the EFFECT=DIFF option in the PROC STD RATE statement is specified, the stratum-specific rate or risk difference effects are displayed. Otherwise, the stratum-specific rate or risk ratio effects are displayed.

MISSING

treats missing values as a valid (nonmissing) category for all STRATA variables. When PROC STD RATE determines levels of a STRATA variable, an observation with missing values for that STRATA variable is excluded, unless the MISSING option is specified.

ORDER=DATA | FORMATTED | INTERNAL

specifies the order in which the values of the categorical variables are to be displayed. You can specify the following values for the ORDER= option:

DATA	sorts by the order in which the values appear in the input data set.
FORMATTED	sorts by their external formatted values.
INTERNAL	sorts by the unformatted values, which yields the same order that the SORT procedure does.

By default, ORDER=INTERNAL. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent.

STATS < (CL=LOGNORMAL | NONE | NORMAL | POISSON) >

displays tables for stratum-specific statistics such as stratum-specific rates and risks. You can specify the following values of the CL= suboption to request confidence limits for the rate or risk estimate in each stratum:

LOGNORMAL

requests confidence limits based on a lognormal approximation.

NONE

suppresses confidence limits.

NORMAL

requests confidence limits based on a normal approximation and also displays the standard error for the rate estimate in each stratum.

POISSON

requests confidence limits based on a Poisson distribution for stratum-specific rates. This values applies only when STAT=RATE in the PROC STD RATE statement.

The default is CL=NORMAL.

SMR < (CL=LOGNORMAL | NONE | NORMAL | POISSON) >

displays tables for stratum-specific SMR estimates. This option applies only when METHOD=INDIRECT is specified in the PROC STD RATE statement. You can specify the following values of the CL= suboption to request confidence limits for the SMR estimate in each stratum:

LOGNORMAL

requests confidence limits based on a lognormal approximation.

NONE

suppresses confidence limits.

NORMAL

requests confidence limits based on a normal approximation and also displays the standard error for the SMR estimate in each stratum.

POISSON

requests confidence limits based on a Poisson distribution for stratum-specific SMR estimates. This values applies only when STAT=RATE in the PROC STDRATE statement.

The default is CL=NORMAL.

Details: STDRATE Procedure

Rate

A major task in epidemiology is to compare event frequencies for groups of people. Both rate and risk are commonly used to measure event frequency in the comparison. Rate is a measure of change in one quantity per unit of another quantity. An event rate measures how fast the events are occurring. In contrast, an event risk is the probability that an event occurs over a specified follow-up time period.

An event rate of a population over a specified time period can be defined as the number of new events divided by the population-time of the population over the same time period,

$$\hat{\lambda} = \frac{d}{\mathcal{T}}$$

where d is the number of events and \mathcal{T} is the population-time that is computed by adding up the time contributed by each subject in the population over the specified time period.

For a general population, the subsets (strata) might not be homogeneous enough to have a similar rate. Thus, the rate for each stratum should be computed separately to reflect this discrepancy. For a population that consists of K homogeneous strata (such as different age groups), the stratum-specific rate for the j th stratum in a population is computed as

$$\hat{\lambda}_j = \frac{d_j}{\mathcal{T}_j}$$

where d_j is the number of events and \mathcal{T}_j is the population-time for subjects in the j th stratum of the population.

Assuming the number of events in the j th stratum, d_j , has a Poisson distribution, the variance of $\hat{\lambda}_j$ is

$$V(\hat{\lambda}_j) = V\left(\frac{d_j}{\mathcal{T}_j}\right) = \frac{1}{\mathcal{T}_j^2} V(d_j) = \frac{d_j}{\mathcal{T}_j^2} = \frac{\hat{\lambda}_j}{\mathcal{T}_j}$$

By using the method of statistical differentials (Elandt-Johnson and Johnson 1980, pp. 70–71), the variance of the logarithm of rate can be estimated by

$$V(\log(\hat{\lambda}_j)) = \frac{1}{\hat{\lambda}_j^2} V(\hat{\lambda}_j) = \frac{1}{\hat{\lambda}_j^2} \frac{\hat{\lambda}_j}{\mathcal{T}_j} = \frac{1}{\hat{\lambda}_j \mathcal{T}_j} = \frac{1}{d_j}$$

Because the rate value can be very small, especially for rare events, it is sometimes expressed in terms of the product of a multiplier and the rate itself. For example, a rate can be expressed as the number of events per 100,000 person-years.

Normal Distribution Confidence Interval for Rate

A $(1 - \alpha)$ confidence interval for $\hat{\lambda}_j$ based on a normal distribution is given by

$$\left(\hat{\lambda}_j - z \sqrt{V(\hat{\lambda}_j)}, \hat{\lambda}_j + z \sqrt{V(\hat{\lambda}_j)} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution.

Lognormal Distribution Confidence Interval for Rate

A $(1 - \alpha)$ confidence interval for $\log(\hat{\lambda}_j)$ based on a normal distribution is given by

$$\left(\log(\hat{\lambda}_j) - z \sqrt{V(\log(\hat{\lambda}_j))}, \log(\hat{\lambda}_j) + z \sqrt{V(\log(\hat{\lambda}_j))} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution and the variance $V(\log(\hat{\lambda}_j)) = 1/d_j$.

Thus, a $(1 - \alpha)$ confidence interval for $\hat{\lambda}_j$ based on a lognormal distribution is given by

$$\left(\hat{\lambda}_j e^{-\frac{z}{\sqrt{d_j}}}, \hat{\lambda}_j e^{\frac{z}{\sqrt{d_j}}} \right)$$

Poisson Distribution Confidence Interval for Rate

Denote the $(\alpha/2)$ quantile for the χ^2 distribution with $2d_j$ degrees of freedom by

$$q_{lj} = (\chi_{2d_j}^2)^{-1}(\alpha/2)$$

Denote the $(1 - \alpha/2)$ quantiles for the χ^2 distribution with $2(d_j + 1)$ degrees of freedom by

$$q_{uj} = (\chi_{2(d_j+1)}^2)^{-1}(1 - \alpha/2)$$

Then a $(1 - \alpha)$ confidence interval for $\hat{\lambda}_j$ based on the χ^2 distribution is given by

$$\left(\frac{q_{lj}}{2\mathcal{T}_j}, \frac{q_{uj}}{2\mathcal{T}_j} \right)$$

Confidence Interval for Rate Difference Statistic

For rate estimates from two independent samples, $\hat{\lambda}_{1j}$ and $\hat{\lambda}_{2j}$, a $(1 - \alpha)$ confidence interval for the rate difference $\hat{\lambda}_{dj} = \hat{\lambda}_{1j} - \hat{\lambda}_{2j}$ is

$$\left(\hat{\lambda}_{dj} - z \sqrt{V(\hat{\lambda}_{dj})}, \hat{\lambda}_{dj} + z \sqrt{V(\hat{\lambda}_{dj})} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution and the variance

$$V(\hat{\lambda}_{dj}) = V(\hat{\lambda}_{1j}) + V(\hat{\lambda}_{2j})$$

Confidence Interval for Rate Ratio Statistic

For rate estimates from two independent samples, $\hat{\lambda}_{1j}$ and $\hat{\lambda}_{2j}$, a $(1 - \alpha)$ confidence interval for the log rate ratio statistic $\log(\hat{\lambda}_{rj}) = \log(\hat{\lambda}_{1j}/\hat{\lambda}_{2j})$ is

$$\left(\log(\hat{\lambda}_{rj}) - z \sqrt{V(\log(\hat{\lambda}_{rj}))}, \log(\hat{\lambda}_{rj}) + z \sqrt{V(\log(\hat{\lambda}_{rj}))} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution and the variance

$$V(\log(\hat{\lambda}_{rj})) = V(\log(\hat{\lambda}_{1j})) + V(\log(\hat{\lambda}_{2j}))$$

Thus, a $(1 - \alpha)$ confidence interval for the rate ratio statistic $\hat{\lambda}_{rj}$ is given by

$$\left(\frac{\hat{\lambda}_{1j}}{\hat{\lambda}_{2j}} e^{-z \sqrt{V(\log(\hat{\lambda}_{rj}))}}, \frac{\hat{\lambda}_{1j}}{\hat{\lambda}_{2j}} e^{z \sqrt{V(\log(\hat{\lambda}_{rj}))}} \right)$$

Confidence Interval for Rate SMR

At stratum j , a stratum-specific standardized morbidity/mortality ratio is

$$\mathcal{R}_j = \frac{d_j}{\mathcal{E}_j}$$

where \mathcal{E}_j is the expected number of events.

With the rate

$$\hat{\lambda}_j = \frac{d_j}{\mathcal{T}_j}$$

SMR can be expressed as

$$\mathcal{R}_j = \frac{\mathcal{T}_j}{\mathcal{E}_j} \hat{\lambda}_j$$

Thus, a $(1 - \alpha)$ confidence interval for \mathcal{R}_j is given by

$$\left(\frac{\mathcal{T}_j}{\mathcal{E}_j} \hat{\lambda}_{jl}, \frac{\mathcal{T}_j}{\mathcal{E}_j} \hat{\lambda}_{ju} \right)$$

where $(\hat{\lambda}_{jl}, \hat{\lambda}_{ju})$ is a $(1 - \alpha)$ confidence interval for the rate $\hat{\lambda}_j$.

Risk

An event risk of a population over a specified time period can be defined as the number of new events in the follow-up time period divided by the event-free population size at the beginning of the time period,

$$\hat{\gamma} = \frac{d}{\mathcal{N}}$$

where \mathcal{N} is the population size.

For a general population, the subsets (strata) might not be homogeneous enough to have a similar risk. Thus, the risk for each stratum should be computed separately to reflect this discrepancy. For a population that consists of K homogeneous strata (such as different age groups), the stratum-specific risk for the j th stratum in a population is computed as

$$\hat{\gamma}_j = \frac{d_j}{\mathcal{N}_j}$$

where \mathcal{N}_j is the population size in the j th stratum of the population.

Assuming the number of events, d_j , has a binomial distribution, then a variance estimate of $\hat{\gamma}_j$ is

$$V(\hat{\gamma}_j) = \frac{\hat{\gamma}_j(1 - \hat{\gamma}_j)}{\mathcal{N}_j}$$

By using the method of statistical differentials (Elandt-Johnson and Johnson 1980, pp. 70–71), the variance of the logarithm of risk can be estimated by

$$V(\log(\hat{\gamma}_j)) = \frac{1}{\hat{\gamma}_j^2} V(\hat{\gamma}_j) = \frac{1}{\hat{\gamma}_j^2} \frac{\hat{\gamma}_j(1 - \hat{\gamma}_j)}{\mathcal{N}_j} = \frac{1 - \hat{\gamma}_j}{\hat{\gamma}_j \mathcal{N}_j} = \frac{1}{d_j} - \frac{1}{\mathcal{N}_j}$$

Normal Distribution Confidence Interval for Risk

A $(1 - \alpha)$ confidence interval for $\hat{\gamma}_j$ based on a normal distribution is given by

$$\left(\hat{\gamma}_j - z \sqrt{V(\hat{\gamma}_j)}, \hat{\gamma}_j + z \sqrt{V(\hat{\gamma}_j)} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution.

Lognormal Distribution Confidence Interval for Risk

A $(1 - \alpha)$ confidence interval for $\log(\hat{\gamma}_j)$ based on a normal distribution is given by

$$\left(\log(\hat{\gamma}_j) - z \sqrt{V(\log(\hat{\gamma}_j))}, \log(\hat{\gamma}_j) + z \sqrt{V(\log(\hat{\gamma}_j))} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution and the variance $V(\log(\hat{\gamma}_j)) = 1/d_j - 1/\mathcal{N}_j$.

Thus, a $(1 - \alpha)$ confidence interval for $\hat{\gamma}_j$ based on a lognormal distribution is given by

$$\left(\hat{\gamma}_j e^{-z \sqrt{\frac{1}{d_j} - \frac{1}{\mathcal{N}_j}}}, \hat{\gamma}_j e^{z \sqrt{\frac{1}{d_j} - \frac{1}{\mathcal{N}_j}}} \right)$$

Confidence Interval for Risk Difference Statistic

For rate estimates from two independent samples, $\hat{\gamma}_{1j}$ and $\hat{\gamma}_{2j}$, a $(1 - \alpha)$ confidence interval for the risk difference $\hat{\gamma}_{dj} = \hat{\gamma}_{1j} - \hat{\gamma}_{2j}$ is

$$\left(\hat{\gamma}_{dj} - z \sqrt{V(\hat{\gamma}_{dj})}, \hat{\gamma}_{dj} + z \sqrt{V(\hat{\gamma}_{dj})} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution and the variance

$$V(\hat{\gamma}_{dj}) = V(\hat{\gamma}_{1j}) + V(\hat{\gamma}_{2j})$$

Confidence Interval for Risk Ratio Statistic

For rate estimates from two independent samples, $\hat{\gamma}_{1j}$ and $\hat{\gamma}_{2j}$, a $(1 - \alpha)$ confidence interval for the log risk ratio statistic $\log(\hat{\gamma}_{rj}) = \log(\hat{\gamma}_{1j}/\hat{\gamma}_{2j})$ is

$$\left(\log(\hat{\gamma}_{rj}) - z \sqrt{V(\log(\hat{\gamma}_{rj}))}, \log(\hat{\gamma}_{rj}) + z \sqrt{V(\log(\hat{\gamma}_{rj}))} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution and the variance

$$V(\log(\hat{\gamma}_{rj})) = V(\log(\hat{\gamma}_{1j})) + V(\log(\hat{\gamma}_{2j}))$$

Thus, a $(1 - \alpha)$ confidence interval for the risk ratio statistic $\hat{\gamma}_{rj}$ is given by

$$\left(\frac{\hat{\gamma}_{1j}}{\hat{\gamma}_{2j}} e^{-z \sqrt{V(\log(\hat{\gamma}_{rj}))}}, \frac{\hat{\gamma}_{1j}}{\hat{\gamma}_{2j}} e^{z \sqrt{V(\log(\hat{\gamma}_{rj}))}} \right)$$

Confidence Interval for Risk SMR

At stratum j , a stratum-specific standardized morbidity/mortality ratio is

$$\mathcal{R}_j = \frac{d_j}{\mathcal{E}_j}$$

where \mathcal{E}_j is the expected number of events.

With the risk

$$\hat{\gamma}_j = \frac{d_j}{\mathcal{N}_j}$$

SMR can be expressed as

$$\mathcal{R}_j = \frac{\mathcal{N}_j}{\mathcal{E}_j} \hat{\gamma}_j$$

Thus, a $(1 - \alpha)$ confidence interval for \mathcal{R}_j is given by

$$\left(\frac{\mathcal{N}_j}{\mathcal{E}_j} \hat{\gamma}_{jl}, \frac{\mathcal{N}_j}{\mathcal{E}_j} \hat{\gamma}_{ju} \right)$$

where $(\hat{\gamma}_{jl}, \hat{\gamma}_{ju})$ is a $(1 - \alpha)$ confidence interval for the risk $\hat{\gamma}_j$.

Direct Standardization

Direct standardization uses the weights from a reference population to compute the standardized rate of a study group as the weighted average of stratum-specific rates in the study population. The standardized rate is computed as

$$\hat{\lambda}_{ds} = \frac{\sum_j \mathcal{T}_{rj} \hat{\lambda}_{sj}}{\mathcal{T}_r}$$

where $\hat{\lambda}_{sj}$ is the rate in the j th stratum of the study population, \mathcal{T}_{rj} is the population-time in the j th stratum of the reference population, and $\mathcal{T}_r = \sum_k \mathcal{T}_{rk}$ is the population-time in the reference population.

Similarly, direct standardization uses the weights from a reference population to compute the standardized risk of a study group as the weighted average of stratum-specific risks in the study population. The standardized risk is computed as

$$\hat{\gamma}_{ds} = \frac{\sum_j \mathcal{N}_{rj} \hat{\gamma}_{sj}}{\mathcal{N}_r}$$

where $\hat{\gamma}_{sj}$ is the risk in the j th stratum of the study population, \mathcal{N}_{rj} is the number of observations in the j th stratum of the reference population, and $\mathcal{N}_r = \sum_k \mathcal{N}_{rk}$ is the total number of observations in the reference population.

That is, the directly standardized rate and risk of a study population are weighted averages of the stratum-specific rates and risks, respectively, where the weights are the corresponding strata population sizes in the reference population. The direct standardization can be used when the study population is large enough to provide stable stratum-specific rates or risks. When the same reference population is used for multiple study populations, directly standardized rates and risks provide valid comparisons between study populations.

The variances of the directly standardized rate and risk are

$$V(\hat{\lambda}_{ds}) = V\left(\frac{\sum_j \mathcal{T}_{rj} \hat{\lambda}_{sj}}{\mathcal{T}_r}\right) = \frac{\sum_j \mathcal{T}_{rj}^2 V(\hat{\lambda}_{sj})}{\mathcal{T}_r^2}$$

$$V(\hat{\gamma}_{ds}) = V\left(\frac{\sum_j \mathcal{N}_{rj} \hat{\gamma}_{sj}}{\mathcal{N}_r}\right) = \frac{\sum_j \mathcal{N}_{rj}^2 V(\hat{\gamma}_{sj})}{\mathcal{N}_r^2}$$

By using the method of statistical differentials (Elandt-Johnson and Johnson 1980, pp. 70–71), the variance of the logarithm of directly standardized rate and risk can be estimated by

$$V(\log(\hat{\lambda}_{ds})) = \frac{1}{\hat{\lambda}_{ds}^2} V(\hat{\lambda}_{ds})$$

$$V(\log(\hat{\gamma}_{ds})) = \frac{1}{\hat{\gamma}_{ds}^2} V(\hat{\gamma}_{ds})$$

The confidence intervals for $\hat{\lambda}_{ds}$ and $\hat{\gamma}_{ds}$ can be constructed based on normal and lognormal distributions. A gamma distribution confidence interval can also be constructed for $\hat{\lambda}_{ds}$.

In the next four subsections, $\beta = \lambda$ denotes the rate statistic and $\beta = \gamma$ denotes the risk statistic.

Normal Distribution Confidence Intervals for Standardized Rate and Risk

A $(1 - \alpha)$ confidence interval for $\hat{\beta}_{ds}$ based on a normal distribution is then given by

$$\left(\hat{\beta}_{ds} - z \sqrt{V(\hat{\beta}_{ds})}, \hat{\beta}_{ds} + z \sqrt{V(\hat{\beta}_{ds})} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution.

Lognormal Distribution Confidence Intervals for Standardized Rate and Risk

A $(1 - \alpha)$ confidence interval for $\log(\hat{\beta}_{ds})$ based on a normal distribution is given by

$$\left(\log(\hat{\beta}_{ds}) - z \sqrt{V(\log(\hat{\beta}_{ds}))}, \log(\hat{\beta}_{ds}) + z \sqrt{V(\log(\hat{\beta}_{ds}))} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution.

Thus, a $(1 - \alpha)$ confidence interval for $\hat{\beta}_{ds}$ based on a lognormal distribution is given by

$$\left(\hat{\beta}_{ds} e^{-z \sqrt{V(\log(\hat{\beta}_{ds}))}}, \hat{\beta}_{ds} e^{z \sqrt{V(\log(\hat{\beta}_{ds}))}} \right)$$

Gamma Distribution Confidence Interval for Standardized Rate

Fay and Feuer (1997) use the relationship between the Poisson and gamma distributions to derive approximate confidence intervals for the standardized rate $\hat{\lambda}_{ds}$ based on the gamma distribution. As in the construction of the asymptotic normal confidence intervals, it is assumed that the number of events has a Poisson distribution, and the standardized rate is a weighted sum of independent Poisson random variables. A confidence interval for $\hat{\lambda}_{ds}$ is then given by

$$\left(\frac{v}{2\hat{\lambda}_{ds}} (\chi^2)^{-1}_{\frac{2\hat{\lambda}_{ds}^2}{v}} \left(\frac{\alpha}{2} \right), \frac{v + w_x^2}{2(\hat{\lambda}_{ds} + w_x)} (\chi^2)^{-1}_{\frac{2(\hat{\lambda}_{ds} + w_x)^2}{v + w_x^2}} \left(1 - \frac{\alpha}{2} \right) \right)$$

where

$$v = \sum_j w_j^2 \frac{\hat{\lambda}_{sj}}{\bar{T}_{sj}}$$

$$w_j = \frac{\bar{T}_{rj}}{\bar{T}_r} \frac{1}{\bar{T}_{sj}}$$

and w_x is the maximum w_j .

Tiwari, Clegg, and Zou (2006) propose a less conservative confidence interval for $\hat{\lambda}_{ds}$ with a different upper confidence limit,

$$\left(\frac{v}{2\hat{\lambda}_{ds}} (\chi^2)^{-1}_{\frac{2\hat{\lambda}_{ds}^2}{v}} \left(\frac{\alpha}{2} \right), \frac{v + w_{2m}}{2(\hat{\lambda}_{ds} + w_m)} (\chi^2)^{-1}_{\frac{2(\hat{\lambda}_{ds} + w_m)^2}{v + w_{2m}}} \left(1 - \frac{\alpha}{2} \right) \right)$$

where w_m is the average w_j and w_{2m} is the average w_j^2 .

Comparing Standardized Rates and Comparing Standardized Risks

By using the same reference population, two directly standardized rates or risks from different populations can be compared. Both the difference and ratio statistics can be used in the comparison. Assume that $\hat{\beta}_1$ and $\hat{\beta}_2$ are directly standardized rates or risks for two populations with variances $V(\hat{\beta}_1)$ and $V(\hat{\beta}_2)$, respectively. The difference test assumes that the difference statistic

$$\hat{\beta}_1 - \hat{\beta}_2$$

has a normal distribution with mean 0 under the null hypothesis $H_0 : \beta_1 = \beta_2$. The variance is given by

$$V(\hat{\beta}_1 - \hat{\beta}_2) = V(\hat{\beta}_1) + V(\hat{\beta}_2)$$

The ratio test assumes that the log ratio statistic,

$$\log \left(\frac{\hat{\beta}_1}{\hat{\beta}_2} \right)$$

has a normal distribution with mean 0 under the null hypothesis $H_0 : \beta_1 = \beta_2$, or equivalently, $\log(\beta_1/\beta_2) = 0$. An estimated variance is given by

$$V \left(\log \left(\frac{\hat{\beta}_1}{\hat{\beta}_2} \right) \right) = V(\log(\hat{\beta}_1)) + V(\log(\hat{\beta}_2)) = \frac{1}{\hat{\beta}_1^2} V(\hat{\beta}_1) + \frac{1}{\hat{\beta}_2^2} V(\hat{\beta}_2)$$

Mantel-Haenszel Effect Estimation

In direct standardization, the derived standardized rates and risks in a study population are the weighted average of the stratum-specific rates and risks in the population, respectively, where the weights are given by the population-time for standardized rate and the number of observations for standardized risk in a reference population.

Assuming that an effect, such as rate difference, rate ratio, risk difference, and risk ratio between two populations, is homogeneous across strata, the Mantel-Haenszel estimates of this effect can be constructed from directly standardized rates or risks in the two populations, where the weights are constructed from the stratum-specific population-times for rate and number of observations for risk of the two populations.

That is, for population k , $k=1$ and 2 , the standardized rate and risk are

$$\hat{\lambda}_k = \frac{\sum_j w_j \hat{\lambda}_{kj}}{\sum_j w_j} \quad \text{and} \quad \hat{\gamma}_k = \frac{\sum_j w_j \hat{\gamma}_{kj}}{\sum_j w_j}$$

where the weights are

$$w_j = \frac{\mathcal{T}_{1j} \mathcal{T}_{2j}}{\mathcal{T}_{1j} + \mathcal{T}_{2j}}$$

for standardized rate, and

$$w_j = \frac{\mathcal{N}_{1j} \mathcal{N}_{2j}}{\mathcal{N}_{1j} + \mathcal{N}_{2j}}$$

for standardized risk.

Rate and Risk Difference Statistics

Denote $\beta = \lambda$ for rate and $\beta = \gamma$ for risk. The variance is

$$V(\hat{\beta}_k) = V\left(\frac{\sum_j w_j \hat{\beta}_{kj}}{\sum_j w_j}\right) = \frac{1}{(\sum_j w_j)^2} \sum_j w_j^2 V(\hat{\beta}_{kj})$$

The Mantel-Haenszel difference statistic is

$$\hat{\beta}_1 - \hat{\beta}_2$$

with variance

$$V(\hat{\beta}_1 - \hat{\beta}_2) = V(\hat{\beta}_1) + V(\hat{\beta}_2)$$

Under the null hypothesis $H_0 : \beta_1 = \beta_2$, the difference statistic $\hat{\beta}_1 - \hat{\beta}_2$ has a normal distribution with mean 0.

Rate Ratio Statistic

The Mantel-Haenszel rate ratio statistic is $\hat{\lambda}_1/\hat{\lambda}_2$, and the log ratio statistic is

$$\log\left(\frac{\hat{\lambda}_1}{\hat{\lambda}_2}\right)$$

Under the null hypothesis $H_0 : \lambda_1 = \lambda_2$ (or equivalently, $\log(\lambda_1/\lambda_2) = 0$), the log ratio statistic has a normal distribution with mean 0 and variance

$$V\left(\log\left(\frac{\hat{\lambda}_1}{\hat{\lambda}_2}\right)\right) = \frac{\sum_j w_j \hat{\lambda}_{pj}}{(\sum_j w_j \hat{\lambda}_{1j}) (\sum_j w_j \hat{\lambda}_{2j})}$$

where

$$\hat{\lambda}_{pj} = \frac{d_{1j} + d_{2j}}{\mathcal{T}_{1j} + \mathcal{T}_{2j}}$$

is the combined rate estimate in stratum j under the null hypothesis of equal rates (Greenland and Robins 1985; Greenland and Rothman 2008, p. 273).

Risk Ratio Statistic

The Mantel-Haenszel risk ratio statistic is $\hat{\gamma}_1/\hat{\gamma}_2$, and the log ratio statistic is

$$\log\left(\frac{\hat{\gamma}_1}{\hat{\gamma}_2}\right)$$

Under the null hypothesis $H_0 : \gamma_1 = \gamma_2$ (or equivalently, $\log(\gamma_1/\gamma_2) = 0$), the log ratio statistic has a normal distribution with mean 0 and variance

$$V\left(\log\left(\frac{\hat{\gamma}_1}{\hat{\gamma}_2}\right)\right) = \frac{\sum_j w_j (\hat{\gamma}_{pj} - \hat{\gamma}_{1j}\hat{\gamma}_{2j})}{(\sum_j w_j \hat{\gamma}_{1j}) (\sum_j w_j \hat{\gamma}_{2j})}$$

where

$$\hat{\gamma}_{pj} = \frac{d_{1j} + d_{2j}}{\mathcal{N}_{1j} + \mathcal{N}_{2j}}$$

is the combined risk estimate in stratum j under the null hypothesis of equal risks (Greenland and Robins 1985; Greenland and Rothman 2008, p. 275).

Indirect Standardization and Standardized Morbidity/Mortality Ratio

Indirect standardization compares the rates of the study and reference populations by applying the stratum-specific rates in the reference population to the study population, where the stratum-specific rates might not be reliable.

The expected number of events in the study population is

$$\mathcal{E} = \sum_j \mathcal{T}_{sj} \hat{\lambda}_{rj}$$

where \mathcal{T}_{sj} is the population-time in the j th stratum of the study population and $\hat{\lambda}_{rj}$ is the rate in the j th stratum of the reference population.

With the expected number of events, \mathcal{E} , the standardized morbidity ratio or standardized mortality ratio can be expressed as

$$\mathcal{R}_{sm} = \frac{\mathcal{D}}{\mathcal{E}}$$

where \mathcal{D} is the observed number of events (Breslow and Day 1987, p. 65).

The ratio $\mathcal{R}_{sm} > 1$ indicates that the mortality rate or risk in the study population is larger than the estimate in the reference population, and $\mathcal{R}_{sm} < 1$ indicates that the mortality rate or risk in the study population is smaller than the estimate in the reference population.

With the ratio \mathcal{R}_{sm} , an indirectly standardized rate for the study population is computed as

$$\hat{\lambda}_{is} = \mathcal{R}_{sm} \hat{\lambda}_r$$

where $\hat{\lambda}_r$ is the overall crude rate in the reference population.

Similarly, to compare the risks of the study and reference populations, the stratum-specific risks in the reference population are used to compute the expected number of events in the study population

$$\mathcal{E} = \sum_j \mathcal{N}_{sj} \hat{\gamma}_{rj}$$

where \mathcal{N}_{sj} is the number of observations in the j th stratum of the study population and $\hat{\gamma}_{rj}$ is the risk in the j th stratum of the reference population.

Also, with the standardized morbidity ratio $\mathcal{R}_{sm} = \mathcal{D}/\mathcal{E}$, an indirectly standardized risk for the study population is computed as

$$\hat{\gamma}_{is} = \mathcal{R}_{sm} \hat{\gamma}_r$$

where $\hat{\gamma}_r$ is the overall crude risk in the reference population.

The observed number of events in the study population is $\mathcal{D} = \sum_j d_{sj}$, where d_{sj} is the number of events in the j th stratum of the population. For the rate estimate, if d_{sj} has a Poisson distribution, then the variance of the standardized mortality ratio $\mathcal{R}_{sm} = \mathcal{D} / \mathcal{E}$ is

$$V(\mathcal{R}_{sm}) = \frac{1}{\mathcal{E}^2} \sum_j V(d_{sj}) = \frac{1}{\mathcal{E}^2} \sum_j d_{sj} = \frac{\mathcal{D}}{\mathcal{E}^2} = \frac{\mathcal{R}_{sm}}{\mathcal{E}}$$

For the risk estimate, if d_{sj} has a binomial distribution, then the variance of $\mathcal{R}_{sm} = \mathcal{D} / \mathcal{E}$ is

$$V(\mathcal{R}_{sm}) = V\left(\frac{1}{\mathcal{E}} \sum_j d_{sj}\right) = \frac{1}{\mathcal{E}^2} \sum_j V(d_{sj}) = \frac{1}{\mathcal{E}^2} \sum_j \mathcal{N}_{sj}^2 V(\hat{\gamma}_{sj})$$

where

$$V(\hat{\gamma}_{sj}) = \frac{\hat{\gamma}_{sj}(1 - \hat{\gamma}_{sj})}{\mathcal{N}_{sj}}$$

By using the method of statistical differentials (Elandt-Johnson and Johnson 1980, pp. 70–71), the variance of the logarithm of \mathcal{R}_{sm} can be estimated by

$$V(\log(\mathcal{R}_{sm})) = \frac{1}{\mathcal{R}_{sm}^2} V(\mathcal{R}_{sm})$$

For the rate estimate,

$$V(\log(\mathcal{R}_{sm})) = \frac{1}{\mathcal{R}_{sm}^2} V(\mathcal{R}_{sm}) = \frac{1}{\mathcal{R}_{sm}^2} \frac{\mathcal{R}_{sm}}{\mathcal{E}} = \frac{1}{\mathcal{R}_{sm}} \frac{1}{\mathcal{E}} = \frac{1}{\mathcal{D}}$$

The confidence intervals for \mathcal{R}_{sm} can be constructed based on normal, lognormal, and Poisson distributions.

Normal Distribution Confidence Interval for SMR

A $(1 - \alpha)$ confidence interval for \mathcal{R}_{sm} based on a normal distribution is given by

$$(\mathcal{R}_l, \mathcal{R}_u) = \left(\mathcal{R}_{sm} - z \sqrt{V(\mathcal{R}_{sm})}, \mathcal{R}_{sm} + z \sqrt{V(\mathcal{R}_{sm})} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution.

A test statistic for the null hypothesis $H_0 : \text{SMR} = 1$ is then given by

$$\frac{\mathcal{R}_{sm} - 1}{\sqrt{V(\mathcal{R}_{sm})}}$$

The test statistic has an approximate standard normal distribution under H_0 .

Lognormal Distribution Confidence Interval for SMR

A $(1 - \alpha)$ confidence interval for $\log(\mathcal{R}_{sm})$ based on a normal distribution is given by

$$\left(\log(\mathcal{R}_{sm}) - z \sqrt{V(\log(\mathcal{R}_{sm}))}, \log(\mathcal{R}_{sm}) + z \sqrt{V(\log(\mathcal{R}_{sm}))} \right)$$

where $z = \Phi^{-1}(1 - \alpha/2)$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution.

Thus, a $(1 - \alpha)$ confidence interval for \mathcal{R}_{sm} based on a lognormal distribution is given by

$$\left(\mathcal{R}_{sm} e^{-z \sqrt{V(\log(\mathcal{R}_{sm}))}}, \mathcal{R}_{sm} e^{z \sqrt{V(\log(\mathcal{R}_{sm}))}} \right)$$

A test statistic for the null hypothesis $H_0 : \text{SMR} = 1$ is then given by

$$\frac{\log(\mathcal{R}_{sm})}{\sqrt{V(\log(\mathcal{R}_{sm}))}}$$

The test statistic has an approximate standard normal distribution under H_0 .

Poisson Distribution Confidence Interval for Rate SMR

Denote the $(\alpha/2)$ quantile for the χ^2 distribution with $2\mathcal{D}$ degrees of freedom by

$$q_l = (\chi_{2\mathcal{D}}^2)^{-1}(\alpha/2)$$

Denote the $(1 - \alpha/2)$ quantiles for the χ^2 distribution with $2(\mathcal{D} + 1)$ degrees of freedom by

$$q_u = (\chi_{2(\mathcal{D}+1)}^2)^{-1}(1 - \alpha/2)$$

Then a $(1 - \alpha)$ confidence interval for \mathcal{R}_{sm} based on the χ^2 distribution is given by

$$(\mathcal{R}_l, \mathcal{R}_u) = \left(\frac{q_l}{2\mathcal{E}}, \frac{q_u}{2\mathcal{E}} \right)$$

A p -value for the test of the null hypothesis $H_0 : \text{SMR} = 1$ is given by

$$2 \min \left(\sum_{k=0}^{\mathcal{D}} \frac{e^{-\mathcal{E}} \mathcal{E}^k}{k!}, \sum_{k=\mathcal{D}}^{\infty} \frac{e^{-\mathcal{E}} \mathcal{E}^k}{k!} \right)$$

Indirectly Standardized Rate and Its Confidence Interval

With a rate-standardized mortality ratio \mathcal{R}_{sm} , an indirectly standardized rate for the study population is computed as

$$\hat{\lambda}_{is} = \mathcal{R}_{sm} \hat{\lambda}_r$$

where $\hat{\lambda}_r$ is the overall crude rate in the reference population.

The $(1 - \alpha/2)$ confidence intervals for $\hat{\lambda}_{is}$ can be constructed as

$$(\mathcal{R}_l \hat{\lambda}_r, \mathcal{R}_u \hat{\lambda}_r)$$

where $(\mathcal{R}_l, \mathcal{R}_u)$ is the confidence interval for \mathcal{R}_{sm} .

Indirectly Standardized Risk and Its Confidence Interval

With a risk-standardized mortality ratio \mathcal{R}_{sm} , an indirectly standardized risk for the study population is computed as

$$\hat{\gamma}_{is} = \mathcal{R}_{sm} \hat{\gamma}_r$$

where $\hat{\gamma}_r$ is the overall crude risk in the reference population.

The $(1 - \alpha/2)$ confidence intervals for $\hat{\gamma}_{is}$ can be constructed as

$$(\mathcal{R}_l \hat{\gamma}_r, \mathcal{R}_u \hat{\gamma}_r)$$

where $(\mathcal{R}_l, \mathcal{R}_u)$ is the confidence interval for \mathcal{R}_{sm} .

Attributable Fraction and Population Attributable Fraction

The attributable fraction measures the excess event rate or risk fraction in the exposed population that is attributable to the exposure. That is, it is the proportion of event rate or risk in the exposed population that would be reduced if the exposure were not present. In contrast, the population attributable fraction measures the excess event rate or risk fraction in the total population that is attributable to the exposure.

In the STDRATE procedure, you can compute the attributable fraction by using either indirect standardization or Mantel-Haenszel estimation.

Indirect Standardization

With indirect standardization, you specify a study population that consists of subjects who are exposed to a factor, such as smoking, and a reference population that consists of subjects who are not exposed to the factor. Denote the numbers of events in the study and reference populations by \mathcal{D}_s and \mathcal{D}_r , respectively.

For the rate estimate, denote the population-times in the study and reference populations by \mathcal{T}_s and \mathcal{T}_r , respectively. Then the event rates in the two populations can be expressed as the following equations, respectively:

$$\hat{\lambda}_s = \frac{\mathcal{D}_s}{\mathcal{T}_s} \quad \text{and} \quad \hat{\lambda}_r = \frac{\mathcal{D}_r}{\mathcal{T}_r}$$

Similarly, for the risk estimate, denote the numbers of observations in the study and reference populations by \mathcal{N}_s and \mathcal{N}_r , respectively. Then the event risks in the two populations can be expressed as the following equations, respectively:

$$\hat{\gamma}_s = \frac{\mathcal{D}_s}{\mathcal{N}_s} \quad \text{and} \quad \hat{\gamma}_r = \frac{\mathcal{D}_r}{\mathcal{N}_r}$$

In the next two subsections, $\beta = \lambda$ denotes the rate statistic and $\beta = \gamma$ denotes the risk statistic.

Attributable Fraction with Indirect Standardization

The attributable fraction is the fraction of event rate or risk in the exposed population that is attributable to exposure:

$$\mathcal{R}_a = \frac{\hat{\beta}_s - \hat{\beta}_r}{\hat{\beta}_s}$$

With a standardized mortality ratio \mathcal{R}_{sm} , the attributable fraction is estimated by

$$\mathcal{R}_a = \frac{\mathcal{R}_{sm} - 1}{\mathcal{R}_{sm}}$$

The confidence intervals for the attributable fraction can be computed using the confidence intervals for \mathcal{R}_{sm} . That is, with a confidence interval $(\mathcal{R}_l, \mathcal{R}_u)$ for \mathcal{R}_{sm} , the corresponding \mathcal{R}_a confidence interval is given by

$$\left(\frac{\mathcal{R}_l - 1}{\mathcal{R}_l}, \frac{\mathcal{R}_u - 1}{\mathcal{R}_u} \right)$$

Population Attributable Fraction with Indirect Standardization

The population attributable fraction for a population is the fraction of event rate or risk in a given time period that is attributable to exposure. The population attributable fraction is

$$\mathcal{R}_{pa} = \frac{\hat{\beta}_0 - \hat{\beta}_r}{\hat{\beta}_0}$$

where

$$\hat{\beta}_0 = \frac{\mathcal{D}_s + \mathcal{D}_r}{\mathcal{T}_s + \mathcal{T}_r}$$

is the combined rate in the total population for the rate statistic and where

$$\hat{\beta}_0 = \frac{\mathcal{D}_s + \mathcal{D}_r}{\mathcal{N}_s + \mathcal{N}_r}$$

is the combined risk in the total population for the risk statistic.

Denote $\rho = \mathcal{D}_s / (\mathcal{D}_s + \mathcal{D}_r)$, the proportion of exposure among events, then \mathcal{R}_{pa} can also be expressed as

$$\mathcal{R}_{pa} = \rho \frac{\mathcal{R}_{sm} - 1}{\mathcal{R}_{sm}}$$

where \mathcal{R}_{sm} is the standardized mortality ratio.

An approximate confidence interval for the population attributable rate \mathcal{R}_{pa} can be derived by using the complementary log transformation (Greenland 2008, p. 296). That is, with

$$\mathcal{H} = \log(1 - \mathcal{R}_{pa})$$

a variance estimator for the estimated \mathcal{H} is given by

$$\text{Var}(\hat{\mathcal{H}}) = \frac{\mathcal{R}_{pa}^2}{(1 - \mathcal{R}_{pa})^2} \left(\frac{\hat{V}}{(\mathcal{R}_{sm} - 1)^2} + \frac{2}{\mathcal{D}_s (\mathcal{R}_{sm} - 1)} + \frac{\mathcal{D}_r}{\mathcal{D}_s (\mathcal{D}_s + \mathcal{D}_r)} \right)$$

where \hat{V} is a variance estimate for $\log(\mathcal{R}_{sm})$.

Mantel-Haenszel Estimation

With Mantel-Haenszel estimation, you specify one study population that consists of subjects who are exposed to a factor and another study population that consists of subjects who are not exposed to the factor. Denote the numbers of events in the exposed and nonexposed study populations by \mathcal{D}_1 and \mathcal{D}_2 , respectively.

For the rate estimate, denote the population-times in the two populations by \mathcal{T}_1 and \mathcal{T}_2 , respectively. Then the event rates in the two populations can be expressed as the following equations, respectively:

$$\hat{\lambda}_1 = \frac{\mathcal{D}_1}{\mathcal{T}_1} \quad \text{and} \quad \hat{\lambda}_2 = \frac{\mathcal{D}_2}{\mathcal{T}_2}$$

Similarly, for the risk estimate, denote the numbers of observations in the two populations by \mathcal{N}_1 and \mathcal{N}_2 , respectively. Then the event risks in the two populations can be expressed as the following equations, respectively:

$$\hat{\gamma}_1 = \frac{\mathcal{D}_1}{\mathcal{N}_1} \quad \text{and} \quad \hat{\gamma}_2 = \frac{\mathcal{D}_2}{\mathcal{N}_2}$$

In the next two subsections, $\beta = \lambda$ denotes the rate statistic and $\beta = \gamma$ denotes the risk statistic.

Attributable Fraction with Mantel-Haenszel Estimation

The attributable fraction is the fraction of event rate or risk in the exposed population that is attributable to exposure:

$$\mathcal{R}_a = \frac{\hat{\beta}_1 - \hat{\beta}_2}{\hat{\beta}_1}$$

Denote the rate or risk ratio by $\mathcal{R} = \hat{\beta}_1 / \hat{\beta}_2$. The attributable fraction is given by

$$\mathcal{R}_a = \frac{\mathcal{R} - 1}{\mathcal{R}}$$

The confidence intervals for the attributable fraction can be computed using the confidence intervals for the rate or risk ratio \mathcal{R} . That is, with a confidence interval $(\mathcal{R}_l, \mathcal{R}_u)$ for \mathcal{R} , the corresponding \mathcal{R}_a confidence interval is given by

$$\left(\frac{\mathcal{R}_l - 1}{\mathcal{R}_l}, \frac{\mathcal{R}_u - 1}{\mathcal{R}_u} \right)$$

For Mantel-Haenszel estimation, you can use the Mantel-Haenszel rate or risk ratio to estimate \mathcal{R} .

Population Attributable Fraction with Mantel-Haenszel Estimation

The population attributable fraction for a population is the fraction of event rate or risk in a given time period that is attributable to exposure. The population attributable fraction is

$$\mathcal{R}_{pa} = \frac{\hat{\beta}_0 - \hat{\beta}_2}{\hat{\beta}_0}$$

where

$$\hat{\beta}_0 = \frac{\mathcal{D}_1 + \mathcal{D}_2}{\mathcal{T}_1 + \mathcal{T}_2}$$

is the combined rate in the total population for the rate statistic and where

$$\hat{\beta}_0 = \frac{\mathcal{D}_1 + \mathcal{D}_2}{\mathcal{N}_1 + \mathcal{N}_2}$$

is the combined risk in the total population for the risk statistic.

Denote the proportion of exposure among events as $\rho = \mathcal{D}_1/(\mathcal{D}_1 + \mathcal{D}_2)$. Then \mathcal{R}_{pa} can also be expressed as

$$\mathcal{R}_{pa} = \rho \frac{\mathcal{R} - 1}{\mathcal{R}}$$

where $\mathcal{R} = \hat{\beta}_1/\hat{\beta}_2$ is the rate or risk ratio.

An approximate confidence interval for the population attributable rate \mathcal{R}_{pa} can be derived by using the complementary log transformation (Greenland 2008, p. 296). That is, with

$$\mathcal{H} = \log(1 - \mathcal{R}_{pa})$$

a variance estimator for the estimated \mathcal{H} is given by

$$\text{Var}(\hat{\mathcal{H}}) = \frac{\mathcal{R}_{pa}^2}{(1 - \mathcal{R}_{pa})^2} \left(\frac{\hat{V}}{(\mathcal{R} - 1)^2} + \frac{2}{\mathcal{D}_1 (\mathcal{R} - 1)} + \frac{\mathcal{D}_2}{\mathcal{D}_1 (\mathcal{D}_1 + \mathcal{D}_2)} \right)$$

where \hat{V} is a variance estimate for $\log(\mathcal{R})$.

For Mantel-Haenszel estimation, you can use the Mantel-Haenszel rate or risk ratio to estimate \mathcal{R} .

Applicable Data Sets and Required Variables for Method Specifications

The METHOD= and DATA= options are required in the STD RATE procedure. The METHOD= option specifies the standardization method, and the DATA= and REFDATA= options specify the study populations and reference population, respectively. You can use the GROUP= option in the POPULATION statement to identify various study populations. Table 88.2 lists applicable data sets for each method.

Table 88.2 Applicable Data Sets for Method Specifications

METHOD=	Number of Populations	
	in DATA= Data Set	REFDATA= Data Set
DIRECT	1	X
	2	X
MH	2	
INDIRECT	1	X

Table 88.3 lists the required variables for each method.

Table 88.3 Required Variables for Method Specifications

METHOD=	STAT=	DATA= Data Set			REFDATA= Data Set		
		RATE	RISK	TOTAL	RATE	RISK	TOTAL
DIRECT	RATE	X					X
	RISK		X				X
MH	RATE	X		X			
	RISK		X	X			
INDIRECT	RATE			X	X		
	RISK			X		X	

The symbol “X” indicates that the variable is either explicitly specified or implicitly available from other variables. For example, when STAT=RATE, the variable RATE is available if the corresponding variables EVENT and TOTAL are specified.

Applicable Confidence Limits for Rate and Risk Statistics

In the STD RATE procedure, the METHOD= option specifies the standardization method, and the STAT= option specifies either either rate or risk for standardization. Table 88.4 lists applicable confidence limits for different methods with standardized rate, rate SMR, standardized risk, and risk SMR.

Table 88.4 Applicable Confidence Limits for Standardized Rate and Risk Statistics

Statistic	METHOD=	Confidence Limits			
		Normal	Lognormal	Gamma	Poisson
Rate	DIRECT	X	X	X	
	MH	X	X	X	
	INDIRECT	X	X		X
Rate SMR	INDIRECT	X	X		X
Risk	DIRECT	X	X		
	MH	X	X		
	INDIRECT	X	X		X
Risk SMR	INDIRECT	X	X		X

Table 88.5 lists applicable confidence limits for stratum-specific rate, rate SMR, risk, and risk SMR.

Table 88.5 Applicable Confidence Limits for Strata Rate and Risk Statistics

Statistic	Confidence Limits		
	Normal	Lognormal	Poisson
Rate	X	X	X
Rate SMR	X	X	X
Risk	X	X	
Risk SMR	X	X	

Table Output

The STD RATE procedure displays the “Standardization Information” table by default. In addition, the procedure also displays the “Standardized Rate Estimates” table (with the default STAT=RATE option in the PROC STD RATE statement) and the “Standardized Risk Estimates” table (with the STAT=RISK option) by default. The rest of this section describes the output tables in alphabetical order.

Attributable Fraction Estimates

The “Attributable Fraction Estimates” table displays the following information:

- Parameter: attributable rate and population attributable rate for the rate statistic, and attributable risk and population attributable risk for the risk statistic
- Estimate: estimate of the parameter
- Method: method to construct confidence limits
- Lower and Upper: lower and upper confidence limits

Effect Estimates

The “Effect Estimates” table displays the following information:

- Standardized Rate: directly standardized rates for study populations
- Standardized Risk: directly standardized risks for study populations

When EFFECT=RATIO, the table displays the following:

- Estimate: the rate or risk ratio estimate
- Log Ratio: the logarithm of rate ratio or risk ratio estimate

- Standard Error: standard error of the logarithm of the ratio estimate
- Z: the standard Z statistic
- $\Pr > |Z|$: the p -value for the test

When EFFECT=DIFF, the table displays the following:

- Estimate: the rate or risk difference estimate
- Standard Error: standard error of the difference estimate
- Z: the standard Z statistic
- $\Pr > |Z|$: the p -value for the test

Standardization Information

The “Standardization Information” table displays the input data sets, type of statistic to be standardized, standardization method, and number of strata. The table also displays the variance divisor for the risk estimate, and the rate multiplier for the rate estimate. With a rate multiplier c , the rates per c population-time units are displayed in the output tables.

Standardized Morbidity/Mortality Ratio

The “Standardized Morbidity/Mortality Ratio” table displays the following information:

- SMR: standardized morbidity/mortality ratio
- Standard Error: standard error for SMR
- Lower and Upper: lower and upper confidence limits for SMR
- Test Statistic: $\text{SMR}-1$, for the test of $\text{SMR}=1$
- Estimate: value of test statistic
- Standard Error: standard error of the estimate
- Z: the standard Z statistic
- $\Pr > |Z|$: the p -value for the test

Standardized Rate Estimates

The “Standardized Rate Estimates” table displays the following information:

- Population: study populations, and reference population for indirect standardization
- Number of Events: number of events in population
- Population-Time: total contributed time in population, for the rate statistic
- Crude Rate: event rate in the population
- Expected Number of Events
- SMR: standardized morbidity/mortality ratio, for indirect standardization
- Standardized Rate: for the rate statistic
- Standard Error: standard error of the standardized estimate of rate
- Confidence Limits: lower and upper confidence limits for standardized estimate

Standardized Risk Estimates

The “Standardized Risk Estimates” table displays the following information:

- Population: study populations, and reference population for indirect standardization
- Number of Events: number of events in population
- Number of Observations: number of observations in population
- Crude Risk: event risk in the population
- Expected Number of Events
- SMR: standardized morbidity/mortality ratio, for indirect standardization
- Standardized Risk
- Standard Error: standard error of the standardized estimate of risk
- Confidence Limits: lower and upper confidence limits for standardized estimate

Strata Effect Estimates

The “Strata Effect Estimates” table displays the following information for each stratum:

- Stratum Index: a sequential stratum identification number
- STRATA variables: the levels of STRATA variables
- Rate: rates for the study populations, for the rate statistic
- Risk: risks for the study populations, for the risk statistic

When EFFECT=DIFF, the table displays the following information for each stratum:

- Estimate: rate or risk difference estimate of the study populations
- Standard Error: the standard error of the difference estimate
- Confidence Limits: confidence limits for the difference estimate

When EFFECT=RATIO, the table displays the following information for each stratum:

- Estimate: rate or risk ratio estimate of the study populations
- Confidence Limits: confidence limits for the ratio estimate

Strata Statistics

For each POPULATION statement, the “Strata Information” table displays the following information for each stratum:

- Stratum Index: a sequential stratum identification number
- STRATA variables: the levels of STRATA variables

If the REFERENCE statement is specified, the table displays the following information for each stratum in the reference population:

- Population-Time Value: population-time for the rate statistic for direct standardization
- Population-Time Proportion: proportion for the population-time
- Number of Observations Value: number of observations for the risk statistic for direct standardization
- Number of Observations Proportion: proportion for the number of observations
- Rate: for the rate statistic for indirect standardization
- Risk: for the risk statistic for indirect standardization

For the rate statistic, the table displays the following information for each stratum in the specified study data set:

- Number of Events
- Population-Time Value
- Population-Time Proportion
- Rate Estimate
- Standard Error: standard error for the rate estimate if the CL=NORMAL suboption is specified in the STATS option in the STRATA statement
- Confidence Limits: confidence limits for the risk estimate if the CL suboption is specified in the STATS option in the STRATA statement
- Expected Number of Events: expected number of events that use the reference population population-time for direct standardization, Mantel-Haenszel weight for Mantel-Haenszel estimation, or reference population rate for indirect standardization

For the risk statistic, the table displays the following information for each stratum in the specified study data set:

- Number of Events
- Number of Observations Value
- Number of Observations Proportion
- Risk
- Standard Error: standard error for the risk estimate, if the CL=NORMAL suboption is specified in the STATS option in the STRATA statement
- Confidence Limits: confidence limits for the risk estimate, if the CL suboption is specified in the STATS option in the STRATA statement
- Expected Number of Events: expected number of events that uses the reference population number of observations for direct standardization, Mantel-Haenszel weight for Mantel-Haenszel estimation, or reference population risk for indirect standardization

Strata SMR Estimates

The “Strata SMR Estimates” table displays the following information for each stratum:

- Stratum Index: a sequential stratum identification number
- STRATA variables: the levels of STRATA variables
- Number of Events

- Expected Number of Observations
- SMR Estimate
- Standard Error: standard error for the SMR estimate, if the CL=NORMAL suboption is specified in the SMR option in the STRATA statement
- Confidence Limits: confidence limits for the SMR estimate, if the CL suboption is specified in the SMR option in the STRATA statement

For the rate statistic, the table also displays the following information for each stratum:

- Population-Time
- Reference Rate

For the risk statistic, the table also displays the following information for each stratum:

- Number of Observations
- Reference Risk

ODS Table Names

PROC STD RATE assigns a name to each table it creates. You must use these names to refer to tables when you use the Output Delivery System (ODS). These names are listed in [Table 88.6](#). For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 88.6 ODS Tables Produced by PROC STD RATE

ODS Table Name	Description	Statement	Option
AttrFraction	Attributable fraction	PROC STD RATE	METHOD=INDIRECT(AF)
		PROC STD RATE	METHOD=MH(AF)
Effect	Effect estimates	PROC STD RATE	EFFECT
SMR	Standardized morbidity/mortality ratio	PROC STD RATE	METHOD=INDIRECT
StdInfo	Standardization information	PROC STD RATE	
StdRate	Standardized rate estimates	PROC STD RATE	STAT=RATE
StdRisk	Standardized risk estimates	PROC STD RATE	STAT=RISK
StrataEffect	Strata effect estimates	STRATA	EFFECT
StrataStats	Strata statistics	STRATA	STATS
StrataSMR	Strata SMR estimates	STRATA	SMR

Graphics Output

This section describes the use of ODS for creating graphics with the STD RATE procedure. To request these graphs, ODS Graphics must be enabled and you must specify the associated graphics options in the PROC STD RATE statement. For more information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).”

Strata Distribution Plot

The PLOTS=DIST option displays the proportion of exposed time or sample size for each stratum in the populations.

Strata Effect Plot

The PLOTS=EFFECT option displays the stratum-specific effect measure of rate difference, rate ratio, risk difference, or risk ratio. In addition, the crude effect measure and confidence limits of these stratum-specific effect estimates are also displayed.

Strata Rate Plot

The PLOTS=RATE option displays the stratum-specific rate estimates and their confidence limits of populations. In addition, the overall crude rates of populations are also displayed.

Strata Risk Plot

The PLOTS=RISK option displays the stratum-specific risk estimates and their confidence limits of populations. In addition, the overall crude risks of populations are also displayed.

Strata SMR Plot

The PLOTS=SMR option displays the SMR for each stratum in the populations.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

PROC STD RATE assigns a name to each graph it creates. You can use these names to refer to the graphs when you use ODS. To request the graph, ODS Graphics must be enabled and you must use the PLOTS option in the PROC STD RATE statement to specify the *plot-request* indicated in [Table 88.7](#).

Table 88.7 Graphs Produced by PROC STD RATE

ODS Graph Name	Plot Description	<i>plot-request</i> in PLOTS Option
StrataDistPlot	Strata proportion of exposed time or sample size	DIST
StrataEffectPlot	Strata effect measure of rate difference, rate ratio, risk difference, or risk ratio	EFFECT
StrataRatePlot	Strata rate estimates	RATE
StrataRiskPlot	Strata risk estimates	RISK
StrataSMRPlot	Strata SMR of rates or risks	SMR

Examples: STD RATE Procedure

Example 88.1: Comparing Directly Standardized Rates

This example computes directly standardized mortality rates for populations in the states of Alaska and Florida, and then compares these two standardized rates with a rate ratio statistic.

The Alaska data set contains the stratum-specific mortality information in a given period of time for the state of Alaska (Alaska Bureau of Vital Statistics 2000a, b). Variables Sex and Age are the grouping variables that form the strata in the standardization, and variables Death and PYear indicate the number of events and person-years, respectively. The COMMA9. format is specified in the DATA step to input numerical values that contain commas in PYear.

```
data Alaska;
  State='Alaska';
  input Sex $ Age $ Death PYear comma9.;
  datalines;
Male    00-14    37    81,205
Male    15-34    68    93,662
Male    35-54   206   108,615
Male    55-74   369    35,139
Male    75+     556     5,491
Female  00-14    78    77,203
Female  15-34   181    85,412
Female  35-54   395   100,386
Female  55-74   555    32,118
Female  75+     479     7,701
;
```

The Florida data set contains the corresponding stratum-specific mortality information for the state of Florida (Florida Department of Health 2000, 2012). Variables Sex and Age are the grouping variables that form the strata in the standardization, and variables Death and PYear indicate the number of events and person-years, respectively.

```

data Florida;
  State='Florida';
  input Sex $ Age $ Death comma8. PYear comma11.;
  datalines;
Male    00-14    1,189  1,505,889
Male    15-34    2,962  1,972,157
Male    35-54   10,279  2,197,912
Male    55-74   26,354  1,383,533
Male    75+     42,443   554,632
Female  00-14     906  1,445,831
Female  15-34    1,234  1,870,430
Female  35-54    5,630  2,246,737
Female  55-74   18,309  1,612,270
Female  75+     53,489   868,838
;

```

The TwoStates data set contains the data sets Alaska and Florida:

```

data TwoStates;
  length State $ 7.;
  set Alaska Florida;
run;

```

The US data set contains the corresponding stratum-specific person-years information for the United States (U.S. Bureau of Census 2011). Variables Sex and Age are the grouping variables that form the strata in the standardization, and the variable PYear indicates the person-years.

```

data US;
  input Sex $ Age $ PYear comma12.;
  datalines;
Male    00-14   30,854,207
Male    15-34   40,199,647
Male    35-54   40,945,028
Male    55-74   19,948,630
Male    75+     6,106,351
Female  00-14   29,399,168
Female  15-34   38,876,268
Female  35-54   41,881,451
Female  55-74   22,717,040
Female  75+    10,494,416
;

```

The following statements invoke the STD RATE procedure and compute the direct standardized rates for the states of Florida and Alaska by using the United States as the reference population. The DATA= option names the data set for the study populations, and the REFDATA= option names the data set for the reference population.

```

ods graphics on;
proc stdrate data=TwoStates
  refdata=US
  method=direct
  stat=rate(mult=1000)
  effect

```

```

plots(only)=(dist effect)
;
population group=State event=Death total=PYear;
reference total=PYear;
strata Sex Age / effect;
run;
ods graphics off;

```

The METHOD=DIRECT option requests direct standardization, and the STAT=RATE option specifies the rate statistic for standardization. With the EFFECT option, the procedure computes the rate effect between the study populations with the default rate ratio statistics.

The “Standardization Information” table in [Output 88.1.1](#) displays the standardization information.

Output 88.1.1 Standardization Information

The STD RATE Procedure	
Standardization Information	
Data Set	WORK.TWOSTATES
Group Variable	State
Reference Data Set	WORK.US
Method	Direct Standardization
Statistic	Rate
Number of Strata	10
Rate Multiplier	1000

With ODS Graphics enabled, the PLOTS(ONLY)=(DIST EFFECT) option displays the strata distribution plot and the strata effect plot, but does not display the default strata rate plot.

The strata distribution plot displays proportions for stratum-specific person-years in the study populations and reference population, as shown in [Output 88.1.2](#).

Output 88.1.2 Strata Distribution Plot

The EFFECT option in the STRATA statement and the STAT=RATE option request that the “Strata Rate Effect Estimates” table in [Output 88.1.3](#) display the stratum-specific rate effect statistics between the two study populations. The default EFFECT=RATIO in the PROC STD RATE statement requests that the stratum-specific rate ratio statistics be displayed.

Output 88.1.3 Strata Effect Estimates

Strata Rate Effect Estimates (Rate Multiplier = 1000)							
Stratum Index	Sex	Age	-----State----- Alaska Florida		Rate Ratio	95% Lognormal Confidence Limits	
1	Female	00-14	1.010	0.6266	1.6123	1.2794	2.0319
2	Female	15-34	2.119	0.6597	3.2121	2.7481	3.7544
3	Female	35-54	3.935	2.5059	1.5702	1.4180	1.7389
4	Female	55-74	17.280	11.3560	1.5217	1.3984	1.6557
5	Female	75+	62.200	5.4191	11.4779	10.4536	12.6026
6	Male	00-14	0.456	0.7896	0.5771	0.4160	0.8004
7	Male	15-34	0.726	1.5019	0.4834	0.3801	0.6148
8	Male	35-54	1.897	4.6767	0.4055	0.3533	0.4655
9	Male	55-74	10.501	19.0483	0.5513	0.4975	0.6109
10	Male	75+	101.257	11.9394	8.4809	7.7634	9.2647

The “Strata Rate Effect Estimates” table shows that except for the age group 75+, Alaska has lower mortality rates for male groups and higher mortality rates for female groups than Florida. For age group 75+, Alaska has much higher mortality rates than Florida for both male and female groups.

With ODS Graphics enabled and two study populations, the PLOTS=EFFECT option displays the stratum-specific effect measures and their associated confidence limits, as shown in [Output 88.1.4](#). The STAT=RATE option and the default EFFECT=RATIO option request that the strata rate ratios be displayed. By default, confidence limits are generated with 95% confidence level. This plot displays the stratum-specific rate ratios in the “Strata Rate Effect Estimates” table in [Output 88.1.3](#).

Output 88.1.4 Strata Effect Measure Plot

The “Directly Standardized Rate Estimates” table in [Output 88.1.5](#) displays directly standardized rates and related statistics.

Output 88.1.5 Directly Standardized Rate Estimates

Directly Standardized Rate Estimates					
Rate Multiplier = 1000					
	-----Study Population-----			-Reference Population-	
State	Observed Events	Population- Time	Crude Rate	Expected Events	Population- Time
Alaska	2924	626932	4.6640	1126924	266481515
Florida	76455	15577105	4.9082	1076187	266481515
Directly Standardized Rate Estimates					
Rate Multiplier = 1000					
	-----Standardized Rate-----				
		Standard	95% Normal		
State	Estimate	Error	Confidence	Limits	
Alaska	4.2289	0.0901	4.0522	4.4056	
Florida	4.0385	0.0156	4.0079	4.0691	

The MULT=1000 suboption in the STAT=RATE option requests that rates per 1,000 person-years be displayed. The table shows that although the crude rate in the Florida population (4.908) is higher than the crude rate in the Alaska population (4.664), the resulting standardized rate in the Florida population (4.0385) is lower than the crude rate in the Alaska population (4.2289).

The EFFECT option requests that the “Rate Effect Estimates” table in [Output 88.1.6](#) display the log rate ratio statistics of the two directly standardized rates by default.

Output 88.1.6 Effect Estimates

Rate Effect Estimates (Rate Multiplier = 1000)						
-----State-----		Rate Ratio	Log Rate Ratio	Standard Error	Z	Pr > Z
Alaska	Florida					
4.2289	4.0385	1.0471	0.0461	0.0217	2.13	0.0335

The table shows that with a log rate ratio statistic 1.047, the resulting *p*-value is 0.0335, which indicates that the death rate is significantly higher in Alaska than in Florida at the 5% significance level.

Example 88.2: Computing Mantel-Haenszel Risk Estimation

This example uses Mantel-Haenszel method to estimate the effect of household smoking on respiratory symptoms of school children, after adjusting for the effects of the student’s grade and household pets.

Suppose that the School data set contains the stratum-specific numbers of cases of respiratory symptoms in a given school year for a school district. Variables Pet and Grade are the grouping variables that form

the strata in the standardization, and the variable Smoking identifies students who have smokers in their households. The variables Case and Student indicate the number of cases with respiratory symptoms and the total number of students, respectively.

```
data School;
  input Smoking $ Pet $ Grade $ Case Student;
  datalines;
Yes   Yes   K-1   109   807
Yes   Yes   2-3   106   791
Yes   Yes   4-5   112   868
Yes   No    K-1   168   1329
Yes   No    2-3   162   1337
Yes   No    4-5   183   1594
No    Yes   K-1   284   2403
No    Yes   2-3   266   2237
No    Yes   4-5   273   2279
No    No    K-1   414   3398
No    No    2-3   372   3251
No    No    4-5   382   3270
;
```

The following statements invoke the STD RATE procedure and compute the Mantel-Haenszel rate difference statistic between students with household smokers and students without household smokers:

```
ods graphics on;
proc stdrate data=School
  method=mh
  stat=risk
  effect=diff
  plots=all
;
  population group=Smoking event=Case total=Student;
  strata Pet Grade / order=data stats(cl=none) effect;
run;
ods graphics off;
```

The ORDER=DATA option in the STRATA statement sorts the strata by the order of appearance in the input data set.

The “Standardization Information” table in [Output 88.2.1](#) displays the standardization information.

Output 88.2.1 Standardization Information

The STDRATE Procedure	
Standardization Information	
Data Set	WORK.SCHOOL
Group Variable	Smoking
Method	Mantel-Haenszel
Statistic	Risk
Number of Strata	6

The STATS option in the STRATA statement requests that the STDRATE procedure display a “Mantel-Haenszel Standardized Strata Statistics” table for study populations, as shown in [Output 88.2.2](#). The table displays the strata information and the expected number of events in each stratum. The Expected Events column shows the expected number of events when the Mantel-Haenszel weights are applied to the corresponding stratum-specific risks in the study populations. The CL=NONE suboption requests that confidence limits for strata risks not be displayed.

Output 88.2.2 Mantel-Haenszel Standardized Strata Statistics

The STDRA Procedure				
Mantel-Haenszel Standardized Strata Statistics				
Smoking	Stratum Index	Pet	Grade	
No	1	Yes	K-1

Yes	5	947.38		114.791	
Yes	6	1071.62		123.028	

With ODS Graphics enabled, the PLOTS=ALL option displays all appropriate plots. With the METHOD=MH and STAT=RISK options, these plots include the strata distribution plot, strata risk plot, and strata effect plot.

The strata distribution plot displays proportions for stratum-specific numbers of students in the study populations, as shown in [Output 88.2.3](#).

Output 88.2.3 Strata Distribution Plot

The strata risk plot displays stratum-specific risk estimates with confidence limits in the study populations, as shown in [Output 88.2.4](#). This plot displays stratum-specific risk estimates in the “Mantel-Haenszel Standardized Strata Statistics” table in [Output 88.2.2](#). In addition, the overall crude risks for the two study populations are also displayed. By default, strata levels are displayed on the vertical axis.

Output 88.2.4 Strata Risk Plot

The EFFECT option in the STRATA statement requests that the “Strata Risk Effect Estimates” table be displayed, as shown in [Output 88.2.5](#). The EFFECT=DIFF option in the PROC STDRA statement requests that strata risk differences be displayed.

Output 88.2.5 Strata Effect Estimates

Strata Risk Effect Estimates						
Stratum Index	Pet	Grade	-----Smoking-----		Risk Difference	Standard Error
			No	Yes		
1	Yes	K-1	0.11819	0.13507	-.016883	0.013716
2	Yes	2-3	0.11891	0.13401	-.015098	0.013912
3	Yes	4-5	0.11979	0.12903	-.009243	0.013257
4	No	K-1	0.12184	0.12641	-.004574	0.010704
5	No	2-3	0.11443	0.12117	-.006740	0.010527
6	No	4-5	0.11682	0.11481	0.002014	0.009762

Strata Risk Effect Estimates		
Stratum Index	95% Normal Confidence Limits	
1	-.043766	0.010001
2	-.042366	0.012169
3	-.035225	0.016740
4	-.025554	0.016405
5	-.027373	0.013892
6	-.017120	0.021148

The “Strata Risk Effect Estimates” table shows that for the stratum of students without household pets in Grade 4–5, the risk is higher for students without household smokers than for students with household smokers. For all other strata, the risk is lower for students without household smokers than for students with household smokers. The difference is not significant in each stratum because the null value 0 is between the lower and upper confidence limits.

With ODS Graphics enabled, the PLOTS=EFFECT option displays the plot with the stratum-specific risk effect measures and their associated confidence limits, as shown in [Output 88.2.6](#). The EFFECT=DIFF option requests that the risk difference be displayed. By default, confidence limits are generated with 95% confidence level. This plot displays the stratum-specific risk differences in the “Strata Risk Effect Estimates” table in [Output 88.2.5](#).

Output 88.2.6 Strata Risk Plot

The “Mantel-Haenszel Standardized Risk Estimates” table in [Output 88.2.7](#) displays the Mantel-Haenszel standardized risks and related statistics.

Output 88.2.7 Standardized Risk Estimates (Mantel-Haenszel Estimation)

Mantel-Haenszel Standardized Risk Estimates					
Smoking	-----Study Population-----			--Mantel-Haenszel--	
	Observed Events	Number of Observations	Crude Risk	Expected Events	Weight
No	1991	16838	0.1182	566.172	4791.43
Yes	840	6726	0.1249	599.602	4791.43
Mantel-Haenszel Standardized Risk Estimates					
Smoking	-----Standardized Risk-----				
	Estimate	Standard Error	95% Normal Confidence Limits		
No	0.1182	0.00250	0.1133	0.1231	
Yes	0.1251	0.00404	0.1172	0.1331	

The EFFECT=DIFF option requests that the “Risk Effect Estimates” table display the risk difference statistic for the two directly standardized risks, as shown in [Output 88.2.8](#).

Output 88.2.8 Mantel-Haenszel Effect Estimates

Risk Effect Estimates					
-----Smoking-----		Risk Difference	Standard Error	Z	Pr > Z
No	Yes				
0.1182	0.1251	-0.00698	0.00475	-1.47	0.1418

The table shows that although the standardized risk for students without household smokes is lower than the standardized risk for students with household smokes, the difference (−0.00698) is not significant at the 5% significance level, (p -value 0.1418).

Example 88.3: Computing Attributable Fraction Estimates

This example computes the excess event risk fraction that is attributable to a specific chemical exposure for workers in a factory.

Suppose that the Factory data set contains the stratum-specific event information for exposure to a specific chemical agent. The variable `Age` is the grouping variable that forms the strata. The variables `Event_E` and `Count_E` indicate the number of events and number of workers for workers with the specific chemical exposure, respectively. The variables `Event_NE` and `Count_NE` indicate the number of events and number of workers for workers without the specific chemical exposure, respectively.

```

data Factory;
  input Age $ Event_E Count_E Event_NE Count_NE;
  datalines;
20-29  31  352  143  2626
30-39  57  486  392  4124
40-49  62  538  459  4662
50-59  50  455  337  3622
60-69  38  322  199  2155
70+    9   68   35   414
;

```

The following statements invoke the STD RATE procedure and compute the attributable risk and population attributable risk for the chemical exposure:

```

ods graphics on;

The “Standardization Information” table in [Output 88.3.1](#) displays the standardization information.

Output 88.3.1 Standardization Information

The STD RATE Procedure	
Standardization Information	
Data Set	WORK.FACTORY
Reference Data Set	WORK.FACTORY
Method	Indirect Standardization
Statistic	Risk
Number of Strata	6

The STATS option in the STRATA statement requests that the “Indirectly Standardized Strata Statistics” table in [Output 88.3.2](#) display the strata information and the expected number of events at each stratum. The Expected Events column shows the expected numbers of events when the stratum-specific risks in the reference data set are applied to the corresponding numbers of workers in the study data set.

Output 88.3.2 Strata Information (Indirect Standardization)

The STDRA TE Procedure						
Indirectly Standardized Strata Statistics						
Stratum Index	Age	-----Study Population-----				
		Observed Events	-Number of Observations- Value	Proportion	Crude Risk	Standard Error
1	20-29	31	352	0.1585	0.088068	0.015105
2	30-39	57	486	0.2188	0.117284	0.014595
3	40-49	62	538	0.2422	0.115242	0.013767
4	50-59	50	455	0.2049	0.109890	0.014662
5	60-69	38	322	0.1450	0.118012	0.017979
6	70+	9	68	0.0306	0.132353	0.041095
Indirectly Standardized Strata Statistics						
Stratum Index	-Study Population- 95% Normal		-----Reference Population-----		Crude Risk	Expected Events
	Confidence Limits		-Number of Observations- Value	Proportion		
1	0.058463	0.117673	2626	0.1492	0.05446	19.1683
2	0.088678	0.145890	4124	0.2343	0.09505	46.1959
3	0.088260	0.142224	4662	0.2648	0.09846	52.9691
4	0.081153	0.138627	3622	0.2058	0.09304	42.3343
5	0.082774	0.153251	2155	0.1224	0.09234	29.7346
6	0.051809	0.212897	414	0.0235	0.08454	5.7488

With ODS Graphics enabled and the specified STAT=RISK option, the default PLOTS=RISK option displays the stratum-specific risk estimates in the study and reference populations, as shown in [Output 88.3.3](#). The STRATUM=HORIZONTAL global option in the PLOTS option displays the strata information on the horizontal axis. The plot displays the stratum-specific risk estimates in the “Indirect Standardized Strata Statistics” table in [Output 88.3.2](#). In addition, confidence limits for the risk estimates in the study population and the overall crude risks for the two populations are also displayed

Output 88.3.3 Strata Risk Plot

The METHOD=INDIRECT option requests that the “Standardized Morbidity/Mortality Ratio” table in [Output 88.3.4](#) display the SMR, its 95% confidence limits, and the test for the null hypothesis $H_0 : \text{SMR} = 1$.

Output 88.3.4 Standardized Morbidity/Mortality Ratio

Standardized Morbidity/Mortality Ratio							
Observed Events	Expected Events	SMR	Standard Error	95% Normal Confidence Limits		Z	Pr > Z
247	196.151	1.2592	0.0755	1.1113	1.4072	3.43	0.0006

The “Standardized Morbidity/Mortality Ratio” table shows that $\text{SMR}=1.259$, the 95% confidence limits do not contain the null value $\text{SMR}=1$, and the null hypothesis of $\text{SMR}=1$ is rejected at $\alpha = 0.05$ level from the normal test.

The “Indirectly Standardized Risk Estimates” table in [Output 88.3.5](#) displays the standardized risks and related statistics.

Output 88.3.5 Standardized Risks (Indirect Standardization)

Indirectly Standardized Risk Estimates					
-----Study Population-----			Reference		
Observed Events	Number of Observations	Crude Risk	Crude Risk	Expected Events	SMR
247	2221	0.1112	0.0889	196.151	1.2592
Indirectly Standardized Risk Estimates					
-----Standardized Risk-----					
Estimate	Standard Error	95% Normal Confidence Limits			
0.1120	0.00671	0.0988	0.1251		

The AF suboption in the METHOD=INDIRECT option requests that the “Attributable Fraction Estimates” table display the attributable risk and population attributable risk, as shown in [Output 88.3.6](#)

Output 88.3.6 Attributable Fraction Estimates

Attributable Fraction Estimates			
Parameter	Estimate	-95% Confidence Limits-	
Attributable Risk	0.20587	0.10013	0.28937
Population Attributable Risk	0.02806	0.01159	0.04426

The attributable risk fraction 0.206 indicates that 20.6% of all events in the chemical exposure group are attributed to the chemical exposure, and the population attributable risk fraction 0.028 indicates that about 2.8% of all events in the total population are attributed to the chemical exposure.

The Attributable fraction can also be computed by using Mantel-Haenszel method.

Suppose that the Factory1 data set contains the stratum-specific event information for exposure to a specific chemical agent. The variable Age is the grouping variable that forms the strata, and the variable Exposure identifies workers with chemical exposure. The variables Event and Count indicate the number of events and number of workers, respectively.

```
data Factory1;
  input Exposure $ Age $ Event Count;
  datalines;
Yes 20-29 31 352
Yes 30-39 57 486
Yes 40-49 62 538
Yes 50-59 50 455
Yes 60-69 38 322
Yes 70+ 9 68
No 20-29 143 2626
```

```

No    30-39    392    4124
No    40-49    459    4662
No    50-59    337    3622
No    60-69    199    2155
No    70+      35     414
;

```

The following statements invoke the STD RATE procedure and compute the attributable risk and population attributable risk for the chemical exposure:

```

proc stdrate data=Factory1
    method=mh (af)
    stat=risk
    effect
;
    population group (order=data)=Exposure event=Event total=Count;
    strata Age;
run;

```

The “Standardization Information” table in [Output 88.3.7](#) displays the standardization information.

Output 88.3.7 Standardization Information

The STD RATE Procedure	
Standardization Information	
Data Set	WORK.FACTORY1
Group Variable	Exposure
Method	Mantel-Haenszel
Statistic	Risk
Number of Strata	6

The “Mantel-Haenszel Standardized Risk Estimates” table in [Output 88.3.8](#) displays the Mantel-Haenszel standardized risks and related statistics.

Output 88.3.8 Standardized Risk Estimates (Mantel-Haenszel Estimation)

Mantel-Haenszel Standardized Risk Estimates					
Exposure	-----Study Population-----			--Mantel-Haenszel--	
	Observed Events	Number of Observations	Crude Risk	Expected Events	Weight
Yes	247	2221	0.1112	219.122	1970.26
No	1565	17603	0.0889	174.134	1970.26

Mantel-Haenszel Standardized Risk Estimates				
Exposure	-----Standardized Risk-----			
	Estimate	Standard Error	95% Normal Confidence Limits	
Yes	0.1112	0.00667	0.0981	0.1243
No	0.0884	0.00214	0.0842	0.0926

The EFFECT option requests that the “Risk Effect Estimates” table display the risk ratio statistic for the two directly standardized risks, as shown in [Output 88.3.9](#).

Output 88.3.9 Mantel-Haenszel Effect Estimates

Risk Effect Estimates						
-----Exposure-----		Risk Ratio	Log Risk Ratio	Standard Error	Z	Pr > Z
Yes	No					
0.1112	0.0884	1.2584	0.2298	0.0647	3.55	0.0004

The AF suboption in the METHOD=MH option requests that the “Attributable Fraction Estimates” table display the attributable risk and population attributable risk, as shown in [Output 88.3.10](#)

Output 88.3.10 Attributable Fraction Estimates

Attributable Fraction Estimates			
Parameter	Estimate	-95% Confidence Limits-	
Attributable Risk	0.20531	0.09789	0.29994
Population Attributable Risk	0.02799	0.01070	0.04497

Similar to the results of using the SMR estimates, the attributable risk fraction (0.205) indicates that 20.5% of all events in the chemical exposure group are attributed to the chemical exposure, and the population attributable risk fraction (0.028) indicates that about 2.8% of all events in the total population are attributed to the chemical exposure.

Example 88.4: Displaying SMR Results from BY Groups

This example illustrates the use of ODS OUTPUT statement to save standardized mortality ratios for different causes and to display these statistics together in a table and in a plot.

The Florida_Cs data set contains the stratum-specific mortality information for stomach cancer and skin cancer in year 2000 for the state of Florida (Florida Department of Health 2000, 2012). The variable Age is the grouping variable that forms the strata in the standardization. The variables Event_C16, Event_C43, and PYear identify the number of events for stomach cancer, the number of events for skin cancer, and the person-years, respectively. The COMMA12. format is specified in the DATA step to input numerical values that contain commas in PYear.

```
data Florida_Cs;
  input Age $1-5 Event_C16 Event_C43 PYear comma12.;
  datalines;
00-04    0    0    953,785
05-14    0    0  1,997,935
15-24    0    4  1,885,014
25-34    1   14  1,957,573
35-44   19   43  2,356,649
45-54   64   72  2,088,000
55-64  114   70  1,548,371
65-74  201  126  1,447,432
75-84  294  136  1,087,524
85+    136   73   335,944
;
```

The following statements construct and list the mortality information by cancer cause:

```
data Florida_Cs;
  set Florida_Cs;
  Cause='Stomach'; Event=Event_C16; output;
  Cause='Skin'; Event=Event_C43; output;
  drop Event_C16 Event_C43;
run;

proc sort data=Florida_Cs;
  by Cause;
run;

proc print data=Florida_Cs;
  var Cause Age Event PYear;
run;
```

Output 88.4.1 Florida Data

Obs	Cause	Age	Event	PYear
1	Skin	00-04	0	953785
2	Skin	05-14	0	1997935
3	Skin	15-24	4	1885014
4	Skin	25-34	14	1957573
5	Skin	35-44	43	2356649
6	Skin	45-54	72	2088000
7	Skin	55-64	70	1548371
8	Skin	65-74	126	1447432
9	Skin	75-84	136	1087524
10	Skin	85+	73	335944
11	Stomach	00-04	0	953785
12	Stomach	05-14	0	1997935
13	Stomach	15-24	0	1885014
14	Stomach	25-34	1	1957573
15	Stomach	35-44	19	2356649
16	Stomach	45-54	64	2088000
17	Stomach	55-64	114	1548371
18	Stomach	65-74	201	1447432
19	Stomach	75-84	294	1087524
20	Stomach	85+	136	335944

The US_Cs data set contains the corresponding stratum-specific mortality information for the United States (Miniño et al. 2002; U.S. Bureau of Census 2011). The variable Age is the grouping variable that forms the strata in the standardization. The variables Event_C16, Event_C43, and PYear identify the number of events for stomach cancer, the number of events for skin cancer, and the person-years, respectively.

```
data US_Cs;
  input Age $1-5 Event_C16 Event_C43 PYear comma12.;
  datalines;
00-04      0      0 19,175,798
05-14      1      1 41,077,577
15-24     14     41 39,183,891
25-34    124    186 39,892,024
35-44    484    626 45,148,527
45-54   1097   1199 37,677,952
55-64   1804   1303 24,274,684
65-74   3054   1637 18,390,986
75-84   3833   1624 12,361,180
85+     2234    803  4,239,587
;
```

The following statements construct and list the mortality information by cancer cause:

```
data US_Cs;
  set US_Cs;
  Cause='Stomach'; Event=Event_C16; output;
  Cause='Skin'; Event=Event_C43; output;
  drop Event_C16 Event_C43;
run;
```

```
proc sort data=US_Cs;
  by Cause;
run;

proc print data=US_Cs;
  var Cause Age Event PYear;
run;
```

Output 88.4.2 lists the mortality information by cancer cause.

Output 88.4.2 Florida Data

Obs	Cause	Age	Event	PYear
1	Skin	00-04	0	19175798
2	Skin	05-14	1	41077577
3	Skin	15-24	41	39183891
4	Skin	25-34	186	39892024
5	Skin	35-44	626	45148527
6	Skin	45-54	1199	37677952
7	Skin	55-64	1303	24274684
8	Skin	65-74	1637	18390986
9	Skin	75-84	1624	12361180
10	Skin	85+	803	4239587
11	Stomach	00-04	0	19175798
12	Stomach	05-14	1	41077577
13	Stomach	15-24	14	39183891
14	Stomach	25-34	124	39892024
15	Stomach	35-44	484	45148527
16	Stomach	45-54	1097	37677952
17	Stomach	55-64	1804	24274684
18	Stomach	65-74	3054	18390986
19	Stomach	75-84	3833	12361180
20	Stomach	85+	2234	4239587

The following statements invoke the STD RATE procedure and request indirect standardization to compute the skin and stomach SMR estimates for the state of Florida. The BY statement requests separate analyses of causes that are defined by the Cause variable.

```
ods graphics on;
ods select StdInfo StrataSmrPlot Smr;
proc stdrate data=Florida_Cs refdata=US_Cs
  stat=rate
  method=indirect
  plots=smr
  ;
  population event=Event total=PYear;
  reference event=Event total=PYear;
  strata Age;
  by Cause;
ods output smr=Smr_Cs;
run;
ods graphics off;
```

Only the tables and plots that are specified in the ODS SELECT statement are displayed.

The STDINFO option in the ODS SELECT statement requests that the “Standardization Information” table display the standardization information for the first BY group, skin cancer, as shown in [Output 88.4.3](#)

Output 88.4.3 Standardization Information

----- Cause=Skin -----	
The STDRATE Procedure	
Standardization Information	
Data Set	WORK.FLORIDA_CS
Reference Data Set	WORK.US_CS
Method	Indirect Standardization
Statistic	Rate
Number of Strata	10
Rate Multiplier	100000

The STRATASMRPLOT option in the ODS SELECT statement requests that the strata SMR plot display stratum-specific SMR estimates for skin cancer with confidence limits, as shown in [Output 88.4.4](#).

Output 88.4.4 Strata SMR Plot

The SMR option in the ODS SELECT statement requests that the “Standardized Morbidity/Mortality Ratio” table display the SMR, its confidence limits, and the test for the null hypothesis $H_0 : \text{SMR} = 1$ for skin cancer, as shown in [Output 88.4.5](#). With the default ALPHA=0.05, 95% confidence limits are constructed.

Output 88.4.5 Standardized Morbidity/Mortality Ratio

----- Cause=Skin -----							
Standardized Morbidity/Mortality Ratio							
Observed Events	Expected Events	SMR	Standard Error	95% Normal Confidence Limits		Z	Pr > Z
538	528.726	1.0175	0.0439	0.9316	1.1035	0.40	0.6893

Similarly, the “Standardization Information” table in [Output 88.4.6](#) displays the standardization information for the second BY group, stomach cancer.

Output 88.4.6 Standardization Information

----- Cause=Stomach -----	
The STDRATE Procedure	
Standardization Information	
Data Set	WORK.FLORIDA_CS
Reference Data Set	WORK.US_CS
Method	Indirect Standardization
Statistic	Rate
Number of Strata	10
Rate Multiplier	100000

The “Strata SMR Plot” displays stratum-specific SMR estimates with confidence limits for stomach cancer, as shown in [Output 88.4.7](#).

Output 88.4.7 Strata SMR Plot

The “Standardized Morbidity/Mortality Ratio” table displays the SMR, its confidence limits, and the test for the null hypothesis $H_0 : \text{SMR} = 1$ for stomach cancer, as shown in [Output 88.4.8](#).

Output 88.4.8 Standardized Morbidity/Mortality Ratio

----- Cause=Stomach -----							
Standardized Morbidity/Mortality Ratio							
Observed Events	Expected Events	SMR	Standard Error	95% Normal Confidence Limits		Z	Pr > Z
829	962.537	0.8613	0.0299	0.8026	0.9199	-4.64	<.0001

The ODS OUTPUT SMR=SMR_CS statement requests that the “Standardized Morbidity/Mortality Ratio” tables for the two cancer causes be saved in the data set Smr_Cs. The following statements display the selected output variables for the data set:

```
proc print data=Smr_Cs;
  var Cause ObservedEvents ExpectedEvents Smr SmrLcl SmrUcl;
run;
```

Output 88.4.9 SMR Results from BY Groups

Obs	Cause	Observed Events	Expected Events	Smr	SmrLcl	SmrUcl
1	Skin	538	528.726	1.0175	0.9316	1.1035
2	Stomach	829	962.537	0.8613	0.8026	0.9199

The table in [Output 88.4.9](#) shows that the study population (state of Florida) has a higher skin cancer rate and a lower stomach cancer rate than the reference population (United States), but only the lower stomach cancer rate is significant because its corresponding SMR upper confidence limit (0.9199) is less than 1.

The following statements display the standardized morbidity/mortality ratios for the two causes in a plot:

```
proc sgplot data=Smr_Cs;
  scatter y=Cause x=Smr / group=Cause;
  highlow y=Cause high=SmrUcl low=SmrLcl / highcap=serif lowcap=serif;
  yaxis type=discrete;
  xaxis label="SMR";
  refline 1 / axis=x transparency=0.5;
run;
```

Output 88.4.10 SMR Results

Alternatively, you can also use the following statements to obtain separate analyses for the two cancer causes, and then to display these standardized mortality ratios together in a table and in a plot:

```

/*----- Perform Separate Analyses for Different Causes -----*/
ods graphics on;
ods select StdInfo StrataSmrPlot Smr;
proc stdrate data=Florida-Cs refdata=US-Cs
    stat=rate
    method=indirect
    plots=smr
    ;
    population event=Event_C43 total=PYear;
    reference event=Event_C43 total=PYear;
    strata Age;
ods output smr=Smr_c43;
run;

```

```

ods select StdInfo StrataSmrPlot Smr;
proc stdrate data=Florida_Cs refdata=US_Cs
            stat=rate
            method=indirect
            plots=smr
            ;
    population event=Event_C16 total=PYear;
    reference  event=Event_C16 total=PYear;
    strata Age;
ods output smr=Smr_c16;
run;
ods graphics off;

/*----- Combine SMRs -----*/
data Smr_C43;
    set Smr_C43;
    length Cause $ 7.;
    Cause='Skin';
run;

data Smr_C16;
    set Smr_C16;
    length Cause $ 7.;
    Cause='Stomach';
run;

data Smr_Cs;
    set Smr_C43 Smr_C16;
run;

/*----- Display the Cause-Specific SMRs -----*/
proc print data=Smr_Cs;
    var Cause ObservedEvents ExpectedEvents Smr SmrLcl SmrUcl;
run;

proc sgplot data=Smr_Cs;
    scatter y=Cause x=Smr / group=Cause;
    highlow y=Cause high=SmrUcl low=SmrLcl / highcap=serif lowcap=serif;
    yaxis type=discrete;
    xaxis label="SMR";
    refline 1 / axis=x transparency=0.5;
run;

```

Overview: STEPDISC Procedure

Given a classification variable and several quantitative variables, the STEPDISC procedure performs a stepwise discriminant analysis to select a subset of the quantitative variables for use in discriminating among the classes. The set of variables that make up each class is assumed to be multivariate normal with a common covariance matrix. The STEPDISC procedure can use forward selection, backward elimination, or stepwise selection (Klecka 1980). The STEPDISC procedure is a useful prelude to further analyses with the CANDISC procedure or the DISCRIM procedure.

With PROC STEPDISC, variables are chosen to enter or leave the model according to one of two criteria:

- the significance level of an F test from an analysis of covariance, where the variables already chosen act as covariates and the variable under consideration is the dependent variable
- the squared partial correlation for predicting the variable under consideration from the CLASS variable, controlling for the effects of the variables already selected for the model

Forward selection begins with no variables in the model. At each step, PROC STEPDISC enters the variable that contributes most to the discriminatory power of the model as measured by Wilks' lambda, the likelihood ratio criterion. When none of the unselected variables meet the entry criterion, the forward selection process stops.

Backward elimination begins with all variables in the model except those that are linearly dependent on previous variables in the VAR statement. At each step, the variable that contributes least to the discriminatory power of the model as measured by Wilks' lambda is removed. When all remaining variables meet the criterion to stay in the model, the backward elimination process stops.

Stepwise selection begins, like forward selection, with no variables in the model. At each step, the model is examined. If the variable in the model that contributes least to the discriminatory power of the model as measured by Wilks' lambda fails to meet the criterion to stay, then that variable is removed. Otherwise, the variable not in the model that contributes most to the discriminatory power of the model is entered. When all variables in the model meet the criterion to stay and none of the other variables meet the criterion to enter, the stepwise selection process stops. Stepwise selection is the default method of variable selection.

It is important to realize that, in the selection of variables for entry, only one variable can be entered into the model at each step. The selection process does not take into account the relationships between variables that have not yet been selected. Thus, some important variables could be excluded in the process. Also, Wilks' lambda might not be the best measure of discriminatory power for your application. However, if you use PROC STEPDISC carefully, in combination with your knowledge of the data and careful cross validation, it can be a valuable aid in selecting variables for a discrimination model.

As with any stepwise procedure, it is important to remember that when many significance tests are performed, each at a level of, for example, 5% (0.05), the overall probability of rejecting at least one true null hypothesis is much larger than 5%. If you want to prevent including any variables that do not contribute to the discriminatory power of the model in the population, you should specify a very small significance level. In most applications, all variables considered have some discriminatory power, however small. To choose the model that provides the best discrimination by using the sample estimates, you need only to guard against estimating more parameters than can be reliably estimated with the given sample size.

Costanza and Afifi (1979) use Monte Carlo studies to compare alternative stopping rules that can be used with the forward selection method in the two-group multivariate normal classification problem. Five different numbers of variables, ranging from 10 to 30, are considered in the studies. The comparison is based on conditional and estimated unconditional probabilities of correct classification. They conclude that the use of a moderate significance level, in the range of 10 to 25 percent, often performs better than the use of a much larger or a much smaller significance level.

The significance level and the squared partial correlation criteria select variables in the same order, although they might select different numbers of variables. Increasing the sample size tends to increase the number of variables selected when you are using significance levels, but it has little effect on the number selected by using squared partial correlations.

See Chapter 10, "[Introduction to Discriminant Procedures](#)," for more information about discriminant analysis.

Getting Started: STEPDISC Procedure

The data in this example are measurements of 159 fish caught in Finland's lake Laengelmavesi; this data set is available from the Puranen. For each of the seven species (bream, roach, whitefish, parkki, perch, pike, and smelt) the weight, length, height, and width of each fish are tallied. Three different length measurements are recorded: from the nose of the fish to the beginning of its tail, from the nose to the notch of its tail, and from the nose to the end of its tail. The height and width are recorded as percentages of the third length variable. The fish data set is available from the Sashelp library. PROC STEPDISC will select a subset of the six quantitative variables that might be useful for differentiating between the fish species. This subset is used in conjunction with PROC CANDISC and PROC DISCRIM to develop discrimination models.

The following steps use PROC STEPDISC to select a subset of potential discriminator variables. By default, PROC STEPDISC uses stepwise selection on all numeric variables that are not listed in other statements, and the significance levels for a variable to enter the subset and to stay in the subset are set to 0.15. The following statements produce [Figure 89.1](#) through [Figure 89.5](#):

```
title 'Fish Measurement Data';

proc stepdisc data=sashelp.fish;
  class Species;
run;
```

PROC STEPDISC begins by displaying summary information about the analysis (see [Figure 89.1](#)). This information includes the number of observations with nonmissing values, the number of classes in the classification variable (specified by the CLASS statement), the number of quantitative variables under consideration, the significance criteria for variables to enter and to stay in the model, and the method of variable selection being used. The frequency of each class is also displayed.

Figure 89.1 Summary Information

Fish Measurement Data			
The STEPDISC Procedure			
The Method for Selecting Variables is STEPWISE			
Total Sample Size	158	Variable(s) in the Analysis	6
Class Levels	7	Variable(s) Will Be Included	0
		Significance Level to Enter	0.15
		Significance Level to Stay	0.15
Number of Observations Read		159	
Number of Observations Used		158	

Figure 89.1 continued

Class Level Information				
Species	Variable Name	Frequency	Weight	Proportion
Bream	Bream	34	34.0000	0.215190
Parkki	Parkki	11	11.0000	0.069620
Perch	Perch	56	56.0000	0.354430
Pike	Pike	17	17.0000	0.107595
Roach	Roach	20	20.0000	0.126582
Smelt	Smelt	14	14.0000	0.088608
Whitefish	Whitefish	6	6.0000	0.037975

For each entry step, the statistics for entry are displayed for all variables not currently selected (see Figure 89.2). The variable selected to enter at this step (if any) is displayed, as well as all the variables currently selected. Next are multivariate statistics that take into account all previously selected variables and the newly entered variable.

Figure 89.2 Step 1: Variable HEIGHT Selected for Entry

Fish Measurement Data					
The STEPDISC Procedure					
Stepwise Selection: Step 1					
Statistics for Entry, DF = 6, 151					
Variable	R-Square	F Value	Pr > F	Tolerance	
Weight	0.3750	15.10	<.0001	1.0000	
Length1	0.6017	38.02	<.0001	1.0000	
Length2	0.6098	39.32	<.0001	1.0000	
Length3	0.6280	42.49	<.0001	1.0000	
Height	0.7553	77.69	<.0001	1.0000	
Width	0.4806	23.29	<.0001	1.0000	
Variable Height will be entered.					
Variable(s) That Have Been Entered					
Height					
Multivariate Statistics					
Statistic	Value	F Value	Num DF	Den DF	Pr > F
Wilks' Lambda	0.244670	77.69	6	151	<.0001
Pillai's Trace	0.755330	77.69	6	151	<.0001
Average Squared Canonical Correlation	0.125888				

For each removal step (Figure 89.3), the statistics for removal are displayed for all variables currently entered. The variable to be removed at this step (if any) is displayed. If no variable meets the criterion to be removed and the maximum number of steps as specified by the MAXSTEP= option has not been attained, then the procedure continues with another entry step.

Figure 89.3 Step 2: No Variable Is Removed; Variable Length2 Added

Fish Measurement Data					
The STEPDISC Procedure					
Stepwise Selection: Step 2					
Statistics for Removal, DF = 6, 151					
Variable	R-Square	F Value	Pr > F		
Height	0.7553	77.69	<.0001		
No variables can be removed.					
Statistics for Entry, DF = 6, 150					
Variable	Partial R-Square	F Value	Pr > F	Tolerance	
Weight	0.7388	70.71	<.0001	0.4690	
Length1	0.9220	295.35	<.0001	0.6083	
Length2	0.9229	299.31	<.0001	0.5892	
Length3	0.9173	277.37	<.0001	0.5056	
Width	0.8783	180.44	<.0001	0.3699	
Variable Length2 will be entered.					
Variable(s) That Have Been Entered					
Length2 Height					
Multivariate Statistics					
Statistic	Value	F Value	Num DF	Den DF	Pr > F
Wilks' Lambda	0.018861	157.04	12	300	<.0001
Pillai's Trace	1.554349	87.78	12	302	<.0001
Average Squared Canonical Correlation	0.259058				

The stepwise procedure terminates either when no variable can be removed and no variable can be entered or when the maximum number of steps as specified by the MAXSTEP= option has been attained. In this example at step 7 no variables can be either removed or entered (Figure 89.4). Steps 3 through 6 are not displayed in this document.

Figure 89.4 Step 7: No Variables Entered or Removed

Fish Measurement Data			
The STEPDISC Procedure			
Stepwise Selection: Step 7			
Statistics for Removal, DF = 6, 146			
Variable	Partial R-Square	F Value	Pr > F
Weight	0.4521	20.08	<.0001
Length1	0.2987	10.36	<.0001
Length2	0.5250	26.89	<.0001
Length3	0.7948	94.25	<.0001
Height	0.7257	64.37	<.0001
Width	0.5757	33.02	<.0001
No variables can be removed.			

PROC STEPDISC ends by displaying a summary of the steps.

Figure 89.5 Step Summary

No further steps are possible.									
Fish Measurement Data									
The STEPDISC Procedure									
Stepwise Selection Summary									
Step	Number In Entered	Removed	Partial R-Square	F Value	Pr > F	Wilks' Lambda	Pr < Lambda	Average Squared Canonical Correlation	Pr > ASCC
1	1 Height		0.7553	77.69	<.0001	0.24466983	<.0001	0.12588836	<.0001
2	2 Length2		0.9229	299.31	<.0001	0.01886065	<.0001	0.25905822	<.0001
3	3 Length3		0.8826	186.77	<.0001	0.00221342	<.0001	0.38427100	<.0001
4	4 Width		0.5775	33.72	<.0001	0.00093510	<.0001	0.45200732	<.0001
5	5 Weight		0.4461	19.73	<.0001	0.00051794	<.0001	0.49488458	<.0001
6	6 Length1		0.2987	10.36	<.0001	0.00036325	<.0001	0.51744189	<.0001

All the variables in the data set are found to have potential discriminatory power. These variables are used to develop discrimination models in both the CANDISC and DISCRIM procedure chapters.

Syntax: STEPDISC Procedure

The following statements are available in the STEPDISC procedure:

```
PROC STEPDISC < options > ;
  CLASS variable ;
  BY variables ;
  FREQ variable ;
  VAR variables ;
  WEIGHT variable ;
```

The BY, CLASS, FREQ, VAR, and WEIGHT statements are described after the PROC STEPDISC statement.

PROC STEPDISC Statement

```
PROC STEPDISC < options > ;
```

The PROC STEPDISC statement invokes the STEPDISC procedure. [Table 89.1](#) summarizes the options available in the PROC STEPDISC statement.

Table 89.1 STEPDISC Procedure Options

Option	Description
Input Data Set	
DATA=	Specifies input SAS data set
Method Details	
MAXMACRO=	Specifies maximum macro variable lists
METHOD=	Specifies method
SINGULAR=	Specifies singularity
Control Stepwise Selection	
SLENTY=	Specifies entry significance
SLSTAY=	Specifies staying significance
PR2ENTRY=	Specifies entry partial R square
PR2STAY=	Specifies staying partial R square
INCLUDE=	Forces inclusion of variables
MAXSTEP=	Specifies maximum number of steps
START=	Specifies variables to begin
STOP=	Specifies number of variables in final model
Control Displayed Output	
ALL	Displays all
BCORR	Displays between correlations
BCOV	Displays between covariances
BSSCP	Displays between SSCPs
PCORR	Displays pooled correlations
PCOV	Displays pooled covariances

Table 89.1 *continued*

Option	Description
PSSCP	Displays pooled SSCPs
SHORT	Suppresses output
SIMPLE	Displays descriptive statistics
STDMEAN	Displays standardized class means
TCORR	Displays total correlations
TCOV	Displays total covariances
TSSCP	Displays total SSCPs
WCORR	Displays within correlations
WCOV	Displays within covariances
WSSCP	Displays within SSCPs

ALL

activates all of the display options.

BCORR

displays between-class correlations.

BCOV

displays between-class covariances. The between-class covariance matrix equals the between-class SSCP matrix divided by $n(c - 1)/c$, where n is the number of observations and c is the number of classes. The between-class covariances should be interpreted in comparison with the total-sample and within-class covariances, not as formal estimates of population parameters.

BSSCP

displays the between-class SSCP matrix.

DATA=SAS-data-set

specifies the data set to be analyzed. The data set can be an ordinary SAS data set or one of several specially structured data sets created by statistical procedures available with SAS/STAT software. These specially structured data sets include TYPE=CORR, COV, CSSCP, and SSCP. If the DATA= option is omitted, the procedure uses the most recently created SAS data set.

INCLUDE=n

includes the first n variables in the VAR statement in every model. By default, INCLUDE=0.

MAXMACRO=n

specifies the maximum number of macro variables with independent variable lists to create. By default, MAXMACRO=100. PROC STEPDISC saves the list of selected variables in a macro variable, &_StdVar. Suppose your input variable list consists of x1-x10; then &_StdVar would be set to x1 x3 x4 x10 if, for example, the first, third, fourth, and tenth variables were selected for the model. This list can be used, for example, in a subsequent procedure's VAR statement as follows:

```
var &_stdvar;
```

With BY processing, one macro variable is created for each BY group, and the macro variables are indexed by the BY-group number. The MAXMACRO= option can be used to either limit or

increase the number of these macro variables in processing data sets with many BY groups. The macro variables are created as follows:

With no BY processing, PROC STEPDISC creates the following:

<code>_StdVar</code>	selected variables
<code>_StdVar1</code>	selected variables
<code>_StdNumBys</code>	number of BY groups (1)
<code>_StdNumMacroBys</code>	number of <code>_StdVari</code> macro variables actually made (1)

With BY processing, PROC STEPDISC creates the following:

<code>_StdVar</code>	selected variables for BY group 1
<code>_StdVar1</code>	selected variables for BY group 1
<code>_StdVar2</code>	selected variables for BY group 2
.	
.	
.	
<code>_StdVarm</code>	selected variables for BY group m , where a number is substituted for m
<code>_StdNumBys</code>	n , the number of BY groups
<code>_StdNumMacroBys</code>	the number m of <code>_StdVari</code> macro variables actually made. This value might be less than <code>_StdNumBys</code> = n , and it is less than or equal to the <code>MAXMACRO</code> = value.

MAXSTEP= n

specifies the maximum number of steps. By default, `MAXSTEP`= two times the number of variables in the VAR statement.

METHOD=BACKWARD | BW

METHOD=FORWARD | FW

METHOD=STEPWISE | SW

specifies the method used to select the variables in the model. The `BACKWARD` method specifies backward elimination, `FORWARD` specifies forward selection, and `STEPWISE` specifies stepwise selection. By default, `METHOD`=`STEPWISE`.

PCORR

displays pooled within-class correlations (partial correlations based on the pooled within-class covariances).

PCOV

displays pooled within-class covariances.

PR2ENTRY= p

PR2E= p

specifies the partial R square for adding variables in the forward selection mode, where $p \leq 1$.

PR2STAY= p

PR2S= p

specifies the partial R square for retaining variables in the backward elimination mode, where $p \leq 1$.

PSSCP

displays the pooled within-class corrected SSCP matrix.

SHORT

suppresses the displayed output from each step.

SIMPLE

displays simple descriptive statistics for the total sample and within each class.

SINGULAR= p

specifies the singularity criterion for entering variables, where $0 < p < 1$. PROC STEPDISC precludes the entry of a variable if the squared multiple correlation of the variable with the variables already in the model exceeds $1 - p$. With more than one variable already in the model, PROC STEPDISC also excludes a variable if it would cause any of the variables already in the model to have a squared multiple correlation (with the entering variable and the other variables in the model) exceeding $1 - p$. By default, SINGULAR= 1E-8.

SLENTRY= p **SLE= p**

specifies the significance level for adding variables in the forward selection mode, where $0 \leq p \leq 1$. The default value is 0.15.

SLSTAY= p **SLS= p**

specifies the significance level for retaining variables in the backward elimination mode, where $0 \leq p \leq 1$. The default value is 0.15.

START= n

specifies that the first n variables in the VAR statement be used to begin the selection process. When you specify METHOD=FORWARD or METHOD=STEPWISE, the default value is 0; when you specify METHOD=BACKWARD, the default value is the number of variables in the VAR statement.

STDMEAN

displays total-sample and pooled within-class standardized class means.

STOP= n

specifies the number of variables in the final model. The STEPDISC procedure stops the selection process when a model with n variables is found. This option applies only when you specify METHOD=FORWARD or METHOD=BACKWARD. When you specify METHOD=FORWARD, the default value is the number of variables in the VAR statement; when you specify METHOD=BACKWARD, the default value is 0.

TCORR

displays total-sample correlations.

TCOV

displays total-sample covariances.

TSSCP

displays the total-sample corrected SSCP matrix.

WCORR

displays within-class correlations for each class level.

WCOV

displays within-class covariances for each class level.

WSSCP

displays the within-class corrected SSCP matrix for each class level.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC STEPDISC to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the STEPDISC procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* ;

The values of the CLASS variable define the groups for analysis. Class levels are determined by the formatted values of the CLASS variable. The CLASS variable can be numeric or character. A CLASS statement is required.

FREQ Statement

FREQ *variable* ;

If a variable in the data set represents the frequency of occurrence for the other values in the observation, include the name of the variable in a FREQ statement. The procedure then treats the data set as if each observation appears n times, where n is the value of the FREQ variable for the observation. The total number of observations is considered to be equal to the sum of the FREQ variable when the procedure determines degrees of freedom for significance probabilities.

If the value of the FREQ variable is missing or is less than one, the observation is not used in the analysis. If the value is not an integer, the value is truncated to an integer.

VAR Statement

VAR *variables* ;

The VAR statement specifies the quantitative variables eligible for selection. The default is all numeric variables not listed in other statements.

WEIGHT Statement

WEIGHT *variable* ;

To use relative weights for each observation in the input data set, place the weights in a variable in the data set and specify the name in a WEIGHT statement. This is often done when the variance associated with each observation is different and the values of the WEIGHT variable are proportional to the reciprocals of the variances. If the value of the WEIGHT variable is missing or is less than zero, then a value of zero for the weight is assumed.

The WEIGHT and FREQ statements have a similar effect except that the WEIGHT statement does not alter the degrees of freedom.

Details: STEPDISC Procedure

Missing Values

Observations containing missing values are omitted from the analysis.

Input Data Sets

The input data set can be an ordinary SAS data set or one of several specially structured data sets created by statistical procedures available with SAS/STAT software. For more information about these data sets, see Appendix A, “[Special SAS Data Sets](#).” The BY variable in these data sets becomes the CLASS variable in PROC STEPDISC. These specially structured data sets include the following:

- TYPE=CORR data sets created by PROC CORR by using a BY statement
- TYPE=COV data sets created by PROC PRINCOMP by using both the COV option and a BY statement
- TYPE=CSSCP data sets created by PROC CORR by using the CSSCP option and a BY statement, where the OUT= data set is assigned TYPE=CSSCP with the TYPE= data set option
- TYPE=SSCP data sets created by PROC REG by using both the OUTSSCP= option and a BY statement

When the input data set is TYPE=CORR, TYPE=COV, or TYPE=CSSCP, the STEPDISC procedure reads the number of observations for each class from the observations with `_TYPE_='N'` and the variable means in each class from the observations with `_TYPE_='MEAN'`. The procedure then reads the within-class correlations from the observations with `_TYPE_='CORR'`, the standard deviations from the observations with `_TYPE_='STD'` (data set TYPE=CORR), the within-class covariances from the observations with `_TYPE_='COV'` (data set TYPE=COV), or the within-class corrected sums of squares and crossproducts from the observations with `_TYPE_='CSSCP'` (data set TYPE=CSSCP).

When the data set does not include any observations with `_TYPE_='CORR'` (data set TYPE=CORR), `_TYPE_='COV'` (data set TYPE=COV), or `_TYPE_='CSSCP'` (data set TYPE=CSSCP) for each class, PROC STEPDISC reads the pooled within-class information from the data set. In this case, the STEPDISC procedure reads the pooled within-class correlations from the observations with `_TYPE_='PCORR'`, the pooled within-class standard deviations from the observations with `_TYPE_='PSTD'` (data set TYPE=CORR), the pooled within-class covariances from the observations with `_TYPE_='PCOV'` (data set TYPE=COV), or the pooled within-class corrected SSCP matrix from the observations with `_TYPE_='PSSCP'` (data set TYPE=CSSCP).

When the input data set is TYPE=SSCP, the STEPDISC procedure reads the number of observations for each class from the observations with `_TYPE_='N'`, the sum of weights of observations from the variable INTERCEPT in observations with `_TYPE_='SSCP'` and `_NAME_='INTERCEPT'`, the variable sums from the analysis variables in observations with `_TYPE_='SSCP'` and `_NAME_='INTERCEPT'`, and the uncorrected sums of squares and crossproducts from the analysis variables in observations with `_TYPE_='SSCP'` and `_NAME_=variable-names`.

Computational Resources

In the following discussion, let

- n = number of observations
- c = number of class levels
- v = number of variables in the VAR list
- l = length of the CLASS variable
- t = $v + c - 1$

Memory Requirements

The amount of memory in bytes for temporary storage needed to process the data is

$$c(4v^2 + 28v + 3l + 4c + 72) + 16v^2 + 92v + 4t^2 + 20t + 4l$$

Additional temporary storage of 72 bytes at each step is also required to store the results.

Time Requirements

The following factors determine the time requirements of a stepwise discriminant analysis:

- The time needed for reading the data and computing covariance matrices is proportional to nv^2 . The STEPDISC procedure must also look up each class level in the list. This is faster if the data are sorted by the CLASS variable. The time for looking up class levels is proportional to a value ranging from n to $n \ln(c)$.
- The time needed for stepwise discriminant analysis is proportional to the number of steps required to select the set of variables in the discrimination model. The number of steps required depends on the data set itself and the selection method and criterion used in the procedure. Each forward or backward step takes time proportional to $(v + c)^2$.

Displayed Output

The displayed output from PROC STEPDISC includes the class level information table. For each level of the classification variable, the following information is provided: the output data set variable name, frequency sum, weight sum, and the proportion of the total sample.

The optional output from PROC STEPDISC includes the following:

The optional output includes the following:

- Within-class SSCP matrices for each group
- Pooled within-class SSCP matrix
- Between-class SSCP matrix
- Total-sample SSCP matrix
- Within-class covariance matrices for each group
- Pooled within-class covariance matrix
- Between-class covariance matrix, equal to the between-class SSCP matrix divided by $n(c - 1)/c$, where n is the number of observations and c is the number of classes
- Total-sample covariance matrix
- Within-class correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the within-class population correlation coefficients are zero
- Pooled within-class correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the partial population correlation coefficients are zero
- Between-class correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the between-class population correlation coefficients are zero
- Total-sample correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the total population correlation coefficients are zero
- Simple statistics, including N (the number of observations), sum, mean, variance, and standard deviation for the total sample and within each class
- Total-sample standardized class means, obtained by subtracting the grand mean from each class mean and dividing by the total-sample standard deviation
- Pooled within-class standardized class means, obtained by subtracting the grand mean from each class mean and dividing by the pooled within-class standard deviation

At each step, the following statistics are displayed:

- for each variable considered for entry or removal: partial R-square, the squared (partial) correlation, the F statistic, and $\text{Pr} > F$, the probability level, from a one-way analysis of covariance
- the minimum tolerance for entering each variable. A variable is entered only if its tolerance and the tolerances for all variables already in the model are greater than the value specified in the SINGULAR= option. The tolerance for the entering variable is $1 - R^2$ from regressing the entering variable on the other variables already in the model. The tolerance for a variable already in the model is $1 - R^2$ from regressing that variable on the entering variable and the other variables already in the model. With m variables already in the model, for each entering variable, $m + 1$ multiple regressions are performed by using the entering variable and each of the m variables already in the model as a dependent variable. These $m + 1$ tolerances are computed for each entering variable, and the minimum tolerance is displayed for each.

The tolerance is computed by using the total-sample correlation matrix. It is customary to compute tolerance by using the pooled within-class correlation matrix (Jennrich 1977), but it is possible for a variable with excellent discriminatory power to have a high total-sample tolerance and a low pooled within-class tolerance. For example, PROC STEPDISC enters a variable that yields perfect discrimination (that is, produces a canonical correlation of one), but a program that uses pooled within-class tolerance does not.

- the variable label, if any
- the name of the variable chosen
- the variables already selected or removed
- Wilks' lambda and the associated F approximation with degrees of freedom and $\text{Pr} < F$, the associated probability level after the selected variable has been entered or removed. Wilks' lambda is the likelihood ratio statistic for testing the hypothesis that the means of the classes on the selected variables are equal in the population (see the section "[Multivariate Tests](#)" on page 92 in Chapter 4, "[Introduction to Regression Procedures](#)."). Lambda is close to zero if any two groups are well separated.
- Pillai's trace and the associated F approximation with degrees of freedom and $\text{Pr} > F$, the associated probability level after the selected variable has been entered or removed. Pillai's trace is a multivariate statistic for testing the hypothesis that the means of the classes on the selected variables are equal in the population (see the section "[Multivariate Tests](#)" on page 92 in Chapter 4, "[Introduction to Regression Procedures](#)").
- Average squared canonical correlation (ASCC). The ASCC is Pillai's trace divided by the number of groups minus 1. The ASCC is close to 1 if all groups are well separated and if all or most directions in the discriminant space show good separation for at least two groups.
- Summary to give statistics associated with the variable chosen at each step. The summary includes the following:
 - Step number
 - Variable entered or removed

- Number in, the number of variables in the model
- Partial R-square
- the F value for entering or removing the variable
- $\Pr > F$, the probability level for the F statistic
- Wilks' lambda
- $\Pr < \text{Lambda}$ based on the F approximation to Wilks' lambda
- Average squared canonical correlation
- $\Pr > \text{ASCC}$ based on the F approximation to Pillai's trace
- the variable label, if any

ODS Table Names

PROC STEPDISC assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 89.2 along with the PROC STEPDISC statement options needed to produce the table. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 89.2 ODS Tables Produced by PROC STEPDISC

ODS Table Name	Description	Option
BCorr	Between-class correlations	BCORR
BCov	Between-class covariances	BCOV
BSSCP	Between-class SSCP matrix	BSSCP
Counts	Number of observations, variables, classes, df	default
CovDF	Nonprinting table of df for covariance matrices	any *COV option
Levels	Class level information	default
Messages	Entry/removal messages	default
Multivariate	Multivariate statistics	default
NObs	Number of observations	default
PCorr	Pooled within-class correlations	PCORR
PCov	Pooled within-class covariances	PCOV
PSSCP	Pooled within-class SSCP matrix	PSSCP
PStdMeans	Pooled standardized class means	STDMEAN
SimpleStatistics	Simple statistics	SIMPLE
Steps	Stepwise selection entry/removal	default
Summary	Stepwise selection summary	default
TCorr	Total-sample correlations	TCORR
TCov	Total-sample covariances	TCOV
TSSCP	Total-sample SSCP matrix	TSSCP
TStdMeans	Total standardized class means	STDMEAN
Variables	Variable lists	default
WCorr	Within-class correlations	WCORR
WCov	Within-class covariances	WCOV
WSSCP	Within-class SSCP matrices	WSSCP

Example: STEPDISC Procedure

Example 89.1: Performing a Stepwise Discriminant Analysis

The iris data published by Fisher (1936) have been widely used for examples in discriminant analysis and cluster analysis. The sepal length, sepal width, petal length, and petal width are measured in millimeters on 50 iris specimens from each of three species: *Iris setosa*, *I. versicolor*, and *I. virginica*. The iris data set is available from the Sashelp library.

A stepwise discriminant analysis is performed by using stepwise selection.

In the PROC STEPDISC statement, the BSSCP and TSSCP options display the between-class SSCP matrix and the total-sample corrected SSCP matrix. By default, the significance level of an F test from an analysis of covariance is used as the selection criterion. The variable under consideration is the dependent variable, and the variables already chosen act as covariates. The following SAS statements produce [Output 89.1.1](#) through [Output 89.1.8](#):

```
title 'Fisher (1936) Iris Data';

%let _stdvar = ;
proc stepdisc data=sashelp.iris bsscp tsscp;
  class Species;
  var SepalLength SepalWidth PetalLength PetalWidth;
run;
```

Output 89.1.1 Iris Data: Summary Information

Fisher (1936) Iris Data				
The STEPDISC Procedure				
The Method for Selecting Variables is STEPWISE				
Total Sample Size	150	Variable(s) in the Analysis	4	
Class Levels	3	Variable(s) Will Be Included	0	
		Significance Level to Enter	0.15	
		Significance Level to Stay	0.15	
Number of Observations Read		150		
Number of Observations Used		150		
Class Level Information				
Species	Variable Name	Frequency	Weight	Proportion
Setosa	Setosa	50	50.0000	0.333333
Versicolor	Versicolor	50	50.0000	0.333333
Virginica	Virginica	50	50.0000	0.333333

Output 89.1.2 Iris Data: Between-Class and Total-Sample SSCP Matrices

Fisher (1936) Iris Data					
The STEPDISC Procedure					
Between-Class SSCP Matrix					
Variable	Label	SepalLength	SepalWidth	PetalLength	PetalWidth
Sepal Length	Sepal Length (mm)	6321.21333	-1995.26667	16524.84000	7127.93333
SepalWidth	Sepal Width (mm)	-1995.26667	1134.49333	-5723.96000	-2293.26667
Petal Length	Petal Length (mm)	16524.84000	-5723.96000	43710.28000	18677.40000
PetalWidth	Petal Width (mm)	7127.93333	-2293.26667	18677.40000	8041.33333
Total-Sample SSCP Matrix					
Variable	Label	SepalLength	SepalWidth	PetalLength	PetalWidth
Sepal Length	Sepal Length (mm)	10216.83333	-632.26667	18987.30000	7692.43333
SepalWidth	Sepal Width (mm)	-632.26667	2830.69333	-4911.88000	-1812.42667
Petal Length	Petal Length (mm)	18987.30000	-4911.88000	46432.54000	19304.58000
PetalWidth	Petal Width (mm)	7692.43333	-1812.42667	19304.58000	8656.99333

In step 1, the tolerance is 1.0 for each variable under consideration because no variables have yet entered the model. The variable `PetalLength` is selected because its F statistic, 1180.161, is the largest among all variables.

Output 89.1.3 Iris Data: Stepwise Selection Step 1

Fisher (1936) Iris Data					
The STEPDISC Procedure					
Stepwise Selection: Step 1					
Statistics for Entry, DF = 2, 147					
Variable	Label	R-Square	F Value	Pr > F	Tolerance
<code>SepalLength</code>	Sepal Length (mm)	0.6187	119.26	<.0001	1.0000
<code>SepalWidth</code>	Sepal Width (mm)	0.4008	49.16	<.0001	1.0000
<code>PetalLength</code>	Petal Length (mm)	0.9414	1180.16	<.0001	1.0000
<code>PetalWidth</code>	Petal Width (mm)	0.9289	960.01	<.0001	1.0000
Variable <code>PetalLength</code> will be entered.					
Variable(s) That Have Been Entered					
<code>PetalLength</code>					
Multivariate Statistics					
Statistic	Value	F Value	Num DF	Den DF	Pr > F
Wilks' Lambda	0.058628	1180.16	2	147	<.0001
Pillai's Trace	0.941372	1180.16	2	147	<.0001
Average Squared Canonical Correlation	0.470686				

In step 2, with the variable `PetalLength` already in the model, `PetalLength` is tested for removal before a new variable is selected for entry. Since `PetalLength` meets the criterion to stay, it is used as a covariate in the analysis of covariance for variable selection. The variable `SepalWidth` is selected because its F statistic, 43.035, is the largest among all variables not in the model and because its associated tolerance, 0.8164, meets the criterion to enter. The process is repeated in steps 3 and 4. The variable `PetalWidth` is entered in step 3, and the variable `SepalLength` is entered in step 4.

Output 89.1.4 Iris Data: Stepwise Selection Step 2

Fisher (1936) Iris Data					
The STEPDISC Procedure

PetalWidth	Petal Width (mm)	0.2570	24.90	<.0001
No variables can be removed.				

Output 89.1.8 Iris Data: Stepwise Selection Summary

No further steps are possible.									
Fisher (1936) Iris Data									
The STEPDISC Procedure									
Stepwise Selection Summary									
Step	Number In Entered	Removed	Label	Partial R-Square	F Value	Pr > F	Wilks' Lambda	Pr < Lambda	
1	1		PetalLength	Petal Length (mm)	0.9414	1180.16	<.0001	0.05862828	<.0001
2	2		SepalWidth	Sepal Width (mm)	0.3709	43.04	<.0001	0.03688411	<.0001
3	3		PetalWidth	Petal Width (mm)	0.3229	34.57	<.0001	0.02497554	<.0001
4	4		SepalLength	Sepal Length (mm)	0.0615	4.72	0.0103	0.02343863	<.0001
Average Squared Canonical Correlation									
Step	Number In Entered	Removed					Pr > ASCC		
1	1		PetalLength		0.47068586		<.0001		
2	2		SepalWidth		0.55995394		<.0001		
3	3		PetalWidth		0.59495691		<.0001		
4	4		SepalLength		0.59594941		<.0001		

PROC STEPDISC automatically creates a list of the selected variables and stores it in a macro variable. You can submit the following statement to see the list of selected variables:

```
* print the macro variable list;
%put &_stdvar;
```

The macro variable `_StdVar` contains the following variable list:

```
SepalLength SepalWidth PetalLength PetalWidth
```

You could use this macro variable if you want to analyze these variables in subsequent steps as follows:

```
proc discrim data=sashelp.iris;
  class Species;
  var &_stdvar;
run;
```

The results of this step are not shown.

Overview: SURVEYFREQ Procedure

The SURVEYFREQ procedure produces one-way to n -way frequency and crosstabulation tables from sample survey data. These tables include estimates of population totals, population proportions, and their standard errors. Confidence limits, coefficients of variation, and design effects are also available. The procedure provides a variety of options to customize the table display.

For one-way frequency tables, PROC SURVEYFREQ provides Rao-Scott chi-square goodness-of-fit tests, which are adjusted for the sample design. You can test a null hypothesis of equal proportions for a one-way frequency table, or you can input custom null hypothesis proportions for the test. For two-way tables, PROC SURVEYFREQ provides design-adjusted tests of independence, or no association, between the row and column variables. These tests include the Rao-Scott chi-square test, the Rao-Scott likelihood ratio test, the Wald chi-square test, and the Wald log-linear chi-square test. For 2×2 tables, PROC SURVEYFREQ computes estimates and confidence limits for risks (row proportions), the risk difference, the odds ratio, and relative risks.

PROC SURVEYFREQ computes variance estimates based on the sample design used to obtain the survey data. The design can be a complex multistage survey design with stratification, clustering, and unequal weighting. PROC SURVEYFREQ provides a choice of variance estimation methods, which include Taylor series linearization, balanced repeated replication (BRR), and the jackknife.

PROC SURVEYFREQ uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For specific information about the statistical graphics available with the SURVEYFREQ procedure, see the [PLOTS=](#) option in the TABLES statement and the section “[ODS Graphics](#)” on page 7669.

Getting Started: SURVEYFREQ Procedure

The following example shows how you can use PROC SURVEYFREQ to analyze sample survey data. The example uses data from a customer satisfaction survey for a student information system (SIS), which is a software product that provides modules for student registration, class scheduling, attendance, grade reporting, and other functions.

The software company conducted a survey of school personnel who use the SIS. A probability sample of SIS users was selected from the study population, which included SIS users at middle schools and high schools

in the three-state area of Georgia, South Carolina, and North Carolina. The sample design for this survey was a two-stage stratified design. A first-stage sample of schools was selected from the list of schools in the three-state area that use the SIS. The list of schools (the first-stage sampling frame) was stratified by state and by customer status (whether the school was a new user of the system or a renewal user). Within the first-stage strata, schools were selected with probability proportional to size and with replacement, where the size measure was school enrollment. From each sample school, five staff members were randomly selected to complete the SIS satisfaction questionnaire. These staff members included three teachers and two administrators or guidance department members.

The SAS data set `SIS_Survey` contains the survey results, as well as the sample design information needed to analyze the data. This data set includes an observation for each school staff member responding to the survey. The variable `Response` contains the staff member's response about overall satisfaction with the system.

The variable `State` contains the school's state, and the variable `NewUser` contains the school's customer status ('New Customer' or 'Renewal Customer'). These two variables determine the first-stage strata from which schools were selected. The variable `School` contains the school identification code and identifies the first-stage sampling units (clusters). The variable `SamplingWeight` contains the overall sampling weight for each respondent. Overall sampling weights were computed from the selection probabilities at each stage of sampling and were adjusted for nonresponse.

Other variables in the data set `SIS_Survey` include `SchoolType` and `Department`. The variable `SchoolType` identifies the school as a high school or a middle school. The variable `Department` identifies the staff member as a teacher, or an administrator or guidance department member.

The following PROC SURVEYFREQ statements request a one-way frequency table for the variable `Response`:

```

title 'Student Information System Survey';
proc surveyfreq data=SIS_Survey;
    tables Response;
    strata State NewUser;
    cluster School;
    weight SamplingWeight;
run;

```

The PROC SURVEYFREQ statement invokes the procedure and identifies the input data set to be analyzed. The TABLES statement requests a one-way frequency table for the variable `Response`. The table request syntax for PROC SURVEYFREQ is very similar to the table request syntax for PROC FREQ. This example shows a request for a single one-way table, but you can also request two-way tables and multiway tables. As in PROC FREQ, you can request more than one table in the same TABLES statement, and you can use multiple TABLES statements in the same invocation of the procedure.

The STRATA, CLUSTER, and WEIGHT statements provide sample design information for the procedure, so that the analysis is done according to the sample design used for the survey, and the estimates apply to the study population. The STRATA statement names the variables `State` and `NewUser`, which identify the first-stage strata. Note that the design for this example also includes stratification at the second stage of selection (by type of school personnel), but you specify only the first-stage strata for PROC SURVEYFREQ. The CLUSTER statement names the variable `School`, which identifies the clusters (primary sampling units). The WEIGHT statement names the sampling weight variable.

Figure 90.1 and Figure 90.2 display the output produced by PROC SURVEYFREQ, which includes the “Data Summary” table and the one-way table, “Table of Response.” The “Data Summary” table is produced by default unless you specify the NOSUMMARY option. This table shows there are 6 strata, 370 clusters or schools, and 1850 observations (respondents) in the SIS_Survey data set. The sum of the sampling weights is approximately 39,000, which estimates the total number of school personnel in the study area that use the SIS.

Figure 90.1 SIS_Survey Data Summary

Student Information System Survey	
The SURVEYFREQ Procedure	
Data Summary	
Number of Strata	6
Number of Clusters	370
Number of Observations	1850
Sum of Weights	38899.6482

Figure 90.2 displays the one-way table of Response, which provides estimates of the population total (weighted frequency) and the population percentage for each category (level) of the variable Response. The response level ‘Very Unsatisfied’ has a frequency of 304, which means that 304 sample respondents fall into this category. It is estimated that 17.17% of all school personnel in the study population fall into this category, and the standard error of this estimate is 1.29%. Note that the estimates apply to the population of all SIS users in the study area, as opposed to describing only the sample of 1850 respondents. The estimate of the total number of school personnel that are ‘Very Unsatisfied’ is 6,678, with a standard deviation of 502. The standard errors computed by PROC SURVEYFREQ are based on the multistage stratified design of the survey. This differs from some of the traditional analysis procedures, which assume the design is simple random sampling from an infinite population.

Figure 90.2 One-Way Table of Response

Table of Response					
Response	Frequency	Weighted Frequency	Std Dev of Wgt Freq	Percent	Std Err of Percent
Very Unsatisfied	304	6678	501.61039	17.1676	1.2872
Unsatisfied	326	6907	495.94101	17.7564	1.2712
Neutral	581	12291	617.20147	31.5965	1.5795
Satisfied	455	9309	572.27868	23.9311	1.4761
Very Satisfied	184	3714	370.66577	9.5483	0.9523
Total	1850	38900	129.85268	100.000	

The following PROC SURVEYFREQ statements request confidence limits for the percentages, a chi-square goodness-of-fit test, and a weighted frequency plot for the one-way table of Response. The ODS GRAPHICS ON statement enables ODS Graphics.

```

title 'Student Information System Survey';
ods graphics on;
proc surveyfreq data=SIS_Survey nosummary;
    tables Response / clwt nopct chisq
        plots=WtFreqPlot;
    strata State NewUser;
    cluster School;
    weight SamplingWeight;
run;
ods graphics off;

```

The NOSUMMARY option in the PROC SURVEYFREQ statement suppresses the “Data Summary” table. In the TABLES statement, the CLWT option requests confidence limits for the weighted frequencies (totals). The NOPCT option suppresses display of the weighted frequencies and their standard deviations. The CHISQ option requests a Rao-Scott chi-square goodness-of-fit test, and the PLOTS= option requests a weighted frequency plot. ODS Graphics must be enabled before producing plots.

Figure 90.3 shows the one-way table of Response, which includes confidence limits for the weighted frequencies. The 95% confidence limits for the total number of users that are ‘Very Unsatisfied’ are 5692 and 7665. To change the α level of the confidence limits, which equals 5% by default, you can use the ALPHA= option. Like the other estimates and standard errors produced by PROC SURVEYFREQ, these confidence limit computations take into account the complex survey design and apply to the entire study population.

Figure 90.3 Confidence Limits for Response Totals

Student Information System Survey					
The SURVEYFREQ Procedure					
Table of Response					
Response	Frequency	Weighted Frequency	Std Dev of Wgt Freq	95% Confidence Limits for Wgt Freq	
Very Unsatisfied	304	6678	501.61039	5692	7665
Unsatisfied	326	6907	495.94101	5932	7882
Neutral	581	12291	617.20147	11077	13505
Satisfied	455	9309	572.27868	8184	10435
Very Satisfied	184	3714	370.66577	2985	4443
Total	1850	38900	129.85268	38644	39155

Figure 90.4 displays the weighted frequency plot of Response. The plot displays weighted frequencies (totals) together with their confidence limits in the form of a vertical bar chart. You can use the PLOTS= option to request a dot plot instead of a bar chart or to plot percentages instead of weighted frequencies.

Figure 90.4 Bar Chart of Response Totals

Figure 90.5 shows the chi-square goodness-of-fit results for the table of Response. The null hypothesis for this test is equal proportions for the levels of the one-way table. (To test a null hypothesis of specified proportions instead of equal proportions, you can use the TESTP= option to specify null hypothesis proportions.)

The chi-square test provided by the CHISQ option is the Rao-Scott design-adjusted chi-square test, which takes the sample design into account and provides inferences for the study population. To produce the Rao-Scott chi-square statistic, PROC SURVEYFREQ first computes the usual Pearson chi-square statistic based on the weighted frequencies, and then adjusts this value with a design correction. An F approximation is also provided. For the table of Response, the F value is 30.0972 with a p -value of <0.0001 , which indicates rejection of the null hypothesis of equal proportions for all response levels.

Figure 90.5 Chi-Square Goodness-of-Fit Test for Response

Pr > F	<.0001
Sample Size = 1850	

Continuing to analyze the SIS_Survey data, the following PROC SURVEYFREQ statements request a two-way table of SchoolType by Response:

```

title 'Student Information System Survey';
ods graphics on;
proc surveyfreq data=SIS_Survey nosummary;
  tables SchoolType * Response /
    plots=wtfreqplot(type=dot scale=percent groupby=row);
  strata State NewUser;
  cluster School;
  weight SamplingWeight;
run;
ods graphics off;

```

The STRATA, CLUSTER, and WEIGHT statements do not change from the one-way table analysis, because the sample design and the input data set are the same. These SURVEYFREQ statements request a different table but specify the same sample design information.

The ODS GRAPHICS ON statement enables ODS Graphics. The PLOTS= option in the TABLES statement requests a plot of SchoolType by Response, and the TYPE=DOT *plot-option* specifies a dot plot instead of the default bar chart. The SCALE=PERCENT *plot-option* requests a plot of percentages instead of totals. The GROUPBY=ROW *plot-option* groups the graph cells by the row variable (SchoolType).

Figure 90.6 shows the two-way table produced for SchoolType by Response. The first variable named in the two-way table request, SchoolType, is referred to as the *row variable*, and the second variable, Response, is referred to as the *column variable*. Two-way tables display all column variable levels for each row variable level. This two-way table lists all levels of the column variable Response for each level of the row variable SchoolType, 'Middle School' and 'High School'. Also SchoolType = 'Total' shows the distribution of Response overall for both types of schools. And Response = 'Total' provides totals over all levels of response, for each type of school and overall. To suppress these totals, you can specify the NOTOTAL option.

Figure 90.6 Two-Way Table of SchoolType by Response

	Very Satisfied	184	3714	370.66577	9.5483	0.9523
	Total	1850	38900	129.85268	100.000	

Figure 90.7 displays the weighted frequency dot plot that PROC SURVEYFREQ produces for the table of SchoolType and Response. The GROUPBY=ROW *plot-option* groups the graph cells by the row variable (SchoolType). If you do not specify GROUPBY=ROW, the procedure groups the graph cells by the column variable by default. You can plot percentages instead of weighted frequencies by specifying the SCALE=PERCENT *plot-option*. You can use other *plot-options* to change the orientation of the plot or to request a different two-way layout.

Figure 90.7 Dot Plot of Percentages for SchoolType by Response

By default, without any other TABLES statement options, a two-way table displays the frequency, the weighted frequency and its standard deviation, and the percentage and its standard error for each table cell (combination of row and column variable levels). But there are several options available to customize your table display by adding more information or by suppressing some of the default information.

The following PROC SURVEYFREQ statements request a two-way table of SchoolType by Response that displays row percentages, and also request a chi-square test of association between the two variables:

```

title 'Student Information System Survey';
proc surveyfreq data=SIS_Survey nosummary;
  tables SchoolType * Response / row nowt chisq;
  strata State NewUser;
  cluster School;
  weight SamplingWeight;
run;

```

The ROW option in the TABLES statement requests row percentages, which give the distribution of Response within each level of the row variable SchoolType. The NOWT option suppresses display of the weighted frequencies and their standard deviations. The CHISQ option requests a Rao-Scott chi-square test of association between SchoolType and Response.

Figure 90.8 displays the two-way table of SchoolType by Response. For middle schools, it is estimated that 25.79% of school personnel are satisfied with the student information system and 12.39% are very satisfied. For high schools, these estimates are 22.67% and 7.61%, respectively.

Figure 90.9 displays the chi-square test results. The Rao-Scott chi-square statistic equals 9.04, and the corresponding F value is 2.26 with a p -value of 0.0605. This indicates an association between school type (middle school or high school) and satisfaction with the student information system at the 10% significance level.

Syntax: SURVEYFREQ Procedure

The following statements are available in the SURVEYFREQ procedure:

```

PROC SURVEYFREQ < options > ;
  BY variables ;
  CLUSTER variables ;
  REPWEIGHTS variables < / options > ;
  STRATA variables < / option > ;
  TABLES requests < / options > ;
  WEIGHT variable ;

```

The PROC SURVEYFREQ statement invokes the procedure, identifies the data set to be analyzed, and specifies the variance estimation method to use. The PROC SURVEYFREQ statement is required.

The TABLES statement specifies frequency or crosstabulation tables and requests tests and statistics for those tables. The STRATA statement lists the variables that form the strata in a stratified sample design. The CLUSTER statement specifies cluster identification variables in a clustered sample design. The WEIGHT statement names the sampling weight variable. The REPWEIGHTS statement names replicate weight variables for BRR or jackknife variance estimation. The BY statement requests completely separate analyses of groups defined by the BY variables.

All statements can appear multiple times except the PROC SURVEYFREQ statement and the WEIGHT statement, which can appear only once.

The rest of this section gives detailed syntax information for the BY, CLUSTER, REPWEIGHTS, STRATA, TABLES, and WEIGHT statements in alphabetical order after the description of the PROC SURVEYFREQ statement.

PROC SURVEYFREQ Statement

PROC SURVEYFREQ < options > ;

The PROC SURVEYFREQ statement invokes the SURVEYFREQ procedure. It also identifies the data set to be analyzed, specifies the variance estimation method to use, and provides sample design information. The **DATA=** option names the input data set to be analyzed. The **VARMETHOD=** option specifies the variance estimation method, which is the Taylor series method by default. For Taylor series variance estimation, you can include a finite population correction factor in the analysis by providing either the sampling rate or population total with the **RATE=** or **TOTAL=** option. If your design is stratified with different sampling rates or totals for different strata, you can input these stratum rates or totals in a SAS data set that contains the stratification variables.

Table 90.1 summarizes the options available in the PROC SURVEYFREQ statement.

Table 90.1 PROC SURVEYFREQ Statement Options

Option	Description
DATA=	Names the input SAS data set
MISSING	Treats missing values as a valid level
NOMCAR	Treats missing values as <i>not missing completely at random</i>
NOSUMMARY	Suppresses the display of the “Data Summary” table
ORDER=	Specifies the order of variable levels
PAGE	Displays only one table per page
RATE=	Specifies the first-stage sampling rate
TOTAL=	Specifies the total number of primary sampling units
VARHEADER=	Specifies the variable identification to display
VARMETHOD=	Specifies the variance estimation method

You can specify the following *options* in the PROC SURVEYFREQ statement:

DATA=SAS-data-set

names the SAS data set to be analyzed by PROC SURVEYFREQ. If you omit the **DATA=** option, the procedure uses the most recently created SAS data set.

MISSING

treats missing values as a valid (nonmissing) category for all categorical variables, which include **TABLES**, **STRATA**, and **CLUSTER** variables.

By default, if you do not specify the **MISSING** option, an observation is excluded from the analysis if it has a missing value for any **STRATA** or **CLUSTER** variable. Additionally, PROC SURVEYFREQ excludes an observation from a frequency or crosstabulation table if that observation has a missing value for any of the variables in the table request, unless you specify the **MISSING** option. For more information, see the section “Missing Values” on page 7627.

NOMCAR

includes observations with missing values of **TABLES** variables in the variance computation as *not missing completely at random* (NOMCAR) for Taylor series variance estimation. When you specify the **NOMCAR** option, PROC SURVEYFREQ computes variance estimates by analyzing the non-

missing values as a domain (subpopulation), where the entire population includes both nonmissing and missing domains. See the section “[Missing Values](#)” on page 7627 for details.

By default, PROC SURVEYFREQ completely excludes an observation from a frequency or crosstabulation table (and the corresponding variance computations) if that observation has a missing value for any of the variables in the table request, unless you specify the [MISSING](#) option. Note that the NOMCAR option has no effect when you specify the MISSING option, which treats missing values as a valid nonmissing level.

The NOMCAR option applies only to Taylor series variance estimation. The replication methods, which you request with the [VARMETHOD=BRR](#) and [VARMETHOD=JACKKNIFE](#) options, do not use the NOMCAR option.

NOSUMMARY

suppresses the display of the “Data Summary” table, which PROC SURVEYFREQ produces by default. For details about this table, see the section “[Data Summary Table](#)” on page 7663.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the order of the variable levels in the frequency and crosstabulation tables, which you request in the [TABLES](#) statement. The ORDER= option also controls the order of the [STRATA](#) variable levels in the “Stratum Information” table.

The ORDER= option can take the following values:

ORDER=	Levels Ordered By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=INTERNAL. The FORMATTED and INTERNAL orders are machine-dependent. Note that the frequency count used by ORDER=FREQ is the nonweighted frequency (sample size), rather than the weighted frequency.

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PAGE

displays only one table per page. Otherwise, PROC SURVEYFREQ displays multiple tables per page as space permits.

RATE=*value* | *SAS-data-set*

R=*value* | *SAS-data-set*

specifies the sampling rate as a nonnegative *value*, or identifies an input data set that provides the stratum sampling rates in a variable named `_RATE_`. PROC SURVEYFREQ uses this information to compute a finite population correction for Taylor series variance estimation. The procedure does not use the RATE= option for BRR or jackknife variance estimation, which you request with the [VARMETHOD=BRR](#) or [VARMETHOD=JACKKNIFE](#) option.

If your sample design has multiple stages, you should specify the *first-stage sampling rate*, which is the ratio of the number of primary sampling units (PSUs) that are selected to the total number of PSUs in the population.

For a nonstratified sample design, or for a stratified sample design with the same sampling rate in all strata, you should specify a nonnegative *value* for the RATE= option. If your design is stratified with different sampling rates in different strata, then you should name a SAS data set that contains the stratification variables and the stratum sampling rates. See the section “[Population Totals and Sampling Rates](#)” on page 7626 for details.

The sampling rate *value* must be a nonnegative number. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC SURVEYFREQ converts that number to a proportion. The procedure treats the value 1 as 100% instead of 1%.

If you do not specify the RATE= or TOTAL= option, then the Taylor series variance estimation does not include a finite population correction. You cannot specify both the TOTAL= option and the RATE= option in the same PROC SURVEYFREQ statement.

TOTAL=*value* | *SAS-data-set*

N=*value* | *SAS-data-set*

specifies the total number of primary sampling units (PSUs) in the study population as a positive *value*, or identifies an input data set that provides the stratum population totals in a variable named `_TOTAL_`. PROC SURVEYFREQ uses this information to compute a finite population correction for Taylor series variance estimation. The procedure does not use the TOTAL= option for BRR or jackknife variance estimation, which you request with the [VARMETHOD=BRR](#) or [VARMETHOD=JACKKNIFE](#) option.

For a nonstratified sample design, or for a stratified sample design with the same population total in all strata, you should specify a positive *value* for the TOTAL= option. If your sample design is stratified with different population totals in different strata, then you should name a SAS data set that contains the stratification variables and the stratum totals. See the section “[Population Totals and Sampling Rates](#)” on page 7626 for details.

If you do not specify the TOTAL= or RATE= option, then the Taylor series variance estimation does not include a finite population correction. You cannot specify both the TOTAL= option and the RATE= option in the same PROC SURVEYFREQ statement.

VARHEADER=*LABEL* | *NAME* | *NAMELABEL*

specifies the variable identification to use in the displayed output. By default VARHEADER=NAME, which displays variable names in the output. The VARHEADER= option affects the headers of the variable level columns in one-way frequency tables, crosstabulation tables, and the “Stratum Information” table. The VARHEADER= option also controls variable identification in the table headers.

The VARHEADER= option can take the following values:

VARHEADER=	Variable Identification Displayed
LABEL	Variable label
NAME	Variable name
NAMELABEL	Variable name and label, as <i>Name (Label)</i>

VARMETHOD=BRR <(method-options)>

VARMETHOD=JACKKNIFE | **JK** <(method-options)>

VARMETHOD=TAYLOR

specifies the variance estimation method. **VARMETHOD=TAYLOR** requests the Taylor series method, which is the default if you do not specify the **VARMETHOD=** option or the **REPWEIGHTS** statement. **VARMETHOD=BRR** requests variance estimation by balanced repeated replication (BRR), and **VARMETHOD=JACKKNIFE** requests variance estimation by the delete-1 jackknife method.

For **VARMETHOD=BRR** and **VARMETHOD=JACKKNIFE**, you can specify *method-options* in parentheses after the variance method name. Table 90.2 summarizes the available *method-options*.

Table 90.2 Variance Estimation Options

VARMETHOD=	Variance Estimation Method	Method Options
BRR	Balanced repeated replication	DFADJ FAY<=value> HADAMARD=SAS-data-set OUTWEIGHTS=SAS-data-set PRINTH REPS=n
JACKKNIFE	Jackknife	DFADJ OUTJKCOEFS=SAS-data-set OUTWEIGHTS=SAS-data-set
TAYLOR	Taylor series linearization	None

Method-options must be enclosed in parentheses after the variance method name. For example:

```
varmethod=BRR(reps=60 outweights=myReplicateWeights)
```

The following values are available for the **VARMETHOD=** option:

BRR < *method-options* >

requests variance estimation by balanced repeated replication (BRR). The BRR method requires a stratified sample design with two primary sampling units (PSUs) in each stratum. If you specify the **VARMETHOD=BRR** option, you must also specify a **STRATA** statement unless you provide replicate weights with a **REPWEIGHTS** statement. See the section “[Balanced Repeated Replication \(BRR\)](#)” on page 7637 for details.

You can specify the following *method-options* in parentheses after **VARMETHOD=BRR**:

DFADJ

computes the degrees of freedom as the number of nonmissing strata for the individual table request. The degrees of freedom for **VARMETHOD=BRR** equal the number of strata, which by default is based on all valid observations in the data set. But if you specify the **DFADJ** *method-option*, PROC SURVEYFREQ does not count any empty strata that occur when observations with missing values of the **TABLES** variables are removed from the analysis of that table.

See the section “[Degrees of Freedom](#)” on page 7645 for more information. See the section “[Data Summary Table](#)” on page 7663 for details about valid observations.

The `DFADJ method-option` has no effect when you specify the `MISSING` option, which treats missing values as a valid nonmissing level. The `DFADJ method-option` is not used when you specify the degrees of freedom in the `DF=` option in the `TABLES` statement.

The `DFADJ method-option` cannot be used when you provide replicate weights with a `REPWEIGHTS` statement. When you use a `REPWEIGHTS` statement, the degrees of freedom equal the number of `REPWEIGHTS` variables (or replicates), unless you specify an alternative value in the `DF=` option in the `REPWEIGHTS` or `TABLES` statement.

FAY <=*value*>

requests Fay’s method, which is a modification of the BRR method. See the section “[Fay’s BRR Method](#)” on page 7638 for details.

You can specify the *value* of the Fay coefficient, which is used in converting the original sampling weights to replicate weights. The Fay coefficient must be a nonnegative number less than 1. By default, the value of the Fay coefficient equals 0.5.

HADAMARD=*SAS-data-set*

H=*SAS-data-set*

names a SAS data set that contains the Hadamard matrix for BRR replicate construction. If you do not provide a Hadamard matrix with the `HADAMARD= method-option`, PROC SURVEYFREQ generates an appropriate Hadamard matrix for replicate construction. See the sections “[Balanced Repeated Replication \(BRR\)](#)” on page 7637 and “[Hadamard Matrix](#)” on page 7639 for details.

If a Hadamard matrix of a given dimension exists, it is not necessarily unique. Therefore, if you want to use a specific Hadamard matrix, you must provide the matrix as a SAS data set in the `HADAMARD=SAS-data-set method-option`.

In the `HADAMARD=` input data set, each variable corresponds to a column of the Hadamard matrix, and each observation corresponds to a row of the matrix. You can use any variable names in the `HADAMARD=` data set. All values in the data set must equal either 1 or –1. You must ensure that the matrix you provide is indeed a Hadamard matrix—that is, $\mathbf{A}'\mathbf{A} = R\mathbf{I}$, where \mathbf{A} is the Hadamard matrix of dimension R and \mathbf{I} is an identity matrix. PROC SURVEYFREQ does not check the validity of the Hadamard matrix that you provide.

The `HADAMARD=` input data set must contain at least H variables, where H denotes the number of first-stage strata in your design. If the data set contains more than H variables, PROC SURVEYFREQ uses only the first H variables. Similarly, the `HADAMARD=` input data set must contain at least H observations.

If you do not specify the `REPS= method-option`, then the number of replicates is taken to be the number of observations in the `HADAMARD=` input data set. If you specify the number of replicates—for example, `REPS=nreps`—then the first $nreps$ observations in the `HADAMARD=` data set are used to construct the replicates.

You can specify the `PRINTH method-option` to display the Hadamard matrix that the procedure uses to construct replicates for BRR.

OUTWEIGHTS=SAS-data-set

names a SAS data set to store the replicate weights that PROC SURVEYFREQ creates for BRR variance estimation. See the section “[Balanced Repeated Replication \(BRR\)](#)” on page 7637 for information about replicate weights. See the section “[Replicate Weight Output Data Set](#)” on page 7662 for details about the contents of the OUTWEIGHTS= data set.

The OUTWEIGHTS= *method-option* is not available when you provide replicate weights with a [REPWEIGHTS](#) statement.

PRINTH

displays the Hadamard matrix used to construct replicates for BRR. When you provide the Hadamard matrix in the [HADAMARD= method-option](#), PROC SURVEYFREQ displays only the rows and columns that are actually used to construct replicates. See the sections “[Balanced Repeated Replication \(BRR\)](#)” on page 7637 and “[Hadamard Matrix](#)” on page 7639 for more information.

The PRINTH *method-option* is not available when you provide replicate weights with a [REPWEIGHTS](#) statement because the procedure does not use a Hadamard matrix in this case.

REPS=*n*

specifies the number of replicates for BRR variance estimation. The value of *n* must be an integer greater than 1.

If you do not provide a Hadamard matrix with the [HADAMARD= method-option](#), the number of replicates should be greater than the number of strata and should be a multiple of 4. See the section “[Balanced Repeated Replication \(BRR\)](#)” on page 7637 for more information. If a Hadamard matrix cannot be constructed for the REPS= value that you specify, the value is increased until a Hadamard matrix of that dimension can be constructed. Therefore, it is possible for the actual number of replicates used to be larger than the REPS= value that you specify.

If you provide a Hadamard matrix with the [HADAMARD= method-option](#), the value of REPS= must not be less than the number of rows in the Hadamard matrix. If you provide a Hadamard matrix and do not specify the REPS= *method-option*, the number of replicates equals the number of rows in the Hadamard matrix.

If you do not specify the REPS= or [HADAMARD= method-option](#) and do not include a [REPWEIGHTS](#) statement, the number of replicates equals the smallest multiple of 4 that is greater than the number of strata.

If you provide replicate weights with a [REPWEIGHTS](#) statement, the procedure does not use the REPS= *method-option*. With a [REPWEIGHTS](#) statement, the number of replicates equals the number of [REPWEIGHTS](#) variables.

JACKKNIFE | JK < method-options >

requests variance estimation by the delete-1 jackknife method. See the section “[The Jackknife Method](#)” on page 7640 for details. If you provide replicate weights with a [REPWEIGHTS](#) statement, [VARMETHOD=JACKKNIFE](#) is the default variance estimation method.

The jackknife method requires at least two primary sampling units (PSUs) in each stratum for stratified designs unless you provide replicate weights with a [REPWEIGHTS](#) statement.

You can specify the following *method-options* in parentheses after `VARMETHOD=JACKKNIFE`:

DFADJ

computes the degrees of freedom by using the number of nonmissing strata and clusters for the individual table request. The degrees of freedom for `VARMETHOD=JACKKNIFE` equal the number of clusters minus the number of strata, which by default is based on all valid observations in the data set. But if you specify the `DFADJ` *method-option*, PROC SURVEYFREQ does not count any empty strata or clusters that occur when observations with missing values of the `TABLES` variables are removed from the analysis of that table.

See the section “[Degrees of Freedom](#)” on page 7645 for more information. See the section “[Data Summary Table](#)” on page 7663 for details about valid observations.

The `DFADJ` *method-option* has no effect when you specify the `MISSING` option, which treats missing values as a valid nonmissing level. The `DFADJ` *method-option* is not used when you specify the degrees of freedom in the `DF=` option in the `TABLES` statement.

The `DFADJ` *method-option* cannot be used when you provide replicate weights with a `REPWEIGHTS` statement. When you include a `REPWEIGHTS` statement, the degrees of freedom equal the number of `REPWEIGHTS` variables (or replicates), unless you specify an alternative value in the `DF=` option in the `REPWEIGHTS` or `TABLES` statement.

OUTJKCOEFS=SAS-data-set

names a SAS data set to store the jackknife coefficients. See the section “[The Jackknife Method](#)” on page 7640 for information about jackknife coefficients. See the section “[Jackknife Coefficient Output Data Set](#)” on page 7662 for details about the contents of the `OUTJKCOEFS=` data set.

OUTWEIGHTS=SAS-data-set

names a SAS data set to store the replicate weights that PROC SURVEYFREQ creates for jackknife variance estimation. See the section “[The Jackknife Method](#)” on page 7640 for information about replicate weights. See the section “[Replicate Weight Output Data Set](#)” on page 7662 for details about the contents of the `OUTWEIGHTS=` data set.

The `OUTWEIGHTS=` *method-option* is not available when you provide replicate weights with a `REPWEIGHTS` statement.

TAYLOR

requests Taylor series variance estimation. This is the default method if you do not specify the `VARMETHOD=` option or a `REPWEIGHTS` statement. See the section “[Taylor Series Variance Estimation](#)” on page 7630 for details.

BY Statement

BY *variables* ;

You can specify a `BY` statement with PROC SURVEYFREQ to obtain separate analyses of observations in groups that are defined by the `BY` variables. When a `BY` statement appears, the procedure expects the input data set to be sorted in order of the `BY` variables. If you specify more than one `BY` statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the SURVEYFREQ procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

Note that using a BY statement provides completely separate analyses of the BY groups. It does not provide a statistically valid domain (subpopulation) analysis, where the total number of units in the subpopulation is not known with certainty. You should include the domain variable(s) in your TABLES request to obtain domain analysis. See the section “[Domain Analysis](#)” on page 7626 for more details.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLUSTER Statement

CLUSTER *variables* ;

The CLUSTER statement names variables that identify the first-stage clusters in a clustered sample design. First-stage clusters are also known as primary sampling units (PSUs). The combinations of categories of CLUSTER variables define the clusters in the sample. If there is a STRATA statement, clusters are nested within strata.

If your sample design has clustering at multiple stages, you should specify only the first-stage clusters (PSUs) in the CLUSTER statement. See the section “[Specifying the Sample Design](#)” on page 7624 for more information.

If you provide replicate weights for BRR or jackknife variance estimation with the REPWEIGHTS statement, you do not need to specify a CLUSTER statement.

The CLUSTER variables are one or more variables in the DATA= input data set. These variables can be either character or numeric, but the procedure treats them as categorical variables. The formatted values of the CLUSTER variables determine the CLUSTER variable levels. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussions of the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference*.

An observation is excluded from the analysis if it has a missing value for any CLUSTER variable unless you specify the MISSING option in the PROC SURVEYFREQ statement. See the section “[Missing Values](#)” on page 7627 for more information.

You can use multiple CLUSTER statements to specify CLUSTER variables. The procedure uses variables from all CLUSTER statements to create clusters.

REPWEIGHTS Statement

REPWEIGHTS *variables* < / *options* > ;

The REPWEIGHTS statement names variables that provide replicate weights for BRR or jackknife variance estimation, which you request with the **VARMETHOD=BRR** or **VARMETHOD=JACKKNIFE** option in the PROC SURVEYFREQ statement. If you do not provide replicate weights for these methods by using a REPWEIGHTS statement, then PROC SURVEYFREQ constructs replicate weights for the analysis. See the sections “[Balanced Repeated Replication \(BRR\)](#)” on page 7637 and “[The Jackknife Method](#)” on page 7640 for information about replicate weights.

Each REPWEIGHTS variable should contain the weights for a single replicate, and the number of replicates equals the number of REPWEIGHTS variables. The REPWEIGHTS variables must be numeric, and the variable values must be nonnegative numbers.

If you provide replicate weights with a REPWEIGHTS statement, you do not need to specify a **CLUSTER** or **STRATA** statement. If you use a REPWEIGHTS statement and do not specify the **VARMETHOD=** option in the PROC SURVEYFREQ statement, the procedure uses **VARMETHOD=JACKKNIFE** by default.

If you specify a REPWEIGHTS statement but do not include a **WEIGHT** statement, PROC SURVEYFREQ uses the average of each observation’s replicate weights as the observation’s weight.

You can specify the following *options* in the REPWEIGHTS statement after a slash (/):

DF=*df*

specifies the degrees of freedom for the analysis. The value of *df* must be a positive number. By default, the degrees of freedom equals the number of REPWEIGHTS variables. See the section “[Degrees of Freedom](#)” on page 7645 for details.

PROC SURVEYFREQ uses the DF= value in computing confidence limits for proportions, totals, and other statistics. See the section “[Confidence Limits for Proportions](#)” on page 7642 for details. PROC SURVEYFREQ also uses the DF= value in computing the denominator degrees of freedom for the *F* statistics in the Rao-Scott and Wald chi-square tests. See the sections “[Rao-Scott Chi-Square Test](#)” on page 7652, “[Rao-Scott Likelihood Ratio Chi-Square Test](#)” on page 7657, “[Wald Chi-Square Test](#)” on page 7659, and “[Wald Log-Linear Chi-Square Test](#)” on page 7660 for more information.

JKCOEFS=*value*

specifies the jackknife coefficient for **VARMETHOD=JACKKNIFE**. The coefficient *value* must be a nonnegative number. See the section “[The Jackknife Method](#)” on page 7640 for details about jackknife coefficients.

You can use this option to specify a single value of the jackknife coefficient, which the procedure uses for all replicates. To specify different coefficients for different replicates, use the **JKCOEFS=(values)** or **JKCOEFS=SAS-data-set** option.

JKCOEFS=< (*>values<*) >

specifies jackknife coefficients for **VARMETHOD=JACKKNIFE**, where each coefficient corresponds to an individual replicate identified by a REPWEIGHTS variable. You can separate *values* with blanks or commas. The coefficient *values* must be nonnegative numbers. The number of *values* must equal the number of replicate weight variables named in the REPWEIGHTS statement. List these values in the same order in which you list the corresponding replicate weight variables in the REPWEIGHTS statement.

See the section “[The Jackknife Method](#)” on page 7640 for details about jackknife coefficients.

To specify different coefficients for different replicates, you can also use the **JKCOEFS=SAS-data-set** option. To specify a single jackknife coefficient for all replicates, use the **JKCOEFS=value** option.

JKCOEFS=SAS-data-set

names a SAS data set that contains the jackknife coefficients for **VARMETHOD=JACKKNIFE**. You provide the jackknife coefficients in the **JKCOEFS=** data set variable **JKCoefficient**. Each coefficient value must be a nonnegative number. The coefficients should correspond to the replicates that are identified by the **REPWEIGHTS** variables. Provide the coefficients as observations in the **JKCOEFS=** data set and order them to match the order in which you list the corresponding replicate weight variables in the **REPWEIGHTS** statement. The number of observations in the **JKCOEFS=** data set must not be less than the number of **REPWEIGHTS** variables.

See the section “[The Jackknife Method](#)” on page 7640 for details about jackknife coefficients.

To specify different coefficients for different replicates, you can also use the **JKCOEFS=values** option. To specify a single jackknife coefficient for all replicates, use the **JKCOEFS=value** option.

STRATA Statement

STRATA *variables* < / *option* > ;

The **STRATA** statement names variables that identify the first-stage strata in a stratified sample design. The combinations of levels of **STRATA** variables define the strata in the sample, where strata are nonoverlapping subgroups that were sampled independently.

If your sample design has stratification at multiple stages, you should specify only the first-stage strata in the **STRATA** statement. See the section “[Specifying the Sample Design](#)” on page 7624 for more information.

If you provide replicate weights for BRR or jackknife variance estimation with a **REPWEIGHTS** statement, you do not need to specify a **STRATA** statement.

The **STRATA** variables are one or more variables in the **DATA=** input data set. These variables can be either character or numeric, but the procedure treats them as categorical variables. The formatted values of the **STRATA** variables determine the **STRATA** variable levels. Thus, you can use formats to group values into levels. See the discussion of the **FORMAT** procedure in the *Base SAS Procedures Guide* and the discussions of the **FORMAT** statement and SAS formats in *SAS Formats and Informats: Reference*.

Note that an observation is excluded from the analysis if it has a missing value for any **STRATA** variable unless you specify the **MISSING** option in the **PROC SURVEYFREQ** statement. See the section “[Missing Values](#)” on page 7627 for more information.

You can use multiple **STRATA** statements to specify **STRATA** variables. The procedure uses variables from all **STRATA** statements to define strata.

You can specify the following *option* in the **STRATA** statement after a slash (/):

LIST

displays the “Stratum Information” table, which lists all strata together with the corresponding values of the **STRATA** variables. This table provides the number of observations and the number of clusters in each stratum, as well as the sampling fraction if you specify the **RATE=** or **TOTAL=** option in the **PROC SURVEYFREQ** statement. See the section “[Stratum Information Table](#)” on page 7663 for more information.

TABLES Statement

TABLES *requests* < / *options* > ;

The TABLES statement requests one-way to *n*-way frequency and crosstabulation tables and statistics for these tables.

If you omit the TABLES statement, PROC SURVEYFREQ generates one-way frequency tables for all **DATA=** data set variables that are not listed in the other statements.

The following argument is required in the TABLES statement:

requests

specify the frequency and crosstabulation tables to produce. A *request* is composed of one variable name or several variable names separated by asterisks. To request a one-way frequency table, use a single variable. To request a two-way crosstabulation table, use an asterisk between two variables. To request a multiway table (an *n*-way table, where *n* > 2), separate the desired variables with asterisks. The unique values of these variables form the rows, columns, and layers of the table.

For two-way tables to multiway tables, the values of the last variable form the crosstabulation table columns, while the values of the next-to-last variable form the rows. Each level (or combination of levels) of the other variables forms one layer. PROC SURVEYFREQ produces a separate crosstabulation table for each layer. For example, a specification of A*B*C*D in a TABLES statement produces *k* tables, where *k* is the number of different combinations of levels for A and B. Each table lists the levels for D (columns) within each level of C (rows).

You can use multiple TABLES statements in a single PROC SURVEYFREQ step. You can also specify any number of table requests in a single TABLES statement. To specify multiple table requests quickly, use a grouping syntax by placing parentheses around several variables and joining other variables or variable combinations. Table 90.3 shows some examples of grouping syntax.

Table 90.3 Grouping Syntax

TABLES Request	Equivalent to
A*(B C)	A*B A*C
(A B)*(C D)	A*C B*C A*D B*D
(A B C)*D	A*D B*D C*D
A -- C	A B C
(A -- C)*D	A*D B*D C*D

The TABLES statement variables are one or more variables from the **DATA=** input data set. These variables can be either character or numeric, but the procedure treats them as categorical variables. PROC SURVEYFREQ uses the formatted values of the TABLES variable to determine the categorical variable levels. So if you assign a format to a variable with a FORMAT statement, PROC SURVEYFREQ formats the values before dividing observations into the levels of a frequency or crosstabulation table. See the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussions of the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference*.

By default, the frequency or crosstabulation table lists the values of both character and numeric variables in ascending order based on internal (unformatted) variable values. You can change the order of the values in the table by specifying the **ORDER=** option in the **PROC SURVEYFREQ** statement. To list the values in ascending order by formatted value, use **ORDER=FORMATTED**.

Without Options

If you request a frequency or crosstabulation table without specifying options, **PROC SURVEYFREQ** produces the following for each table level or cell:

- frequency (sample size)
- weighted frequency, which estimates the population total
- standard deviation of the weighted frequency
- percentage, which estimates the population proportion
- standard error of the percentage

The table displays weighted frequencies if your analysis includes a **WEIGHT** statement, or if you specify the **WTFREQ** option in the **TABLES** statement. The table also displays the number of observations with missing values. See the sections “**One-Way Frequency Tables**” on page 7664 and “**Crosstabulation Tables**” on page 7665 for more information.

Options

Table 90.4 summarizes the *options* available in the **TABLES** statement. Descriptions of the *options* follow the table in alphabetical order.

Table 90.4 TABLES Statement Options

Option	Description
Control Statistical Analysis	
ALPHA=	Sets the level for confidence limits
CHISQ	Requests Rao-Scott chi-square test
DF=	Specifies degrees of freedom
LRCHISQ	Requests Rao-Scott likelihood ratio test
OR	Requests odds ratio and relative risks
RISK	Requests risks and risk difference
TESTP=	Specifies null proportions for one-way chi-square test
WCHISQ	Requests Wald chi-square test
WLLCHISQ	Requests Wald log-linear chi-square test

Table 90.4 *continued*

Option	Description
Request Additional Table Information	
CL	Displays confidence limits for percentages and specifies confidence limit type for percentages
CLWT	Displays confidence limits for weighted frequencies
COLUMN	Displays column percentages and standard errors
CV	Displays coefficients of variation for percentages
CVWT	Displays coefficients of variation for weighted frequencies
DEFF	Displays design effects for percentages
EXPECTED	Displays expected weighted frequencies (two-way tables)
ROW	Displays row percentages and standard errors
VAR	Displays variances for percentages
VARWT	Displays variances for weighted frequencies
WTFREQ	Displays totals and standard errors when there is no WEIGHT statement
Control Displayed Output	
NOCELLPERCENT	Suppresses display of overall percentages
NOFREQ	Suppresses display of frequency counts
NOPERCENT	Suppresses display of all percentages
NOPRINT	Suppresses display of tables but displays statistical tests
NOSPARE	Suppresses display of zero rows and columns
NOSTD	Suppresses display of standard errors for all estimates
NOTOTAL	Suppresses display of row and column totals
NOWT	Suppresses display of weighted frequencies
Produce Statistical Graphics	
PLOTS=	Requests plots from ODS Graphics

You can specify the following *options* in a TABLES statement:

ALPHA= α

sets the level for confidence limits. The value of α must be between 0 and 1, and the default is 0.05. A confidence level of α produces $100(1 - \alpha)\%$ confidence limits. The default of ALPHA=0.05 produces 95% confidence limits.

You request confidence limits for percentages with the **CL** option, and you request confidence limits for weighted frequencies with the **CLWT** option. See the sections “[Confidence Limits for Proportions](#)” on page 7642 and “[Confidence Limits for Totals](#)” on page 7642 for more information.

The ALPHA= option also applies to confidence limits for the risks and risk difference, which you request with the **RISK** option, and to confidence limits for the odds ratio and relative risks, which you request with the **OR** option. See the sections “[Risks and Risk Difference](#)” on page 7648 and “[Odds Ratio and Relative Risks](#)” on page 7650 for details.

CHISQ <(options)>

requests the Rao-Scott chi-square test. This is a design-adjusted test that is computed by applying a design correction to the weighted Pearson chi-square statistic. By default, PROC SURVEYFREQ provides a first-order Rao-Scott chi-square test. If you specify **CHISQ(SECONDORDER)**, the pro-

cedure provides a second-order (Satterthwaite) Rao-Scott chi-square test. See the section “[Rao-Scott Chi-Square Test](#)” on page 7652 for details.

For one-way tables, the CHISQ option produces a design-based goodness-of-fit test. By default, this is a goodness-of-fit test for equal proportions. If you specify the null hypothesis proportions in the **TESTP=** option, the CHISQ option produces a chi-square goodness-of-fit test for the specified proportions.

By default for one-way tables, and for first-order tests for two-way tables, the design correction is computed from proportion estimates. If you specify **CHISQ(MODIFIED)**, the design correction is computed from null hypothesis proportions. For second-order tests for two-way tables, the design correction is always computed from null hypothesis proportions.

You can specify the following *options* in parentheses after the CHISQ option:

FIRSTORDER

requests a first-order Rao-Scott chi-square test. This is the default for the CHISQ option; if you do not specify **CHISQ(SECONDORDER)**, the procedure provides a first-order Rao-Scott test.

MODIFIED

uses the null hypothesis proportions to compute the Rao-Scott design correction. By default (if you do not specify **CHISQ(MODIFIED)**), the procedure uses proportion estimates to compute the design correction for all first-order tests and for second-order tests for one-way tables. For second-order tests for two-way tables, the procedure always uses null hypothesis proportions to compute the design correction.

SECONDORDER

requests a second-order (Satterthwaite) Rao-Scott chi-square test. See the section “[Rao-Scott Chi-Square Test](#)” on page 7652 for details.

CL <(options)>

requests confidence limits for the percentages (proportions) in the crosstabulation table. By default, PROC SURVEYFREQ computes standard Wald (“linear”) confidence limits for proportions by using the variance estimates that are based on the sample design. See the section “[Confidence Limits for Proportions](#)” on page 7642 for more information. The procedure determines the confidence coefficient from the **ALPHA=** option, which by default equals 0.05 and produces 95% confidence limits.

You can specify *options* in parentheses after the CL option to control the confidence limit computations. You can use the **TYPE=** option to request an alternative confidence limit type. In addition to Wald confidence limits, the following types of design-based confidence limits are available for proportions: modified Clopper-Pearson (exact), modified Wilson (score), and logit confidence limits.

If you specify the **PSMALL** option, PROC SURVEYFREQ uses the alternative confidence limit type for extreme (small or large) proportion estimates and uses Wald confidence limits for all other proportion estimates. If you do not specify the **PSMALL** option, PROC SURVEYFREQ computes the specified confidence limit type for all proportion values.

You can specify the following *options* in parentheses after the CL option:

ADJUST=NO | YES

controls the degrees-of-freedom adjustment to the effective sample size for the modified Clopper-Pearson and Wilson confidence limits. By default, **ADJUST=YES**. If you specify **ADJUST=NO**, the confidence limit computations do not apply the degrees-of-freedom adjustment to the effective sample size. See the section “[Modified Confidence Limits](#)” on page 7643 for details.

The ADJUST= option is available for [TYPE=CLOPPERPEARSON](#) and [TYPE=WILSON](#) confidence limits.

PSMALL <=p>

uses the alternative confidence limit type that you specify with the TYPE= option for extreme (small or large) proportion values.

The PSMALL value p defines the range of extreme proportion values, where those proportions less than or equal to p or greater than or equal to $(1 - p)$ are considered to be extreme, and those proportions between p and $(1 - p)$ are not extreme. If you do not specify a PSMALL value p , PROC SURVEYFREQ uses $p = 0.25$ by default. For $p = 0.25$, the procedure computes Wald confidence limits for proportions between 0.25 and 0.75 and computes the alternative confidence limit type for proportions less than or equal to 0.25 or greater than or equal to 0.75.

The PSMALL value p must be a nonnegative number. You can specify p as a proportion between 0 and 0.5. Or you can specify p in percentage form as a number between 1 and 50, and PROC SURVEYFREQ converts that number to a proportion. The procedure treats the value 1 as the percentage form 1%.

The PSMALL option is available for [TYPE=CLOPPERPEARSON](#), [TYPE=LOGIT](#), and [TYPE=WILSON](#) confidence limits. See the section “[Confidence Limits for Proportions](#)” on page 7642 for details.

TRUNCATE=NO | YES

controls the truncation of the effective sample size for the modified Clopper-Pearson and Wilson confidence limits. By default, TRUNCATE=YES truncates the effective sample size if it is larger than the original sample size. If you specify TRUNCATE=NO, the effective sample size is not truncated. See the section “[Modified Confidence Limits](#)” on page 7643 for details.

The TRUNCATE= option is available for [TYPE=CLOPPERPEARSON](#) and [TYPE=WILSON](#) confidence limits.

TYPE=name

specifies the type of confidence limits to compute for proportions. If you do not specify the TYPE= option, PROC SURVEYFREQ computes Wald confidence limits (TYPE=WALD) by default.

If you specify the [CL\(PSMALL\)](#) option, the procedure uses the specified confidence limit type for extreme proportions (outside the PSMALL range) and uses Wald confidence limits for proportions that are not outside the range. If you do not specify the [CL\(PSMALL\)](#) option, the procedure uses the specified confidence limit type for all proportions.

The following *names* are available for the TYPE= option:

CLOPPERPEARSON | CP

requests modified Clopper-Pearson (exact) confidence limits for proportions. See the section “[Modified Clopper-Pearson Confidence Limits](#)” on page 7644 for details.

LOGIT

requests logit confidence limits for proportions. See the section “[Logit Confidence Limits](#)” on page 7645 for details.

WALD

requests standard Wald (“linear”) confidence limits for proportions. This is the default confidence limit type if you do not specify the TYPE= option. See the section “[Wald Confidence Limits](#)” on page 7643 for details.

WILSON | SCORE

requests modified Wilson (score) confidence limits for proportions. See the section “[Modified Wilson Confidence Limits](#)” on page 7644 for details.

CLWT

requests confidence limits for the weighted frequencies (totals) in the crosstabulation table. PROC SURVEYFREQ determines the confidence coefficient from the ALPHA= option, which by default equals 0.05 and produces 95% confidence limits. See the section “[Confidence Limits for Totals](#)” on page 7642 for more information.

COLUMN <(option)>

displays the column percentage (estimated proportion of the column total) for each cell in a two-way table. The COLUMN option also provides the standard errors of the column percentages. See the section “[Row and Column Proportions](#)” on page 7635 for more information. This option has no effect for one-way tables.

You can specify the following *option* in parentheses after the COLUMN option:

DEFF

displays the design effect for each column percentage in the crosstabulation table. See the section “[Design Effect](#)” on page 7646 for more information.

CV

displays the coefficient of variation for each percentage (proportion) estimate in the crosstabulation table. See the section “[Coefficient of Variation](#)” on page 7646 for more information.

CVWT

displays the coefficient of variation for each weighted frequency (estimated total), in the crosstabulation table. See the section “[Coefficient of Variation](#)” on page 7646 for more information.

DEFF

displays the design effect for each overall percentage (proportion) estimate in the crosstabulation table. See the section “[Design Effect](#)” on page 7646 for more information.

To request design effects for row or column percentages, specify the DEFF option in parentheses after the ROW or COLUMN option.

DF=df

specifies the degrees of freedom for the analysis. The value of *df* must be a nonnegative number. By default, PROC SURVEYFREQ computes the degrees of freedom as described in the section “[Degrees of Freedom](#)” on page 7645.

PROC SURVEYFREQ uses the DF= value in computing confidence limits for proportions, totals, and other statistics. See the section “[Confidence Limits for Proportions](#)” on page 7642 for details. PROC SURVEYFREQ also uses the DF= value in computing the denominator degrees of freedom for the *F* statistics in the Rao-Scott and Wald chi-square tests. See the sections “[Rao-Scott Chi-Square Test](#)” on page 7652, “[Rao-Scott Likelihood Ratio Chi-Square Test](#)” on page 7657, “[Wald Chi-Square Test](#)” on page 7659, and “[Wald Log-Linear Chi-Square Test](#)” on page 7660 for more information.

EXPECTED

displays expected weighted frequencies (totals) for the table cells in a two-way table. The expected weighted frequencies are computed under the null hypothesis that the row and column variables are independent. See the section “[Expected Weighted Frequency](#)” on page 7647 for more information. This option has no effect for one-way tables.

LRCHISQ <(options)>

requests the Rao-Scott likelihood ratio chi-square test. This is a design-adjusted test that is computed by applying a design correction to the weighted likelihood ratio chi-square statistic. By default, PROC SURVEYFREQ provides a first-order Rao-Scott likelihood ratio test. If you specify [LRCHISQ\(SECONDORDER\)](#), the procedure provides a second-order (Satterthwaite) Rao-Scott likelihood ratio test. See the section “[Rao-Scott Likelihood Ratio Chi-Square Test](#)” on page 7657 for details.

For one-way tables, the LRCHISQ option produces a design-based likelihood ratio goodness-of-fit test. By default, the null hypothesis is equal proportions. If you specify null hypothesis proportions in the [TESTP=](#) option, the LRCHISQ option produces a design-based likelihood ratio test for the specified proportions.

By default for one-way tables, and for first-order tests for two-way tables, the design correction is computed from proportion estimates. If you specify [LRCHISQ\(MODIFIED\)](#), the design correction is computed from null hypothesis proportions. For second-order tests for two-way tables, the design correction is always computed from null hypothesis proportions.

You can specify the following *options* in parentheses after the LRCHISQ option:

FIRSTORDER

requests a first-order Rao-Scott likelihood ratio test. This is the default for the LRCHISQ option; if you do not specify [LRCHISQ\(SECONDORDER\)](#), the procedure provides a first-order Rao-Scott test.

MODIFIED

uses the null hypothesis proportions to compute the Rao-Scott design correction. By default (if you do not specify [LRCHISQ\(MODIFIED\)](#)), the procedure uses proportion estimates to compute the design correction for all first-order tests and for second-order tests for one-way tables. For second-order tests for two-way tables, the procedure always uses null hypothesis proportions to compute the design correction.

SECONDORDER

requests a second-order (Satterthwaite) Rao-Scott likelihood ratio test. See the section “[Rao-Scott Likelihood Ratio Chi-Square Test](#)” on page 7657 for details.

NOCELLPERCENT

suppresses the display of overall cell percentages in the crosstabulation table, as well as the standard errors of the percentages. The NOCELLPERCENT option does not suppress the display of row or column percentages, which you request with the [ROW](#) or [COLUMN](#) option.

NOFREQ

suppresses the display of cell frequencies in the crosstabulation table. The NOFREQ option also suppresses the display of row, column, and overall table frequencies.

NOPERCENT

suppresses the display of all percentages in the crosstabulation table. The NOPERCENT option also suppresses the display of standard errors of the percentages. Use the [NOCELLPERCENT](#) option to suppress display of overall cell percentages but allow display of row or column percentages.

NOPRINT

suppresses the display of frequency and crosstabulation tables but displays all requested statistical tests. Note that this option disables the Output Delivery System (ODS) for the suppressed tables. For more information, see Chapter 20, “[Using the Output Delivery System.](#)”

NOSPARE

suppresses the display of variable levels with zero frequency in two-way tables. By default, the procedure displays all levels of the column variable within each level of the row variable, including any column variable levels with zero frequency for that row. For multiway tables, the procedure displays all levels of the row variable for each layer of the table by default, including any row variable levels with zero frequency for the layer.

NOSTD

suppresses the display of all standard errors in the crosstabulation table.

NOTOTAL

suppresses the display of row totals, column totals, and overall totals in the crosstabulation table.

NOWT

suppresses the display of weighted frequencies in the crosstabulation table. The NOWT option also suppresses the display of standard errors of the weighted frequencies.

OR | RELRISK

requests estimates of the odds ratio, the column 1 relative risk, and the column 2 relative risk for 2×2 tables. The OR option also provides confidence limits for these statistics. See the section “[Odds Ratio and Relative Risks](#)” on page 7650 for details.

To compute confidence limits for the odds ratio and relative risks, PROC SURVEYFREQ determines the confidence coefficient from the [ALPHA=](#) option, which by default equals 0.05 and produces 95% confidence limits.

PLOTS <(global-plot-options)> <=plot-request <(plot-options)>>

PLOTS <(global-plot-options)>

<=(plot-request <(plot-options)> <...plot-request <(plot-options)>>>

controls the plots that are produced through ODS Graphics. *Plot-requests* identify the plots, and *plot-options* control the appearance and content of the plots. You can specify *plot-options* in parentheses after a *plot-request*. A *global-plot-option* applies to all plots for which it is available unless it is altered by a specific *plot-option*. You can specify *global-plot-options* in parentheses after the PLOTS option.

When you specify only one *plot-request*, you can omit the parentheses around the *plot-request*. For example:

```
plots=all
plots=wtfreqplot
plots=(wtfreqplot oddsratioplot)
plots(only)=(riskdiffplot relriskplot)
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc surveyfreq;
  tables treatment*response / chisq plots=wtfreqplot;
  weight wt;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

If ODS Graphics is enabled but you do not specify the PLOTS= option, PROC SURVEYFREQ produces all plots that are associated with the analyses that you request with the exception of weighted frequency plots and mosaic plots. To produce a weighted frequency plot or mosaic plot when ODS Graphics is enabled, you must specify the [WTFREQPLOT](#) or [MOSAICPLOT](#) *plot-request*, respectively, in the PLOTS= option, or you must specify the [PLOTS=ALL](#) option. PROC SURVEYFREQ produces the remaining plots (listed in [Table 90.5](#)) by default when you request the corresponding TABLES statement options. You can suppress default plots and request specific plots by using the [PLOTS\(ONLY\)=](#) option; [PLOTS\(ONLY\)=\(plot-requests\)](#) produces only the plots that are specified as *plot-requests*. You can suppress all plots by specifying the [PLOTS=NONE](#) option.

See [Figure 90.4](#) and [Figure 90.7](#) for examples of plots that PROC SURVEYFREQ produces. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).”

Plot Requests

[Table 90.5](#) lists the available *plot-requests* together with their required TABLES statement options. Descriptions of the *plot-requests* follow the table in alphabetical order.

Table 90.5 Plot Requests

Plot Request	Description	Required TABLES Statement Option
ALL	All plots	None
MOSAICPLOT	Mosaic plot	Crosstabulation table request
NONE	No plots	None
ODDSRATIOPLOT	Odds ratio plot	OR ($h \times 2 \times 2$ table)
RELRISKPLOT	Relative risk plot	OR ($h \times 2 \times 2$ table)
RISKDIFFPLOT	Risk difference plot	RISK , RISK1 , or RISK2 ($h \times 2 \times 2$ table)
WTFREQPLOT	Weighted frequency plot	Frequency or crosstabulation table request

The following *plot-requests* are available with the PLOTS= option:

ALL

requests all plots that are associated with the specified analyses. If you specify the PLOTS=ALL option, PROC SURVEYFREQ produces the weighted frequency and mosaic plots that are associated with the tables that you request. (PROC SURVEYFREQ does not produce weighted frequency and mosaic plots by default when ODS Graphics is enabled.)

MOSAICPLOT <(plot-option)>

requests a mosaic plot. Mosaic plots are available for crosstabulation tables. For multiway tables, PROC SURVEYFREQ provides a mosaic plot for each two-way table layer.

To produce a mosaic plot, you must specify the MOSAICPLOT *plot-request* in the PLOTS= option, or you must specify the **PLOTS=ALL** option. PROC SURVEYFREQ does not produce mosaic plots by default when ODS Graphics is enabled.

Mosaic plots display tiles that correspond to the crosstabulation table cells. The areas of the tiles are proportional to the weighted frequencies of the table cells. The column variable is displayed on the X axis, and the tile widths are proportional to the relative weighted frequencies of the column variable levels. The row variable is displayed on the Y axis, and the tile heights are proportional to the relative weighted frequencies of the row levels within column levels. The colors of the tiles correspond to the row variable levels. See Friendly (2000) for more information.

You can specify the following *plot-option* in parentheses after the MOSAICPLOT *plot-request*:

SQUARE

produces a square mosaic plot, where the height of the Y axis equals the width of the X axis. In a square mosaic plot, the scale of the relative weighted frequencies is the same on both axes. By default, PROC SURVEYFREQ produces a rectangular mosaic plot.

NONE

suppresses all plots.

ODDSRATIOPLOT <(plot-options)>

requests a plot of odds ratios with confidence limits. Odds ratio plots are available for multiway 2×2 tables and display the odds ratio (with confidence limits) for each 2×2 table layer. To produce an odds ratio plot, you must also specify the **OR** option in the TABLES statement for a multiway 2×2 table.

Table 90.6 lists the *plot-options* that are available for odds ratio plots. See the subsection “Plot Options for ODDSRATIOPLOT, RELRISKPLOT, and RISKDIFFPLOT” for descriptions of the *plot-options*.

Table 90.6 Plot Options for ODDSRATIOPLOT, RELRISKPLOT, and RISKDIFFPLOT

Plot Option	Description	Values
CLDISPLAY=	Error bar type	SERIF*, LINE, or BAR
COLUMN=**	Risk column	1* or 2
LOGBASE=***	Axis scale	2, E, or 10
NPANELPOS=	Statistics per graphic	Number (All*)
ORDER=	Order of two-way levels	ASCENDING or DESCENDING
RANGE=	Range to display	Values or CLIP
STATS	Displays statistics	None

*Default

** Available for RELRISKPLOT and RISKDIFFPLOT

*** Available for ODDSRATIOPLOT and RELRISKPLOT

RELRIKSPLOT <(plot-options)>

requests a plot of relative risks with confidence limits. Relative risk plots are available for multiway 2×2 tables and display the relative risk (with confidence limits) for each 2×2 table layer. To produce a relative risk plot, you must also specify the **OR** option in the **TABLES** statement for a multiway 2×2 table.

Table 90.6 lists the *plot-options* that are available for relative risk plots. See the subsection “Plot Options for **ODDSRATIO**PLOT, **RELRIKSPLOT**, and **RISKDIFF**PLOT” for descriptions of the *plot-options*.

RISKDIFFPLOT <(plot-options)>

requests a plot of risk differences with confidence limits. Risk difference plots are available for multiway 2×2 tables and display the risk difference (with confidence limits) for each 2×2 table layer. To produce a risk difference plot, you must also specify the **RISK**, **RISK1**, or **RISK2** option in the **TABLES** statement for a multiway 2×2 table.

Table 90.6 lists the *plot-options* that are available for risk difference plots. See the subsection “Plot Options for **ODDSRATIO**PLOT, **RELRIKSPLOT**, and **RISKDIFF**PLOT” for descriptions of the *plot-options*.

WTFREQPLOT <(plot-options)>

requests a weighted frequency plot. Weighted frequency plots are available for frequency and crosstabulation tables. For multiway tables, PROC SURVEYFREQ provides a two-way weighted frequency plot for each two-way table layer.

To produce a weighted frequency plot, you must specify the **WTFREQPLOT** *plot-request* in the **PLOTS=** option, or you must specify the **PLOTS=ALL** option. PROC SURVEYFREQ does not produce weighted frequency plots by default when ODS Graphics is enabled.

By default, PROC SURVEYFREQ displays weighted frequency plots as bar charts. You can specify the **TYPE=DOTPLOT** *plot-option* to display frequency plots as dot plots. You can plot weighted percentages instead of frequencies by specifying the **SCALE=PERCENT** *plot-option*. There are four frequency plot layouts available, which you can request by specifying the **TWOWAY=** *plot-option*. See the subsection “Plot Options for **WTFREQPLOT**” for more information.

By default, the primary grouping of graph cells in a two-way layout is by column variable. Row variable levels are then displayed within column variable levels. You can specify the **GROUPBY=ROW** *plot-option* to group first by row variable.

Weighted frequency plots for one-way tables display confidence limits by default. For two-way tables, weighted frequency plots display confidence limits by default in the **TWOWAY=GROUPVERTICAL** and **TWOWAY=GROUPHORIZONTAL** layouts. You can suppress confidence limits by specifying the **CLBAR=NO** *plot-option*. Confidence limits are not available for two-way plots in the **TWOWAY=CLUSTER** and **TWOWAY=STACKED** layouts.

Table 90.7 lists the *plot-options* that are available for weighted frequency plots. See the subsection “Plot Options for **WTFREQPLOT**” for descriptions of the *plot-options*.

Table 90.7 Plot Options for WTFREQPLOT

Plot Option	Description	Values
CLBAR=	Confidence limit bars	YES* or NO
GROUPBY=**	Primary group	COLUMN* or ROW
NPANELPOS=**	Sections per panel	Number (4*)
ORIENT=	Orientation	VERTICAL* or HORIZONTAL
SCALE=	Scale	WTFREQ* or PERCENT
TWOWAY=**	Two-way layout	CLUSTER, GROUPHORIZONTAL, GROUPVERTICAL*, or STACKED
TYPE=	Type	BARCHART* or DOTPLOT

*Default

**For two-way tables

Global Plot Options

A *global-plot-option* applies to all plots for which the option is available unless it is altered by an individual *plot-option*. All *plot-options* that are listed in Table 90.7 and Table 90.6 are available as *global-plot-options*. The **ONLY** option is also available as a *global-plot-option*.

You can specify *global-plot-options* in parentheses after the PLOTS option. For example:

```
plots(order=ascending stats)=(riskdiffplot oddsratioplot)
plots(only)=wtfreqplot
```

In addition to the *plot-options* that are listed in Table 90.7 and Table 90.6, you can specify the following *global-plot-option* in parentheses after the PLOTS option:

ONLY

suppresses the default plots and requests only the plots that are specified as *plot-requests*.

Plot Options for ODDSRATIOPLOT, RELRISKPLOT, and RISKDIFFPLOT

You can specify the following *plot-options* in parentheses after the **ODDSRATIOPLOT**, **RELRISKPLOT**, or **RISKDIFFPLOT** *plot-request*:

CLDISPLAY=SERIF | LINE | BAR < width >

controls the appearance of the confidence limit error bars. The default value is **CLDISPLAY=SERIF**, which displays the confidence limits as lines with serifs. **CLDISPLAY=LINE** displays the confidence limits as plain lines without serifs.

CLDISPLAY=BAR displays the confidence limits as bars. By default, the width of the bars equals the size of the marker for the estimate. You can control the width of the bars and the size of the marker by specifying the value of *width* as a percentage of the distance between bars, $0 < width \leq 1$. The bar might disappear when the value of *width* is very small.

COLUMN=1 | 2

specifies the 2×2 table column to use to compute the risk (proportion). The **COLUMN=** *plot-option* is available for the relative risk plot (**REL**RISKPLOT) and the risk difference plot (**RISKDIFF**PLOT). If you specify **COLUMN=1**, the plot displays the column 1 relative risks or the column 1 risk differences. Similarly, if you specify **COLUMN=2**, the plot displays the column 2 relative risks or risk differences.

The **COLUMN=** *plot-option* does not apply to odds ratio plots. The default is **COLUMN=1** for relative risks plots.

If you request both column 1 and column 2 risk differences with the **RISK** option, **COLUMN=1** is the default for the risk difference plot. If you request computation of only column 1 (or only column 2) risk differences with the **RISK1** (or **RISK2**) option, by default the risk difference plot displays the corresponding risk differences.

LOGBASE=2 | E | 10

applies to the odds ratio plot (**ODDSRATIO**PLOT) and the relative risk plot (**REL**RISKPLOT). The **LOGBASE=** *plot-option* displays the odds ratio or relative risk axis on the log scale that you specify.

NPANELPOS=*n*

divides the plot into multiple panels that display at most $|n|$ statistics (odds ratios, relative risks, or risk differences) per panel. If n is positive, the number of statistics per panel is balanced; if n is negative, the number of statistics per panel is not balanced. For example, suppose you want to display 21 odds ratios. **NPANELPOS=20** displays two panels, the first with 11 odds ratios and the second with 10 odds ratios; **NPANELPOS=-20** displays 20 odds ratios in the first panel but only one in the second panel.

By default, $n = 0$ and all statistics are displayed in a single panel.

ORDER=ASCENDING | DESCENDING

displays the statistics (odds ratios, relative risks, or risk differences) in sorted order. By default, the statistics are displayed in the order in which the two-way table layers appear in the multiway table.

RANGE=(*< min >* *<, max >*) | CLIP

specifies the range of values to display. If you specify **RANGE=CLIP**, the confidence limits are clipped and the display range is determined by the minimum and maximum values of the estimates. By default, the display range includes all confidence limits.

STATS

displays the values of the statistics and their confidence limits on the right side of the plot. If you do not specify the **STATS** option, the statistic values are not displayed.

Plot Options for WTFREQPLOT

You can specify the following *plot-options* in parentheses after the **WTFREQPLOT** *plot-request*:

CLBAR=NO | YES

controls the confidence limit error bars in the plots. CLBAR=NO suppresses confidence limit error bars. CLBAR=YES is the default for all weighted frequency plots except two-way plots that are displayed in the **TWOWAY=CLUSTER** or **TWOWAY=STACKED** layout. Confidence limit error bars are not available in the **TWOWAY=CLUSTER** and **TWOWAY=STACKED** layouts.

GROUPBY=COLUMN | ROW

specifies the primary grouping for two-way weighted frequency plots. The default is **GROUPBY=COLUMN**, which groups graph cells first by column variable and displays row variable levels within column variable levels. You can specify **GROUPBY=ROW** to group first by row variable. In two-way and multiway table requests, the column variable is the last variable specified and forms the columns of the crosstabulation table. The row variable is the next-to-last variable specified and forms the rows of the table.

By default for a bar chart that is displayed in the **TWOWAY=STACKED** layout, bars correspond to the column variable levels and row levels are displayed (stacked) within each column bar. By default for a bar chart that is displayed in the **TWOWAY=CLUSTER** layout, bars are first grouped by column variable levels, and row levels are displayed as adjacent bars within each column-level group. You can reverse the default row and column variable groupings by specifying **GROUPBY=ROW**.

NPANELPOS=*n*

divides a two-way weighted frequency plot into multiple panels that display at most $|n|$ sections per panel. Sections correspond to row or column variable levels, depending on the type of plot and the grouping.

The **NPANELPOS= *plot-option*** applies to two-way plots that are displayed in the **TWOWAY=GROUPVERTICAL** or **TWOWAY=GROUPHORIZONTAL** layout. The **NPANELPOS= *plot-option*** does not apply to the **TWOWAY=CLUSTER** and **TWOWAY=STACKED** layouts, which are always displayed in a single panel.

If n is positive, the number of sections per panel is balanced; if n is negative, the number of sections per panel is not balanced. For example, suppose your two-way table has 21 sections. **NPANELPOS=20** displays two panels, the first with 11 sections and the second with 10 sections; **NPANELPOS=-20** displays 20 sections in the first panel but only 1 section in the second panel.

By default, $n = 4$ and each panel includes at most four sections.

ORIENT=HORIZONTAL | VERTICAL

controls the orientation of the weighted frequency plot. The **ORIENT=HORIZONTAL *plot-option*** places the variable levels on the Y axis and the weighted frequencies or percentages on the X axis. **ORIENT=VERTICAL** places the variable levels on the X axis. The default is **ORIENT=VERTICAL** for bar charts (**TYPE=BARCHART**) and **ORIENT=HORIZONTAL** for dot plots (**TYPE=DOTPLOT**).

SCALE=WTFREQ | PERCENT

specifies the scale of the frequencies to display. **SCALE=WTFREQ** displays weighted frequencies (totals), and **SCALE=PERCENT** displays percentages. The default is **SCALE=WTFREQ**.

TWOWAY=CLUSTER | GROUPTHORIZONTAL | GROUPVERTICAL | STACKED

specifies the layout for two-way weighted frequency plots.

All TWOWAY= layouts are available for bar charts (**TYPE=BARCHART**). All TWOWAY= layouts except TWOWAY=CLUSTER are available for dot plots (**TYPE=DOTPLOT**). Confidence limits (**CLBAR=**) can be displayed in the GROUPVERTICAL and GROUPTHORIZONTAL layouts. Confidence limits are not available in the STACKED and CLUSTER layouts. The **ORIENT=** and **GROUPBY=** *plot-options* are available for all TWOWAY= layouts.

The default two-way layout is TWOWAY=GROUPVERTICAL, which produces a grouped plot that has a vertical common baseline. By default for bar charts (**TYPE=BARCHART**, **ORIENT=VERTICAL**), the X axis displays column variable levels, and the Y axis displays weighted frequencies. The plot includes a vertical (Y-axis) block for each row variable level. The relative positions of the graph cells in this plot layout are the same as the relative positions of the table cells in the crosstabulation table. You can reverse the default row and column grouping by specifying the **GROUPBY=ROW** *plot-option*.

The TWOWAY=GROUPTHORIZONTAL layout produces a grouped plot that has a horizontal common baseline. By default (**GROUPBY=COLUMN**), the plot displays a block on the X axis for each column variable level. Within each column-level block, the plot displays row variable levels.

The TWOWAY=STACKED layout produces stacked displays of weighted frequencies. By default (**GROUPBY=COLUMN**) in a stacked bar chart, the bars correspond to column variable levels, and row levels are stacked within each column level. By default in a stacked dot plot, the dotted lines correspond to column levels, and cell weighted frequencies are plotted as data dots on the corresponding column line. The dot color identifies the row level.

The TWOWAY=CLUSTER layout, which is available only for bar charts, displays groups of adjacent bars. By default, the primary grouping is by column variable level, and row levels are displayed within each column level.

You can reverse the default row and column grouping in any layout by specifying the **GROUPBY=ROW** *plot-option*. The default is **GROUPBY=COLUMN**, which groups first by column variable.

TYPE=BARCHART | DOTPLOT

specifies the type of the weighted frequency plot. **TYPE=BARCHART** produces a bar chart and **TYPE=DOTPLOT** produces a dot plot. The default type is **TYPE=BARCHART**.

RISK | RISKDIFF

requests risk statistics for 2×2 tables. The RISK option also provides standard errors and confidence limits for these statistics. Risk statistics include the row 1 risk (proportion), row 2 risk, overall risk, and risk difference. See the section “[Risks and Risk Difference](#)” on page 7648 for details.

The RISK option provides both column 1 and column 2 risks. To request only column 1 or column 2 risks, use the **RISK1** or **RISK2** option.

To compute confidence limits for the risks and risk difference, PROC SURVEYFREQ determines the confidence coefficient from the **ALPHA=** option, which by default equals 0.05 and produces 95% confidence limits.

RISK1

requests column 1 risk statistics for 2×2 tables, together with their standard errors and confidence limits. Risk statistics include the row 1 risk (proportion), row 2 risk, overall risk, and risk difference. See the section “[Risks and Risk Difference](#)” on page 7648 for details.

To compute confidence limits for the risks and risk difference, PROC SURVEYFREQ determines the confidence coefficient from the [ALPHA=](#) option, which by default equals 0.05 and produces 95% confidence limits.

RISK2

requests column 2 risk statistics for 2×2 tables, together with their standard errors and confidence limits. Risk statistics include the row 1 risk (proportion), row 2 risk, overall risk, and risk difference. See the section “[Risks and Risk Difference](#)” on page 7648 for details.

To compute confidence limits for the risks and risk difference, PROC SURVEYFREQ determines the confidence coefficient from the [ALPHA=](#) option, which by default equals 0.05 and produces 95% confidence limits.

ROW <option>

displays the row percentage (estimated proportion of the row total) for each cell in a two-way table. The ROW option also provides the standard errors of the row percentages. See the section “[Row and Column Proportions](#)” on page 7635 for more information. This option has no effect for one-way tables.

You can specify the following *option* in parentheses after the ROW option:

DEFF

displays the design effect for each row percentage in the crosstabulation table. See the section “[Design Effect](#)” on page 7646 for more information.

TESTP=(values)

specifies null hypothesis proportions (test percentages) for chi-square tests for one-way tables (goodness-of-fit tests). You can separate *values* with blanks or commas. Specify *values* in probability form as numbers between 0 and 1, where the proportions sum to 1. Or specify *values* in percentage form as numbers between 0 and 100, where the percentages sum to 100. PROC SURVEYFREQ treats the value 1 as the percentage form 1%. The number of TESTP= values must equal the number of variable levels in the one-way table. List these values in the same order in which the corresponding variable levels appear in the output.

When you specify the TESTP= option, PROC SURVEYFREQ displays the specified test percentages in the one-way frequency table. The TESTP= option has no effect for two-way tables.

PROC SURVEYFREQ uses the TESTP= values for the one-way Rao-Scott chi-square test ([CHISQ](#)) and for the one-way Rao-Scott likelihood ratio chi-square test ([LRCHISQ](#)). See the sections “[Rao-Scott Chi-Square Test](#)” on page 7652 and “[Rao-Scott Likelihood Ratio Chi-Square Test](#)” on page 7657 for details.

VAR

displays the variance estimate for each percentage in the crosstabulation table. See the section “[Proportions](#)” on page 7634 for details. By default, PROC SURVEYFREQ displays the standard errors of the percentages.

VARWT

displays the variance estimate for each weighted frequency, or estimated total, in the crosstabulation table. See the section “[Totals](#)” on page 7632 for details. By default, PROC SURVEYFREQ displays the standard deviations of the weighted frequencies.

WCHISQ

requests the Wald chi-square test for two-way tables. See the section “[Wald Chi-Square Test](#)” on page 7659 for details.

WLLCHISQ

requests the Wald log-linear chi-square test for two-way tables. See the section “[Wald Log-Linear Chi-Square Test](#)” on page 7660 for details.

WTFREQ

displays totals (weighted frequencies) and their standard errors when you do not specify a [WEIGHT](#) or [REPWEIGHTS](#) statement. PROC SURVEYFREQ displays the weighted frequencies by default when you include a [WEIGHT](#) or [REPWEIGHTS](#) statement. Without a [WEIGHT](#) or [REPWEIGHTS](#) statement, PROC SURVEYFREQ assigns all observations a weight of one.

WEIGHT Statement

WEIGHT *variable* ;

The [WEIGHT](#) statement names the variable that contains the sampling weights. This variable must be numeric, and the sampling weights must be positive numbers. If an observation has a weight that is nonpositive or missing, then the procedure omits that observation from the analysis. See the section “[Missing Values](#)” on page 7627 for more information. If you specify more than one [WEIGHT](#) statement, the procedure uses only the first [WEIGHT](#) statement and ignores the rest.

If you do not specify a [WEIGHT](#) statement but provide replicate weights with a [REPWEIGHTS](#) statement, PROC SURVEYFREQ uses the average of each observation’s replicate weights as the observation’s weight.

If you do not specify a [WEIGHT](#) statement or a [REPWEIGHTS](#) statement, PROC SURVEYFREQ assigns all observations a weight of one.

Details: SURVEYFREQ Procedure

Specifying the Sample Design

PROC SURVEYFREQ produces tables and statistics that are based on the sample design used to obtain the survey data. PROC SURVEYFREQ can be used for single-stage or multistage designs, with or without stratification, and with or without unequal weighting. To analyze your survey data with PROC SURVEYFREQ, you need to provide sample design information for the procedure. This information can include design strata, clusters, and sampling weights. You can provide sample design information with the [STRATA](#), [CLUSTER](#), and [WEIGHT](#) statements, and with the [RATE=](#) or [TOTAL=](#) option in the [PROC SURVEYFREQ](#) statement.

If you provide replicate weights for BRR or jackknife variance estimation, you do not need to specify a STRATA or CLUSTER statement. Otherwise, you should specify STRATA and CLUSTER statements whenever your design includes stratification and clustering.

When there are clusters (PSUs) in the sample design, the procedure estimates variance by using the PSUs, as described in the section “[Statistical Computations](#)” on page 7630. For a multistage sample design, the variance estimation depends only on the first stage of the sample design. Therefore, the required input includes only first-stage cluster (PSU) and first-stage stratum identification. You do not need to input design information about any additional stages of sampling.

Stratification

If your sample design is stratified at the first stage of sampling, use the [STRATA](#) statement to name the variables that form the strata. The combinations of categories of STRATA variables define the strata in the sample, where strata are nonoverlapping subgroups that were sampled independently. If your sample design has stratification at multiple stages, you should identify only the first-stage strata in the STRATA statement.

If you use a [REPWEIGHTS](#) statement to provide replicate weights for BRR or jackknife variance estimation, you do not need to specify a STRATA statement. Otherwise, you should specify a STRATA statement whenever your design includes stratification. If you do not specify a STRATA statement or a REPWEIGHTS statement, then PROC SURVEYFREQ assumes there is no stratification at the first stage.

Clustering

If your sample design selects clusters at the first stage of sampling, use the [CLUSTER](#) statement to name the variables that identify the first-stage clusters, which are also called primary sampling units (PSUs). The combinations of categories of CLUSTER variables define the clusters in the sample. If there is a STRATA statement, clusters are nested within strata. If your sample design has clustering at multiple stages, you should specify only the first-stage clusters (PSUs) in the CLUSTER statement. PROC SURVEYFREQ assumes that each cluster that is defined by the CLUSTER statement variables represents a PSU in the sample, and that each observation belongs to one PSU.

If you use a [REPWEIGHTS](#) statement to provide replicate weights for BRR or jackknife variance estimation, you do not need to specify a CLUSTER statement. Otherwise, you should specify a CLUSTER statement whenever your design includes clustering at the first stage of sampling. If you do not specify a CLUSTER statement, then PROC SURVEYFREQ treats each observation as a PSU.

Weighting

If your sample design includes unequal weighting, use the [WEIGHT](#) statement to name the variable that contains the sampling weights. Sampling weights must be positive numbers. If an observation has a weight that is nonpositive or missing, then the procedure omits that observation from the analysis. See the section “[Missing Values](#)” on page 7627 for more information.

If you do not specify a WEIGHT statement but include a [REPWEIGHTS](#) statement, PROC SURVEYFREQ uses the average of each observation’s replicate weights as the observation’s weight. If you do not specify a WEIGHT statement or a REPWEIGHTS statement, PROC SURVEYFREQ assigns all observations a weight of one.

Population Totals and Sampling Rates

To include a finite population correction (*fpc*) in Taylor series variance estimation, you can input either the sampling rate or the population total by using the **RATE=** or **TOTAL=** option in the **PROC SURVEYFREQ** statement. (You cannot specify both of these options in the same **PROC SURVEYFREQ** statement.) The **RATE=** and **TOTAL=** options apply only to Taylor series variance estimation. The procedure does not use a finite population correction for BRR or jackknife variance estimation.

If you do not specify the **RATE=** or **TOTAL=** option, Taylor series variance estimation does not include a finite population correction. For fairly small sampling fractions, it is appropriate to ignore this correction. See Cochran (1977) and Kish (1965) for more information.

If your design has multiple stages of selection and you are specifying the **RATE=** option, you should input the first-stage sampling rate, which is the ratio of the number of PSUs in the sample to the total number of PSUs in the study population. If you are specifying the **TOTAL=** option for a multistage design, you should input the total number of PSUs in the study population.

For a nonstratified sample design, or for a stratified sample design with the same sampling rate or the same population total in all strata, you can use the **RATE=value** or **TOTAL=value** option. If your sample design is stratified with different sampling rates or population totals in different strata, use the **RATE=SAS-data-set** or **TOTAL=SAS-data-set** option to name a SAS data set that contains the stratum sampling rates or totals. This data set is called a *secondary data set*, as opposed to the *primary data set* that you specify with the **DATA=** option.

The secondary data set must contain all the stratification variables listed in the **STRATA** statement and all the variables in the **BY** statement. Furthermore, the **BY** groups must appear in the same order as in the primary data set. If there are formats that are associated with the **STRATA** variables and the **BY** variables, then the formats must be consistent in the primary and the secondary data sets. If you specify the **TOTAL=SAS-data-set** option, the secondary data set must have a variable named **_TOTAL_** that contains the stratum population totals. If you specify the **RATE=SAS-data-set** option, the secondary data set must have a variable named **_RATE_** that contains the stratum sampling rates. If the secondary data set contains more than one observation for any one stratum, the procedure uses the first value of **_TOTAL_** or **_RATE_** for that stratum and ignores the rest.

The *value* in the **RATE=** option or the values of **_RATE_** in the secondary data set must be nonnegative numbers. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and **PROC SURVEYFREQ** converts that number to a proportion. The procedure treats the value 1 as 100% instead of 1%.

If you specify the **TOTAL=value** option, *value* must not be less than the sample size. If you provide stratum population totals in a secondary data set, these values must not be less than the corresponding stratum sample sizes.

Domain Analysis

PROC SURVEYFREQ provides domain analysis through its multiway table capability. *Domain analysis* refers to the computation of statistics for domains (subpopulations), in addition to the computation of statistics for the entire study population. Formation of subpopulations can be unrelated to the sample design, and so the domain sample sizes can actually be random variables. Domain analysis takes this variability into account by using the entire sample in estimating the variance of domain estimates. Domain analysis is also

known as subgroup analysis, subpopulation analysis, and subdomain analysis. For more information about domain analysis, see Lohr (2010); Cochran (1977); Fuller et al. (1989).

To request domain analysis with PROC SURVEYFREQ, you should include the domain variable(s) in your **TABLES** statement request. For example, specifying `DOMAIN * A * B` in a **TABLES** statement produces separate two-way tables of *A* by *B* for each level of *DOMAIN*. If your domains are formed by more than one variable, you can specify `DomainVariable_1 * DomainVariable_2 * A * B`, for example, to obtain two-way tables of *A* by *B* for each domain formed by the different combinations of levels for *DomainVariable_1* and *DomainVariable_2*. See [Example 90.2](#) for an example of domain analysis.

If you specify `DOMAIN * A` in a **TABLES** statement, the values of the variable *DOMAIN* form the table rows. The two-way table lists levels of the variable *A* within each level of the row variable *DOMAIN*. Specify the **ROW** option in the **TABLES** statement to obtain the row percentages and their standard errors. This provides the one-way distribution of *A* for each domain (level of the variable *DOMAIN*).

Including the domain variables in a **TABLES** statement request provides a different analysis from that obtained by using a **BY** statement, which provides completely separate analyses of the **BY** groups. The **BY** statement can also be used to analyze the data set by subgroups, but it is critical to note that this does *not* produce a valid domain analysis. The **BY** statement is appropriate only when the number of units in each subgroup is known with certainty. For example, the **BY** statement can be used to obtain stratum level estimates when you have fixed sample sizes for the strata. When the subgroup sample size is a random variable, include the domain variables in your **TABLES** statement request.

Missing Values

WEIGHT Variable

If an observation has a missing value or a nonpositive value for the **WEIGHT** variable, then PROC SURVEYFREQ excludes that observation from the analysis.

REPWEIGHTS Variables

If you provide replicate weights with a **REPWEIGHTS** statement for BRR or jackknife variance estimation, all **REPWEIGHTS** variable values must be nonmissing. Similarly, if you provide jackknife coefficients with the **JKCOEFS=** option in the **REPWEIGHTS** statement, all values of the **JKCoefficient** variable must be nonmissing. The procedure does not perform the analysis when any replicate weight or jackknife coefficient value is missing.

STRATA and CLUSTER Variables

An observation is excluded from the analysis if it has a missing value for any **STRATA** or **CLUSTER** variable, unless you specify the **MISSING** option in the **PROC SURVEYFREQ** statement. If you specify the **MISSING** option, the procedure treats missing values as a valid (nonmissing) category for all categorical variables, which include **STRATA** variables, **CLUSTER** variables, and **TABLES** variables.

TABLES Variables

By default, PROC SURVEYFREQ excludes an observation from a crosstabulation table (and all associated analyses) if the observation has a missing value for any of the variables in the **TABLES** request, unless

you specify the **MISSING** or **NOMCAR** option in the **PROC SURVEYFREQ** statement. When the procedure excludes observations with missing values from a table, it displays the total frequency of missing observations below the table.

If you specify the **MISSING** option, the procedure treats missing values as a valid (nonmissing) level for each **TABLES** variable. These levels are displayed in the crosstabulation table and included in computations of totals, percentages, and all other table statistics.

If you specify the **NOMCAR** option in the **PROC SURVEYFREQ** statement for Taylor series variance estimation, the procedure includes observations with missing values of **TABLES** variables in the variance computations. The **NOMCAR** option does not display missing levels in the crosstabulation table or compute percentages and totals for missing levels.

The **NOMCAR** Option

The **NOMCAR** option in the **PROC SURVEYFREQ** statement includes observations with missing values of **TABLES** variables in the variance computations as *not missing completely at random* (**NOMCAR**) for Taylor series variance estimation. By default, observations are completely excluded from the analysis if they have missing values for any of the variables in the current **TABLES** request. This default treatment is based on the assumption that the values are *missing completely at random* (**MCAR**), and assumes that the analysis results should not be substantially different between the missing and nonmissing groups. See the section “[Analysis Considerations](#)” on page 7629 for more information.

When you specify the **NOMCAR** option, **PROC SURVEYFREQ** computes variance estimates by analyzing the nonmissing values as a domain (subpopulation), where the entire population includes both nonmissing and missing domains.

Note that the **NOMCAR** option has no effect when you specify the **MISSING** option, which treats missing values as a valid nonmissing level. The **NOMCAR** option does not affect the inclusion of observations with missing values of the **WEIGHT**, **CLUSTER**, or **STRATA** variables. Observations with missing values of the **WEIGHT** variable are always excluded from the analysis. Observations with missing values of the **CLUSTER** or **STRATA** variables are excluded unless you specify the **MISSING** option.

The **NOMCAR** option applies only to Taylor series variance estimation **VARMETHOD=TAYLOR**. The replication methods, which you request with the **VARMETHOD=BRR** and **VARMETHOD=JACKKNIFE** options, do not use the **NOMCAR** option.

Degrees of Freedom

PROC SURVEYFREQ computes degrees of freedom to obtain the *t*-percentile for confidence limits for proportions, totals, and other statistics. The procedure also uses degrees of freedom for the *F* statistics in the Rao-Scott and Wald chi-square tests. The degrees of freedom computation depends on the variance estimation method that you request. See the section “[Degrees of Freedom](#)” on page 7645 for details. Missing values can affect the degrees of freedom computation.

Taylor Series Variance Estimation

The degrees of freedom can depend on the number of clusters, the number of strata, and the number of observations. For Taylor series variance estimation, these numbers are based on the observations included in the analysis of the individual table. These numbers do not count observations that are excluded from the table due to missing values. If all values in a stratum are excluded from the analysis of a table as missing values, then that stratum is called an *empty stratum*. Empty strata are not counted in the total number of

strata for the table. Similarly, empty clusters and missing observations are not included in the total counts of clusters and observations that are used to compute the degrees of freedom for the analysis.

If you specify the **MISSING** option, missing values are treated as valid nonmissing levels and are included in computing degrees of freedom. If you specify the **NOMCAR** option for Taylor series variance estimation, observations with missing values of the **TABLES** variables are included in computing degrees of freedom.

Replicate-Based Variance Estimation

For BRR or jackknife variance estimation, by default PROC SURVEYFREQ computes the degrees of freedom by using all valid observations in the input data set. A valid observation is an observation that has a positive value of the **WEIGHT** variable and nonmissing values of the **STRATA** and **CLUSTER** variables unless you specify the **MISSING** option. See the section “Data Summary Table” on page 7663 for details about valid observations.

If you specify the **DFADJ** *method-option* for **VARMETHOD=BRR** or **VARMETHOD=JACKKNIFE**, the procedure computes the degrees of freedom based on the nonmissing observations included in the individual table analysis. This excludes any empty strata or clusters that occur when observations with missing values of the **TABLES** variables are removed from the analysis for that table.

Table Summary Output Data Set

For each table request, PROC SURVEYFREQ produces a nondisplayed ODS table, “Table Summary,” which contains the number of (nonmissing) observations, strata, and clusters that are included in the analysis of the individual table. If there are missing observations, empty strata, or empty clusters excluded from the analysis, the “Table Summary” data set also contains this information. If you request any confidence limits or chi-square tests for the table, which require degrees of freedom, the “Table Summary” data set provides the degrees of freedom.

Due to missing values, the number of observations used for an individual table analysis can differ from the number of valid observations in the input data set, which is reported in the “Data Summary” table. Similarly, a difference can also occur for the number of clusters or strata. See [Example 90.3](#) for more information about the “Table Summary” output data set.

If you specify the **NOMCAR** option for Taylor series variance estimation, the “Table Summary” data set reflects all observations used for variance estimation, which includes those observations with missing values of the **TABLES** variables.

Analysis Considerations

If you have missing values in your survey data for any reason (such as nonresponse), this can compromise the quality of your survey results. An observation without missing values is called a *complete respondent*, and an observation with missing values is called an *incomplete respondent*. If the complete respondents are different from the incomplete respondents with regard to a survey effect or outcome, then survey estimates will be biased and will not accurately represent the survey population. There are a variety of techniques in sample design and survey operations that can reduce nonresponse. After data collection is complete, you can use imputation to replace missing values with acceptable values, and you can use sampling weight adjustments to compensate for nonresponse. You should complete this data preparation and adjustment before you analyze your data with PROC SURVEYFREQ. For more details, see Cochran (1977); Kalton and Kaspyzyk (1986); Brick and Kalton (1996).

Statistical Computations

Variance Estimation

PROC SURVEYFREQ provides a choice of variance estimation methods for complex survey data. In addition to the Taylor series linearization method, the procedures offer two replication-based (resampling) methods—balanced repeated replication (BRR) and the delete-1 jackknife. These variance estimation methods usually give similar, satisfactory results (Lohr 2010; Särndal, Swensson, and Wretman 1992; Wolter 1985). The choice of a variance estimation method can depend on the sample design used, the sample design information available, the parameters to be estimated, and computational issues. See Lohr (2010) for more details.

Taylor Series Variance Estimation

The Taylor series linearization method can be used to estimate standard errors of proportions and other statistics for crosstabulation tables. For sample survey data, the proportion estimator is a ratio estimator formed from estimators of totals. For example, to estimate the proportion in a crosstabulation table cell, the procedure uses the ratio of the estimator of the cell total frequency to the estimator of the overall population total, where these totals are linear statistics computed from the survey data. The Taylor series expansion method obtains a first-order linear approximation for the ratio estimator and then uses the variance estimate for this approximation to estimate the variance of the estimate itself (Woodruff 1971; Fuller 1975). For more information about Taylor series variance estimation for sample survey data, see Lohr (2010); Särndal, Swensson, and Wretman (1992); Lee, Forthofer, and Lorimor (1989); Wolter (1985).

When there are clusters (PSUs) in the sample design, the Taylor series method estimates variance from the variance among PSUs. When the design is stratified, the procedure combines stratum variance estimates to compute the overall variance estimate. For a multistage sample design, the variance estimation depends only on the first stage of the sample design. So the required input includes only first-stage cluster (PSU) and first-stage stratum identification. You do not need to input design information about any additional stages of sampling. This variance estimation method assumes that the first-stage sampling fraction is small, or the first-stage sample is drawn with replacement, as it often is in practice.

See the sections “Proportions” on page 7634, “Row and Column Proportions” on page 7635, “Risks and Risk Difference” on page 7648, and “Odds Ratio and Relative Risks” on page 7650 for details and formulas for Taylor series variance estimates.

Replication-Based Variance Estimation

Replication-based methods for variance estimation draw multiple replicates (subsamples) from the full sample by following a specific resampling scheme. Commonly used resampling schemes include *balanced repeated replication* (BRR) and the *jackknife*. PROC SURVEYFREQ estimates the parameter of interest (a proportion, total, odds ratio, or other statistic) from each replicate, and then uses the variability among replicate estimates to estimate the overall variance of the parameter estimate. See Wolter (1985) and Lohr (2010) for more information.

The BRR variance estimation method requires a stratified sample design with two PSUs in each stratum. Each replicate is obtained by deleting one PSU per stratum according to the corresponding Hadamard matrix and adjusting the original weights of the remaining PSUs. The adjusted weights are called *replicate weights*. PROC SURVEYFREQ also provides Fay’s method, which is a modification of the BRR method. See the section “Balanced Repeated Replication (BRR)” on page 7637 for details.

The jackknife method deletes one PSU at a time from the full sample to create replicates, and modifies the original weights to obtain replicate weights. The total number of replicates equals the number of PSUs. If the sample design is stratified, each stratum must contain at least two PSUs, and the jackknife is applied separately within each stratum. See the section “[The Jackknife Method](#)” on page 7640 for details.

Instead of having PROC SURVEYFREQ generate replicate weights for the analysis, you can input your own replicate weights with a [REPWEIGHTS](#) statement. This can be useful if you need to do multiple analyses with the same set of replicate weights, or if you have access to replicate weights instead of design information. See the section “[Replicate Weight Output Data Set](#)” on page 7662 for more information.

Definitions and Notation

For a stratified clustered sample design, define the following:

h	$= 1, 2, \dots, H$	is the stratum number, with a total of H strata
i	$= 1, 2, \dots, n_h$	is the cluster number within stratum h , with a total of n_h sample clusters in stratum h
j	$= 1, 2, \dots, m_{hi}$	is the unit number within cluster i of stratum h , with a total of m_{hi} sample units from cluster i of stratum h
n	$= \sum_{h=1}^H \sum_{i=1}^{n_h} m_{hi}$	is the total number of observations in the sample
f_h	$=$	first-stage sampling rate for stratum h
W_{hij}	$=$	sampling weight of unit j in cluster i of stratum h

The sampling rate f_h , which is used in Taylor series variance estimation, is the fraction of first-stage units (PSUs) selected for the sample. You can specify the stratum sampling rates with the [RATE=](#) option. Or if you specify population totals with the [TOTAL=](#) option, PROC SURVEYFREQ computes f_h as the ratio of stratum sample size to the stratum total, in terms of PSUs. See the section “[Population Totals and Sampling Rates](#)” on page 7626 for details. If you do not specify the [RATE=](#) option or the [TOTAL=](#) option, then the procedure assumes that the stratum sampling rates f_h are negligible and does not use a finite population correction when computing variances.

This notation is also applicable to other sample designs. For example, for a design without stratification, you can let $H = 1$; for a sample design without clustering, you can let $m_{hi} = 1$ for every h and i , which replaces clusters with individual sampling units.

For a two-way table representing the crosstabulation of two variables, define the following, where there are R levels of the row variable and C levels of the column variable:

r	$= 1, 2, \dots, R$	is the row number, with a total of R rows
c	$= 1, 2, \dots, C$	is the column number, with a total of C columns
N_{rc}		is the population total in row r and column c
$N_{r\cdot}$	$= \sum_{c=1}^C N_{rc}$	is the total in row r
$N_{\cdot c}$	$= \sum_{r=1}^R N_{rc}$	is the total in column c
N	$= \sum_{r=1}^R \sum_{c=1}^C N_{rc}$	is the overall total

$P_{rc} = N_{rc} / N$ is the population proportion in row r and column c

$P_{r.} = N_{r.} / N$ is the proportion in row r

$P_{.c} = N_{.c} / N$ is the proportion in column c

$P_{rc}^r = N_{rc} / N_{r.}$ is the row proportion for table cell (r, c)

$P_{rc}^c = N_{rc} / N_{.c}$ is the column proportion for table cell (r, c)

For a specified observation (identified by stratum, cluster, and unit number within the cluster), define the following to indicate whether or not that observation belongs to cell (r, c) , row r and column c , of the two-way table, for $r = 1, 2, \dots, R$ and $c = 1, 2, \dots, C$:

$$\delta_{hij}(r, c) = \begin{cases} 1 & \text{if observation } (hij) \text{ is in cell } (r, c) \\ 0 & \text{otherwise} \end{cases}$$

Similarly, define the following functions to indicate the observation's row and column classification:

$$\delta_{hij}(r \cdot) = \begin{cases} 1 & \text{if observation } (hij) \text{ is in row } r \\ 0 & \text{otherwise} \end{cases}$$

$$\delta_{hij}(\cdot c) = \begin{cases} 1 & \text{if observation } (hij) \text{ is in column } c \\ 0 & \text{otherwise} \end{cases}$$

Totals

PROC SURVEYFREQ estimates population frequency totals for the specified crosstabulation tables, including totals for two-way table cells, rows, columns, and overall totals. The procedure computes the estimate of the total frequency in table cell (r, c) as the weighted frequency sum,

$$\hat{N}_{rc} = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \delta_{hij}(r, c) W_{hij}$$

Similarly, PROC SURVEYFREQ computes estimates of row totals, column totals, and overall totals as

$$\hat{N}_{r.} = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \delta_{hij}(r \cdot) W_{hij}$$

$$\hat{N}_{.c} = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \delta_{hij}(\cdot c) W_{hij}$$

$$\hat{N} = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} W_{hij}$$

PROC SURVEYFREQ estimates the variances of totals by using the variance estimation method that you request. If you request BRR variance estimation (by specifying the [VARMETHOD=BRR](#) option in the PROC SURVEYFREQ statement), the procedure estimates the variances as described in the section “[Balanced](#)

Repeated Replication (BRR)” on page 7637. If you request jackknife variance estimation (by specifying the **VARMETHOD=JACKKNIFE** option), the procedure estimates the variances as described in the section “The Jackknife Method” on page 7640.

If you do not specify the **VARMETHOD=** option or a **REPWEIGHTS** statement, the default variance estimation method is Taylor series, which you can also request with the **VARMETHOD=TAYLOR** option. Since totals are linear statistics, their variances can be estimated directly, without the approximation that is used for proportions and other nonlinear statistics. PROC SURVEYFREQ estimates the variance of the total frequency in table cell (r, c) as

$$\widehat{\text{Var}}(\widehat{N}_{rc}) = \sum_{h=1}^H \widehat{\text{Var}}_h(\widehat{N}_{rc})$$

where if $n_h > 1$,

$$\begin{aligned} \widehat{\text{Var}}_h(\widehat{N}_{rc}) &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (n_{rc}^{hi} - \bar{n}_{rc}^h)^2 \\ n_{rc}^{hi} &= \sum_{j=1}^{m_{hi}} \delta_{hij}(r, c) W_{hij} \\ \bar{n}_{rc}^h &= \left(\sum_{i=1}^{n_h} n_{rc}^{hi} \right) / n_h \end{aligned}$$

and if $n_h = 1$,

$$\widehat{\text{Var}}_h(\widehat{N}_{rc}) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

The standard deviation of the total is computed as

$$\text{Std}(\widehat{N}_{rc}) = \sqrt{\widehat{\text{Var}}(\widehat{N}_{rc})}$$

The variances and standard deviations are computed in a similar manner for row totals, column totals, and overall table totals.

Covariance of Totals

The covariance matrix of the table cell totals \widehat{N}_{rc} is an $rc \times rc$ matrix $\widehat{\mathbf{V}}(\widehat{\mathbf{N}})$, which contains the pairwise table cell covariances $\widehat{\text{Cov}}(\widehat{N}_{rc}, \widehat{N}_{ab})$, for $r = 1, \dots, R$; $c = 1, \dots, C$; $a = 1, \dots, R$; and $b = 1, \dots, C$.

PROC SURVEYFREQ estimates the covariances by using the variance estimation method that you request. If you request BRR variance estimation (by specifying the **VARMETHOD=BRR** option in the PROC SURVEYFREQ statement), the procedure estimates the covariances by the method described in the section “Balanced Repeated Replication (BRR)” on page 7637. If you request jackknife variance estimation (by specifying the **VARMETHOD=JACKKNIFE** option), the procedure uses the method described in the section “The Jackknife Method” on page 7640.

Otherwise (by default, or if you request the Taylor series method), PROC SURVEYFREQ estimates the covariance between total frequency estimates for table cells (r, c) and (a, b) as

$$\widehat{\text{Cov}}(\hat{N}_{rc}, \hat{N}_{ab}) = \sum_{h=1}^H \left(\frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (n_{rc}^{hi} - \bar{n}_{rc}^h) (n_{ab}^{hi} - \bar{n}_{ab}^h) \right)$$

Proportions

PROC SURVEYFREQ computes the estimate of the proportion in table cell (r, c) as the ratio of the estimated total for the table cell to the estimated overall total,

$$\begin{aligned} \hat{P}_{rc} &= \hat{N}_{rc} / \hat{N} \\ &= \left(\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \delta_{hij}(r, c) W_{hij} \right) / \left(\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} W_{hij} \right) \end{aligned}$$

If you request BRR variance estimation (by specifying the [VARMETHOD=BRR](#) option in the PROC SURVEYFREQ statement), the procedure estimates the variances of proportion estimates as described in the section “[Balanced Repeated Replication \(BRR\)](#)” on page 7637. If you request jackknife variance estimation (by specifying the [VARMETHOD=JACKKNIFE](#) option), the procedure estimates the variances as described in the section “[The Jackknife Method](#)” on page 7640.

If you do not specify the [VARMETHOD=](#) option or a [REPWEIGHTS](#) statement, the default variance estimation method is Taylor series, which you can also request with the [VARMETHOD=TAYLOR](#) option. By using Taylor series linearization, the variance of a proportion estimate can be expressed as

$$\widehat{\text{Var}}(\hat{P}_{rc}) = \sum_{h=1}^H \widehat{\text{Var}}_h(\hat{P}_{rc})$$

where if $n_h > 1$,

$$\begin{aligned} \widehat{\text{Var}}_h(\hat{P}_{rc}) &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (e_{rc}^{hi} - \bar{e}_{rc}^h)^2 \\ e_{rc}^{hi} &= \left(\sum_{j=1}^{m_{hi}} (\delta_{hij}(r, c) - \hat{P}_{rc}) W_{hij} \right) / \hat{N} \\ \bar{e}_{rc}^h &= \left(\sum_{i=1}^{n_h} e_{rc}^{hi} \right) / n_h \end{aligned}$$

and if $n_h = 1$,

$$\widehat{\text{Var}}_h(\hat{P}_{rc}) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

The standard error of the proportion is computed as

$$\text{StdErr}(\hat{P}_{rc}) = \sqrt{\widehat{\text{Var}}(\hat{P}_{rc})}$$

Similarly, the estimate of the proportion in row r is

$$\hat{P}_{r\cdot} = \hat{N}_{r\cdot} / \hat{N}$$

And its variance estimate is

$$\widehat{\text{Var}}(\hat{P}_{r\cdot}) = \sum_{h=1}^H \widehat{\text{Var}}_h(\hat{P}_{r\cdot})$$

where if $n_h > 1$,

$$\begin{aligned} \widehat{\text{Var}}_h(\hat{P}_{r\cdot}) &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (e_{r\cdot}^{hi} - \bar{e}_{r\cdot}^h)^2 \\ e_{r\cdot}^{hi} &= \left(\sum_{j=1}^{m_{hi}} (\delta_{hij}(r\cdot) - \hat{P}_{r\cdot}) W_{hij} \right) / \hat{N} \\ \bar{e}_{r\cdot}^h &= \left(\sum_{i=1}^{n_h} e_{r\cdot}^{hi} \right) / n_h \end{aligned}$$

and if $n_h = 1$,

$$\widehat{\text{Var}}_h(\hat{P}_{r\cdot}) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

The standard error of the proportion in row r is computed as

$$\text{StdErr}(\hat{P}_{r\cdot}) = \sqrt{\widehat{\text{Var}}(\hat{P}_{r\cdot})}$$

Computations for the proportion in column c are done in the same way.

Row and Column Proportions

PROC SURVEYFREQ computes the estimate of the row proportion for table cell (r, c) as the ratio of the estimated total for the table cell to the estimated total for row r ,

$$\begin{aligned} \hat{P}_{rc}^r &= \hat{N}_{rc} / \hat{N}_{r\cdot} \\ &= \left(\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \delta_{hij}(r, c) W_{hij} \right) / \left(\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \delta_{hij}(r\cdot) W_{hij} \right) \end{aligned}$$

Similarly, PROC SURVEYFREQ estimates the column proportion for table cell (r, c) as the ratio of the estimated total for the table cell to the estimated total for column c ,

$$\begin{aligned}\hat{P}_{rc}^c &= \hat{N}_{rc} / \hat{N}_{\cdot c} \\ &= \left(\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \delta_{hij}(r, c) W_{hij} \right) / \left(\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \delta_{hij}(\cdot, c) W_{hij} \right)\end{aligned}$$

If you request BRR variance estimation (**VARMETHOD=BRR**), PROC SURVEYFREQ estimates the variances of the row and column proportions as described in the section “[Balanced Repeated Replication \(BRR\)](#)” on page 7637. If you request jackknife variance estimation (**VARMETHOD=JACKKNIFE**), the procedure estimates the variances as described in the section “[The Jackknife Method](#)” on page 7640.

If you do not specify the **VARMETHOD=** option or a **REPWEIGHTS** statement, the default variance estimation method is Taylor series (**VARMETHOD=TAYLOR**). By using Taylor series linearization, the variance of the row proportion estimate can be expressed as

$$\widehat{\text{Var}}(\hat{P}_{rc}^r) = \sum_{h=1}^H \widehat{\text{Var}}_h(\hat{P}_{rc}^r)$$

where if $n_h > 1$,

$$\begin{aligned}\widehat{\text{Var}}_h(\hat{P}_{rc}^r) &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (g_{rc}^{hi} - \bar{g}_{rc}^h)^2 \\ g_{rc}^{hi} &= \left(\sum_{j=1}^{m_{hi}} (\delta_{hij}(r, c) - \hat{P}_{rc}^r \delta_{hij}(r, \cdot)) W_{hij} \right) / \hat{N}_r \\ \bar{g}_{rc}^h &= \left(\sum_{i=1}^{n_h} g_{rc}^{hi} \right) / n_h\end{aligned}$$

and if $n_h = 1$,

$$\widehat{\text{Var}}_h(\hat{P}_{rc}^r) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

The standard error of the row proportion is computed as

$$\text{StdErr}(\hat{P}_{rc}^r) = \sqrt{\widehat{\text{Var}}(\hat{P}_{rc}^r)}$$

The Taylor series variance estimate for the column proportion is computed as described previously for the row proportion, but with

$$g_{rc}^{hi} = \left(\sum_{j=1}^{m_{hi}} (\delta_{hij}(r, c) - \hat{P}_{rc}^c \delta_{hij}(\cdot, c)) W_{hij} \right) / \hat{N}_{\cdot c}$$

Balanced Repeated Replication (BRR)

If you specify the `VARMETHOD=BRR` option, then PROC SURVEYFREQ uses balanced repeated replication (BRR) for variance estimation. The BRR variance estimation method requires a stratified sample design with two PSUs in each stratum. You can provide replicate weights for BRR variance estimation by using a `REPWEIGHTS` statement, or the procedure can construct replicate weights for the analysis. PROC SURVEYFREQ estimates the parameter of interest (a proportion, total, odds ratio, or other statistic) from each replicate, and then uses the variability among replicate estimates to estimate the overall variance of the parameter estimate. See Wolter (1985) and Lohr (2010) for more information about BRR variance estimation.

If you do not provide replicate weights with a `REPWEIGHTS` statement, PROC SURVEYFREQ constructs replicates based on the stratified design with two PSUs in each stratum. This section describes replicate construction by the traditional BRR method. If you specify the `FAY` *method-option* for `VARMETHOD=BRR`, the procedure uses Fay's modified BRR method, which is described in the section “Fay's BRR Method” on page 7638.

With the traditional BRR method, each replicate is obtained by deleting one PSU per stratum according to the corresponding Hadamard matrix of dimension R , where R is the number of replicates. The number of replicates equals the smallest multiple of 4 that is greater than the number of strata H . Alternatively, you can specify the number of replicates with the `REPS=` *method-option*. If a Hadamard matrix cannot be constructed for the `REPS=` value that you specify, the value is increased until a Hadamard matrix of that dimension can be constructed. Therefore, it is possible for the actual number of replicates used to be larger than the `REPS=` value that you specify.

You can provide a Hadamard matrix for BRR replicate construction by using the `HADAMARD=` *method-option*. Otherwise, PROC SURVEYFREQ generates an appropriate Hadamard matrix. See the section “Hadamard Matrix” on page 7639 for more information. You can display the Hadamard matrix by specifying the `PRINTH` *method-option*.

PROC SURVEYFREQ constructs replicates by using the first H columns of the $R \times R$ Hadamard matrix, where H denotes the number of strata. The r th replicate ($r = 1, 2, \dots, R$) is drawn from the full sample according to the r th row of the Hadamard matrix as follows:

- If element (r, h) of the Hadamard matrix equals 1, then the first PSU of stratum h is included in the r th replicate, and the second PSU of stratum h is excluded.
- If element (r, h) of the Hadamard matrix equals -1 , then the second PSU of stratum h is included in the r th replicate, and the first PSU of stratum h is excluded.

For the PSUs included in replicate r , the original weights are doubled to form the replicate r weights. For the PSUs not included in replicate r , the replicate r weights equal zero. You can use the `OUTWEIGHTS=SAS-data-set` *method-option* to store the replicate weights in a SAS data set. See the section “Replicate Weight Output Data Set” on page 7662 for details about the contents of the `OUTWEIGHTS=` data set. You can provide these replicate weights to the procedure for subsequent analyses by using a `REPWEIGHTS` statement.

Let θ denote the population parameter to be estimated—for example, a proportion, total, odds ratio, or other statistic. Let $\hat{\theta}$ denote the estimate of θ from the full sample, and let $\hat{\theta}_r$ denote the estimate from the r th BRR

replicate, which is computed by using the replicate weights. The BRR variance estimate for $\hat{\theta}$ is computed as

$$\widehat{V}(\hat{\theta}) = \frac{1}{R} \sum_{r=1}^R (\hat{\theta}_r - \hat{\theta})^2$$

where R is the total number of replicates.

If a parameter cannot be estimated from some replicate(s), then the variance estimate is computed by using those replicates from which the parameter can be estimated. For example, suppose the parameter is a column proportion—the proportion of column j for table cell (i, j) . If a replicate r contains no observations in column j , then the column j proportion is not estimable from replicate r . In this case, the BRR variance estimate is computed as

$$\widehat{V}(\hat{\theta}) = \frac{1}{R'} \sum_{r=1}^{R'} (\hat{\theta}_r - \hat{\theta})^2$$

where the summation is over the replicates where the parameter θ is estimable, and R' is the number of those replicates.

Fay's BRR Method

If you specify the **FAY** *method-option* for **VARMETHOD=BRR**, then PROC SURVEYFREQ uses Fay's BRR method, which is a modification of the traditional BRR variance estimation method. As for traditional BRR, Fay's method requires a stratified sample design with two PSUs in each stratum. You can provide replicate weights by using a **REPWEIGHTS** statement, or the procedure can construct replicate weights for the analysis. PROC SURVEYFREQ estimates the parameter of interest (a proportion, total, odds ratio, or other statistic) from each replicate, and then uses the variability among replicate estimates to estimate the overall variance of the parameter estimate.

If you do not provide replicate weights with a **REPWEIGHTS** statement, PROC SURVEYFREQ constructs replicates based on the stratified design with two PSUs in each stratum. As for traditional BRR, the number of replicates R equals the smallest multiple of 4 that is greater than the number of strata H , or you can specify the number of replicates with the **REPS=** *method-option*. You can provide a Hadamard matrix for replicate construction by using the **HADAMARD=** *method-option*, or PROC SURVEYFREQ generates an appropriate Hadamard matrix.

The traditional BRR method constructs half-sample replicates by deleting one PSU per stratum according to the Hadamard matrix and doubling the original weights to form replicate weights. Fay's BRR method adjusts the original weights by a coefficient ϵ , where $0 \leq \epsilon < 1$. You can specify the value of ϵ with the **FAY=** *method-option*. If you do not specify the value of ϵ , PROC SURVEYFREQ uses $\epsilon = 0.5$ by default. See Judkins (1990) and Rao and Shao (1999) for information about the value of the Fay coefficient. When $\epsilon = 0$, Fay's method becomes the traditional BRR method. For more information, see Dipppo, Fay, and Morganstein (1984); Fay (1989); Judkins (1990).

PROC SURVEYFREQ constructs Fay BRR replicates by using the first H columns of the $R \times R$ Hadamard matrix, where H denotes the number of strata. The r th replicate ($r = 1, 2, \dots, R$) is drawn from the full sample according to the r th row of the Hadamard matrix as follows:

- If element (r, h) of the Hadamard matrix equals 1, the sampling weight of the first PSU in stratum h is multiplied by ϵ , and the sampling weight of the second PSU is multiplied by $(2 - \epsilon)$ to form the r th replicate weights.
- If element (r, h) of the Hadamard matrix equals -1 , then the sampling weight of the second PSU in stratum h is multiplied by ϵ , and the sampling weight of the first PSU is multiplied by $(2 - \epsilon)$ to form the r th replicate weights.

You can use the `OUTWEIGHTS= method-option` to store the replicate weights in a SAS data set. See the section “Replicate Weight Output Data Set” on page 7662 for details about the contents of the OUTWEIGHTS= data set. You can provide these replicate weights to the procedure for subsequent analyses by using a `REPWEIGHTS` statement.

Let θ denote the population parameter to be estimated—for example, a proportion, total, odds ratio, or other statistic. Let $\hat{\theta}$ denote the estimate of θ from the full sample, and let $\hat{\theta}_r$ denote the estimate from the r th BRR replicate, which is computed by using the replicate weights. The Fay BRR variance estimate for $\hat{\theta}$ is computed as

$$\widehat{V}(\hat{\theta}) = \frac{1}{R(1 - \epsilon)^2} \sum_{r=1}^R (\hat{\theta}_r - \hat{\theta})^2$$

where R is the total number of replicates and ϵ is the Fay coefficient.

If you request Fay’s BRR method and also include a `REPWEIGHTS` statement, PROC SURVEYFREQ uses the replicate weights that you provide and includes the Fay coefficient ϵ in the denominator of the variance estimate in the preceding expression.

If a parameter cannot be estimated from some replicate(s), then the variance estimate is computed by using those replicates from which the parameter can be estimated. For example, suppose the parameter is a column proportion—the proportion of column j for table cell (i, j) . If a replicate r contains no observations in column j , then the column j proportion is not estimable from replicate r . In this case, the BRR variance estimate is computed as

$$\widehat{V}(\hat{\theta}) = \frac{1}{R'(1 - \epsilon)^2} \sum_{r=1}^{R'} (\hat{\theta}_r - \hat{\theta})^2$$

where the summation is over the replicates where the parameter θ is estimable, and R' is the number of those replicates.

Hadamard Matrix

PROC SURVEYFREQ uses a Hadamard matrix to construct replicates for BRR variance estimation. You can provide a Hadamard matrix for replicate construction by using the `HADAMARD= method-option` for `VARMETHOD=BRR`. Otherwise, PROC SURVEYFREQ generates an appropriate Hadamard matrix. You can display the Hadamard matrix by specifying the `PRINTH method-option`.

A Hadamard matrix \mathbf{A} of dimension R is a square matrix that has all elements equal to 1 or -1 . A Hadamard matrix must satisfy the requirement that $\mathbf{A}'\mathbf{A} = R\mathbf{I}$, where \mathbf{I} is an identity matrix. The dimension of a Hadamard matrix must equal 1, 2, or a multiple of 4.

For example, the following matrix is a Hadamard matrix of dimension $k = 8$:

1	1	1	1	1	1	1	1
1	-1	1	-1	1	-1	1	-1
1	1	-1	-1	1	1	-1	-1
1	-1	-1	1	1	-1	-1	1
1	1	1	1	-1	-1	-1	-1
1	-1	1	-1	-1	1	-1	1
1	1	-1	-1	-1	-1	1	1
1	-1	-1	1	-1	1	1	-1

For BRR replicate construction, the dimension of the Hadamard matrix must be at least H , where H denotes the number of first-stage strata in your design. If a Hadamard matrix of a given dimension exists, it is not necessarily unique. Therefore, if you want to use a specific Hadamard matrix, you must provide the matrix as a SAS data set in the `HADAMARD=SAS-data-set method-option`. You must ensure that the matrix that you provide is actually a Hadamard matrix; PROC SURVEYFREQ does not check the validity of your Hadamard matrix.

See the section “[Balanced Repeated Replication \(BRR\)](#)” on page 7637 and “[Fay’s BRR Method](#)” on page 7638 for details about how the Hadamard matrix is used to construct replicates for BRR variance estimation.

The Jackknife Method

If you specify the `VARMETHOD=JACKKNIFE` option, PROC SURVEYFREQ uses the delete-1 jackknife method for variance estimation. The jackknife method can be used for stratified sample designs and for designs with no stratification. If your design is stratified, the jackknife method requires at least two PSUs in each stratum. You can provide replicate weights for jackknife variance estimation by using a `REPWEIGHTS` statement, or the procedure can construct replicate weights for the analysis. PROC SURVEYFREQ estimates the parameter of interest (a proportion, total, odds ratio, or other statistic) from each replicate, and then uses the variability among replicate estimates to estimate the overall variance of the parameter estimate. See Wolter (1985) and Lohr (2010) for more information about jackknife variance estimation.

If you do not provide replicate weights with a `REPWEIGHTS` statement, PROC SURVEYFREQ constructs the replicates. The number of replicates R equals the number of PSUs, and the procedure deletes one PSU from the full sample to form each replicate. The sampling weights are modified by the jackknife coefficient for the replicate to create the replicate weights.

If your design is not stratified (no `STRATA` statement), the jackknife coefficient has the same value for each replicate r . The jackknife coefficient equals

$$\alpha_r = (R - 1)/R \quad \text{for } r = 1, 2, \dots, R$$

where R is the total number of replicates (or total number of PSUs). For the PSUs included in a replicate, the replicate weights are computed by dividing the original sampling weights by the jackknife coefficient. For the deleted PSU, which is not included in the replicate, the replicate weights equal zero. The replicate weight for the j th member of the i th PSU can be expressed as follows when the design is not stratified:

$$W_{ij}^r = \begin{cases} W_{ij}/\alpha_r & \text{if PSU } i \text{ is included in replicate } r \\ 0 & \text{otherwise} \end{cases}$$

where W_{ij} is the original sampling weight of unit (ij) , r is the replicate number, and α_r is the jackknife coefficient.

If your design is stratified, the jackknife method requires at least two PSUs in each stratum. Let stratum h_r' be the stratum from which a PSU is deleted to form the r th replicate. Stratum h_r' is called the *donor stratum*. The jackknife coefficients are defined as

$$\alpha_r = (n_{h_r'} - 1)/n_{h_r'} \quad \text{for } r = 1, 2, \dots, R$$

where $n_{h_r'}$ is the total number of PSUs in the donor stratum for replicate r . For all strata other than the donor stratum, the replicate r weights equal the original sampling weights. For PSUs included from the donor stratum, the replicate weights are computed by dividing the original sampling weights by the jackknife coefficient. For the deleted PSU, which is not included in the replicate, the replicate weights equal zero. The replicate weight for the j th member of the i th PSU in stratum h can be expressed as

$$W_{hij}^r = \begin{cases} W_{hij} & \text{if } h \neq h_r' \\ W_{hij}/\alpha_r & \text{if } h = h_r' \text{ and PSU } (hi) \text{ is included in replicate } r \\ 0 & \text{if } h = h_r' \text{ and PSU } (hi) \text{ is not included in replicate } r \end{cases}$$

You can use the `OUTWEIGHTS=method-option` to store the replicate weights in a SAS data set. You can also use the `OUTJKCOEFS=method-option` to store the jackknife coefficients in a SAS data set. See the sections “[Jackknife Coefficient Output Data Set](#)” on page 7662 and “[Replicate Weight Output Data Set](#)” on page 7662 for details about the contents of these output data sets. You can provide replicate weights and jackknife coefficients to the procedure for subsequent analyses by using a `REPWEIGHTS` statement. If you provide replicate weights but do not provide jackknife coefficients, PROC SURVEYFREQ uses $\alpha_r = (R - 1)/R$ as the jackknife coefficient for all replicates.

Let θ denote the population parameter to be estimated—for example, a proportion, total, odds ratio, or other statistic. Let $\hat{\theta}$ denote the estimate of θ from the full sample, and let $\hat{\theta}_r$ be the estimate from the r th jackknife replicate, which is computed by using the replicate weights. The jackknife variance estimate for $\hat{\theta}$ is computed as

$$\widehat{V}(\hat{\theta}) = \sum_{r=1}^R \alpha_r (\hat{\theta}_r - \hat{\theta})^2$$

where R is the total number of replicates and α_r is the jackknife coefficient for replicate r .

If a parameter cannot be estimated from some replicate(s), then the variance estimate is computed by using those replicates from which the parameter can be estimated. For example, suppose the parameter is a column proportion—the proportion of column j for table cell (i, j) . If a replicate r contains no observations in column j , then the column j proportion is not estimable from replicate r . In this case, the jackknife variance estimate is computed as

$$\widehat{V}(\hat{\theta}) = \frac{R}{R'} \sum_{r=1}^{R'} \alpha_r (\hat{\theta}_r - \hat{\theta})^2$$

where the summation is over the replicates where the parameter θ is estimable, and R' is the number of those replicates.

Confidence Limits for Totals

If you specify the **CLWT** option in the TABLES statement, PROC SURVEYFREQ computes confidence limits for the weighted frequencies (totals) in the crosstabulation tables.

For the total in table cell (r, c) , the confidence limits are computed as

$$\hat{N}_{rc} \pm \left(t_{df, \alpha/2} \times \text{StdErr}(\hat{N}_{rc}) \right)$$

where \hat{N}_{rc} is the estimate of the total frequency in table cell (r, c) , $\text{StdErr}(\hat{N}_{rc})$ is the standard error of the estimate, and $t_{df, \alpha/2}$ is the $100(1-\alpha/2)$ percentile of the t distribution with df degrees of freedom calculated as described in the section “[Degrees of Freedom](#)” on page 7645. The confidence level α is determined by the value of the **ALPHA=** option, which by default equals 0.05 and produces 95% confidence limits.

The confidence limits for row totals, column totals, and the overall total are computed similarly to the confidence limits for table cell totals.

For each table request, PROC SURVEYFREQ produces a nondisplayed ODS table, “Table Summary,” which contains the number of observations, strata, and clusters that are included in the analysis of the requested table. When you request confidence limits, the “Table Summary” data set also contains the degrees of freedom df and the value of $t_{df, \alpha/2}$ that is used to compute the confidence limits. See [Example 90.3](#) for more information about this output data set.

Confidence Limits for Proportions

If you specify the **CL** option in the TABLES statement, PROC SURVEYFREQ computes confidence limits for the proportions in the frequency and crosstabulation tables.

By default, PROC SURVEYFREQ computes Wald (“linear”) confidence limits if you do not specify an alternative confidence limit type with the **CL(TYPE=)** option. In addition to Wald confidence limits, the following types of design-based confidence limits are available for proportions: modified Clopper-Pearson (exact), modified Wilson (score), and logit confidence limits.

PROC SURVEYFREQ also provides the **CL(PSMALL)** option, which uses the alternative confidence limit type for extreme (small or large) proportions and uses the Wald confidence limits for all other proportions (not extreme). For the default **PSMALL=** value of 0.25, the procedure computes Wald confidence limits for proportions between 0.25 and 0.75 and computes the alternative confidence limit type for proportions that are outside of this range. See Curtin et al. (2006).

For details about confidence limits for proportions based on complex survey data, including comparisons of their performance, see Korn and Graubard (1999, 1998); Curtin et al. (2006); Sukasih and Jang (2005). Also, in addition to the other references cited in the following sections, for information about binomial confidence limits see Brown, Cai, and DasGupta (2001); Agresti and Coull (1998).

For each table request, PROC SURVEYFREQ produces a nondisplayed ODS table, “Table Summary,” which contains the number of observations, strata, and clusters that are included in the analysis of the requested table. When you request confidence limits, the “Table Summary” data set also contains the degrees of freedom df and the value of $t_{df, \alpha/2}$ that is used to compute the confidence limits. See [Example 90.3](#) for more information about this output data set.

Wald Confidence Limits

PROC SURVEYFREQ computes standard Wald (“linear”) confidence limits for proportions by default. These confidence limits use the variance estimates that are based on the sample design. For the proportion in table cell (r, c) , the Wald confidence limits are computed as

$$\hat{P}_{rc} \pm \left(t_{df, \alpha/2} \times \text{StdErr}(\hat{P}_{rc}) \right)$$

where \hat{P}_{rc} is the estimate of the proportion in table cell (r, c) , $\text{StdErr}(\hat{P}_{rc})$ is the standard error of the estimate, and $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df degrees of freedom calculated as described in the section “[Degrees of Freedom](#)” on page 7645. The confidence level α is determined by the value of the `ALPHA=` option, which by default equals 0.05 and produces 95% confidence limits.

The confidence limits for row proportions and column proportions are computed similarly to the confidence limits for table cell proportions.

Modified Confidence Limits

PROC SURVEYFREQ uses the modification described in Korn and Graubard (1998) to compute design-based Clopper-Pearson (exact) and Wilson (score) confidence limits. This modification substitutes the degrees-of-freedom adjusted effective sample size for the original sample size in the confidence limit computations.

The effective sample size n_e is computed as

$$n_e = n / \text{Deff}$$

where n is the original sample size (unweighted frequency) that corresponds to the total domain of the proportion estimate, and `Deff` is the design effect.

If the proportion is computed for a table cell of a two-way table, then the domain is the two-way table, and the sample size n is the frequency of the two-way table. If the proportion is a row proportion, which is based on a two-way table row, then the domain is the row, and the sample size n is the frequency of the row.

The design effect for an estimate is the ratio of the actual variance (estimated based on the sample design) to the variance of a simple random sample with the same number of observations. See the section “[Design Effect](#)” on page 7646 for details about how PROC SURVEYFREQ computes the design effect.

If you do not specify the `CL(ADJUST=NO)` option, the procedure applies a degrees-of-freedom adjustment to the effective sample size to compute the modified sample size. If you specify `CL(ADJUST=NO)`, the procedure does not apply the adjustment and uses the effective sample size n_e in the confidence limit computations.

The modified sample size n_e^* is computed by applying a degrees-of-freedom adjustment to the effective sample size n_e as

$$n_e^* = n_e \left(\frac{t_{(n-1), \alpha/2}}{t_{df, \alpha/2}} \right)^2$$

where df is the degrees of freedom and $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df degrees of freedom. The section “[Degrees of Freedom](#)” on page 7645 describes the computation of

the degrees of freedom df , which is based on the variance estimation method and the sample design. The confidence level α is determined by the value of the **ALPHA=** option, which by default equals 0.05 and produces 95% confidence limits.

The design effect is usually greater than 1 for complex survey designs, and in that case the effective sample size is less than the actual sample size. If the adjusted effective sample size n_e^* is greater than the actual sample size n , then the procedure truncates the value of n_e^* to n , as recommended by Korn and Graubard (1998). If you specify the **CL(TRUNCATE=NO)** option, the procedure does not truncate the value of n_e^* .

Modified Clopper-Pearson Confidence Limits Clopper-Pearson (exact) confidence limits for the binomial proportion are constructed by inverting the equal-tailed test based on the binomial distribution. This method is attributed to Clopper and Pearson (1934). See Leemis and Trivedi (1996) for a derivation of the F distribution expression for the confidence limits.

PROC SURVEYFREQ computes modified Clopper-Pearson confidence limits according to the approach of Korn and Graubard (1998). The degrees-of-freedom adjusted effective sample size n_e^* is substituted for the sample size in the Clopper-Pearson computation, and the adjusted effective sample size times the proportion estimate $n_e^* \hat{p}$ is substituted for the number of positive responses. (Or if you specify the **CL(ADJUST=NO)** option, the procedure uses the unadjusted effective sample size n_e instead of n_e^* .)

The modified Clopper-Pearson confidence limits for a proportion (P_L and P_U) are computed as

$$P_L = \left(1 + \frac{n_e^* - \hat{p}n_e^* + 1}{\hat{p}n_e^* F(\alpha/2, 2\hat{p}n_e^*, 2(n_e^* - \hat{p}n_e^* + 1))} \right)^{-1}$$

$$P_U = \left(1 + \frac{n_e^* - \hat{p}n_e^*}{(\hat{p}n_e^* + 1) F(1 - \alpha/2, 2(\hat{p}n_e^* + 1), 2(n_e^* - \hat{p}n_e^*))} \right)^{-1}$$

where $F(\alpha/2, b, c)$ is the $\alpha/2$ percentile of the F distribution with b and c degrees of freedom, n_e^* is the adjusted effective sample size, and \hat{p} is the proportion estimate.

Modified Wilson Confidence Limits Wilson confidence limits for the binomial proportion are also known as score confidence limits and are attributed to Wilson (1927). The confidence limits are based on inverting the normal test that uses the null proportion in the variance (the score test). See Newcombe (1998) and Korn and Graubard (1999) for details.

PROC SURVEYFREQ computes modified Wilson confidence limits by substituting the degrees-of-freedom adjusted effective sample size n_e^* for the original sample size in the standard Wilson computation. (Or if you specify the **CL(ADJUST=NO)** option, the procedure substitutes the unadjusted effective sample size n_e .)

The modified Wilson confidence limits for a proportion are computed as

$$(\hat{p} + (\kappa)^2/2n_e^*) \pm \left(\kappa \sqrt{(\hat{p}(1 - \hat{p}) + (\kappa)^2)/4n_e^* / (1 + (\kappa)^2/n_e^*)} \right)$$

where n_e^* is the adjusted effective sample size and \hat{p} is the estimate of the proportion. With the degrees-of-freedom adjusted effective sample size n_e^* , the computation uses $\kappa = z_{\alpha/2}$. With the unadjusted effective sample size, which you request with the **ADJUST=NO** option, the computation uses $\kappa = t_{df, \alpha/2}$. See Curtin et al. (2006) for details.

Logit Confidence Limits

If you specify the `CL(TYPE=LOGIT)` option, PROC SURVEYFREQ computes logit confidence limits for proportions. See Agresti (2002) and Korn and Graubard (1998) for more information.

Logit confidence limits for proportions are based on the logit transformation $Y = \log(\hat{p}/(1 - \hat{p}))$. The logit confidence limits P_L and P_U are computed as

$$P_L = \exp(Y_L) / (1 + \exp(Y_L))$$

$$P_U = \exp(Y_U) / (1 + \exp(Y_U))$$

where

$$(Y_L, Y_U) = \log(\hat{p}/(1 - \hat{p})) \pm (t_{df, \alpha/2} \times \text{StdErr}(\hat{p}) / (\hat{p}(1 - \hat{p})))$$

where \hat{p} is the estimate of the proportion, $\text{StdErr}(\hat{p})$ is the standard error of the estimate, and $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df degrees of freedom. The degrees of freedom are calculated as described in the section “Degrees of Freedom” on page 7645. The confidence level α is determined by the value of the `ALPHA=` option, which by default equals 0.05 and produces 95% confidence limits.

Degrees of Freedom

PROC SURVEYFREQ uses the degrees of freedom of the variance estimator to obtain the t -percentile for confidence limits for proportions, totals, and other statistics. The procedure also uses the degrees of freedom in computing the F statistics for the Rao-Scott and Wald chi-square tests.

PROC SURVEYFREQ computes the degrees of freedom based on the variance estimation method and the sample design. Alternatively, you can specify the degrees of freedom in the `DF=` option in the `TABLES` statement instead of having the procedure compute it.

For Taylor series variance estimation, PROC SURVEYFREQ calculates the degrees of freedom (df) as the number of clusters minus the number of strata. If there are no clusters, then df equals the number of observations minus the number of strata. If the design is not stratified, then df equals the number of clusters minus one. These numbers are based on the observations included in the analysis of the individual table request. These numbers do not count observations that are excluded from the table due to missing values. See the section “Missing Values” on page 7627 for details. If you specify the `MISSING` option, missing values are treated as valid nonmissing levels and are included in computing degrees of freedom. If you specify the `NOMCAR` option for Taylor series variance estimation, observations with missing values of the `TABLES` variables are included in computing degrees of freedom.

If you provide replicate weights with a `REPWEIGHTS` statement, the degrees of freedom is equal the number of replicates, which is the number of `REPWEIGHTS` variables that you provide. Alternatively, you can specify the degrees of freedom in the `DF=` option in the `REPWEIGHTS` or `TABLES` statement.

For BRR variance estimation (when you do not use a `REPWEIGHTS` statement), PROC SURVEYFREQ calculates the degrees of freedom as the number of strata. PROC SURVEYFREQ bases the number of strata on all valid observations in the data set, unless you specify the `DFADJ method-option` for `VARMETHOD=BRR`. When you specify the `DFADJ` option, the procedure computes the degrees of freedom as the number of nonmissing strata for the individual table request. This excludes any empty strata that occur when observations with missing values of the `TABLES` variables are removed from the analysis for that table.

For jackknife variance estimation (when you do not use a `REPWEIGHTS` statement), PROC SURVEYFREQ calculates the degrees of freedom as the number of clusters minus the number of strata. If there are no clusters, then df equals the number of observations minus the number of strata. If the design is not stratified, then df equals the number of clusters minus one. For jackknife variance estimation, PROC SURVEYFREQ bases the number of strata and clusters on all valid observations in the data set, unless you specify the `DFADJ method-option` for `VARMETHOD=JACKKNIFE`. When you specify the `DFADJ` option, the procedure computes the degrees of freedom from the number of nonmissing strata and clusters for the individual table request. This excludes any empty strata or clusters that occur when observations with missing values of the `TABLES` variables are removed from the analysis for that table.

For each table request, PROC SURVEYFREQ produces a nondisplayed ODS table, “Table Summary,” which contains the number of (nonmissing) observations, strata, and clusters that are included in the analysis of the table. If there are missing observations, empty strata, or empty clusters excluded from the analysis, the “Table Summary” data set also contains this information. If you request confidence limits or chi-square tests, which depend on the degrees of freedom of the variance estimator, the “Table Summary” data set provides the degrees of freedom df . See [Example 90.3](#) for more information about this output data set.

Coefficient of Variation

If you specify the `CV` option in the `TABLES` statement, PROC SURVEYFREQ computes the coefficients of variation for the proportion estimates in the frequency and crosstabulation tables. The coefficient of variation is the ratio of the standard error to the estimate.

For the proportion in table cell (r, c) , the coefficient of variation is computed as

$$CV(\hat{P}_{rc}) = \text{StdErr}(\hat{P}_{rc}) / \hat{P}_{rc}$$

where \hat{P}_{rc} is the estimate of the proportion in table cell (r, c) , and $\text{StdErr}(\hat{P}_{rc})$ is the standard error of the estimate. The coefficients of variation for row proportions and column proportions are computed similarly.

If you specify the `CVWT` option in the `TABLES` statement, PROC SURVEYFREQ computes the coefficients of variation for the weighted frequencies (estimated totals) in the crosstabulation tables. For the total in table cell (r, c) , the coefficient of variation is computed as

$$CV(\hat{N}_{rc}) = \text{StdErr}(\hat{N}_{rc}) / \hat{N}_{rc}$$

where \hat{N}_{rc} is the estimate of the total in table cell (r, c) , and $\text{StdErr}(\hat{N}_{rc})$ is the standard error of the estimate. The coefficients of variation for row totals, column totals, and the overall total are computed similarly.

Design Effect

If you specify the `DEFF` option in the `TABLES` statement, PROC SURVEYFREQ computes design effects for the overall proportion estimates in the frequency and crosstabulation tables. If you specify the `ROW(DEFF)` or `COLUMN(DEFF)` option, the procedure provides design effects for the row or column proportion estimates, respectively. The design effect for an estimate is the ratio of the actual variance (estimated based on the sample design) to the variance of a simple random sample with the same number of observations. See Lohr (2010) and Kish (1965) for details.

For Taylor series variance estimation, PROC SURVEYFREQ computes the design effect for the proportion in table cell (r, c) as

$$\begin{aligned}\text{Deff}(\hat{P}_{rc}) &= \widehat{\text{Var}}(\hat{P}_{rc}) / \widehat{\text{Var}}_{\text{srs}}(\hat{P}_{rc}) \\ &= \widehat{\text{Var}}(\hat{P}_{rc}) / \left((1 - f) \hat{P}_{rc} (1 - \hat{P}_{rc}) / (n - 1) \right)\end{aligned}$$

where \hat{P}_{rc} is the estimate of the proportion in table cell (r, c) , $\widehat{\text{Var}}(\hat{P}_{rc})$ is the variance of the estimate, f is the overall sampling fraction, and n is the sample size (unweighted frequency) for the two-way table.

For Taylor series variance estimation, PROC SURVEYFREQ determines the value of f , the overall sampling fraction, based on the **RATE=** or **TOTAL=** option. If you do not specify either of these options, PROC SURVEYFREQ assumes the value of f is negligible and does not use a finite population correction in the analysis, as described in the section “**Population Totals and Sampling Rates**” on page 7626. If you specify **RATE=value**, PROC SURVEYFREQ uses this value as the overall sampling fraction f . If you specify **TOTAL=value**, PROC SURVEYFREQ computes f as the ratio of the number of PSUs in the sample to the specified total.

If you specify stratum sampling rates with the **RATE=SAS-data-set** option, then PROC SURVEYFREQ computes stratum totals based on these stratum sampling rates and the number of sample PSUs in each stratum. The procedure sums the stratum totals to form the overall total, and computes f as the ratio of the number of sample PSUs to the overall total. Alternatively, if you specify stratum totals with the **TOTAL=SAS-data-set** option, then PROC SURVEYFREQ sums these totals to compute the overall total. The overall sampling fraction f is then computed as the ratio of the number of sample PSUs to the overall total.

For BRR and jackknife variance estimation, PROC SURVEYFREQ computes the design effect for the proportion in table cell (r, c) as

$$\begin{aligned}\text{Deff}(\hat{P}_{rc}) &= \widehat{\text{Var}}(\hat{P}_{rc}) / \widehat{\text{Var}}_{\text{srs}}(\hat{P}_{rc}) \\ &= \widehat{\text{Var}}(\hat{P}_{rc}) / \left(\hat{P}_{rc} (1 - \hat{P}_{rc}) / (n - 1) \right)\end{aligned}$$

where \hat{P}_{rc} is the estimate of the proportion in table cell (r, c) , $\widehat{\text{Var}}(\hat{P}_{rc})$ is the variance of the estimate, and n is the sample size (unweighted frequency) for the two-way table. This computation does not include the overall sampling fraction.

The procedure computes design effects similarly for proportions in one-way frequency tables, and also for row and column proportions in two-way tables. In these design effect computations, the value of n is the sample size (unweighted frequency) that corresponds to the total domain of the proportion estimate. For table cell proportions of a two-way table, the domain is the two-way table and the sample size n is the frequency of the two-way table. For row proportions, which are based on a two-way table row, the domain is the row and the sample size n is the frequency of the row.

Expected Weighted Frequency

If you specify the **EXPECTED** option in the **TABLES** statement, PROC SURVEYFREQ computes expected weighted frequencies for the table cells in two-way tables. The expected weighted frequencies are computed

under the null hypothesis that the row and column variables are independent. The expected weighted frequency for table cell (r, c) equals

$$E_{rc} = \hat{N}_{r.} \hat{N}_{.c} / \hat{N}$$

where $\hat{N}_{r.}$ is the estimated total for row r , $\hat{N}_{.c}$ is the estimated total for column c , and \hat{N} is the estimated overall total. Equivalently, the expected weighted frequency can be expressed as

$$E_{rc} = \hat{P}_{r.} \hat{P}_{.c} \hat{N}$$

These expected values are used in the design-based chi-square tests of independence, as described in the sections “[Rao-Scott Chi-Square Test](#)” on page 7652 and “[Wald Chi-Square Test](#)” on page 7659.

Risks and Risk Difference

The **RISK** option provides estimates of risks (binomial proportions) and risk differences for 2×2 tables, together with their standard errors and confidence limits. Risk statistics include the row 1 risk, row 2 risk, overall risk, and risk difference. If you specify the **RISK** option, PROC SURVEYFREQ provides both column 1 and column 2 risks. You can request only column 1 (or only column 2) risks by specifying the **RISK1** (or **RISK2**) option.

The column 1 risk for row 1 is the row 1 proportion for table cell (1,1). The column 1 risk estimate is computed as the ratio of the estimated total for table cell (1,1) to the estimated total for row 1,

$$\hat{P}_{11}^{(1)} = \hat{N}_{11} / \hat{N}_{1.}$$

where the total estimates are computed as described in the section “[Totals](#)” on page 7632. The column 1 risk for row 2 is the row 2 proportion for table cell (2,1), which is estimated as

$$\hat{P}_{21}^{(2)} = \hat{N}_{21} / \hat{N}_{2.}$$

The overall column 1 risk is the overall proportion in column 1, and its estimate is computed as

$$\hat{P}_{.1} = \hat{N}_{.1} / \hat{N}$$

The column 2 risk estimates are computed similarly.

The row 1 and row 2 risks are the same as the row proportions for a 2×2 table, and their variances are computed as described in the section “[Row and Column Proportions](#)” on page 7635. The overall risk is the overall proportion in the column, and its variance computation is described in the section “[Proportions](#)” on page 7634. Confidence limits for the column 1 risk for row 1 are computed as

$$\hat{P}_{11}^{(1)} \pm \left(t_{df, \alpha/2} \times \text{StdErr}(\hat{P}_{11}^{(1)}) \right)$$

where $\text{StdErr}(\hat{P}_{11}^{(1)})$ is the standard error of the risk estimate, and $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df degrees of freedom calculated as described in the section “[Degrees of Freedom](#)” on page 7645. The value of the confidence coefficient α is determined by the **ALPHA=** option, which by default equals 0.05 and produces 95% confidence limits. Confidence limits for the other risks are computed similarly.

The risk difference is defined as the row 1 risk minus the row 2 risk. The estimate of the column 1 risk difference \widehat{RD}_1 is computed as

$$\begin{aligned}\widehat{RD}_1 &= \widehat{P}_{11}^{(1)} - \widehat{P}_{21}^{(2)} \\ &= \left(\widehat{N}_{11} / \widehat{N}_{1\cdot} \right) - \left(\widehat{N}_{21} / \widehat{N}_{2\cdot} \right)\end{aligned}$$

The column 2 risk difference is computed similarly.

PROC SURVEYFREQ estimates the variance of the risk difference by using the variance estimation method that you request. If you request BRR variance estimation (**VARMETHOD=BRR**), the procedure estimates the variance as described in the section “[Balanced Repeated Replication \(BRR\)](#)” on page 7637. If you request jackknife variance estimation (**VARMETHOD=JACKKNIFE**), the procedure estimates the variance as described in the section “[The Jackknife Method](#)” on page 7640.

If you do not specify the **VARMETHOD=** option or a **REPWEIGHTS** statement, the default variance estimation method is Taylor series (**VARMETHOD=TAYLOR**). By using Taylor series linearization, the variance estimate for the column 1 risk difference $\widehat{\text{Var}}(\widehat{RD}_1)$ can be expressed as

$$\widehat{\text{Var}}(\widehat{RD}_1) = \widehat{\mathbf{D}} \widehat{\mathbf{V}}(\widehat{\mathbf{X}}) \widehat{\mathbf{D}}'$$

where $\widehat{\mathbf{V}}(\widehat{\mathbf{X}})$ is the covariance matrix of $\widehat{\mathbf{X}}$,

$$\widehat{\mathbf{X}} = \left(\widehat{N}_{11}, \widehat{N}_{1\cdot}, \widehat{N}_{21}, \widehat{N}_{2\cdot} \right)$$

and $\widehat{\mathbf{D}}$ is an array that contains the partial derivatives of the risk difference with respect to the elements of $\widehat{\mathbf{X}}$,

$$\widehat{\mathbf{D}} = \left(1/\widehat{N}_{1\cdot}, -\widehat{N}_{11}/\widehat{N}_{1\cdot}^2, -1/\widehat{N}_{2\cdot}, -\widehat{N}_{21}/\widehat{N}_{2\cdot}^2 \right)$$

See Wolter (1985, pp. 239–242) for details. The variance estimate for the column 2 risk difference is computed similarly.

The standard error of the column 1 risk difference is

$$\text{StdErr}(\widehat{RD}_1) = \sqrt{\widehat{\text{Var}}(\widehat{RD}_1)}$$

Confidence limits for the column 1 risk difference are computed as

$$\widehat{RD}_1 \pm \left(t_{df, \alpha/2} \times \text{StdErr}(\widehat{RD}_1) \right)$$

where $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df degrees of freedom calculated as described in the section “[Degrees of Freedom](#)” on page 7645. The value of the confidence coefficient α is determined by the **ALPHA=** option, which by default equals 0.05 and produces 95% confidence limits. Confidence limits for the column 2 risk difference are computed in the same way.

Odds Ratio and Relative Risks

The **OR** option provides estimates of the odds ratio, the column 1 relative risk, and the column 2 relative risk for 2×2 tables, together with their confidence limits.

Odds Ratio

For a 2×2 table, the odds of a positive (column 1) response in row 1 is N_{11}/N_{12} . Similarly, the odds of a positive response in row 2 is N_{21}/N_{22} . The odds ratio is formed as the ratio of the row 1 odds to the row 2 odds. The estimate of the odds ratio is computed as

$$\widehat{OR} = \frac{\widehat{N}_{11} / \widehat{N}_{12}}{\widehat{N}_{21} / \widehat{N}_{22}} = \frac{\widehat{N}_{11} \widehat{N}_{22}}{\widehat{N}_{12} \widehat{N}_{21}}$$

The value of the odds ratio can be any nonnegative number. When the row and column variables are independent, the true value of the odds ratio equals 1. An odds ratio greater than 1 indicates that the odds of a positive response are higher in row 1 than in row 2. An odds ratio less than 1 indicates that the odds of positive response are higher in row 2. The strength of association increases with the deviation from 1. For details, see Stokes, Davis, and Koch (2000); Agresti (2007).

PROC SURVEYFREQ constructs confidence limits for the odds ratio by using the log transform. The $100(1 - \alpha)\%$ confidence limits for the odds ratio are computed as

$$\left(\widehat{OR} \times \exp(-t_{df, \alpha/2} \sqrt{v}), \widehat{OR} \times \exp(t_{df, \alpha/2} \sqrt{v}) \right)$$

where

$$v = \widehat{\text{Var}}(\ln \widehat{OR}) = \widehat{\text{Var}}(\widehat{OR}) / \widehat{OR}^2$$

is the estimate of the variance of the log odds ratio, and where $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df degrees of freedom. The computation of df is described in the section “[Degrees of Freedom](#)” on page 7645. The value of the confidence coefficient α is determined by the **ALPHA=** option, which by default equals 0.05 and produces 95% confidence limits.

If you request BRR variance estimation (**VARMETHOD=BRR**), PROC SURVEYFREQ estimates the variance of the odds ratio as described in the section “[Balanced Repeated Replication \(BRR\)](#)” on page 7637. If you request jackknife variance estimation (**VARMETHOD=JACKKNIFE**), the procedure estimates the variance as described in the section “[The Jackknife Method](#)” on page 7640.

If you do not specify the **VARMETHOD=** option or a **REPWEIGHTS** statement, the default variance estimation method is Taylor series (**VARMETHOD=TAYLOR**). By using Taylor series linearization, the variance estimate for the odds ratio can be expressed as

$$\widehat{\text{Var}}(\widehat{OR}) = \widehat{\mathbf{D}} \widehat{\mathbf{V}}(\widehat{\mathbf{N}}) \widehat{\mathbf{D}}'$$

where $\widehat{\mathbf{V}}(\widehat{\mathbf{N}})$ is the covariance matrix of the estimates of the cell totals $\widehat{\mathbf{N}}$,

$$\widehat{\mathbf{N}} = \begin{pmatrix} \widehat{N}_{11} & \widehat{N}_{12} & \widehat{N}_{21} & \widehat{N}_{22} \end{pmatrix}$$

and $\widehat{\mathbf{D}}$ is an array that contains the partial derivatives of the odds ratio with respect to the elements of $\widehat{\mathbf{N}}$. The section “[Covariance of Totals](#)” on page 7633 describes the computation of $\widehat{\mathbf{V}}(\widehat{\mathbf{N}})$. The array $\widehat{\mathbf{D}}$ is computed as

$$\widehat{\mathbf{D}} = \begin{pmatrix} \widehat{N}_{22}/(\widehat{N}_{12}\widehat{N}_{21}), & -\widehat{N}_{11}\widehat{N}_{22}/(\widehat{N}_{21}\widehat{N}_{12}^2), & -\widehat{N}_{11}\widehat{N}_{22}/(\widehat{N}_{12}\widehat{N}_{21}^2), & \widehat{N}_{11}/(\widehat{N}_{12}\widehat{N}_{21}) \end{pmatrix}$$

See Wolter (1985, pp. 239–242) for more information.

Relative Risks

For a 2×2 table, the column 1 relative risk is the ratio of the column 1 risks for row 1 to row 2. As described in the section “[Risks and Risk Difference](#)” on page 7648, the column 1 risk for row 1 is the proportion of row 1 observations classified in column 1, and the column 1 risk for row 2 is the proportion of row 2 observations classified in column 1. The estimate of the column 1 relative risk is computed as

$$\widehat{RR}_1 = \frac{\widehat{N}_{11} / \widehat{N}_{1.}}{\widehat{N}_{21} / \widehat{N}_{2.}}$$

Similarly, the estimate of the column 2 relative risk is computed as

$$\widehat{RR}_2 = \frac{\widehat{N}_{12} / \widehat{N}_{1.}}{\widehat{N}_{22} / \widehat{N}_{2.}}$$

A relative risk greater than 1 indicates that the probability of positive response is greater in row 1 than in row 2. Similarly, a relative risk less than 1 indicates that the probability of positive response is less in row 1 than in row 2. The strength of association increases with the deviation from 1. For more information, see Stokes, Davis, and Koch (2000); Agresti (2007).

PROC SURVEYFREQ constructs confidence limits for the relative risk by using the log transform, which is similar to the odds ratio computations described previously. The $100(1 - \alpha)\%$ confidence limits for the column 1 relative risk are computed as

$$\left(\widehat{RR}_1 \times \exp(-t_{df, \alpha/2} \sqrt{v}), \widehat{RR}_1 \times \exp(t_{df, \alpha/2} \sqrt{v}) \right)$$

where

$$v = \widehat{\text{Var}}(\ln \widehat{RR}_1) = \widehat{\text{Var}}(\widehat{RR}_1) / \widehat{RR}_1^2$$

is the estimate of the variance of the log column 1 relative risk, and where $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df degrees of freedom. The computation of df is described in the section “[Degrees of Freedom](#)” on page 7645. The value of the confidence coefficient α is determined by the **ALPHA=** option, which by default equals 0.05 and produces 95% confidence limits.

If you request BRR variance estimation (**VARMETHOD=BRR**), PROC SURVEYFREQ estimates the variance of the column 1 relative risk as described in the section “[Balanced Repeated Replication \(BRR\)](#)” on page 7637. If you request jackknife variance estimation (**VARMETHOD=JACKKNIFE**), the procedure estimates the variance as described in the section “[The Jackknife Method](#)” on page 7640.

If you do not specify the **VARMETHOD=** option or a **REPWEIGHTS** statement, the default variance estimation method is Taylor series (**VARMETHOD=TAYLOR**). By using Taylor series linearization, the variance estimate for the column 1 relative risk can be expressed as

$$\widehat{\text{Var}}(\widehat{RR}_1) = \widehat{\mathbf{D}} \widehat{\mathbf{V}}(\widehat{\mathbf{X}}) \widehat{\mathbf{D}}'$$

where $\widehat{\mathbf{V}}(\widehat{\mathbf{X}})$ is the covariance matrix of $\widehat{\mathbf{X}}$,

$$\widehat{\mathbf{X}} = \left(\widehat{N}_{11}, \widehat{N}_{1.}, \widehat{N}_{21}, \widehat{N}_{2.} \right)$$

and $\widehat{\mathbf{D}}$ is an array that contains the partial derivatives of the column 1 relative risk with respect to the elements of $\widehat{\mathbf{X}}$,

$$\widehat{\mathbf{D}} = \left(\widehat{N}_{2.}/(\widehat{N}_{21}\widehat{N}_{1.}), -\widehat{N}_{11}\widehat{N}_{2.}/(\widehat{N}_{21}\widehat{N}_{1.}^2), -\widehat{N}_{11}\widehat{N}_{2.}/(\widehat{N}_{1.}\widehat{N}_{21}^2), \widehat{N}_{11}/(\widehat{N}_{21}\widehat{N}_{1.}) \right)$$

See Wolter (1985, pp. 239–242) for more information.

Confidence limits for the column 2 relative risk are computed similarly.

Rao-Scott Chi-Square Test

The Rao-Scott chi-square test is a design-adjusted version of the Pearson chi-square test, which involves differences between observed and expected frequencies. For information about design-adjusted chi-square tests, see Lohr (2010, Section 10.3.2), Rao and Scott (1981, 1984, 1987); Thomas, Singh, and Roberts (1996).

PROC SURVEYFREQ provides a first-order Rao-Scott chi-square test by default. If you specify the **CHISQ(SECONDORDER)** option, PROC SURVEYFREQ provides a second-order (Satterthwaite) Rao-Scott chi-square test. The first-order design correction depends only on the design effects of the table cell proportion estimates and, for two-way tables, the design effects of the marginal proportion estimates. The second-order design correction requires computation of the full covariance matrix of the proportion estimates. The second-order test requires more computational resources than the first-order test, but it can provide some performance advantages (for Type I error and power), particularly when the design effects are variable (Thomas and Rao 1987; Rao and Thomas 1989).

One-Way Tables

For one-way tables, the CHISQ option provides a Rao-Scott (design-based) goodness-of-fit test for one-way tables. By default, this is a test for the null hypothesis of equal proportions. If you specify null hypothesis proportions in the **TESTP=** option, the goodness-of-fit test uses the specified proportions.

First-Order Test The first-order Rao-Scott chi-square statistic for the goodness-of-fit test is computed as

$$Q_{RS1} = Q_P / D$$

where Q_P is the Pearson chi-square based on the estimated totals and D is the first-order design correction described in the section “[First-Order Design Correction](#)” on page 7653. See Rao and Scott (1979, 1981, 1984) for details.

For a one-way table with C levels, the Pearson chi-square is computed as

$$Q_P = (n/\hat{N}) \sum_c (\hat{N}_c - E_c)^2 / E_c$$

where n is the sample size, \hat{N} is the estimated overall total, \hat{N}_c is the estimated total for level c , and E_c is the expected total for level c under the null hypothesis. For the null hypothesis of equal proportions, the expected total for each level is

$$E_c = \hat{N} / C$$

For specified null proportions, the expected total for level c equals

$$E_c = \hat{N} \times P_c^0$$

where P_c^0 is the null proportion that you specify for level c .

Under the null hypothesis, the first-order Rao-Scott chi-square Q_{RS1} approximately follows a chi-square distribution with $(C - 1)$ degrees of freedom. A better approximation can be obtained by the F statistic,

$$F_1 = Q_{RS1} / (C - 1)$$

which has an F distribution with $(C - 1)$ and $\kappa(C - 1)$ degrees of freedom under the null hypothesis (Thomas and Rao 1984, 1987). The value of κ is the degrees of freedom for the variance estimator, which depends on the sample design and the variance estimation method. The section “[Degrees of Freedom](#)” on page 7645 describes the computation of κ .

First-Order Design Correction By default for one-way tables, the first-order design correction is computed from the proportion estimates as

$$D = \sum_c (1 - \hat{P}_c) \text{Deff}(\hat{P}_c) / (C - 1)$$

where

$$\begin{aligned} \text{Deff}(\hat{P}_c) &= \widehat{\text{Var}}(\hat{P}_c) / \text{Var}_{\text{srs}}(\hat{P}_c) \\ &= \widehat{\text{Var}}(\hat{P}_c) / \left((1 - f) \hat{P}_c (1 - \hat{P}_c) / (n - 1) \right) \end{aligned}$$

as described in the section “**Design Effect**” on page 7646. \hat{P}_c is the proportion estimate for level c , $\widehat{\text{Var}}(\hat{P}_c)$ is the variance of the estimate, f is the overall sampling fraction, and n is the number of observations in the sample. The factor $(1 - f)$ is included only for Taylor series variance estimation (**VARMETHOD=TAYLOR**) when you specify the **RATE=** or **TOTAL=** option. See the section “**Design Effect**” on page 7646 for details.

If you specify the **CHISQ(MODIFIED)** or **LRCHISQ(MODIFIED)** option, the design correction is computed by using null hypothesis proportions instead of proportion estimates. By default, null hypothesis proportions are equal proportions for all levels of the one-way table. Alternatively, you can specify null proportion values in the **TESTP=** option. The modified design correction D_0 is computed from null hypothesis proportions as

$$D_0 = \sum_c (1 - P_c^0) \text{Deff}_0(\hat{P}_c) / (C - 1)$$

where

$$\begin{aligned} \text{Deff}_0(\hat{P}_c) &= \widehat{\text{Var}}(\hat{P}_c) / \text{Var}_{\text{srs}}(P_c^0) \\ &= \widehat{\text{Var}}(\hat{P}_c) / \left((1 - f) P_c^0 (1 - P_c^0) / (n - 1) \right) \end{aligned}$$

The null hypothesis proportion P_c^0 equals $1/C$ for equal proportions (the default), or P_c^0 equals the null proportion that you specify for level c if you use the **TESTP=** option.

Second-Order Test The second-order (Satterthwaite) Rao-Scott chi-square statistic for the goodness-of-fit test is computed as

$$Q_{RS2} = Q_{RS1} / (1 + \hat{a}^2)$$

where Q_{RS1} is the first-order Rao-Scott chi-square statistic described in the section “**First-Order Test**” on page 7652 and \hat{a}^2 is the second-order design correction described in the section “**Second-Order Design Correction**” on page 7654. For details, see Rao and Scott (1979, 1981); Rao and Thomas (1989).

Under the null hypothesis, the second-order Rao-Scott chi-square Q_{RS2} approximately follows a chi-square distribution with $(C - 1)/(1 + \hat{a}^2)$ degrees of freedom. The corresponding F statistic is

$$F_{RS2} = Q_{RS2} / (C - 1)$$

which has an F distribution with $(C - 1)/(1 + \hat{a}^2)$ and $\kappa(C - 1)/(1 + \hat{a}^2)$ degrees of freedom under the null hypothesis (Thomas and Rao 1984, 1987). The value of κ is the degrees of freedom for the variance estimator, which depends on the sample design and the variance estimation method. The section “**Degrees of Freedom**” on page 7645 describes the computation of κ .

Second-Order Design Correction The second-order (Satterthwaite) design correction for one-way tables is computed from the eigenvalues of the estimated design effects matrix $\hat{\Delta}$, which are known as *generalized design effects*. The design effects matrix is computed as

$$\hat{\Delta} = (n - 1)/(1 - f) \left(\text{Cov}_{\text{srs}}(\hat{\mathbf{P}})^{-1} \widehat{\text{Cov}}(\hat{\mathbf{P}}) \right)$$

where $\text{Cov}_{\text{srs}}(\hat{\mathbf{P}})$ is the covariance under multinomial sampling (*srs* with replacement) and $\widehat{\text{Cov}}(\hat{\mathbf{P}})$ is the covariance matrix of the first $(C - 1)$ proportion estimates. See Rao and Scott (1979, 1981) and Rao and Thomas (1989) for details.

By default, the *srs* covariance matrix is computed from the proportion estimates as

$$\text{Cov}_{\text{srs}}(\hat{\mathbf{P}}) = \text{Diag}(\hat{\mathbf{P}}) - \hat{\mathbf{P}} \hat{\mathbf{P}}'$$

where $\hat{\mathbf{P}}$ is an array of $(C - 1)$ proportion estimates. If you specify the **CHISQ(MODIFIED)** or **LRCHISQ(MODIFIED)** option, the *srs* covariance matrix is computed from the null hypothesis proportions \mathbf{P}_0 as

$$\text{Cov}_{\text{srs}}(\mathbf{P}_0) = \text{Diag}(\mathbf{P}_0) - \mathbf{P}_0 \mathbf{P}_0'$$

where \mathbf{P}_0 is an array of $(C - 1)$ null hypothesis proportions. The null hypothesis proportions equal $1/C$ by default. If you use the **TESTP=** option to specify null hypothesis proportions, \mathbf{P}_0 is an array of $(C - 1)$ proportions that you specify.

The second-order design correction is computed as

$$\hat{a}^2 = \left(\sum_{c=1}^{C-1} d_c^2 / (C - 1) \bar{d}^2 \right) - 1$$

where d_c are the eigenvalues of the design effects matrix $\hat{\Delta}$ and \bar{d} is the average of the eigenvalues.

Two-Way Tables

For two-way tables, the **CHISQ** option provides a Rao-Scott (design-based) test of association between the row and column variables. PROC SURVEYFREQ provides a first-order Rao-Scott chi-square test by default. If you specify the **CHISQ(SECONDORDER)** option, PROC SURVEYFREQ provides a second-order (Satterthwaite) Rao-Scott chi-square test.

First-Order Test The first-order Rao-Scott chi-square statistic is computed as

$$Q_{RS1} = Q_P / D$$

where Q_P is the Pearson chi-square based on the estimated totals and D is the design correction described in the section “**First-Order Design Correction**” on page 7655. See Rao and Scott (1979, 1984, 1987) for details.

For a two-way tables with R rows and C columns, the Pearson chi-square is computed as

$$Q_P = (n/\hat{N}) \sum_r \sum_c (\hat{N}_{rc} - E_{rc})^2 / E_{rc}$$

where n is the sample size, \hat{N} is the estimated overall total, \hat{N}_{rc} is the estimated total for table cell (r, c) , and E_{rc} is the expected total for table cell (r, c) under the null hypothesis of no association,

$$E_{rc} = \hat{N}_{r.} \hat{N}_{.c} / \hat{N}$$

Under the null hypothesis of no association, the first-order Rao-Scott chi-square Q_{RS1} approximately follows a chi-square distribution with $(R - 1)(C - 1)$ degrees of freedom. A better approximation can be obtained by the F statistic,

$$F_1 = Q_{RS1} / (R - 1)(C - 1)$$

which has an F distribution with $(R - 1)(C - 1)$ and $\kappa(R - 1)(C - 1)$ degrees of freedom under the null hypothesis (Thomas and Rao 1984, 1987). The value of κ is the degrees of freedom for the variance estimator, which depends on the sample design and the variance estimation method. The section “[Degrees of Freedom](#)” on page 7645 describes the computation of κ .

First-Order Design Correction By default for a first-order test, PROC SURVEYFREQ computes the design correction from proportion estimates. If you specify the [CHISQ\(MODIFIED\)](#) or [LRCHISQ\(MODIFIED\)](#) option for a first-order test, the procedure computes the design correction from null hypothesis proportions.

Second-order tests, which you request by specifying the [CHISQ\(SECONDORDER\)](#) or [LRCHISQ\(SECONDORDER\)](#) option, are computed by applying both first-order and second-order design corrections to the weighted chi-square statistic. For second-order tests for two-way tables, PROC SURVEYFREQ always uses null hypothesis proportions to compute both the first-order and second-order design corrections.

The first-order design correction D that is based on proportion estimates is computed as

$$D = \left(\sum_r \sum_c (1 - \hat{P}_{rc}) \text{Deff}(\hat{P}_{rc}) - \sum_r (1 - \hat{P}_{r.}) \text{Deff}(\hat{P}_{r.}) - \sum_c (1 - \hat{P}_{.c}) \text{Deff}(\hat{P}_{.c}) \right) / (R - 1)(C - 1)$$

where

$$\begin{aligned} \text{Deff}(\hat{P}_{rc}) &= \widehat{\text{Var}}(\hat{P}_{rc}) / \text{Var}_{\text{srs}}(\hat{P}_{rc}) \\ &= \text{Var}(\hat{P}_{rc}) / \left((1 - f) \hat{P}_{rc} (1 - \hat{P}_{rc}) / (n - 1) \right) \end{aligned}$$

as described in the section “[Design Effect](#)” on page 7646. \hat{P}_{rc} is the estimate of the proportion in table cell (r, c) , $\widehat{\text{Var}}(\hat{P}_{rc})$ is the variance of the estimate, f is the overall sampling fraction, and n is the number of observations in the sample. The factor $(1 - f)$ is included only for Taylor series variance estimation ([VARMETHOD=TAYLOR](#)) when you specify the [RATE=](#) or [TOTAL=](#) option. See the section “[Design Effect](#)” on page 7646 for details.

The design effects for the estimate of the proportion in row r and the estimate of the proportion in column c ($\text{Deff}(\hat{P}_{r.})$ and $\text{Deff}(\hat{P}_{.c})$, respectively) are computed in the same way.

If you specify the **CHISQ(MODIFIED)** or **LRCHISQ(MODIFIED)** option for a first-order Rao-Scott test, or if you request a second-order test for a two-way table (**CHISQ(SECONDORDER)** or **LRCHISQ(SECONDORDER)**), the procedure computes the design correction from the null hypothesis cell proportions instead of the estimated cell proportions. For two-way tables, the null hypothesis cell proportions are computed as the products of the corresponding row and column proportion estimates. The modified design correction D_0 (based on null hypothesis proportions) is computed as

$$D_0 = \left(\sum_r \sum_c (1 - P_{rc}^0) \text{Deff}_0(\hat{P}_{rc}) - \sum_r (1 - \hat{P}_{r.}) \text{Deff}(\hat{P}_{r.}) - \sum_c (1 - \hat{P}_{.c}) \text{Deff}(\hat{P}_{.c}) \right) / (R - 1)(C - 1)$$

where

$$P_{rc}^0 = \hat{P}_{r.} \times \hat{P}_{.c}$$

and

$$\begin{aligned} \text{Deff}_0(\hat{P}_{rc}) &= \widehat{\text{Var}}(\hat{P}_{rc}) / \text{Var}_{\text{srs}}(P_{rc}^0) \\ &= \widehat{\text{Var}}(\hat{P}_{rc}) / ((1 - f) P_{rc}^0 (1 - P_{rc}^0) / (n - 1)) \end{aligned}$$

Second-Order Test The second-order (Satterthwaite) Rao-Scott chi-square statistic for two-way tables is computed as

$$Q_{RS2} = Q_{RS1} / (1 + \hat{a}^2)$$

where Q_{RS1} is the first-order Rao-Scott chi-square statistic described in the section “**First-Order Test**” on page 7654 and \hat{a}^2 is the second-order design correction described in the section “**Second-Order Design Correction**” on page 7656. See Rao and Scott (1979, 1981) and Rao and Thomas (1989) for details.

Under the null hypothesis, the second-order Rao-Scott chi-square Q_{RS2} approximately follows a chi-square distribution with $(R - 1)(C - 1)/(1 + \hat{a}^2)$ degrees of freedom. The corresponding F statistic is

$$F_{RS2} = Q_{RS2} (1 + \hat{a}^2) / (R - 1)(C - 1)$$

which has an F distribution with $(R - 1)(C - 1)/(1 + \hat{a}^2)$ and $\kappa(R - 1)(C - 1)/(1 + \hat{a}^2)$ degrees of freedom under the null hypothesis (Thomas and Rao 1984, 1987). The value of κ is the degrees of freedom for the variance estimator, which depends on the sample design and the variance estimation method. The section “**Degrees of Freedom**” on page 7645 describes the computation of κ .

Second-Order Design Correction The second-order (Satterthwaite) design correction for two-way tables is computed from the eigenvalues of the estimated design effects matrix $\hat{\Delta}$, which are known as *generalized design effects*. The design effects matrix is defined as

$$\hat{\Delta} = (n - 1)/(1 - f) \left(\text{Cov}_{\text{srs}}(\hat{\mathbf{P}})^{-1} \mathbf{H} \widehat{\text{Cov}}(\hat{\mathbf{P}}) \mathbf{H}' \right)$$

where $\widehat{\text{Cov}}(\hat{\mathbf{P}})$ is the covariance matrix of the $R \times C$ proportion estimates and $\text{Cov}_{\text{srs}}(\hat{\mathbf{P}})$ is the covariance under multinomial sampling (*srs* with replacement). See Rao and Scott (1979, 1981) and Rao and Thomas (1989) for details.

The second-order design correction is computed from the design effects matrix $\hat{\Delta}$ as

$$\hat{a}^2 = \left(\sum_{i=1}^K d_c^2 / K \bar{d}^2 \right) - 1$$

where $K = (R - 1)(C - 1)$, d_c are the eigenvalues of $\hat{\Delta}$, and \bar{d} is the average eigenvalue.

The *srs* covariance matrix is computed as

$$\text{Cov}_{\text{srs}}(\hat{\mathbf{P}}) = \hat{\mathbf{P}}_{\mathbf{r}} \otimes \hat{\mathbf{P}}_{\mathbf{c}}$$

where $\hat{\mathbf{P}}_{\mathbf{r}}$ is an $(R - 1) \times (R - 1)$ matrix that is constructed from the array of $(R - 1)$ row proportion estimates $\hat{\mathbf{p}}_{\mathbf{r}}$ as

$$\hat{\mathbf{P}}_{\mathbf{r}} = \text{Diag}(\hat{\mathbf{p}}_{\mathbf{r}}) - \hat{\mathbf{p}}_{\mathbf{r}} \hat{\mathbf{p}}_{\mathbf{r}}'$$

Similarly, $\hat{\mathbf{P}}_{\mathbf{c}}$ is a $(C - 1) \times (C - 1)$ matrix that is constructed from the array of $(C - 1)$ column proportion estimates $\hat{\mathbf{p}}_{\mathbf{c}}$ as

$$\hat{\mathbf{P}}_{\mathbf{c}} = \text{Diag}(\hat{\mathbf{p}}_{\mathbf{c}}) - \hat{\mathbf{p}}_{\mathbf{c}} \hat{\mathbf{p}}_{\mathbf{c}}'$$

The $(R - 1)(C - 1) \times (R - 1)(C - 1)$ matrix \mathbf{H} is computed as

$$\mathbf{H} = \mathbf{J}_{\mathbf{r}} \otimes \mathbf{J}_{\mathbf{c}} - (\hat{\mathbf{p}}_{\mathbf{r}} \mathbf{l}_{\mathbf{r}}') \otimes \mathbf{J}_{\mathbf{c}} - \mathbf{J}_{\mathbf{r}} \otimes (\hat{\mathbf{p}}_{\mathbf{r}} \mathbf{l}_{\mathbf{r}}')$$

where $\mathbf{J}_{\mathbf{r}} = (\mathbf{I}_{(R-1)} | \mathbf{0})$, $\mathbf{J}_{\mathbf{c}} = (\mathbf{I}_{(C-1)} | \mathbf{0})$, $\mathbf{l}_{\mathbf{r}}$ is an $(R \times 1)$ array of ones, and $\mathbf{l}_{\mathbf{c}}$ is an $(C \times 1)$ array of ones. See Rao and Scott (1979, p. 61) for details.

Rao-Scott Likelihood Ratio Chi-Square Test

The Rao-Scott likelihood ratio chi-square test is a design-adjusted version of the likelihood ratio test, which involves ratios of observed and expected frequencies. For details about design-adjusted chi-square tests, see Lohr (2010, Section 10.3.2), Rao and Scott (1981, 1984, 1987); Thomas, Singh, and Roberts (1996).

PROC SURVEYFREQ provides a first-order Rao-Scott likelihood ratio test by default. If you specify the **LRCHISQ(SECONDORDER)** option, PROC SURVEYFREQ provides a second-order (Satterthwaite) likelihood ratio chi-square test.

The procedure computes the Rao-Scott likelihood ratio test by applying design adjustments to the weighted likelihood ratio statistic that is based on estimated totals. This computation is identical to the Rao-Scott chi-square test computation except that it uses the likelihood ratio statistic G^2 in place of the Pearson chi-square statistic Q_P . See the section “[Rao-Scott Chi-Square Test](#)” on page 7652 for details.

One-Way Tables

For one-way tables, the LRCHISQ option provides a Rao-Scott (design-based) goodness-of-fit test for one-way tables. By default, this is a test for the null hypothesis of equal proportions. If you specify null hypothesis proportions in the **TESTP=** option, the goodness-of-fit test uses the specified proportions.

The Rao-Scott likelihood ratio test uses the likelihood ratio statistic that is based on the estimated totals,

$$G^2 = 2 (n / \hat{N}) \sum_c \hat{N}_c \ln (\hat{N}_c / E_c)$$

where n is the sample size, \hat{N} is the estimated overall total, \hat{N}_c is the estimated total for level c , and E_c is the expected total for level c under the null hypothesis. For the null hypothesis of equal proportions, the expected total for each level equals

$$E_c = \hat{N} / C$$

For specified null proportions, the expected total for level c equals

$$E_c = \hat{N} \times P_c^0$$

where P_c^0 is the null proportion that you specify for level c .

The computation of the Rao-Scott likelihood ratio test for one-way tables uses G^2 in place of Q_P in the Rao-Scott chi-square test computation and is otherwise identical to the chi-square test computation. See the sections “[First-Order Test](#)” on page 7652 and “[Second-Order Test](#)” on page 7653 for details.

If you specify the **LRCHISQ(MODIFIED)** option, PROC SURVEYFREQ computes the design corrections by using null hypothesis proportions instead of proportion estimates. By default, null hypothesis proportions are equal proportions for all levels of the one-way table. Alternatively, you can specify null proportion values in the **TESTP=** option.

Two-Way Tables

For two-way tables, the **LRCHISQ** option provides a Rao-Scott (design-based) test of association between the row and column variables.

The Rao-Scott likelihood ratio test uses the likelihood ratio statistic that is based on the estimated totals,

$$G^2 = 2 (n/\hat{N}) \sum_r \sum_c \hat{N}_{rc} \ln(\hat{N}_{rc} / E_{rc})$$

where n is the sample size, \hat{N} is the estimated overall total, \hat{N}_{rc} is the estimated total for table cell (r, c) , and E_{rc} is the expected total for cell (r, c) under the null hypothesis of no association. The expected total for cell (r, c) equals

$$E_{rc} = \hat{N}_{r.} \hat{N}_{.c} / \hat{N}$$

The computation of the Rao-Scott likelihood ratio test for two-way tables uses G^2 in place of Q_P in the Rao-Scott chi-square test computation and is otherwise identical to the chi-square test computation. See the sections “[First-Order Test](#)” on page 7654 and “[Second-Order Test](#)” on page 7656 for details.

By default for a first-order test, PROC SURVEYFREQ computes the design correction from proportion estimates. If you specify the **LRCHISQ(MODIFIED)** option for a first-order test, the procedure computes the design correction from null hypothesis proportions.

Second-order tests, which you request by specifying the **LRCHISQ(SECONDORDER)** option, are computed by applying both first-order and second-order design corrections to the weighted likelihood ratio statistic. For second-order tests for two-way tables, PROC SURVEYFREQ always uses null hypothesis proportions to compute both the first-order and second-order design corrections.

Wald Chi-Square Test

PROC SURVEYFREQ provides two Wald chi-square tests for independence of the row and column variables in a two-way table: a Wald chi-square test based on the difference between observed and expected weighted cell frequencies, and a Wald log-linear chi-square test based on the log odds ratios. These statistics test for independence of the row and column variables in two-way tables, taking into account the complex survey design. For information about Wald statistics and their applications to categorical data analysis, see Bedrick (1983); Koch, Freeman, and Freeman (1975); Wald (1943).

For these two tests, PROC SURVEYFREQ computes the generalized Wald chi-square statistic, the corresponding Wald F statistic, and also an adjusted Wald F statistic for tables larger than 2×2 . Under the null hypothesis of independence, the Wald chi-square statistic approximately follows a chi-square distribution with $(R - 1)(C - 1)$ degrees of freedom for large samples. However, it has been shown that this test can perform poorly in terms of actual significance level and power, especially for tables with a large number of cells or for samples with a relatively small number of clusters. See Thomas and Rao (1984, 1985) and Lohr (2010) for more information. See Fellgi (1980) and Hidiroglou, Fuller, and Hickman (1980) for information about the adjusted Wald F statistic. Thomas and Rao (1984) found that the adjusted Wald F statistic provides a more stable test than the chi-square statistic, although its power can be low when the number of sample clusters is not large. See also Korn and Graubard (1990) and Thomas, Singh, and Roberts (1996).

If you specify the **WCHISQ** option in the TABLES statement, PROC SURVEYFREQ computes a Wald test for independence in the two-way table based on the differences between the observed (weighted) cell frequencies and the expected frequencies.

Under the null hypothesis of independence of the row and column variables, the expected cell frequencies are computed as

$$E_{rc} = \hat{N}_{r.} \hat{N}_{.c} / \hat{N}$$

where $\hat{N}_{r.}$ is the estimated total for row r , $\hat{N}_{.c}$ is the estimated total for column c , and \hat{N} is the estimated overall total, as described in the section “[Expected Weighted Frequency](#)” on page 7647. The null hypothesis that the population weighted frequencies equal the expected frequencies can be expressed as

$$H_0: Y_{rc} = N_{rc} - E_{rc} = 0$$

for all $r = 1, \dots, (R - 1)$ and $c = 1, \dots, (C - 1)$. This null hypothesis can be stated equivalently in terms of cell proportions, with the expected cell proportions computed as the products of the marginal row and column proportions.

The generalized Wald chi-square statistic Q_W is computed as

$$Q_W = \hat{\mathbf{Y}}' (\mathbf{H} \hat{\mathbf{V}}(\hat{\mathbf{N}}) \mathbf{H}')^{-1} \hat{\mathbf{Y}}$$

where $\hat{\mathbf{Y}}$ is an array of $(R - 1)(C - 1)$ differences between the observed and expected weighted frequencies ($\hat{N}_{rc} - E_{rc}$), and $(\mathbf{H} \hat{\mathbf{V}}(\hat{\mathbf{N}}) \mathbf{H}')$ estimates the variance of $\hat{\mathbf{Y}}$.

$\hat{\mathbf{V}}(\hat{\mathbf{N}})$ is the covariance matrix of the estimates \hat{N}_{rc} , and its computation is described in the section “[Covariance of Totals](#)” on page 7633.

\mathbf{H} is an $(R - 1)(C - 1)$ by RC matrix that contains the partial derivatives of the elements of $\hat{\mathbf{Y}}$ with respect to the elements of $\hat{\mathbf{N}}$. The elements of \mathbf{H} are computed as follows, where a denotes a row different from row r , and b denotes a column different from column c :

$$\partial \hat{Y}_{rc} / \partial \hat{N}_{rc} = 1 - \left(\hat{N}_{r\cdot} + \hat{N}_{\cdot c} - \hat{N}_{\cdot c} \hat{N}_{r\cdot} / \hat{N} \right) / \hat{N}$$

$$\partial \hat{Y}_{rc} / \partial \hat{N}_{ac} = - \left(\hat{N}_{r\cdot} - \hat{N}_{r\cdot} \hat{N}_{\cdot c} / \hat{N} \right) / \hat{N}$$

$$\partial \hat{Y}_{rc} / \partial \hat{N}_{rb} = - \left(\hat{N}_{\cdot c} - \hat{N}_{r\cdot} \hat{N}_{\cdot c} / \hat{N} \right) / \hat{N}$$

$$\partial \hat{Y}_{rc} / \partial \hat{Y}_{ab} = \hat{N}_{r\cdot} \hat{N}_{\cdot c} / \hat{N}^2$$

Under the null hypothesis of independence, the statistic Q_W approximately follows a chi-square distribution with $(R - 1)(C - 1)$ degrees of freedom for large samples.

PROC SURVEYFREQ computes the Wald F statistic as

$$F_W = Q_W / (R - 1)(C - 1)$$

Under the null hypothesis of independence, F_W approximately follows an F distribution with $(R - 1)(C - 1)$ numerator degrees of freedom. The denominator degrees of freedom are the degrees of freedom for the variance estimator and depend on the sample design and the variance estimation method. The section “[Degrees of Freedom](#)” on page 7645 describes the computation of the denominator degrees of freedom. Alternatively, you can specify the denominator degrees of freedom with the **DF=** option in the TABLES statement.

For tables larger than 2×2 , PROC SURVEYFREQ also computes the adjusted Wald F statistic as

$$F_{Adj_W} = Q_W (s - k + 1) / (ks)$$

where $k = (R - 1)(C - 1)$, and s is the degrees of freedom, which are computed as described in the section “[Degrees of Freedom](#)” on page 7645. Alternatively, you can specify the value of s with the **DF=** option in the TABLES statement. Note that for 2×2 tables, $k = (R - 1)(C - 1) = 1$, and therefore the adjusted Wald F statistic equals the (unadjusted) Wald F statistic, with the same numerator and denominator degrees of freedom.

Under the null hypothesis, F_{Adj_W} approximately follows an F distribution with k numerator degrees of freedom and $(s - k + 1)$ denominator degrees of freedom.

Wald Log-Linear Chi-Square Test

If you specify the **WLLCHISQ** option in the TABLES statement, PROC SURVEYFREQ computes a Wald test for independence based on the log odds ratios. See the section “[Wald Chi-Square Test](#)” on page 7659 for more information about Wald tests.

For a two-way table of R rows and C columns, the Wald log-linear test is based on the $(R - 1)(C - 1)$ -dimensional array of elements \hat{Y}_{rc} ,

$$\hat{Y}_{rc} = \log \hat{N}_{rc} - \log \hat{N}_{r\cdot} - \log \hat{N}_{\cdot c} + \log \hat{N}$$

where \hat{N}_{rc} is the estimated total for table cell (r, c) . The null hypothesis of independence between the row and column variables can be expressed as $H_0: Y_{rc} = 0$ for all $r = 1, \dots, (R - 1)$ and $c = 1, \dots, (C - 1)$. This null hypothesis can be stated equivalently in terms of cell proportions.

The generalized Wald log-linear chi-square statistic is computed as

$$Q_L = \hat{\mathbf{Y}}' \hat{\mathbf{V}}(\hat{\mathbf{Y}})^{-1} \hat{\mathbf{Y}}$$

where $\hat{\mathbf{Y}}$ is the $(R - 1)(C - 1)$ -dimensional array of the \hat{Y}_{rc} , and $\hat{\mathbf{V}}(\hat{\mathbf{Y}})$ estimates the variance of $\hat{\mathbf{Y}}$,

$$\hat{\mathbf{V}}(\hat{\mathbf{Y}}) = \mathbf{A} \mathbf{D}^{-1} \hat{\mathbf{V}}(\hat{\mathbf{N}}) \mathbf{D}^{-1} \mathbf{A}'$$

where $\hat{\mathbf{V}}(\hat{\mathbf{N}})$ is the covariance matrix of the estimates \hat{N}_{rc} , which is computed as described in the section “[Covariance of Totals](#)” on page 7633. \mathbf{D} is a diagonal matrix with the estimated totals \hat{N}_{rc} on the diagonal, and \mathbf{A} is the $(R - 1)(C - 1)$ by $RC \times RC$ linear contrast matrix.

Under the null hypothesis of independence, the statistic Q_L approximately follows a chi-square distribution with $(R - 1)(C - 1)$ degrees of freedom for large samples.

PROC SURVEYFREQ computes the Wald log-linear F statistic as

$$F_L = Q_L / (R - 1)(C - 1)$$

Under the null hypothesis of independence, F_L approximately follows an F distribution with $(R - 1)(C - 1)$ numerator degrees of freedom. PROC SURVEYFREQ computes the denominator degrees of freedom as described in the section “[Degrees of Freedom](#)” on page 7645. Alternatively, you can specify the denominator degrees of freedom with the **DF=** option in the TABLES statement.

For tables larger than 2×2 , PROC SURVEYFREQ also computes the adjusted Wald log-linear F statistic as

$$F_{Adj_L} = Q_L (s - k + 1) / (ks)$$

where $k = (R - 1)(C - 1)$, and s is the denominator degrees of freedom, which is computed as described in the section “[Degrees of Freedom](#)” on page 7645. Alternatively, you can specify the value of s with the **DF=** option in the TABLES statement. Note that for 2×2 tables, $k = (R - 1)(C - 1) = 1$, and therefore the adjusted Wald F statistic equals the (unadjusted) Wald F statistic, with the same numerator and denominator degrees of freedom.

Under the null hypothesis, F_{Adj_L} approximately follows an F distribution with k numerator degrees of freedom and $(s - k + 1)$ denominator degrees of freedom.

Output Data Sets

You can use the Output Delivery System to create a SAS data set from any piece of PROC SURVEYFREQ output. See the section “[ODS Table Names](#)” on page 7668 and [Example 90.3](#) for more information.

PROC SURVEYFREQ also provides an output data set that stores the replicate weights for BRR or jackknife variance estimation and an output data set that stores the jackknife coefficients for jackknife variance estimation.

Replicate Weight Output Data Set

If you specify the `OUTWEIGHTS= method-option` for `VARMETHOD=BRR` or `VARMETHOD=JACKKNIFE`, PROC SURVEYFREQ stores the replicate weights in an output data set. The `OUTWEIGHTS=` output data set contains all observations from the `DATA=` input data set that are valid (used in the analysis). A valid observation must have a positive value of the `WEIGHT` variable. A valid observations must also have nonmissing values of the `STRATA` and `CLUSTER` variables unless you specify the `MISSING` option in the PROC SURVEYFREQ statement. See the section “Data Summary Table” on page 7663 for details about valid observations.

The `OUTWEIGHTS=` data set contains the following variables:

- all variables in the `DATA=` input data set
- `RepWt_1`, `RepWt_2`, ..., `RepWt_n`, which are the replicate weight variables, where `n` is the total number of replicates in the analysis

Each replicate weight variable contains the replicate weights for the corresponding replicate. Replicate weights equal zero for those observations not included in the replicate.

After the procedure creates and stores replicate weights for a particular input data set and survey design, you can use them again in subsequent analyses, either in PROC SURVEYFREQ or in another survey procedure. You use a `REPWEIGHTS` statement to provide replicate weights to the procedure.

Jackknife Coefficient Output Data Set

If you specify the `OUTJKCOEFS= method-option` for `VARMETHOD=JACKKNIFE`, PROC SURVEYFREQ stores the jackknife coefficients in an output data set. The `OUTJKCOEFS=` output data set contains one observation for each replicate. The `OUTJKCOEFS=` data set contains the following variables:

- `Replicate`, which is the replicate number for the jackknife coefficient
- `JKCoefficient`, which is the jackknife coefficient
- `DonorStratum`, which is the stratum of the PSU that was deleted to construct the replicate, if you specify a `STRATA` statement

After the procedure creates jackknife coefficients for a particular input data set and survey design, you can use the `OUTJKCOEFS= method-option` to store these coefficients and then use them again in subsequent analyses, either in PROC SURVEYFREQ or in another survey procedure. You use the `JKCOEFS=` option in the `REPWEIGHTS` statement to provide jackknife coefficients for the procedure.

Displayed Output

Data Summary Table

The “Data Summary” table provides information about the input data set and the sample design. PROC SURVEYFREQ displays this table unless you specify the **NOSUMMARY** option in the PROC SURVEYFREQ statement.

The “Data Summary” table displays the total number of valid observations. To be considered *valid*, an observation must have a nonmissing, positive sampling weight value if you specify a **WEIGHT** statement. If you do not specify the **MISSING** option, a valid observation must also have nonmissing values for all **STRATA** and **CLUSTER** variables. The number of valid observations can differ from the number of nonmissing observations for an individual table request, which the procedure displays in the frequency or crosstabulation tables. See the section “**Missing Values**” on page 7627 for more information.

PROC SURVEYFREQ displays the following information in the “Data Summary” table:

- Number of Strata, if you specify a **STRATA** statement
- Number of Clusters, if you specify a **CLUSTER** statement
- Number of Observations, which is the total number of valid observations
- Sum of Weights, which is the sum over all valid observations, if you specify a **WEIGHT** or **REPWEIGHTS** statement

Stratum Information Table

If you specify the **LIST** option in the **STRATA** statement, PROC SURVEYFREQ displays a “Stratum Information” table. This table provides the following information for each stratum:

- Stratum Index, which is a sequential stratum identification number
- **STRATA** variables, which list the levels of **STRATA** variables for the stratum
- Number of Observations, which is the number of valid observations in the stratum
- Population Total for the stratum, if you specify the **TOTAL=** option
- Sampling Rate for the stratum, if you specify the **TOTAL=** or **RATE=** option. If you specify the **TOTAL=** option, the sampling rate is based on the number of valid observations in the stratum.
- Number of Clusters, which is the number of clusters in the stratum, if you specify a **CLUSTER** statement

Variance Estimation Table

If you specify the `VARMETHOD=BRR`, `VARMETHOD=JACKKNIFE`, or `NOMCAR` option in the PROC SURVEYFREQ statement, the procedure displays a “Variance Estimation” table. If you do not specify any of these options, the procedure creates a “Variance Estimation” table but does not display it. You can store this nondisplayed table in an output data set by using the Output Delivery System (ODS). See the section “ODS Table Names” on page 7668 for more information.

The “Variance Estimation” table provides the following information:

- Method, which is the variance estimation method—Taylor Series, Balanced Repeated Replication, or Jackknife
- Replicate Weights input data set name, if you provide replicate weights with a `REPWEIGHTS` statement
- Number of Replicates, for `VARMETHOD=BRR` or `VARMETHOD=JACKKNIFE`
- Hadamard Data Set name, if you specify the `HADAMARD= method-option` for `VARMETHOD=BRR`
- Fay Coefficient, if you specify the `FAY method-option` for `VARMETHOD=BRR`
- Missing Levels Included (MISSING), if you specify the `MISSING` option
- Missing Levels Included (NOMCAR), if you specify the `NOMCAR` option

Hadamard Matrix

If you specify the `PRINTH method-option` for `VARMETHOD=BRR`, PROC SURVEYFREQ displays the Hadamard matrix used to construct replicates for BRR variance estimation. If you provide a Hadamard matrix with the `HADAMARD= method-option` for `VARMETHOD=BRR` but the procedure does not use the entire matrix, the procedure displays only the rows and columns that are actually used to construct replicates.

One-Way Frequency Tables

PROC SURVEYFREQ displays one-way frequency tables for all one-way table requests in the `TABLES` statements, unless you specify the `NOPRINT` option in the `TABLES` statement. A one-way table shows the sample frequency distribution of a single variable, and provides estimates for its population distribution in terms of totals and proportions.

If you request a one-way table without specifying options, PROC SURVEYFREQ displays the following information for each level of the variable:

- Frequency count, which is the number of sample observations in the level
- Weighted Frequency, which estimates the population total for the level
- Standard Deviation of Weighted Frequency
- Percent, which estimates the population proportion for the level
- Standard Error of Percent

The one-way table displays weighted frequencies if your analysis includes a **WEIGHT** or **REPWEIGHTS** statement, or if you specify the **WTFREQ** option in the **TABLES** statement.

The one-way table also displays the Frequency Missing, which is the number of observations with missing values.

You can suppress the frequency counts by specifying the **NOFREQ** option in the **TABLES** statement. Also, the **NOWT** option suppresses the weighted frequencies and their standard deviations. The **NOPERCENT** option suppresses the percentages and their standard errors. The **NOSTD** option suppresses the standard errors of the percentages and the standard deviations of the weighted frequencies. The **NOTOTAL** option suppresses the total row of the one-way table.

PROC SURVEYFREQ optionally displays the following information in a one-way table:

- Variance of Weighted Frequency, if you specify the **VARWT** option
- Confidence Limits for Weighted Frequency, if you specify the **CLWT** option
- Coefficient of Variation for Weighted Frequency, if you specify the **CVWT** option
- Test Percent, if you specify the **TESTP=** option
- Variance of Percent, if you specify the **VAR** option
- Confidence Limits for Percent, if you specify the **CL** option
- Coefficient of Variation for Percent, if you specify the **CV** option
- Design Effect for Percent, if you specify the **DEFF** option

Crosstabulation Tables

PROC SURVEYFREQ displays all table requests in the **TABLES** statements, unless you specify the **NOPRINT** option in the **TABLES** statement. For two-way to multiway crosstabulation tables, the values of the last variable in the table request form the table columns. The values of the next-to-last variable form the rows. Each level (or combination of levels) of the other variables forms one layer. PROC SURVEYFREQ produces a separate two-way crosstabulation table for each layer of a multiway table.

For each layer, the crosstabulation table displays the row and column variable names and values (levels). Each two-way table lists levels of the column variable within each level of the row variable.

By default, the procedure displays all levels of the column variable within each level of the row variables, including any column variable levels with zero frequency for that row. For multiway tables, the procedure displays all levels of the row variable for each layer of the table by default, including any row levels with zero frequency for that layer. You can suppress the display of zero frequency levels by specifying the **NOSPARE** option.

If you request a crosstabulation table without specifying options, the table displays the following information for each combination of variable levels (table cell):

- Frequency, which is the number of sample observations in the table cell
- Weighted Frequency, which estimates the population total for the table cell

- Standard Deviation of Weighted Frequency
- Percent, which estimates the population proportion for the table cell
- Standard Error of Percent

The two-way table displays weighted frequencies if your analysis includes a **WEIGHT** or **REPWEIGHTS** statement, or if you specify the **WTFREQ** option in the **TABLES** statement.

The two-way table also displays the Frequency Missing, which is the number of observations with missing values.

You can suppress the frequency counts by specifying the **NOFREQ** option in the **TABLES** statement. Also, the **NOWT** option suppresses the weighted frequencies and their standard deviations. The **NOPERCENT** option suppresses all percentages and their standard errors. The **NOCELLPERCENT** option suppresses overall cell percentages and their standard errors, but displays any other percentages (and standard errors) that you request, such as row or column percentages. The **NOSTD** option suppresses the standard errors of the percentages and the standard deviations of the weighted frequencies. The **NOTOTAL** option suppresses the row totals and column totals, as well as the overall total.

PROC SURVEYFREQ optionally displays the following information in a two-way table:

- Expected Weighted Frequency, if you specify the **EXPECTED** option
- Variance of Weighted Frequency, if you specify the **VARWT** option
- Confidence Limits for Weighted Frequency, if you specify the **CLWT** option
- Coefficient of Variation for Weighted Frequency, if you specify the **CVWT** option
- Variance of Percent, if you specify the **VAR** option
- Confidence Limits for Percent, if you specify the **CL** option
- Coefficient of Variation for Percent, if you specify the **CV** option
- Design Effect for Percent, if you specify the **DEFF** option
- Row Percent, which estimates the population proportion of the row total, if you specify the **ROW** option
- Standard Error of Row Percent, if you specify the **ROW** option
- Variance of Row Percent, if you specify the **VAR** option and the **ROW** option
- Confidence Limits for Row Percent, if you specify the **CL** option and the **ROW** option
- Coefficient of Variation for Row Percent, if you specify the **CV** option and the **ROW** option
- Design Effect for Row Percent, if you specify the **ROW(DEFF)** option
- Column Percent, which estimates the population proportion of the column total, if you specify the **COLUMN** option
- Standard Error of Column Percent, if you specify the **COLUMN** option

- Variance of Column Percent, if you specify the **VAR** option and the **COLUMN** option
- Confidence Limits for Column Percent, if you specify the **CL** option and the **COLUMN** option
- Coefficient of Variation for Column Percent, if you specify the **CV** option and the **COLUMN** option
- Design Effects for Column Percent, if you specify the **COLUMN(DEFF)** option

Statistical Tests

If you specify the **CHISQ** option for the Rao-Scott chi-square test or the **LRCHISQ** option for the Rao-Scott likelihood ratio chi-square test, PROC SURVEYFREQ displays the following information:

- Pearson Chi-Square, if you specify the **CHISQ** option
- Likelihood Ratio Chi-Square, if you specify the **LRCHISQ** option
- Design Correction
- Rao-Scott Chi-Square, by default or if you specify the **FIRSTORDER** option
- First-Order Chi-Square, if you specify the **SECONDORDER** option
- Second-Order Chi-Square, if you specify the **SECONDORDER** option
- DF, which is the degrees of freedom for the chi-square test
- $\text{Pr} > \text{ChiSq}$, which is the p -value for the chi-square test
- F Value
- Num DF, which is the numerator degrees of freedom for F
- Den DF, which is the denominator degrees of freedom for F
- $\text{Pr} > F$, which is the p -value for the F test

If you specify the **WCHISQ** option for the Wald chi-square test or the **WLLCHISQ** option for the Wald log-linear chi-square test, PROC SURVEYFREQ displays the following information:

- Wald Chi-Square, if you specify the **WCHISQ** option
- Wald Log-Linear Chi-Square, if you specify the **WLLCHISQ** option
- F Value
- Num DF, which is the numerator degrees of freedom for F
- Den DF, which is the denominator degrees of freedom for F
- $\text{Pr} > F$, which is the p -value for the F test
- Adjusted F Value, for tables larger than 2×2

- Num DF, which is the numerator degrees of freedom for Adjusted F
- Den DF, which is the denominator degrees of freedom for Adjusted F
- $Pr > Adj F$, which is the p -value for the Adjusted F test

Risks and Risk Difference

If you specify the **RISK** option in the TABLES statement for a 2×2 table, PROC SURVEYFREQ displays “Column 1 Risk Estimates” and “Column 2 Risk Estimates” tables. You can display only column 1 or column 2 risks by specifying the **RISK1** or **RISK2** option, respectively.

The “Risk Estimates” table displays the following information for Row 1, Row 2, Total, and Difference:

- Row, which identifies the risk as Row 1, Row 2, Total, or Difference
- Risk estimate
- Standard Error
- Confidence Limits

In the “Column 1 Risk Estimates” table, the row 1 risk is the column 1 percentage of row 1. The row 2 risk is the column 1 percentage of row 2, and the total risk is the column 1 percentage of the entire table. The risk difference is the row 1 risk minus the row 2 risk. In the “Column 2 Risk Estimates” table, these computations are based on column 2.

Odds Ratio and Relative Risks

If you specify the **OR** option in the TABLES statement for a 2×2 table, PROC SURVEYFREQ displays the “Odds Ratio” table. This table includes the following information:

- Statistic, which identifies the statistic as the Odds Ratio, the Column 1 Relative Risk, or the Column 2 Relative Risk
- Estimate
- Confidence Limits

ODS Table Names

PROC SURVEYFREQ assigns a name to each table that it creates. You can use these names to refer to tables when you use the Output Delivery System (ODS) to select tables and create output data sets. For more information about ODS, see Chapter 20, “Using the Output Delivery System.” See [Example 90.3](#) for examples of storing PROC SURVEYFREQ tables as output data sets.

[Table 90.8](#) lists the ODS table names together with their descriptions and the options required to produce the tables.

Table 90.8 ODS Tables Produced by PROC SURVEYFREQ

ODS Table Name	Description	Statement	Option
ChiSq	Chi-square test	TABLES	CHISQ
ChiSq1	Modified chi-square test	TABLES	CHISQ(MODIFIED)
CrossTabs	Crosstabulation table	TABLES	<i>n</i> -way table request, <i>n</i> > 1

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

When ODS Graphics is enabled, you can request specific plots with the PLOTS= option in the TABLES statement. To produce a weighted frequency plot, you must specify the WTFREQPLOT *plot-request* in the PLOTS= option. By default, PROC SURVEYFREQ produces all other plots that are associated with the analyses that you request in the TABLES statement. You can suppress default plots and request specific plots by using the PLOTS(ONLY)= option. See the description of the PLOTS= option for more information.

PROC SURVEYFREQ assigns a name to each graph that it creates with ODS Graphics. You can use these names to refer to the graphs. [Table 90.9](#) lists the names of the graphs that PROC SURVEYFREQ generates together with their descriptions, their PLOTS= options (*plot-requests*), and the TABLES statement options that are required to produce the graphs.

Table 90.9 ODS Graphs Produced by PROC SURVEYFREQ

ODS Graph Name	Description	PLOTS= Option	TABLES Statement Option
WtFreqPlot	Weighted frequency plot	WTFREQPLOT	Any table request
ORPlot	Odds ratio plot	ODDSRATIOPLOT	OR ($h \times 2 \times 2$ table)
RelRiskPlot	Relative risk plot	RELRIKSPLOT	OR ($h \times 2 \times 2$ table)
RiskDiffPlot	Risk difference plot	RISKDIFFPLOT	RISK ($h \times 2 \times 2$ table)

Examples: SURVEYFREQ Procedure

Example 90.1: Two-Way Tables

This example uses the SIS_Survey data set from the section “Getting Started: SURVEYFREQ Procedure” on page 7588. The data set contains results from a customer satisfaction survey for a student information system (SIS).

The following PROC SURVEYFREQ statements request a two-way table for Department by Response and customize the crosstabulation table display:

```

title 'Student Information System Survey';
proc surveyfreq data=SIS_Survey;
    tables Department * Response / cv deff nowt nostd nototal;
    strata State NewUser / list;
    cluster School;
    weight SamplingWeight;
run;

```

The TABLES statement requests a two-way table of Department by Response. The CV option requests coefficients of variation for the percentage estimates. The DEFF option requests design effects for the percentage estimates. The NOWT option suppresses display of the weighted frequencies, and the NOSTD option suppresses display of standard errors for the estimates. The NOTOTAL option suppresses the row totals, column totals, and overall totals.

The STRATA, CLUSTER, and WEIGHT statements provide sample design information for the procedure, so that the analysis is done according to the sample design used for the survey. The STRATA statement names the variables State and NewUser, which identify the first-stage strata. The LIST option in the STRATA statement requests a “Stratum Information” table. The CLUSTER statement names the variable School, which identifies the clusters (primary sampling units). The WEIGHT statement names the sampling weight variable.

Output 90.1.1 displays the “Data Summary” and “Stratum Information” tables produced by PROC SURVEYFREQ. The “Stratum Information” table lists the six strata in the survey and shows the number of observations and the number of clusters (schools) in each stratum.

Output 90.1.1 Data Summary and Stratum Information

Student Information System Survey				
The SURVEYFREQ Procedure				
Data Summary				
Number of Strata			6	
Number of Clusters			370	
Number of Observations			1850	
Sum of Weights			38899.6482	
Stratum Information				
Stratum Index	State	NewUser	Number of Obs	Number of Clusters
1	GA	Renewal Customer	315	63
2	GA	New Customer	355	71
3	NC	Renewal Customer	280	56
4	NC	New Customer	420	84
5	SC	Renewal Customer	210	42
6	SC	New Customer	270	54

Output 90.1.2 displays the two-way table of Department by Response. According to the TABLES statement options that are specified, this two-way table includes coefficients of variation and design effects for the percentage estimates, and it does not show the weighted frequencies or the standard errors of the estimates. It also does not show the row, column, and overall totals.

Output 90.1.2 Two-Way Table of Department by Response

Table of Department by Response					
Department	Response	Frequency	Percent	CV for Percent	Design Effect
Faculty	Very Unsatisfied	209	13.4987	0.0865	2.1586
	Unsatisfied	203	13.0710	0.0868	2.0962
	Neutral	346	22.4127	0.0629	2.1157
	Satisfied	254	16.2006	0.0806	2.3232
	Very Satisfied	98	6.2467	0.1362	2.2842
Admin/Guidance	Very Unsatisfied	95	3.6690	0.1277	1.1477
	Unsatisfied	123	4.6854	0.1060	1.0211
	Neutral	235	9.1838	0.0700	0.9166
	Satisfied	201	7.7305	0.0756	0.8848
	Very Satisfied	86	3.3016	0.1252	0.9892

The following PROC SURVEYFREQ statements request a two-way table of Department by Response that includes row percentages, and also a Wald chi-square test of association between the two table variables:

```

title 'Student Information System Survey';
proc surveyfreq data=SIS_Survey nosummary;
  tables Department * Response / row nowt wchisq;
  strata State NewUser;
  cluster School;
  weight SamplingWeight;
run;

```

Output 90.1.3 displays the two-way table. The row percentages show the distribution of Response for Department = 'Faculty' and for Department = 'Admin/Guidance'. This is equivalent to a domain (subpopulation) analysis of Response, where the domains are Department = 'Faculty' and Department = 'Admin/Guidance'.

Output 90.1.4 displays the Wald chi-square test of association between Department and Response. The Wald chi-square is 11.44, and the corresponding adjusted F value is 2.84 with a p -value of 0.0243. This indicates a significant association between department (faculty or admin/guidance) and satisfaction with the student information system.

Output 90.1.3 Table of Department by Response with Row Percentages

Student Information System Survey						
The SURVEYFREQ Procedure						
Table of Department by Response						
Department	Response	Frequency	Percent	Std Err of Percent	Row Percent	Std Err of Row Percent

	Total	1850	100.000			

Output 90.1.4 Wald Chi-Square Test

Wald Chi-Square Test	
Chi-Square	11.4454
F Value	2.8613
Num DF	4
Den DF	364
Pr > F	0.0234
Adj F Value	2.8378
Num DF	4
Den DF	361
Pr > Adj F	0.0243
Sample Size = 1850	

Example 90.2: Multiway Tables (Domain Analysis)

Continuing to use the SIS_Survey data set from the section “Getting Started: SURVEYFREQ Procedure” on page 7588, this example shows how to produce multiway tables. The following PROC SURVEYFREQ statements request a table of Department by SchoolType by Response for the student information system survey:

```

title 'Student Information System Survey';
proc surveyfreq data=SIS_Survey;
  tables Department * SchoolType * Response
         SchoolType * Response;
  strata State NewUser;
  cluster School;
  weight SamplingWeight;
run;

```

The TABLES statement requests a multiway table with SchoolType as the row variable, Response as the column variable, and Department as the layer variable. This request produces a separate two-way table of SchoolType by Response for each level of the variable Department. The TABLES statement also requests a two-way table of SchoolType by Response, which totals the multiway table over both levels of Department. As in the previous examples, the STRATA, CLUSTER, and WEIGHT statements provide sample design information, so that the analysis will be done according to the design used for this survey.

Output 90.2.1 displays the multiway table produced by PROC SURVEYFREQ, which includes a table of SchoolType by Response for Department = ‘Faculty’ and for Department = ‘Admin/Guidance’. This is equivalent to a domain (subpopulation) analysis of SchoolType by Response, where the domains are Department = ‘Faculty’ and Department = ‘Admin/Guidance’.

Output 90.2.1 Multiway Table of Department by SchoolType by Response

Student Information System Survey						
The SURVEYFREQ Procedure						
Table of SchoolType by Response						
Controlling for Department=Faculty

Example 90.3: Output Data Sets

PROC SURVEYFREQ uses the Output Delivery System (ODS) to create output data sets. This is a departure from older SAS procedures that provide OUTPUT statements for similar functionality. By using ODS, you can create a SAS data set from any piece of PROC SURVEYFREQ output. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

When selecting tables for ODS output data sets, you refer to tables by their ODS table names. Each table created by PROC SURVEYFREQ is assigned a name. See the section “ODS Table Names” on page 7668 for a list of the table names provided by PROC SURVEYFREQ.

To save the one-way table of Response from Figure 90.3 in an output data set, use an ODS OUTPUT statement as follows:

```
proc surveyfreq data=SIS_Survey;
  tables Response / cl nowt;
  ods output OneWay=ResponseTable;
  strata State NewUser;
  cluster School;
  weight SamplingWeight;
run;
```

Output 90.3.1 displays the output data set ResponseTable, which contains the one-way table of Response. This data set has six observations, and each of these observations corresponds to a row of the one-way table. The first five observations correspond to the five levels of Response, as they are ordered in the one-way table display, and the last observation corresponds to the overall total, which is the last row of the one-way table. The data set ResponseTable includes a variable corresponding to each column of the one-way table. For example, the variable Percent contains the percentage estimates, and the variables LowerCL and UpperCL contain the lower and upper confidence limits for the percentage estimates.

Output 90.3.1 ResponseTable Output Data Set

Obs	Table	Response	Frequency	Percent	StdErr	LowerCL	UpperCL
1	Table Response	Very Unsatisfied	304	17.1676	1.2872	14.6364	19.6989
2	Table Response	Unsatisfied	326	17.7564	1.2712	15.2566	20.2562
3	Table Response	Neutral	581	31.5965	1.5795	28.4904	34.7026
4	Table Response	Satisfied	455	23.9311	1.4761	21.0285	26.8338
5	Table Response	Very Satisfied	184	9.5483	0.9523	7.6756	11.4210
6	Table Response	.	1850	100.000	—	—	—

PROC SURVEYFREQ also creates a table summary that is not displayed. Some of the information in this table is similar to that contained in the “Data Summary” table, but the table summary describes the data that are used to analyze the specified table, while the data summary describes the entire input data set. Due to missing values, for example, the number of observations (or strata or clusters) used to analyze a particular table can differ from the number of observations (or strata or clusters) reported for the input data set in the “Data Summary” table. See the section “Missing Values” on page 7627 for more details. If you request confidence limits, the “Table Summary” table also contains the degrees of freedom and the *t*-value used to compute the confidence limits.

The following statements store the nondisplayed “Table Summary” table in the output data set ResponseSummary:

```
proc surveyfreq data=SIS_Survey;
  tables Response / cl nowt;
  ods output TableSummary=ResponseSummary;
  strata State NewUser;
  cluster School;
  weight SamplingWeight;
run;
```

Output 90.3.2 displays the output data set ResponseSummary.

Output 90.3.2 ResponseSummary Output Data Set

Obs	Table	Number of Observations	Number of Strata	Number of Clusters	Degrees of Freedom	t Percentile
1	Table Response	1850	6	370	364	1.966503

Overview: SURVEYLOGISTIC Procedure

Categorical responses arise extensively in sample survey. Common examples of responses include the following:

- binary: for example, attended graduate school or not
- ordinal: for example, mild, moderate, and severe pain
- nominal: for example, ABC, NBC, CBS, FOX TV network viewed at a certain hour

Logistic regression analysis is often used to investigate the relationship between such discrete responses and a set of explanatory variables. For a description of logistic regression for sample survey data, see Binder (1981, 1983); Roberts, Rao, and Kumar (1987); Skinner, Holt, and Smith (1989); Morel (1989); Lehtonen and Pahkinen (1995).

For binary response models, the response of a sampling unit can take a specified value or not (for example, attended graduate school or not). Suppose \mathbf{x} is a row vector of explanatory variables and π is the response probability to be modeled. The linear logistic model has the form

$$\text{logit}(\pi) \equiv \log\left(\frac{\pi}{1-\pi}\right) = \alpha + \mathbf{x}\boldsymbol{\beta}$$

where α is the intercept parameter and $\boldsymbol{\beta}$ is the vector of slope parameters.

The logistic model shares a common feature with the more general class of generalized linear models—namely, that a function $g = g(\mu)$ of the expected value, μ , of the response variable is assumed to be linearly related to the explanatory variables. Since μ implicitly depends on the stochastic behavior of the response, and since the explanatory variables are assumed to be fixed, the function g provides the link between the random (stochastic) component and the systematic (deterministic) component of the response variable. For this reason, Nelder and Wedderburn (1972) refer to $g(\cdot)$ as a link function. One advantage of the logit function over other link functions is that differences on the logistic scale are interpretable regardless

of whether the data are sampled prospectively or retrospectively (McCullagh and Nelder 1989, Chapter 4). Other link functions that are widely used in practice are the probit function and the complementary log-log function. The SURVEYLOGISTIC procedure enables you to choose one of these link functions, resulting in fitting a broad class of binary response models of the form

$$g(\pi) = \alpha + \mathbf{x}\boldsymbol{\beta}$$

For ordinal response models, the response Y of an individual or an experimental unit might be restricted to one of a usually small number of ordinal values, denoted for convenience by $1, \dots, D, D + 1$ ($D \geq 1$). For example, pain severity can be classified into three response categories as 1=mild, 2=moderate, and 3=severe. The SURVEYLOGISTIC procedure fits a common slopes cumulative model, which is a parallel lines regression model based on the cumulative probabilities of the response categories rather than on their individual probabilities. The cumulative model has the form

$$g(\Pr(Y \leq d \mid \mathbf{x})) = \alpha_d + \mathbf{x}\boldsymbol{\beta}, \quad 1 \leq d \leq D$$

where $\alpha_1, \dots, \alpha_k$ are k intercept parameters and $\boldsymbol{\beta}$ is the vector of slope parameters. This model has been considered by many researchers. Aitchison and Silvey (1957) and Ashford (1959) employ a probit scale and provide a maximum likelihood analysis; Walker and Duncan (1967) and Cox and Snell (1989) discuss the use of the log-odds scale. For the log-odds scale, the cumulative logit model is often referred to as the *proportional odds* model.

For nominal response logistic models, where the $D + 1$ possible responses have no natural ordering, the logit model can also be extended to a *generalized logit* model, which has the form

$$\log \left(\frac{\Pr(Y = i \mid \mathbf{x})}{\Pr(Y = D + 1 \mid \mathbf{x})} \right) = \alpha_i + \mathbf{x}\boldsymbol{\beta}_i, \quad i = 1, \dots, D$$

where the $\alpha_1, \dots, \alpha_D$ are D intercept parameters and the $\boldsymbol{\beta}_1, \dots, \boldsymbol{\beta}_D$ are D vectors of parameters. These models were introduced by McFadden (1974) as the *discrete choice* model, and they are also known as *multinomial* models.

The SURVEYLOGISTIC procedure fits linear logistic regression models for discrete response survey data by the method of maximum likelihood. For statistical inferences, PROC SURVEYLOGISTIC incorporates complex survey sample designs, including designs with stratification, clustering, and unequal weighting.

The maximum likelihood estimation is carried out with either the Fisher scoring algorithm or the Newton-Raphson algorithm. You can specify starting values for the parameter estimates. The logit link function in the ordinal logistic regression models can be replaced by the probit function or the complementary log-log function.

Odds ratio estimates are displayed along with parameter estimates. You can also specify the change in the explanatory variables for which odds ratio estimates are desired.

Variances of the regression parameters and odds ratios are computed by using either the Taylor series (linearization) method or replication (resampling) methods to estimate sampling errors of estimators based on complex sample designs (Binder 1983; Särndal, Swensson, and Wretman 1992; Wolter 2007; Rao, Wu, and Yue 1992).

The SURVEYLOGISTIC procedure enables you to specify categorical variables (also known as CLASS variables) as explanatory variables. It also enables you to specify interaction terms in the same way as in the LOGISTIC procedure.

Like many procedures in SAS/STAT software that allow the specification of CLASS variables, the SURVEYLOGISTIC procedure provides a **CONTRAST** statement for specifying customized hypothesis tests concerning the model parameters. The CONTRAST statement also provides estimation of individual rows of contrasts, which is particularly useful for obtaining odds ratio estimates for various levels of the CLASS variables.

Getting Started: SURVEYLOGISTIC Procedure

The SURVEYLOGISTIC procedure is similar to the LOGISTIC procedure and other regression procedures in the SAS System. See Chapter 54, “[The LOGISTIC Procedure](#),” for general information about how to perform logistic regression by using SAS. PROC SURVEYLOGISTIC is designed to handle sample survey data, and thus it incorporates the sample design information into the analysis.

The following example illustrates how to use PROC SURVEYLOGISTIC to perform logistic regression for sample survey data.

In the customer satisfaction survey example in the section “[Getting Started: SURVEYSELECT Procedure](#)” on page 8021 of Chapter 95, “[The SURVEYSELECT Procedure](#),” an Internet service provider conducts a customer satisfaction survey. The survey population consists of the company’s current subscribers from four states: Alabama (AL), Florida (FL), Georgia (GA), and South Carolina (SC). The company plans to select a sample of customers from this population, interview the selected customers and ask their opinions on customer service, and then make inferences about the entire population of subscribers from the sample data. A stratified sample is selected by using the probability proportional to size (PPS) method. The sample design divides the customers into strata depending on their types (‘Old’ or ‘New’) and their states (AL, FL, GA, SC). There are eight strata in all. Within each stratum, customers are selected and interviewed by using the PPS with replacement method, where the size variable is Usage. The stratified PPS sample contains 192 customers. The data are stored in the SAS data set SampleStrata. [Figure 91.1](#) displays the first 10 observations of this data set.

Figure 91.1 Stratified PPS Sample (First 10 Observations)

Customer Satisfaction Survey Stratified PPS Sampling (First 10 Observations)						
Obs	State	Type	Customer ID	Rating	Usage	Sampling Weight
1	AL	New	24394278	Neutral	13.17	26.358
2	AL	New	64798692	Extremely Unsatisfied	15.53	22.352
3	AL	New	75375074	Unsatisfied	99.11	3.501
4	AL	New	262831809	Neutral	5.40	64.228
5	AL	New	294428658	Extremely Satisfied	1.17	297.488
6	AL	New	336222949	Unsatisfied	38.69	8.970
7	AL	New	351929023	Extremely Satisfied	2.72	127.475
8	AL	New	366142640	Satisfied	2.61	132.958
9	AL	New	371478614	Neutral	14.36	24.173
10	AL	New	477172230	Neutral	4.06	85.489

In the SAS data set `SampleStrata`, the variable `CustomerID` uniquely identifies each customer. The variable `State` contains the state of the customer's address. The variable `Type` equals 'Old' if the customer has subscribed to the service for more than one year; otherwise, the variable `Type` equals 'New'. The variable `Usage` contains the customer's average monthly service usage, in hours. The variable `Rating` contains the customer's responses to the survey. The sample design uses an unequal probability sampling method, with the sampling weights stored in the variable `SamplingWeight`.

The following SAS statements fit a cumulative logistic model between the satisfaction levels and the Internet usage by using the stratified PPS sample:

```

title 'Customer Satisfaction Survey';
proc surveylogistic data=SampleStrata;
  strata state type/list;
  model Rating (order=internal) = Usage;
  weight SamplingWeight;
run;

```

The PROC SURVEYLOGISTIC statement invokes the SURVEYLOGISTIC procedure. The STRATA statement specifies the stratification variables `State` and `Type` that are used in the sample design. The LIST option requests a summary of the stratification. In the MODEL statement, `Rating` is the response variable and `Usage` is the explanatory variable. The ORDER=internal is used for the response variable `Rating` to ask the procedure to order the response levels by using the internal numerical value (1–5) instead of the formatted character value. The WEIGHT statement specifies the variable `SamplingWeight` that contains the sampling weights.

The results of this analysis are shown in the following figures.

Figure 91.2 Stratified PPS Sample, Model Information

Customer Satisfaction Survey		
The SURVEYLOGISTIC Procedure		
Model Information		
Data Set	WORK.SAMPLESTRATA	
Response Variable	Rating	
Number of Response Levels	5	
Stratum Variables	State Type	
Number of Strata	8	
Weight Variable	SamplingWeight	Sampling Weight
Model	Cumulative Logit	
Optimization Technique	Fisher's Scoring	
Variance Adjustment	Degrees of Freedom (DF)	

PROC SURVEYLOGISTIC first lists the following model fitting information and sample design information in Figure 91.2:

- The link function is the logit of the cumulative of the lower response categories.
- The Fisher scoring optimization technique is used to obtain the maximum likelihood estimates for the regression coefficients.
- The response variable is Rating, which has five response levels.
- The stratification variables are State and Type.
- There are eight strata in the sample.
- The weight variable is SamplingWeight.
- The [variance adjustment method](#) used for the regression coefficients is the default degrees of freedom adjustment.

Figure 91.3 lists the number of observations in the data set and the number of observations used in the analysis. Since there is no missing value in this example, observations in the entire data set are used in the analysis. The sums of weights are also reported in this table.

Figure 91.3 Stratified PPS Sample, Number of Observations

Number of Observations Read	192
Number of Observations Used	192
Sum of Weights Read	11326.25
Sum of Weights Used	11326.25

The “Response Profile” table in Figure 91.4 lists the five response levels, their ordered values, and their total frequencies and total weights for each category. Due to the ORDER=INTERNAL option for the response variable Rating, the category “Extremely Unsatisfied” has the Ordered Value 1, the category “Unsatisfied” has the Ordered Value 2, and so on.

Figure 91.4 Stratified PPS Sample, Response Profile

Response Profile			
Ordered Value	Rating	Total Frequency	Total Weight
1	Extremely Unsatisfied	58	2368.8598
2	Unsatisfied	47	1606.9657
3	Neutral	44	2594.3564
4	Satisfied	35	1898.5839
5	Extremely Satisfied	8	2857.4848
Probabilities modeled are cumulated over the lower Ordered Values.			

Figure 91.5 displays the output of the stratification summary. There are a total of eight strata, and each stratum is defined by the customer types within each state. The table also shows the number of customers within each stratum.

Figure 91.5 Stratified PPS Sample, Stratification Summary

Stratum Information			
Stratum Index	State	Type	N Obs
1	AL	New	24
2		Old	23
3	FL	New	25
4		Old	22
5	GA	New	25
6		Old	24
7	SC	New	24
8		Old	25

Figure 91.6 shows the chi-square test for testing the proportional odds assumption. The test is highly significant, which indicates that the cumulative logit model might not adequately fit the data.

Figure 91.6 Stratified PPS Sample, Testing the Proportional Odds Assumption

Score Test for the Proportional Odds Assumption		
Chi-Square	DF	Pr > ChiSq
617.8597	3	<.0001

Figure 91.7 shows the iteration algorithm converged to obtain the MLE for this example. The “Model Fit Statistics” table contains the Akaike information criterion (AIC), the Schwarz criterion (SC), and the negative of twice the log likelihood ($-2 \log L$) for the intercept-only model and the fitted model. AIC and SC can be used to compare different models, and the ones with smaller values are preferred.

Figure 91.7 Stratified PPS Sample, Model Fitting Information

Model Convergence Status		
Convergence criterion (GCONV=1E-8) satisfied.		
Model Fit Statistics		
Criterion	Intercept Only	Intercept and Covariates
AIC	35996.656	35312.584
SC	36009.686	35328.872
-2 Log L	35988.656	35302.584

The table “Testing Global Null Hypothesis: BETA=0” in Figure 91.8 shows the likelihood ratio test, the efficient score test, and the Wald test for testing the significance of the explanatory variable (Usage). All tests are significant.

Figure 91.8 Stratified PPS Sample

Testing Global Null Hypothesis: BETA=0			
Test	Chi-Square	DF	Pr > ChiSq
Likelihood Ratio	686.0718	1	<.0001
Score	420.7314	1	<.0001
Wald	3.9793	1	0.0461

Figure 91.9 shows the parameter estimates of the logistic regression and their standard errors.

Figure 91.9 Stratified PPS Sample, Parameter Estimates

Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept Extremely Unsatisfied	1	-1.6784	0.3874	18.7741	<.0001
Intercept Unsatisfied	1	-0.9356	0.3645	6.5900	0.0103
Intercept Neutral	1	0.0438	0.4177	0.0110	0.9165
Intercept Satisfied	1	0.8440	0.5699	2.1930	0.1386
Usage	1	0.0350	0.0175	3.9793	0.0461

Figure 91.10 displays the odds ratio estimate and its confidence limits.

Figure 91.10 Stratified PPS Sample, Odds Ratios

Odds Ratio Estimates			
Effect	Point Estimate	95% Wald Confidence Limits	
Usage	1.036	1.001	1.072

Syntax: SURVEYLOGISTIC Procedure

The following statements are available in the SURVEYLOGISTIC procedure:

```
PROC SURVEYLOGISTIC < options > ;
  BY variables ;
  CLASS variable < (v-options) > < variable < (v-options) > ... > < / v-options > ;
  CLUSTER variables ;
  CONTRAST 'label' effect values < , ... effect values > < / options > ;
  DOMAIN variables < variable*variable variable*variable*variable ... > ;
  EFFECT name = effect-type (variables < / options >) ;
  ESTIMATE < 'label' > estimate-specification < / options > ;
  FREQ variable ;
  LSMEANS < model-effects > < / options > ;
  LSMESTIMATE model-effect lsmestimate-specification < / options > ;
  MODEL events/trials = < effects < / options > > ;
  MODEL variable < (v-options) > = < effects > < / options > ;
  OUTPUT < OUT=SAS-data-set > < options > < / option > ;
  REPWEIGHTS variables < / options > ;
  SLICE model-effect < / options > ;
  STORE < OUT= > item-store-name < / LABEL='label' > ;
  STRATA variables < / option > ;
  < label: > TEST equation1 < , ... , equationk > < / options > ;
  UNITS independent1 = list1 < ... independentk = listk > < / option > ;
  WEIGHT variable ;
```

The PROC SURVEYLOGISTIC and MODEL statements are required.

The CLASS, CLUSTER, CONTRAST, EFFECT, ESTIMATE, LSMEANS, LSMESTIMATE, REPWEIGHTS, SLICE, STRATA, TEST statements can appear multiple times. You should use only one of each following statements: MODEL, WEIGHT, STORE, OUTPUT, and UNITS.

The CLASS statement (if used) must precede the MODEL statement, and the CONTRAST statement (if used) must follow the MODEL statement.

The rest of this section provides detailed syntax information for each of the preceding statements, except the EFFECT, ESTIMATE, LSMEANS, LSMESTIMATE, SLICE, STORE statements. These statements are also available in many other procedures. Summary descriptions of functionality and syntax for these statements are shown in this chapter, and full documentation about them is available in Chapter 19, “[Shared Concepts and Topics](#).”

The syntax descriptions begin with the PROC SURVEYLOGISTIC statement; the remaining statements are covered in alphabetical order.

PROC SURVEYLOGISTIC Statement

PROC SURVEYLOGISTIC <options> ;

The PROC SURVEYLOGISTIC statement invokes the SURVEYLOGISTIC procedure. Optionally, it identifies input data sets, controls the ordering of the response levels, and specifies the variance estimation method. The PROC SURVEYLOGISTIC statement is required.

Table 91.1 summarizes the options available in the PROC SURVEYLOGISTIC statement.

Table 91.1 PROC SURVEYLOGISTIC Statement Options

Option	Description
ALPHA=	Sets the confidence level for confidence limits
DATA=	Names the SAS data set containing the data to be analyze
INEST=	Names the SAS data set that contains initial estimates
MISSING	Treats missing values as a nonmissing category
NAMELEN=	Specifies the length of effect names
NOMCAR	Treats missing values as <i>not missing completely at random</i>
NOSORT	Suppresses the internal sorting process
ORDER=	Specifies the sort order
RATE=	Specifies the sampling rate
TOTAL=	Specifies the total number of primary sampling units
VARMETHOD=	Specifies the variance estimation method

ALPHA=value

sets the confidence level for confidence limits. The value of the ALPHA= option must be between 0 and 1, and the default value is 0.05. A confidence level of α produces $100(1 - \alpha)\%$ confidence limits. The default of ALPHA=0.05 produces 95% confidence limits.

DATA=SAS-data-set

names the SAS data set containing the data to be analyzed. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

INEST=SAS-data-set

names the SAS data set that contains initial estimates for all the parameters in the model. BY-group processing is allowed in setting up the INEST= data set. See the section “[INEST= Data Set](#)” on page 7733 for more information.

MISSING

treats missing values as a valid (nonmissing) category for all categorical variables, which include [CLASS](#), [STRATA](#), [CLUSTER](#), and [DOMAIN](#) variables.

By default, if you do not specify the MISSING option, an observation is excluded from the analysis if it has a missing value. For more information, see the section “[Missing Values](#)” on page 7723.

NAMELEN=*n*

specifies the length of effect names in tables and output data sets to be *n* characters, where *n* is a value between 20 and 200. The default length is 20 characters.

NOMCAR

requests that the procedure treat missing values in the variance computation as *not missing completely at random* (NOMCAR) for Taylor series variance estimation. When you specify the NOMCAR option, PROC SURVEYLOGISTIC computes variance estimates by analyzing the nonmissing values as a domain or subpopulation, where the entire population includes both nonmissing and missing domains. See the section “[Missing Values](#)” on page 7723 for more details.

By default, PROC SURVEYLOGISTIC completely excludes an observation from analysis if that observation has a missing value, unless you specify the [MISSING](#) option. Note that the NOMCAR option has no effect on a classification variable when you specify the MISSING option, which treats missing values as a valid nonmissing level.

The NOMCAR option applies only to Taylor series variance estimation. The replication methods, which you request with the [VARMETHOD=BRR](#) and [VARMETHOD=JACKKNIFE](#) options, do not use the NOMCAR option.

NOSORT

suppresses the internal sorting process to shorten the computation time if the data set is presorted by the [STRATA](#) and [CLUSTER](#) variables. By default, the procedure sorts the data by the STRATA variables if you use the STRATA statement; then the procedure sorts the data by the CLUSTER variables within strata. If your data are already stored by the order of STRATA and CLUSTER variables, then you can specify this option to omit this sorting process to reduce the usage of computing resources, especially when your data set is very large. However, if you specify this NOSORT option while your data are not presorted by STRATA and CLUSTER variables, then any changes in these variables creates a new stratum or cluster.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of the response variable. This option, except for ORDER=FREQ, also determines the sort order for the levels of CLUSTER and DOMAIN variables and controls STRATA variable levels in the “Stratum Information” table. By default, ORDER=INTERNAL. However, if an [ORDER=](#) option is specified after the response variable, in the [MODEL](#) statement, it overrides this option for the response variable. This option does not affect the ordering of the CLASS variable levels; see the [ORDER=](#) option in the [CLASS](#) statement for more information.

RATE=*value* | SAS-data-set**R=*value* | SAS-data-set**

specifies the sampling rate as a nonnegative *value*, or specifies an input data set that contains the stratum sampling rates. The procedure uses this information to compute a finite population correction for Taylor series variance estimation. The procedure does not use the RATE= option for BRR or jackknife variance estimation, which you request with the [VARMETHOD=BRR](#) or [VARMETHOD=JACKKNIFE](#) option.

If your sample design has multiple stages, you should specify the *first-stage sampling rate*, which is the ratio of the number of PSUs selected to the total number of PSUs in the population.

For a nonstratified sample design, or for a stratified sample design with the same sampling rate in all strata, you should specify a nonnegative *value* for the RATE= option. If your design is stratified with different sampling rates in the strata, then you should name a SAS data set that contains the stratification variables and the sampling rates. See the section “[Specification of Population Totals and Sampling Rates](#)” on page 7734 for more details.

The *value* in the RATE= option or the values of _RATE_ in the secondary data set must be nonnegative numbers. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC SURVEYLOGISTIC converts that number to a proportion. The procedure treats the value 1 as 100% instead of 1%.

If you do not specify the TOTAL= or RATE= option, then the Taylor series variance estimation does not include a finite population correction. You cannot specify both the TOTAL= and RATE= options.

TOTAL=*value* | *SAS-data-set*

N=*value* | *SAS-data-set*

specifies the total number of primary sampling units in the study population as a positive *value*, or specifies an input data set that contains the stratum population totals. The procedure uses this information to compute a finite population correction for Taylor series variance estimation. The procedure does not use the TOTAL= option for BRR or jackknife variance estimation, which you request with the [VARMETHOD=BRR](#) or [VARMETHOD=JACKKNIFE](#) option.

For a nonstratified sample design, or for a stratified sample design with the same population total in all strata, you should specify a positive *value* for the TOTAL= option. If your sample design is stratified with different population totals in the strata, then you should name a SAS data set that contains the stratification variables and the population totals. See the section “[Specification of Population Totals and Sampling Rates](#)” on page 7734 for more details.

If you do not specify the TOTAL= or [RATE=](#) option, then the Taylor series variance estimation does not include a finite population correction. You cannot specify both the TOTAL= and RATE= options.

VARMETHOD=BRR <(method-options)>

VARMETHOD=JACKKNIFE | **JK** <(method-options)>

VARMETHOD=TAYLOR

specifies the variance estimation method. VARMETHOD=TAYLOR requests the Taylor series method, which is the default if you do not specify the VARMETHOD= option or the REPWEIGHTS statement. VARMETHOD=BRR requests variance estimation by balanced repeated replication (BRR), and VARMETHOD=JACKKNIFE requests variance estimation by the delete-1 jackknife method.

For VARMETHOD=BRR and VARMETHOD=JACKKNIFE you can specify *method-options* in parentheses. [Table 91.2](#) summarizes the available *method-options*.

Table 91.2 Variance Estimation Options

VARMETHOD=	Variance Estimation Method	Method-Options
BRR	Balanced repeated replication	FAY <=value> HADAMARD=SAS-data-set OUTWEIGHTS=SAS-data-set PRINTH REPS=number
JACKKNIFE	Jackknife	OUTJKCOEFS=SAS-data-set OUTWEIGHTS=SAS-data-set
TAYLOR	Taylor series linearization	None

Method-options must be enclosed in parentheses following the method keyword. For example:

```
varmethod=BRR( reps=60 outweights=myReplicateWeights)
```

The following values are available for the VARMETHOD= option:

BRR <(method-options)>

requests **balanced repeated replication** (BRR) variance estimation. The BRR method requires a stratified sample design with two primary sampling units (PSUs) per stratum. See the section “**Balanced Repeated Replication (BRR) Method**” on page 7740 for more information.

You can specify the following *method-options* in parentheses following VARMETHOD=BRR:

FAY <=value>

requests **Fay’s method**, a modification of the **BRR** method, for variance estimation. See the section “**Fay’s BRR Method**” on page 7741 for more information.

You can specify the *value* of the Fay coefficient, which is used in converting the original sampling weights to replicate weights. The Fay coefficient must be a nonnegative number less than 1. By default, the value of the Fay coefficient equals 0.5.

HADAMARD=SAS-data-set

H=SAS-data-set

names a SAS data set that contains the **Hadamard matrix** for BRR replicate construction. If you do not provide a Hadamard matrix with the HADAMARD= *method-option*, PROC SURVEYLOGISTIC generates an appropriate Hadamard matrix for replicate construction. See the sections “**Balanced Repeated Replication (BRR) Method**” on page 7740 and “**Hadamard Matrix**” on page 7743 for details.

If a Hadamard matrix of a given dimension exists, it is not necessarily unique. Therefore, if you want to use a specific Hadamard matrix, you must provide the matrix as a SAS data set in the HADAMARD= *method-option*.

In the HADAMARD= input data set, each variable corresponds to a column of the Hadamard matrix, and each observation corresponds to a row of the matrix. You can use any variable names in the HADAMARD= data set. All values in the data set must equal either 1 or -1. You must ensure that the matrix you provide is indeed a Hadamard matrix—that is, $\mathbf{A}'\mathbf{A} = R\mathbf{I}$, where \mathbf{A} is the Hadamard matrix of dimension R and \mathbf{I} is an identity matrix. PROC SURVEYLOGISTIC does not check the validity of the Hadamard matrix that you provide.

The HADAMARD= input data set must contain at least H variables, where H denotes the number of first-stage strata in your design. If the data set contains more than H variables, the procedure uses only the first H variables. Similarly, the HADAMARD= input data set must contain at least H observations.

If you do not specify the REPS= *method-option*, then the number of replicates is taken to be the number of observations in the HADAMARD= input data set. If you specify the number of replicates—for example, REPS=*nreps*—then the first *nreps* observations in the HADAMARD= data set are used to construct the replicates.

You can specify the PRINTH option to display the Hadamard matrix that the procedure uses to construct replicates for BRR.

OUTWEIGHTS=SAS-data-set

names a SAS data set that contains replicate weights. See the section “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7740 for information about replicate weights. See the section “[Replicate Weights Output Data Set](#)” on page 7751 for more details about the contents of the OUTWEIGHTS= data set.

The OUTWEIGHTS= *method-option* is not available when you provide replicate weights with the [REPWEIGHTS](#) statement.

PRINTH

displays the Hadamard matrix.

When you provide your own Hadamard matrix with the HADAMARD= *method-option*, only the rows and columns of the Hadamard matrix that are used by the procedure are displayed. See the sections “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7740 and “[Hadamard Matrix](#)” on page 7743 for details.

The PRINTH *method-option* is not available when you provide replicate weights with the [REPWEIGHTS](#) statement because the procedure does not use a Hadamard matrix in this case.

REPS=number

specifies the number of replicates for BRR variance estimation. The value of *number* must be an integer greater than 1.

If you do not provide a Hadamard matrix with the HADAMARD= *method-option*, the number of replicates should be greater than the number of strata

and should be a multiple of 4. See the section “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7740 for more information. If a Hadamard matrix cannot be constructed for the REPS= value that you specify, the value is increased until a Hadamard matrix of that dimension can be constructed. Therefore, it is possible for the actual number of replicates used to be larger than the REPS= value that you specify.

If you provide a Hadamard matrix with the HADAMARD= *method-option*, the value of REPS= must not be less than the number of rows in the Hadamard matrix. If you provide a Hadamard matrix and do not specify the REPS= *method-option*, the number of replicates equals the number of rows in the Hadamard matrix.

If you do not specify the REPS= or HADAMARD= *method-option* and do not include a [REPWEIGHTS](#) statement, the number of replicates equals the smallest multiple of 4 that is greater than the number of strata.

If you provide replicate weights with the REPWEIGHTS statement, the procedure does not use the REPS= *method-option*. With a REPWEIGHTS statement, the number of replicates equals the number of REPWEIGHTS variables.

JACKKNIFE | JK <(method-options)>

requests variance estimation by the delete-1 jackknife method. See the section “[Jackknife Method](#)” on page 7742 for details. If you provide replicate weights with a [REPWEIGHTS](#) statement, VARMETHOD=JACKKNIFE is the default variance estimation method.

You can specify the following *method-options* in parentheses following VARMETHOD=JACKKNIFE:

OUTJKCOEFS=SAS-data-set

names a SAS data set that contains jackknife coefficients. See the section “[Jackknife Method](#)” on page 7742 for information about [jackknife coefficients](#). See the section “[Jackknife Coefficients Output Data Set](#)” on page 7751 for more details about the contents of the OUTJKCOEFS= data set.

OUTWEIGHTS=SAS-data-set

names a SAS data set that contains replicate weights. See the section “[Jackknife Method](#)” on page 7742 for information about replicate weights. See the section “[Replicate Weights Output Data Set](#)” on page 7751 for more details about the contents of the OUTWEIGHTS= data set.

The OUTWEIGHTS= *method-option* is not available when you provide replicate weights with the [REPWEIGHTS](#) statement.

TAYLOR

requests Taylor series variance estimation. This is the default method if you do not specify the VARMETHOD= option or a [REPWEIGHTS](#) statement. See the section “[Taylor Series \(Linearization\)](#)” on page 7739 for more information.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC SURVEYLOGISTIC to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the SURVEYLOGISTIC procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

Note that using a BY statement provides completely separate analyses of the BY groups. It does not provide a statistically valid domain (subpopulation) analysis, where the total number of units in the subpopulation is not known with certainty. You should use the DOMAIN statement to obtain domain analysis. For more information about subpopulation analysis for sample survey data, see Cochran (1977).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* < (*v-options*) > < *variable* < (*v-options*) > ... > < / *v-options* > ;

The CLASS statement names the classification variables to be used in the analysis. The CLASS statement must precede the **MODEL** statement. You can specify various *v-options* for each variable by enclosing them in parentheses after the variable name. You can also specify global *v-options* for the CLASS statement by placing them after a slash (/). Global *v-options* are applied to all the variables specified in the CLASS statement. However, individual CLASS variable *v-options* override the global *v-options*.

CPREFIX= *n*

specifies that, at most, the first *n* characters of a CLASS variable name be used in creating names for the corresponding dummy variables. The default is 32—min(32, max(2, *f*)), where *f* is the formatted length of the CLASS variable.

DESCENDING

DESC

reverses the sort order of the classification variable.

LPREFIX= *n*

specifies that, at most, the first *n* characters of a CLASS variable label be used in creating labels for the corresponding dummy variables.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the order in which to sort the levels of the classification variables.

This option applies to the levels for all classification variables, except when you use the (default) ORDER=FORMATTED option with numeric classification variables that have no explicit format. With this option, the levels of such variables are ordered by their internal value.

The ORDER= option can take the following values:

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent. For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PARAM=keyword

specifies the parameterization method for the classification variable or variables. Design matrix columns are created from CLASS variables according to the following coding schemes; the default is PARAM=EFFECT.

EFFECT	specifies effect coding
GLM	specifies less-than-full-rank, reference cell coding; this option can be used only as a global option
ORDINAL	specifies the cumulative parameterization for an ordinal CLASS variable
POLYNOMIAL POLY	specifies polynomial coding
REFERENCE REF	specifies reference cell coding
ORTHEFFECT	orthogonalizes PARAM=EFFECT
ORTHORDINAL ORTHOTHERM	orthogonalizes PARAM=ORDINAL
ORTHPOLY	orthogonalizes PARAM=POLYNOMIAL
ORTHREF	orthogonalizes PARAM=REFERENCE

If PARAM=ORTHPOLY or PARAM=POLY, and the CLASS levels are numeric, then the ORDER= option in the CLASS statement is ignored, and the internal, unformatted values are used.

EFFECT, POLYNOMIAL, REFERENCE, ORDINAL, and their orthogonal parameterizations are full rank. The REF= option in the CLASS statement determines the reference level for EFFECT, REFERENCE, and their orthogonal parameterizations.

Parameter names for a CLASS predictor variable are constructed by concatenating the CLASS variable name with the CLASS levels. However, for the POLYNOMIAL and orthogonal parameterizations, parameter names are formed by concatenating the CLASS variable name and keywords that reflect the parameterization.

REFERENCE= 'level' | keyword

REF= 'level' | keyword

specifies the reference level for PARAM=EFFECT or PARAM=REFERENCE. For an individual (but not a global) variable REF= *option*, you can specify the *level* of the variable to use as the reference level. For a global or individual variable REF= *option*, you can use one of the following *keywords*. The default is REF=LAST.

FIRST	designates the first ordered level as reference
LAST	designates the last ordered level as reference

CLUSTER Statement

CLUSTER *variables* ;

The CLUSTER statement names variables that identify the clusters in a clustered sample design. The combinations of categories of CLUSTER variables define the clusters in the sample. If there is a [STRATA](#) statement, clusters are nested within strata.

If you provide replicate weights for BRR or jackknife variance estimation with the [REPWEIGHTS](#) statement, you do not need to specify a CLUSTER statement.

If your sample design has clustering at multiple stages, you should identify only the first-stage clusters (primary sampling units (PSUs)), in the CLUSTER statement. See the section “[Primary Sampling Units \(PSUs\)](#)” on page 7734 for more information.

The CLUSTER *variables* are one or more variables in the DATA= input data set. These variables can be either character or numeric. The formatted values of the CLUSTER variables determine the CLUSTER variable levels. Thus, you can use formats to group values into levels. See the FORMAT procedure in the *Base SAS Procedures Guide* and the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference* for more information.

When determining levels of a CLUSTER variable, an observation with missing values for this CLUSTER variable is excluded, unless you specify the [MISSING](#) option. For more information, see the section “[Missing Values](#)” on page 7723.

You can use multiple CLUSTER statements to specify cluster variables. The procedure uses variables from all CLUSTER statements to create clusters.

CONTRAST Statement

CONTRAST *'label'* *row-description* <, ..., *row-description* </ options>> ;

where a *row-description* is defined as follows:

effect values <, ..., *effect values*>

The CONTRAST statement provides a mechanism for obtaining customized hypothesis tests. It is similar to the CONTRAST statement in PROC LOGISTIC and PROC GLM, depending on the coding schemes used with any classification variables involved.

The CONTRAST statement enables you to specify a matrix, \mathbf{L} , for testing the hypothesis $\mathbf{L}\boldsymbol{\theta} = 0$, where $\boldsymbol{\theta}$ is the parameter vector. You must be familiar with the details of the model parameterization that PROC SURVEYLOGISTIC uses (for more information, see the [PARAM=](#) option in the section “[CLASS Statement](#)” on page 7697). Optionally, the CONTRAST statement enables you to estimate each row, $\mathbf{l}_i\boldsymbol{\theta}$, of $\mathbf{L}\boldsymbol{\theta}$ and test the hypothesis $\mathbf{l}_i\boldsymbol{\theta} = 0$. Computed statistics are based on the asymptotic chi-square distribution of the Wald statistic.

There is no limit to the number of CONTRAST statements that you can specify, but they must appear after the [MODEL](#) statement.

The following parameters can be specified in the CONTRAST statement:

- label* identifies the contrast on the output. A label is required for every contrast specified, and it must be enclosed in quotes.
- effect* identifies an effect that appears in the MODEL statement. The name INTERCEPT can be used as an effect when one or more intercepts are included in the model. You do not need to include all effects that are included in the MODEL statement.
- values* are constants that are elements of the \mathbf{L} matrix associated with the effect. To correctly specify your contrast, it is crucial to know the ordering of parameters within each effect and the variable levels associated with any parameter. The “Class Level Information” table shows the ordering of levels within variables. The E option, described later in this section, enables you to verify the proper correspondence of *values* to parameters.

The rows of \mathbf{L} are specified in order and are separated by commas. Multiple degree-of-freedom hypotheses can be tested by specifying multiple *row-descriptions*. For any of the full-rank parameterizations, if an effect is not specified in the CONTRAST statement, all of its coefficients in the \mathbf{L} matrix are set to 0. If too many values are specified for an effect, the extra ones are ignored. If too few values are specified, the remaining ones are set to 0.

When you use effect coding (by default or by specifying [PARAM=EFFECT](#) in the CLASS statement), all parameters are directly estimable (involve no other parameters).

For example, suppose an effect that is coded CLASS variable A has four levels. Then there are three parameters ($\alpha_1, \alpha_2, \alpha_3$) that represent the first three levels, and the fourth parameter is represented by

$$-\alpha_1 - \alpha_2 - \alpha_3$$

To test the first versus the fourth level of A, you would test

$$\alpha_1 = -\alpha_1 - \alpha_2 - \alpha_3$$

or, equivalently,

$$2\alpha_1 + \alpha_2 + \alpha_3 = 0$$

which, in the form $\mathbf{L}\boldsymbol{\theta} = 0$, is

$$\begin{bmatrix} 2 & 1 & 1 \end{bmatrix} \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{bmatrix} = 0$$

Therefore, you would use the following CONTRAST statement:

```
contrast '1 vs. 4' A 2 1 1;
```

To contrast the third level with the average of the first two levels, you would test

$$\frac{\alpha_1 + \alpha_2}{2} = \alpha_3$$

or, equivalently,

$$\alpha_1 + \alpha_2 - 2\alpha_3 = 0$$

Therefore, you would use the following CONTRAST statement:

```
contrast '1&2 vs. 3' A 1 1 -2;
```

Other CONTRAST statements are constructed similarly. For example:

```
contrast '1 vs. 2' A 1 -1 0;
contrast '1&2 vs. 4' A 3 3 2;
contrast '1&2 vs. 3&4' A 2 2 0;
contrast 'Main Effect' A 1 0 0,
                        A 0 1 0,
                        A 0 0 1;
```

When you use the less-than-full-rank parameterization (by specifying `PARAM=GLM` in the `CLASS` statement), each row is checked for estimability. If `PROC SURVEYLOGISTIC` finds a contrast to be nonestimable, it displays missing values in corresponding rows in the results. `PROC SURVEYLOGISTIC` handles missing level combinations of classification variables in the same manner as `PROC LOGISTIC`. Parameters corresponding to missing level combinations are not included in the model. This convention can affect the way in which you specify the **L** matrix in your CONTRAST statement. If the elements of **L** are not specified for an effect that contains a specified effect, then the elements of the specified effect are distributed over the levels of the higher-order effect just as the `LOGISTIC` procedure does for its CONTRAST and ESTIMATE statements. For example, suppose that the model contains effects **A** and **B** and their interaction **A*B**. If you specify a CONTRAST statement involving **A** alone, the **L** matrix contains nonzero terms for both **A** and **A*B**, since **A*B** contains **A**.

The degrees of freedom is the number of linearly independent constraints implied by the CONTRAST statement—that is, the rank of **L**.

You can specify the following options after a slash (/):

ALPHA=*value*

sets the confidence level for confidence limits. The value of the ALPHA= option must be between 0 and 1, and the default value is 0.05. A confidence level of α produces $100(1 - \alpha)\%$ confidence limits. The default of ALPHA=0.05 produces 95% confidence limits.

E

requests that the **L** matrix be displayed.

ESTIMATE=*keyword*

requests that each individual contrast (that is, each row, $\mathbf{l}_i \boldsymbol{\beta}$, of $\mathbf{L}\boldsymbol{\beta}$) or exponentiated contrast ($e^{\mathbf{l}_i \boldsymbol{\beta}}$) be estimated and tested. PROC SURVEYLOGISTIC displays the point estimate, its standard error, a Wald confidence interval, and a Wald chi-square test for each contrast. The significance level of the confidence interval is controlled by the ALPHA= option. You can estimate the contrast or the exponentiated contrast ($e^{\mathbf{l}_i \boldsymbol{\beta}}$), or both, by specifying one of the following *keywords*:

PARM	specifies that the contrast itself be estimated
EXP	specifies that the exponentiated contrast be estimated
BOTH	specifies that both the contrast and the exponentiated contrast be estimated

SINGULAR=*value*

tunes the estimability checking. If \mathbf{v} is a vector, define $\text{ABS}(\mathbf{v})$ to be the largest absolute value of the elements of \mathbf{v} . For a row vector \mathbf{l} of the matrix \mathbf{L} , define

$$c = \begin{cases} \text{ABS}(\mathbf{l}) & \text{if } \text{ABS}(\mathbf{l}) > 0 \\ 1 & \text{otherwise} \end{cases}$$

If $\text{ABS}(\mathbf{l} - \mathbf{lH})$ is greater than $c * \text{value}$, then $\mathbf{l}\boldsymbol{\beta}$ is declared nonestimable. The \mathbf{H} matrix is the Hermite form matrix $\mathbf{I}_0^- \mathbf{I}_0$, where \mathbf{I}_0^- represents a generalized inverse of the information matrix \mathbf{I}_0 of the null model. The *value* must be between 0 and 1; the default is 10^{-4} .

DOMAIN Statement

DOMAIN *variables* < *variable*variable variable*variable*variable* ... > ;

The DOMAIN statement requests analysis for domains (subpopulations) in addition to analysis for the entire study population. The DOMAIN statement names the variables that identify domains, which are called domain variables.

It is common practice to compute statistics for domains. The formation of these domains might be unrelated to the sample design. Therefore, the sample sizes for the domains are random variables. Use a DOMAIN statement to incorporate this variability into the variance estimation.

Note that a DOMAIN statement is different from a BY statement. In a BY statement, you treat the sample sizes as fixed in each subpopulation, and you perform analysis within each BY group independently. See the section “[Domain Analysis](#)” on page 7744 for more details.

Use the DOMAIN statement on the entire data set to perform a domain analysis. Creating a new data set from a single domain and analyzing that with PROC SURVEYLOGISTIC yields inappropriate estimates of variance.

A domain variable can be either character or numeric. The procedure treats domain variables as categorical variables. If a variable appears by itself in a DOMAIN statement, each level of this variable determines a domain in the study population. If two or more variables are joined by asterisks (*), then every possible combination of levels of these variables determines a domain. The procedure performs a descriptive analysis within each domain that is defined by the domain variables.

When determining levels of a DOMAIN variable, an observation with missing values for this DOMAIN variable is excluded, unless you specify the **MISSING** option. For more information, see the section “[Missing Values](#)” on page 7723.

The formatted values of the domain variables determine the categorical variable levels. Thus, you can use formats to group values into levels. See the **FORMAT** procedure in the *Base SAS Procedures Guide* and the **FORMAT** statement and SAS formats in *SAS Formats and Informats: Reference* for more information.

EFFECT Statement

EFFECT *name=effect-type (variables < / options>);*

The **EFFECT** statement enables you to construct special collections of columns for design matrices. These collections are referred to as *constructed effects* to distinguish them from the usual model effects that are formed from continuous or classification variables, as discussed in the section “[GLM Parameterization of Classification Variables and Effects](#)” on page 383 in Chapter 19, “[Shared Concepts and Topics](#).”

You can specify the following *effect-types*:

COLLECTION	is a collection effect that defines one or more variables as a single effect with multiple degrees of freedom. The variables in a collection are considered as a unit for estimation and inference.
LAG	is a classification effect in which the level that is used for a given period corresponds to the level in the preceding period.
MULTIMEMBER MM	is a multimember classification effect whose levels are determined by one or more variables that appear in a CLASS statement.
POLYNOMIAL POLY	is a multivariate polynomial effect in the specified numeric variables.
SPLINE	is a regression spline effect whose columns are univariate spline expansions of one or more variables. A spline expansion replaces the original variable with an expanded or larger set of new variables.

Table 91.3 summarizes the *options* available in the **EFFECT** statement.

Table 91.3 EFFECT Statement Options

Option	Description
Collection Effects Options	
DETAILS	Displays the constituents of the collection effect
Lag Effects Options	
DESIGNROLE=	Names a variable that controls to which lag design an observation is assigned

Table 91.3 continued

Option	Description
DETAILS	Displays the lag design of the lag effect
NLAG=	Specifies the number of periods in the lag
PERIOD=	Names the variable that defines the period
WITHIN=	Names the variable or variables that define the group within which each period is defined
Multimember Effects Options	
NOEFFECT	Specifies that observations with all missing levels for the multi-member variables should have zero values in the corresponding design matrix columns
WEIGHT=	Specifies the weight variable for the contributions of each of the classification effects
Polynomial Effects Options	
DEGREE=	Specifies the degree of the polynomial
MDEGREE=	Specifies the maximum degree of any variable in a term of the polynomial
STANDARDIZE=	Specifies centering and scaling suboptions for the variables that define the polynomial
Spline Effects Options	
BASIS=	Specifies the type of basis (B-spline basis or truncated power function basis) for the spline expansion
DEGREE=	Specifies the degree of the spline transformation
KNOTMETHOD=	Specifies how to construct the knots for spline effects

For more information about the syntax of these *effect-types* and how columns of constructed effects are computed, see the section “EFFECT Statement” on page 393 in Chapter 19, “Shared Concepts and Topics.”

ESTIMATE Statement

```
ESTIMATE <'label'> estimate-specification <(divisor=n)>
      <,...<'label'> estimate-specification <(divisor=n)>>
      </options>;
```

The ESTIMATE statement provides a mechanism for obtaining custom hypothesis tests. Estimates are formed as linear estimable functions of the form $L\beta$. You can perform hypothesis tests for the estimable functions, construct confidence limits, and obtain specific nonlinear transformations.

Table 91.4 summarizes the options available in the ESTIMATE statement.

Table 91.4 ESTIMATE Statement Options

Option	Description
Construction and Computation of Estimable Functions	
DIVISOR=	Specifies a list of values to divide the coefficients
NOFILL	Suppresses the automatic fill-in of coefficients for higher-order effects
SINGULAR=	Tunes the estimability checking difference
Degrees of Freedom and p-values	
ADJUST=	Determines the method for multiple comparison adjustment of estimates
ALPHA= α	Determines the confidence level ($1 - \alpha$)
LOWER	Performs one-sided, lower-tailed inference
STEPPDOWN	Adjusts multiplicity-corrected p -values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits
CORR	Displays the correlation matrix of estimates
COV	Displays the covariance matrix of estimates
E	Prints the L matrix
JOINT	Produces a joint F or chi-square test for the estimable functions
SEED=	Specifies the seed for computations that depend on random numbers
Generalized Linear Modeling	
CATEGORY=	Specifies how to construct estimable functions with multinomial data
EXP	Exponentiates and displays estimates
ILINK	Computes and displays estimates and standard errors on the inverse linked scale

For details about the syntax of the ESTIMATE statement, see the section “[ESTIMATE Statement](#)” on page 437 in Chapter 19, “[Shared Concepts and Topics](#).”

FREQ Statement

FREQ *variable* ;

The *variable* in the FREQ statement identifies a variable that contains the frequency of occurrence of each observation. PROC SURVEYLOGISTIC treats each observation as if it appears n times, where n is the value of the FREQ variable for the observation. If it is not an integer, the frequency value is truncated to

an integer. If the frequency value is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1.

If you use the [events/trials](#) syntax in the MODEL statement, the FREQ statement is not allowed because the event and trial variables represent the frequencies in the data set.

If you use the FREQ statement and specify the [VARMETHOD=BRR](#) or [VARMETHOD=JACKKNIFE](#) option to estimate the variance, then you must identify the primary sampling units with a CLUSTER statement unless you also provide replicate weights with a REPWEIGHTS statement.

LSMEANS Statement

LSMEANS < *model-effects* > < / *options* > ;

The LSMEANS statement computes and compares least squares means (LS-means) of fixed effects. LS-means are *predicted margins*—that is, they estimate the marginal means over a hypothetical balanced population.

Table 91.5 summarizes available options in the LSMEANS statement.

Table 91.5 LSMEANS Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies the covariate value in computing LS-means
BYLEVEL	Computes separate margins
DIFF	Requests differences of LS-means
OM=	Specifies the weighting scheme for LS-means computation as determined by the input data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and <i>p</i>-values	
ADJUST=	Determines the method for multiple-comparison adjustment of LS-means differences
ALPHA= α	Determines the confidence level ($1 - \alpha$)
STEPDOWN	Adjusts multiple-comparison <i>p</i> -values further in a step-down fashion
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the L matrix
LINES	Produces a “Lines” display for pairwise LS-means differences
MEANS	Prints the LS-means
PLOTS=	Requests graphs of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers

Table 91.5 *continued*

Option	Description
Generalized Linear Modeling	
EXP	Exponentiates and displays estimates of LS-means or LS-means differences
ILINK	Computes and displays estimates and standard errors of LS-means (but not differences) on the inverse linked scale
ODDSRATIO	Reports (simple) differences of least squares means in terms of odds ratios if permitted by the link function

For details about the syntax of the LSMEANS statement, see the section “[LSMEANS Statement](#)” on page 453 of Chapter 19, “[Shared Concepts and Topics](#).”

LSMESTIMATE Statement

```
LSMESTIMATE model-effect <'label'> values <divisor=n>
              < , ... <'label'> values <divisor=n> >
              </ options> ;
```

The LSMESTIMATE statement provides a mechanism for obtaining custom hypothesis tests among least squares means.

Table 91.6 summarizes the options available in the LSMESTIMATE statement.

Table 91.6 LSMESTIMATE Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies covariate values in computing LS-means
BYLEVEL	Computes separate margins
DIVISOR=	Specifies a list of values to divide the coefficients
OM=	Specifies the weighting scheme for LS-means computation as determined by a data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and <i>p</i>-values	
ADJUST=	Determines the method for multiple-comparison adjustment of LS-means differences
ALPHA= α	Determines the confidence level $(1 - \alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiple-comparison <i>p</i> -values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference

Table 91.6 *continued*

Option	Description
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the L matrix
ELSM	Prints the K matrix
JOINT	Produces a joint <i>F</i> or chi-square test for the LS-means and LS-means differences
SEED=	Specifies the seed for computations that depend on random numbers
Generalized Linear Modeling	
CATEGORY=	Specifies how to construct estimable functions with multinomial data
EXP	Exponentiates and displays LS-means estimates
ILINK	Computes and displays estimates and standard errors of LS-means (but not differences) on the inverse linked scale

For details about the syntax of the LSMESTIMATE statement, see the section “[LSMESTIMATE Statement](#)” on page 470 in Chapter 19, “[Shared Concepts and Topics](#).”

MODEL Statement

MODEL *events/trials* = < *effects* < / *options* > > ;

MODEL *variable* < (*v-options*) > = < *effects* > < / *options* > ;

The MODEL statement names the response variable and the explanatory effects, including covariates, main effects, interactions, and nested effects; see the section “[Specification of Effects](#)” on page 3324 of Chapter 42, “[The GLM Procedure](#),” for more information. If you omit the explanatory variables, the procedure fits an intercept-only model. [Model options](#) can be specified after a slash (/).

Two forms of the MODEL statement can be specified. The first form, referred to as *single-trial* syntax, is applicable to binary, ordinal, and nominal response data. The second form, referred to as *events/trials* syntax, is restricted to the case of binary response data. The single-trial syntax is used when each observation in the DATA= data set contains information about only a single trial, such as a single subject in an experiment. When each observation contains information about multiple binary-response trials, such as the counts of the number of subjects observed and the number responding, then events/trials syntax can be used.

In the events/trials syntax, you specify two variables that contain count data for a binomial experiment. These two variables are separated by a slash. The value of the first variable, *events*, is the number of positive responses (or events), and it must be nonnegative. The value of the second variable, *trials*, is the number of trials, and it must not be less than the value of *events*.

In the single-trial syntax, you specify one variable (on the left side of the equal sign) as the response variable. This variable can be character or numeric. [Options](#) specific to the response variable can be specified immediately after the response variable with parentheses around them.

For both forms of the MODEL statement, explanatory *effects* follow the equal sign. Variables can be either continuous or classification variables. Classification variables can be character or numeric, and they must be declared in the CLASS statement. When an effect is a classification variable, the procedure enters a set of coded columns into the design matrix instead of directly entering a single column containing the values of the variable.

Response Variable Options

You specify the following options by enclosing them in parentheses after the response variable:

DESCENDING

DESC

reverses the order of response categories. If both the DESCENDING and the [ORDER=](#) options are specified, PROC SURVEYLOGISTIC orders the response categories according to the ORDER= option and then reverses that order. See the section “[Response Level Ordering](#)” on page 7724 for more detail.

EVENT=*'category'* | *keyword*

specifies the event category for the binary response model. PROC SURVEYLOGISTIC models the probability of the event category. The EVENT= option has no effect when there are more than two response categories. You can specify the value (formatted if a format is applied) of the event category in quotes or you can specify one of the following keywords. The default is EVENT=FIRST.

FIRST designates the first ordered category as the event

LAST designates the last ordered category as the event

One of the most common sets of response levels is $\{0,1\}$, with 1 representing the event for which the probability is to be modeled. Consider the example where Y takes the values 1 and 0 for event and nonevent, respectively, and Exposure is the explanatory variable. To specify the value 1 as the event category, use the following MODEL statement:

```
model Y(event='1') = Exposure;
```

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of the response variable. By default, ORDER=INTERNAL. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent.

When the default ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format,

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

REFERENCE='category' | keyword

REF='category' | keyword

specifies the reference category for the generalized logit model and the binary response model. For the generalized logit model, each nonreference category is contrasted with the reference category. For the binary response model, specifying one response category as the reference is the same as specifying the other response category as the event category. You can specify the value (formatted if a format is applied) of the reference category in quotes or you can specify one of the following keywords. The default is REF=LAST.

FIRST	designates the first ordered category as the reference
LAST	designates the last ordered category as the reference

Model Options

Model options can be specified after a slash (/). [Table 91.7](#) summarizes the options available in the MODEL statement.

Table 91.7 MODEL Statement Options

Option	Description
Model Specification Options	
LINK=	Specifies link function
NOINT	Suppresses intercept(s)
OFFSET=	Specifies offset variable
Convergence Criterion Options	
ABSFCNV=	Specifies absolute function convergence criterion
FCONV=	Specifies relative function convergence criterion
GCONV=	Specifies relative gradient convergence criterion
XCONV=	Specifies relative parameter convergence criterion
MAXITER=	Specifies maximum number of iterations
NOCHECK	Suppresses checking for infinite parameters
RIDGING=	Specifies technique used to improve the log-likelihood function when its value is worse than that of the previous step
SINGULAR=	Specifies tolerance for testing singularity

Table 91.7 (continued)

Option	Description
TECHNIQUE=	Specifies iterative algorithm for maximization
Options for Adjustment to Variance Estimation	
VADJUST=	Chooses variance estimation adjustment method
Options for Confidence Intervals	
ALPHA=	Specifies α for the $100(1 - \alpha)\%$ confidence intervals
CLPARM	Computes confidence intervals for parameters
CLODDS	Computes confidence intervals for odds ratios
Options for Display of Details	
CORRB	Displays correlation matrix
COVB	Displays covariance matrix
EXPB	Displays exponentiated values of estimates
ITPRINT	Displays iteration history
NODUMMYPRINT	Suppresses “Class Level Information” table
PARMLABEL	Displays parameter labels
RSQUARE	Displays generalized R^2
STB	Displays standardized estimates

The following list describes these options:

ABSFCNV=value

specifies the absolute function convergence criterion. Convergence requires a small change in the log-likelihood function in subsequent iterations:

$$|l^{(i)} - l^{(i-1)}| < value$$

where $l^{(i)}$ is the value of the log-likelihood function at iteration i . See the section “[Convergence Criteria](#)” on page 7731.

ALPHA=value

sets the level of significance α for $100(1 - \alpha)\%$ confidence intervals for regression parameters or odds ratios. The value α must be between 0 and 1. By default, α is equal to the value of the [ALPHA=](#) option in the PROC SURVEYLOGISTIC statement, or $\alpha = 0.05$ if the ALPHA= option is not specified. This option has no effect unless confidence limits for the parameters or odds ratios are requested.

CLODDS

requests confidence intervals for the odds ratios. Computation of these confidence intervals is based on individual Wald tests. The confidence coefficient can be specified with the [ALPHA=](#) option.

See the section “[Wald Confidence Intervals for Parameters](#)” on page 7745 for more information.

CLPARM

requests confidence intervals for the parameters. Computation of these confidence intervals is based on the individual Wald tests. The confidence coefficient can be specified with the [ALPHA=](#) option.

See the section “[Wald Confidence Intervals for Parameters](#)” on page 7745 for more information.

CORRB

displays the correlation matrix of the parameter estimates.

COVB

displays the covariance matrix of the parameter estimates.

EXPB**EXPEST**

displays the exponentiated values ($e^{\hat{\theta}_i}$) of the parameter estimates $\hat{\theta}_i$ in the “Analysis of Maximum Likelihood Estimates” table for the logit model. These exponentiated values are the estimated odds ratios for the parameters corresponding to the continuous explanatory variables.

FCONV=value

specifies the relative function convergence criterion. Convergence requires a small relative change in the log-likelihood function in subsequent iterations:

$$\frac{|l^{(i)} - l^{(i-1)}|}{|l^{(i-1)}| + 1\text{E-}6} < \text{value}$$

where $l^{(i)}$ is the value of the log likelihood at iteration i . See the section “[Convergence Criteria](#)” on page 7731 for details.

GCONV=value

specifies the relative gradient convergence criterion. Convergence requires that the normalized prediction function reduction is small:

$$\frac{\mathbf{g}^{(i)'} \mathbf{I}^{(i)} \mathbf{g}^{(i)}}{|l^{(i)}| + 1\text{E-}6} < \text{value}$$

where $l^{(i)}$ is the value of the log-likelihood function, $\mathbf{g}^{(i)}$ is the gradient vector, and $\mathbf{I}^{(i)}$ the (expected) information matrix. All of these functions are evaluated at iteration i . This is the default convergence criterion, and the default value is 1E–8. See the section “[Convergence Criteria](#)” on page 7731 for details.

ITPRINT

displays the iteration history of the maximum-likelihood model fitting. The ITPRINT option also displays the last evaluation of the gradient vector and the final change in the $-2 \log L$.

LINK=keyword**L=keyword**

specifies the link function that links the response probabilities to the linear predictors. You can specify one of the following keywords. The default is LINK=LOGIT.

CLOGLOG specifies the complementary log-log function. PROC SURVEYLOGISTIC fits the binary complementary log-log model for binary response and fits the cumulative complementary log-log model when there are more than two response categories. Aliases: CCLOGLOG, CCLL, CUMCLOGLOG.

GLOGIT specifies the generalized logit function. PROC SURVEYLOGISTIC fits the generalized logit model where each nonreference category is contrasted with the reference category. You can use the response variable option [REF=](#) to specify the reference category.

LOGIT	specifies the cumulative logit function. PROC SURVEYLOGISTIC fits the binary logit model when there are two response categories and fits the cumulative logit model when there are more than two response categories. Aliases: CLOGIT, CUMLOGIT.
PROBIT	specifies the inverse standard normal distribution function. PROC SURVEYLOGISTIC fits the binary probit model when there are two response categories and fits the cumulative probit model when there are more than two response categories. Aliases: NORMIT, CPROBIT, CUMPROBIT.

See the section [“Link Functions and the Corresponding Distributions”](#) on page 7727 for details.

MAXITER=*n*

specifies the maximum number of iterations to perform. By default, MAXITER=25. If convergence is not attained in *n* iterations, the displayed output created by the procedure contains results that are based on the last maximum likelihood iteration.

NOCHECK

disables the checking process to determine whether maximum likelihood estimates of the regression parameters exist. If you are sure that the estimates are finite, this option can reduce the execution time when the estimation takes more than eight iterations. For more information, see the section [“Existence of Maximum Likelihood Estimates”](#) on page 7731.

NODUMMYPRINT

suppresses the “Class Level Information” table, which shows how the design matrix columns for the **CLASS** variables are coded.

NOINT

suppresses the intercept for the binary response model or the first intercept for the ordinal response model.

OFFSET=*name*

names the offset variable. The regression coefficient for this variable is fixed at 1.

PARMLABEL

displays the labels of the parameters in the “Analysis of Maximum Likelihood Estimates” table.

RIDGING=ABSOLUTE | RELATIVE | NONE

specifies the technique used to improve the log-likelihood function when its value in the current iteration is less than that in the previous iteration. If you specify the RIDGING=ABSOLUTE option, the diagonal elements of the negative (expected) Hessian are inflated by adding the ridge value. If you specify the RIDGING=RELATIVE option, the diagonal elements are inflated by a factor of 1 plus the ridge value. If you specify the RIDGING=NONE option, the crude line search method of taking half a step is used instead of ridging. By default, RIDGING=RELATIVE.

RSQUARE

requests a generalized R^2 measure for the fitted model.

For more information, see the section [“Generalized Coefficient of Determination”](#) on page 7733.

SINGULAR=value

specifies the tolerance for testing the singularity of the Hessian matrix (Newton-Raphson algorithm) or the expected value of the Hessian matrix (Fisher scoring algorithm). The Hessian matrix is the matrix of second partial derivatives of the log likelihood. The test requires that a pivot for sweeping this matrix be at least this *value* times a norm of the matrix. Values of the SINGULAR= option must be numeric. By default, SINGULAR= 10^{-12} .

STB

displays the standardized estimates for the parameters for the continuous explanatory variables in the “Analysis of Maximum Likelihood Estimates” table. The standardized estimate of θ_i is given by $\hat{\theta}_i/(s/s_i)$, where s_i is the total sample standard deviation for the i th explanatory variable and

$$s = \begin{cases} \pi/\sqrt{3} & \text{Logistic} \\ 1 & \text{Normal} \\ \pi/\sqrt{6} & \text{Extreme-value} \end{cases}$$

For the intercept parameters and parameters associated with a CLASS variable, the standardized estimates are set to missing.

TECHNIQUE=FISHER | NEWTON**TECH=FISHER | NEWTON**

specifies the optimization technique for estimating the regression parameters. NEWTON (or NR) is the Newton-Raphson algorithm and FISHER (or FS) is the Fisher scoring algorithm. Both techniques yield the same estimates, but the estimated covariance matrices are slightly different except for the case where the LOGIT link is specified for binary response data. The default is TECHNIQUE=FISHER. If the LINK=GLOGIT option is specified, then Newton-Raphson is the default and only available method. See the section “[Iterative Algorithms for Model Fitting](#)” on page 7729 for details.

VADJUST=DF**VADJUST=MOREL <(Morel-options)>****VADJUST=NONE**

specifies an [adjustment to the variance estimation](#) for the regression coefficients.

By default, PROC SURVEYLOGISTIC uses the degrees of freedom adjustment VADJUST=DF.

If you do not want to use any variance adjustment, you can specify the VADJUST=NONE option. You can specify the VADJUST=MOREL option for the variance adjustment proposed by Morel (1989).

You can specify the following *Morel-options* within parentheses after the VADJUST=MOREL option:

ADJBOUND= ϕ

sets the upper bound coefficient ϕ in the variance adjustment. This upper bound must be positive. By default, the procedure uses $\phi = 0.5$. See the section “[Adjustments to the Variance Estimation](#)” on page 7740 for more details on how this upper bound is used in the variance estimation.

DEFFBOUND= δ

sets the lower bound of the estimated design effect in the variance adjustment. This lower bound must be positive. By default, the procedure uses $\delta = 1$. See the section “[Adjustments to the Variance Estimation](#)” on page 7740 for more details about how this lower bound is used in the variance estimation.

XCONV=value

specifies the relative parameter convergence criterion. Convergence requires a small relative parameter change in subsequent iterations:

$$\max_j |\delta_j^{(i)}| < \text{value}$$

where

$$\delta_j^{(i)} = \begin{cases} \theta_j^{(i)} - \theta_j^{(i-1)} & |\theta_j^{(i-1)}| < 0.01 \\ \frac{\theta_j^{(i)} - \theta_j^{(i-1)}}{\theta_j^{(i-1)}} & \text{otherwise} \end{cases}$$

and $\theta_j^{(i)}$ is the estimate of the j th parameter at iteration i . See the section “[Convergence Criteria](#)” on page 7731 for details.

OUTPUT Statement

OUTPUT <OUT=SAS-data-set> <options> </option> ;

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimated linear predictors and their standard error estimates, the estimates of the cumulative or individual response probabilities, and the confidence limits for the cumulative probabilities. Formulas for the statistics are given in the section “[Linear Predictor, Predicted Probability, and Confidence Limits](#)” on page 7749.

If you use the single-trial syntax, the data set also contains a variable named `_LEVEL_`, which indicates the level of the response that the given row of output is referring to. For example, the value of the cumulative probability variable is the probability that the response variable is as large as the corresponding value of `_LEVEL_`. For details, see the section “[OUT= Data Set in the OUTPUT Statement](#)” on page 7750.

The estimated linear predictor, its standard error estimate, all predicted probabilities, and the confidence limits for the cumulative probabilities are computed for all observations in which the explanatory variables have no missing values, even if the response is missing. By adding observations with missing response values to the input data set, you can compute these statistics for new observations, or for settings of the explanatory variables not present in the data, without affecting the model fit.

Table 91.8 summarizes the options available in the OUTPUT statement.

Table 91.8 OUTPUT Statement Options

Option	Description
ALPHA=	Sets the level of significance
LOWER	Names the variable that contains the lower confidence limits
OUT=	Names the output data set
PREDICTED	Names the variable that contains the predicted probabilities
PREDPROBS=	Requests predicted probabilities
STDXBETA=	Names the variable that contains the standard error estimates
UPPER	Names the variable that contains the upper confidence limits
XBETA=	Names the variable that contains the estimates of the linear predictor

You can specify the following options in the OUTPUT statement:

LOWER | L=name

names the variable that contains the lower confidence limits for π , where π is the probability of the event response if events/trials syntax or the single-trial syntax with binary response is specified; π is cumulative probability (that is, the probability that the response is less than or equal to the value of `_LEVEL_`) for a cumulative model; and π is the individual probability (that is, the probability that the response category is represented by the value of `_LEVEL_`) for the generalized logit model. See the [ALPHA=](#) option for information about setting the confidence level.

OUT=SAS-data-set

names the output data set. If you omit the OUT= option, the output data set is created and given a default name by using the `DATA n` convention.

The statistic options in the OUTPUT statement specify the statistics to be included in the output data set and name the new variables that contain the statistics.

PREDICTED | P=name

names the variable that contains the predicted probabilities. For the events/trials syntax or the single-trial syntax with binary response, it is the predicted event probability. For a cumulative model, it is the predicted cumulative probability (that is, the probability that the response variable is less than or equal to the value of `_LEVEL_`); and for the generalized logit model, it is the predicted individual probability (that is, the probability of the response category represented by the value of `_LEVEL_`).

PREDPROBS=(keywords)

requests individual, cumulative, or cross validated predicted probabilities. Descriptions of the *keywords* are as follows.

INDIVIDUAL | I requests the predicted probability of each response level. For a response variable Y with three levels, 1, 2, and 3, the individual probabilities are $\Pr(Y=1)$, $\Pr(Y=2)$, and $\Pr(Y=3)$.

CUMULATIVE | C requests the cumulative predicted probability of each response level. For a response variable Y with three levels, 1, 2, and 3, the cumulative probabilities are $\Pr(Y \leq 1)$, $\Pr(Y \leq 2)$, and $\Pr(Y \leq 3)$. The cumulative probability for the last response level always has the constant value of 1. For generalized logit models, the cumulative predicted probabilities are not computed and are set to missing.

CROSSVALIDATE | XVALIDATE | X requests the cross validated individual predicted probability of each response level. These probabilities are derived from the leave-one-out principle; that is, dropping the data of one subject and reestimating the parameter estimates. PROC SURVEYLOGISTIC uses a less expensive one-step approximation to compute the parameter estimates. This option is valid only for binary response models; for nominal and ordinal models, the cross validated probabilities are not computed and are set to missing.

See the section “[Details of the PREDPROBS= Option](#)” on page 7717 at the end of this section for further details.

STDXBETA=*name*

names the variable that contains the standard error estimates of **XBETA** (the definition of which follows).

UPPER | U=*name*

names the variable that contains the upper confidence limits for π , where π is the probability of the event response if events/trials syntax or single-trial syntax with binary response is specified; π is cumulative probability (that is, the probability that the response is less than or equal to the value of `_LEVEL_`) for a cumulative model; and π is the individual probability (that is, the probability that the response category is represented by the value of `_LEVEL_`) for the generalized logit model. See the **ALPHA=** option for information about setting the confidence level.

XBETA=*name*

names the variable that contains the estimates of the linear predictor $\alpha_i + \mathbf{x}\boldsymbol{\beta}$, where i is the corresponding ordered value of `_LEVEL_`.

You can specify the following option in the OUTPUT statement after a slash (/):

ALPHA=*value*

sets the level of significance α for $100(1 - \alpha)\%$ confidence limits for the appropriate response probabilities. The value α must be between 0 and 1. By default, α is equal to the value of the **ALPHA=** option in the PROC SURVEYLOGISTIC statement, or 0.05 if the ALPHA= option is not specified.

Details of the PREDPROBS= Option

You can request any of the three given types of predicted probabilities. For example, you can request both the individual predicted probabilities and the cross validated probabilities by specifying **PREDPROBS=(I X)**.

When you specify the **PREDPROBS=** option, two automatic variables `_FROM_` and `_INTO_` are included for the single-trial syntax and only one variable, `_INTO_`, is included for the events/trials syntax. The `_FROM_` variable contains the formatted value of the observed response. The variable `_INTO_` contains the formatted value of the response level with the largest individual predicted probability.

If you specify **PREDPROBS=INDIVIDUAL**, the OUTPUT data set contains k additional variables representing the individual probabilities, one for each response level, where k is the maximum number of response levels across all BY groups. The names of these variables have the form `IP_xxx`, where `xxx` represents the particular level. The representation depends on the following situations:

- If you specify the events/trials syntax, `xxx` is either Event or Nonevent. Thus, the variable that contains the event probabilities is named `IP_Event` and the variable containing the nonevent probabilities is named `IP_Nonevent`.
- If you specify the single-trial syntax with more than one BY group, `xxx` is 1 for the first ordered level of the response, 2 for the second ordered level of the response, and so forth, as given in the “Response Profile” table. The variable that contains the predicted probabilities $\Pr(Y=1)$ is named `IP_1`, where Y is the response variable. Similarly, `IP_2` is the name of the variable containing the predicted probabilities $\Pr(Y=2)$, and so on.
- If you specify the single-trial syntax with no BY-group processing, `xxx` is the left-justified formatted value of the response level (the value can be truncated so that `IP_xxx` does not exceed 32 characters).

For example, if *Y* is the response variable with response levels ‘None,’ ‘Mild,’ and ‘Severe,’ the variables representing individual probabilities $\Pr(Y=\text{‘None’})$, $\Pr(Y=\text{‘Mild’})$, and $\Pr(Y=\text{‘Severe’})$ are named *IP_None*, *IP_Mild*, and *IP_Severe*, respectively.

If you specify *PREDPROBS=CUMULATIVE*, the OUTPUT data set contains *k* additional variables that represent the cumulative probabilities, one for each response level, where *k* is the maximum number of response levels across all BY groups. The names of these variables have the form *CP_xxx*, where *xxx* represents the particular response level. The naming convention is similar to that given by *PREDPROBS=INDIVIDUAL*. The *PREDPROBS=CUMULATIVE* values are the same as those output by the *PREDICT=keyword*, but they are arranged in variables in each output observation rather than in multiple output observations.

If you specify *PREDPROBS=CROSSVALIDATE*, the OUTPUT data set contains *k* additional variables representing the cross validated predicted probabilities of the *k* response levels, where *k* is the maximum number of response levels across all BY groups. The names of these variables have the form *XP_xxx*, where *xxx* represents the particular level. The representation is the same as that given by *PREDPROBS=INDIVIDUAL*, except that for the events/trials syntax there are four variables for the cross validated predicted probabilities instead of two:

XP_EVENT_R1E is the cross validated predicted probability of an event when a current event trial is removed.

XP_NONEVENT_R1E is the cross validated predicted probability of a nonevent when a current event trial is removed.

XP_EVENT_R1N is the cross validated predicted probability of an event when a current nonevent trial is removed.

XP_NONEVENT_R1N is the cross validated predicted probability of a nonevent when a current nonevent trial is removed.

REPWEIGHTS Statement

REPWEIGHTS *variables* < / *options* > ;

The REPWEIGHTS statement names variables that provide replicate weights for BRR or jackknife variance estimation, which you request with the *VARMETHOD=BRR* or *VARMETHOD=JACKKNIFE* option in the PROC SURVEYLOGISTIC statement. If you do not provide replicate weights for these methods by using a REPWEIGHTS statement, then the procedure constructs replicate weights for the analysis. See the sections “Balanced Repeated Replication (BRR) Method” on page 7740 and “Jackknife Method” on page 7742 for information about replicate weights.

Each REPWEIGHTS variable should contain the weights for a single replicate, and the number of replicates equals the number of REPWEIGHTS variables. The REPWEIGHTS variables must be numeric, and the variable values must be nonnegative numbers.

If you provide replicate weights with a REPWEIGHTS statement, you do not need to specify a *CLUSTER* or *STRATA* statement. If you use a REPWEIGHTS statement and do not specify the *VARMETHOD=* option in the PROC SURVEYLOGISTIC statement, the procedure uses *VARMETHOD=JACKKNIFE* by default.

If you specify a REPWEIGHTS statement but do not include a [WEIGHT](#) statement, the procedure uses the average of replicate weights of each observation as the observation's weight.

You can specify the following options in the REPWEIGHTS statement after a slash (/):

DF=*df*

specifies the degrees of freedom for the analysis. The value of *df* must be a positive number. By default, the degrees of freedom equals the number of REPWEIGHTS variables.

JKCOEFS=*value*

specifies a [jackknife coefficient](#) for [VARMETHOD=JACKKNIFE](#). The coefficient *value* must be a nonnegative number. See the section “[Jackknife Method](#)” on page 7742 for details about jackknife coefficients.

You can use this option to specify a single value of the jackknife coefficient, which the procedure uses for all replicates. To specify different coefficients for different replicates, use the [JKCOEFS=values](#) or [JKCOEFS=SAS-data-set](#) option.

JKCOEFS=*values*

specifies jackknife coefficients for [VARMETHOD=JACKKNIFE](#), where each coefficient corresponds to an individual replicate that is identified by a REPWEIGHTS variable. You can separate *values* with blanks or commas. The coefficient *values* must be nonnegative numbers. The number of *values* must equal the number of replicate weight variables named in the REPWEIGHTS statement. List these values in the same order in which you list the corresponding replicate weight variables in the REPWEIGHTS statement.

See the section “[Jackknife Method](#)” on page 7742 for details about jackknife coefficients.

To specify different coefficients for different replicates, you can also use the [JKCOEFS=SAS-data-set](#) option. To specify a single jackknife coefficient for all replicates, use the [JKCOEFS=value](#) option.

JKCOEFS=*SAS-data-set*

names a SAS data set that contains the jackknife coefficients for [VARMETHOD=JACKKNIFE](#). You provide the jackknife coefficients in the JKCOEFS= data set variable JKCoefficient. Each coefficient value must be a nonnegative number. The observations in the JKCOEFS= data set should correspond to the replicates that are identified by the REPWEIGHTS variables. Arrange the coefficients or observations in the JKCOEFS= data set in the same order in which you list the corresponding replicate weight variables in the REPWEIGHTS statement. The number of observations in the JKCOEFS= data set must not be less than the number of REPWEIGHTS variables.

See the section “[Jackknife Method](#)” on page 7742 for details about jackknife coefficients.

To specify different coefficients for different replicates, you can also use the [JKCOEFS=values](#) option. To specify a single jackknife coefficient for all replicates, use the [JKCOEFS=value](#) option.

SLICE Statement

SLICE *model-effect* < / options > ;

The SLICE statement provides a general mechanism for performing a partitioned analysis of the LS-means for an interaction. This analysis is also known as an analysis of simple effects.

The SLICE statement uses the same options as the LSMEANS statement, which are summarized in Table 19.21. For details about the syntax of the SLICE statement, see the section “SLICE Statement” on page 498 in Chapter 19, “Shared Concepts and Topics.”

STORE Statement

STORE < **OUT=** *item-store-name* < / **LABEL=** 'label' > ;

The STORE statement requests that the procedure save the context and results of the statistical analysis. The resulting item store has a binary file format that cannot be modified. The contents of the item store can be processed with the PLM procedure.

For details about the syntax of the STORE statement, see the section “STORE Statement” on page 501 in Chapter 19, “Shared Concepts and Topics.”

STRATA Statement

STRATA *variables* < / *option* > ;

The STRATA statement specifies variables that form the strata in a stratified sample design. The combinations of categories of STRATA variables define the strata in the sample.

If your sample design has stratification at multiple stages, you should identify only the first-stage strata in the STRATA statement. See the section “Specification of Population Totals and Sampling Rates” on page 7734 for more information.

If you provide replicate weights for BRR or jackknife variance estimation with the REPWEIGHTS statement, you do not need to specify a STRATA statement.

The STRATA *variables* are one or more variables in the DATA= input data set. These variables can be either character or numeric. The formatted values of the STRATA variables determine the levels. Thus, you can use formats to group values into levels. See the FORMAT procedure in the *Base SAS Procedures Guide* and the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference* for more information.

When determining levels of a STRATA variable, an observation with missing values for this STRATA variable is excluded, unless you specify the MISSING option. For more information, see the section “Missing Values” on page 7723.

You can use multiple STRATA statements to specify stratum variables.

You can specify the following option in the STRATA statement after a slash (/):

LIST

displays a “Stratum Information” table, which includes values of the STRATA variables and the number of observations, number of clusters, population total, and sampling rate for each stratum. See the section “Stratum Information” on page 7754 for more details.

TEST Statement

< label: > TEST equation1 <, equation2, ... > < / option > ;

The TEST statement tests linear hypotheses about the regression coefficients. The Wald test is used to jointly test the null hypotheses ($H_0: \mathbf{L}\boldsymbol{\theta} = \mathbf{c}$) specified in a single TEST statement. When $\mathbf{c} = \mathbf{0}$ you should specify a **CONTRAST** statement instead.

Each *equation* specifies a linear hypothesis (a row of the **L** matrix and the corresponding element of the **c** vector); multiple *equations* are separated by commas. The label, which must be a valid SAS name, is used to identify the resulting output and should always be included. You can submit multiple TEST statements.

The form of an *equation* is as follows:

term < ± term ... > < = ± term < ± term ... > >

where *term* is a parameter of the model, or a constant, or a constant times a parameter. For a binary response model, the intercept parameter is named INTERCEPT; for an ordinal response model, the intercept parameters are named INTERCEPT, INTERCEPT2, INTERCEPT3, and so on. When no equal sign appears, the expression is set to 0. The following illustrates possible uses of the TEST statement:

```
proc surveylogistic;
  model y= a1 a2 a3 a4;
  test1: test intercept + .5 * a2 = 0;
  test2: test intercept + .5 * a2;
  test3: test a1=a2=a3;
  test4: test a1=a2, a2=a3;
run;
```

Note that the first and second TEST statements are equivalent, as are the third and fourth TEST statements.

You can specify the following option in the TEST statement after a slash (/):

PRINT

displays intermediate calculations in the testing of the null hypothesis $H_0: \mathbf{L}\boldsymbol{\theta} = \mathbf{c}$. This includes $\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})\mathbf{L}'$ bordered by $(\mathbf{L}\hat{\boldsymbol{\theta}} - \mathbf{c})$ and $[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})\mathbf{L}']^{-1}$ bordered by $[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})\mathbf{L}']^{-1}(\mathbf{L}\hat{\boldsymbol{\theta}} - \mathbf{c})$, where $\hat{\boldsymbol{\theta}}$ is the pseudo-estimator of $\boldsymbol{\theta}$ and $\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})$ is the estimated covariance matrix of $\hat{\boldsymbol{\theta}}$.

For more information, see the section “[Testing Linear Hypotheses about the Regression Coefficients](#)” on page 7745.

UNITS Statement

UNITS independent1 = list1 < ... independentk = listk > < / option > ;

The UNITS statement enables you to specify units of change for the continuous explanatory variables so that customized odds ratios can be estimated. An estimate of the corresponding odds ratio is produced for each unit of change specified for an explanatory variable. The UNITS statement is ignored for CLASS variables. If the **CLODDS** option is specified in the MODEL statement, the corresponding confidence limits for the odds ratios are also displayed.

The term *independent* is the name of an explanatory variable, and *list* represents a list of units of change, separated by spaces, that are of interest for that variable. Each unit of change in a list has one of the following forms:

- *number*
- SD or –SD
- *number* * SD

where *number* is any nonzero number and SD is the sample standard deviation of the corresponding independent variable. For example, $X = -2$ requests an odds ratio that represents the change in the odds when the variable X is decreased by two units. $X = 2*SD$ requests an estimate of the change in the odds when X is increased by two sample standard deviations.

You can specify the following option in the UNITS statement after a slash (/):

DEFAULT=*list*

gives a list of units of change for all explanatory variables that are not specified in the UNITS statement. Each unit of change can be in any of the forms described previously. If the DEFAULT= option is not specified, PROC SURVEYLOGISTIC does not produce customized odds ratio estimates for any explanatory variable that is not listed in the UNITS statement.

For more information, see the section “[Odds Ratio Estimation](#)” on page 7745.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement names the variable that contains the sampling weights. This variable must be numeric, and the sampling weights must be positive numbers. If an observation has a weight that is nonpositive or missing, then the procedure omits that observation from the analysis. See the section “[Missing Values](#)” on page 7723 for more information. If you specify more than one WEIGHT statement, the procedure uses only the first WEIGHT statement and ignores the rest.

If you do not specify a WEIGHT statement but provide replicate weights with a [REPWEIGHTS](#) statement, PROC SURVEYLOGISTIC uses the average of replicate weights of each observation as the observation’s weight.

If you do not specify a WEIGHT statement or a REPWEIGHTS statement, PROC SURVEYLOGISTIC assigns all observations a weight of one.

Details: SURVEYLOGISTIC Procedure

Missing Values

If you have missing values in your survey data for any reason, such as nonresponse, this can compromise the quality of your survey results. If the respondents are different from the nonrespondents with regard to a survey effect or outcome, then survey estimates might be biased and cannot accurately represent the survey population. There are a variety of techniques in sample design and survey operations that can reduce nonresponse. After data collection is complete, you can use imputation to replace missing values with acceptable values, and/or you can use sampling weight adjustments to compensate for nonresponse. You should complete this data preparation and adjustment before you analyze your data with PROC SURVEYLOGISTIC. For more information, see Cochran (1977); Kalton and Kaspyzyk (1986); Brick and Kalton (1996).

If an observation has a missing value or a nonpositive value for the **WEIGHT** or **FREQ** variable, then that observation is excluded from the analysis.

An observation is also excluded if it has a missing value for any design (**STRATA**, **CLUSTER**, or **DOMAIN**) variable, unless you specify the **MISSING** option in the PROC SURVEYLOGISTIC statement. If you specify the **MISSING** option, the procedure treats missing values as a valid (nonmissing) category for all categorical variables.

By default, if an observation contains missing values for the response, offset, or any explanatory variables used in the independent effects, the observation is excluded from the analysis. This treatment is based on the assumption that the missing values are missing completely at random (MCAR). However, this assumption is not true sometimes. For example, evidence from other surveys might suggest that observations with missing values are systematically different from observations without missing values. If you believe that missing values are not missing completely at random, then you can specify the **NOMCAR** option to include these observations with missing values in the dependent variable and the independent variables in the variance estimation.

Whether or not the **NOMCAR** option is used, observations with missing or invalid values for **WEIGHT**, **FREQ**, **STRATA**, **CLUSTER**, or **DOMAIN** variables are always excluded, unless the **MISSING** option is also specified.

When you specify the **NOMCAR** option, the procedure treats observations with and without missing values for variables in the regression model as two different domains, and it performs a domain analysis in the domain of nonmissing observations.

If you use a **REPWEIGHTS** statement, all **REPWEIGHTS** variables must contain nonmissing values.

Model Specification

Response Level Ordering

Response level ordering is important because, by default, PROC SURVEYLOGISTIC models the probabilities of response levels with lower *Ordered Values*. Ordered Values, displayed in the “Response Profile” table, are assigned to response levels in ascending sorted order. That is, the lowest response level is assigned Ordered Value 1, the next lowest is assigned Ordered Value 2, and so on. For example, if your response variable Y takes values in $\{1, \dots, D + 1\}$, then the functions of the response probabilities modeled with the cumulative model are

$$\text{logit}(\Pr(Y \leq i | \mathbf{x})), i = 1, \dots, D$$

and for the generalized logit model they are

$$\log \left(\frac{\Pr(Y = i | \mathbf{x})}{\Pr(Y = D + 1 | \mathbf{x})} \right), i = 1, \dots, D$$

where the highest Ordered Value $Y = D + 1$ is the reference level. You can change these default functions by specifying the **EVENT=**, **REF=**, **DESCENDING**, or **ORDER=** response variable options in the MODEL statement.

For binary response data with event and nonevent categories, the procedure models the function

$$\text{logit}(p) = \log \left(\frac{p}{1 - p} \right)$$

where p is the probability of the response level assigned to Ordered Value 1 in the “Response Profiles” table. Since

$$\text{logit}(p) = -\text{logit}(1 - p)$$

the effect of reversing the order of the two response levels is to change the signs of α and β in the model $\text{logit}(p) = \alpha + \mathbf{x}\beta$.

If your event category has a higher Ordered Value than the nonevent category, the procedure models the nonevent probability. You can use response variable options to model the event probability. For example, suppose the binary response variable Y takes the values 1 and 0 for event and nonevent, respectively, and *Exposure* is the explanatory variable. By default, the procedure assigns Ordered Value 1 to response level $Y=0$, and Ordered Value 2 to response level $Y=1$. Therefore, the procedure models the probability of the nonevent (Ordered Value=1) category. To model the event probability, you can do the following:

- Explicitly state which response level is to be modeled by using the response variable option **EVENT=** in the MODEL statement:

```
model Y(event='1') = Exposure;
```

- Specify the response variable option **DESCENDING** in the MODEL statement:

```
model Y(descending)=Exposure;
```

- Specify the response variable option **REF=** in the MODEL statement as the nonevent category for the response variable. This option is most useful when you are fitting a generalized logit model.

```
model Y(ref='0') = Exposure;
```

- Assign a format to Y such that the first formatted value (when the formatted values are put in sorted order) corresponds to the event. For this example, Y=1 is assigned formatted value 'event' and Y=0 is assigned formatted value 'nonevent.' Since **ORDER= FORMATTED** by default, Ordered Value 1 is assigned to response level Y=1 so the procedure models the event.

```
proc format;
  value Disease 1='event' 0='nonevent';
run;

proc surveylogistic;
  format Y Disease.;
  model Y=Exposure;
run;
```

CLASS Variable Parameterization

Consider a model with one **CLASS** variable A with four levels: 1, 2, 5, and 7. Details of the possible choices for the **PARAM=** option follow.

EFFECT Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three dummy variables have a value of -1. For instance, if the reference level is 7 (REF=7), the design matrix columns for A are as follows.

Design Matrix			
A	A1	A2	A5
1	1	0	0
2	0	1	0
5	0	0	1
7	-1	-1	-1

For **CLASS** main effects that use the **EFFECT** coding scheme, individual parameters correspond to the difference between the effect of each nonreference level and the average over all four levels.

GLM As in **PROC GLM**, four columns are created to indicate group membership. The design matrix columns for A are as follows.

Design Matrix				
A	A1	A2	A5	A7
1	1	0	0	0
2	0	1	0	0
5	0	0	1	0
7	0	0	0	1

For CLASS main effects that use the GLM coding scheme, individual parameters correspond to the difference between the effect of each level and the last level.

ORDINAL

Three columns are created to indicate group membership of the higher levels of the effect. For the first level of the effect (which for A is 1), all three dummy variables have a value of 0. The design matrix columns for A are as follows.

Design Matrix			
A	A2	A5	A7
1	0	0	0
2	1	0	0
5	1	1	0
7	1	1	1

The first level of the effect is a control or baseline level.

For CLASS main effects that use the ORDINAL coding scheme, the first level of the effect is a control or baseline level; individual parameters correspond to the difference between effects of the current level and the preceding level. When the parameters for an ordinal main effect have the same sign, the response effect is monotonic across the levels.

POLYNOMIAL | POLY Three columns are created. The first represents the linear term (x), the second represents the quadratic term (x^2), and the third represents the cubic term (x^3), where x is the level value. If the CLASS levels are not numeric, they are translated into 1, 2, 3, ... according to their sort order. The design matrix columns for A are as follows.

Design Matrix			
A	APOLY1	APOLY2	APOLY3
1		1	1
2		2	4
5		5	25
7		7	49

REFERENCE | REF Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three dummy variables have a value of 0. For instance, if the reference level is 7 (REF=7), the design matrix columns for A are as follows.

Design Matrix			
A	A1	A2	A5
1	1	0	0
2	0	1	0
5	0	0	1
7	0	0	0

For CLASS main effects that use the REFERENCE coding scheme, individual parameters correspond to the difference between the effect of each nonreference level and the reference level.

ORTHEFFECT The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=EFFECT. The design matrix columns for A are as follows.

Design Matrix			
A	AOEFF1	AOEFF2	AOEFF3
1	1.41421	-0.81650	-0.57735
2	0.00000	1.63299	-0.57735
5	0.00000	0.00000	1.73205
7	-1.41421	-0.81649	-0.57735

ORTHORDINAL | **ORTHOTHERM** The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=ORDINAL. The design matrix columns for A are as follows.

Design Matrix			
A	AOORD1	AOORD2	AOORD3
1	-1.73205	0.00000	0.00000
2	0.57735	-1.63299	0.00000
5	0.57735	0.81650	-1.41421
7	0.57735	0.81650	1.41421

ORTHPOLY The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=POLY. The design matrix columns for A are as follows.

Design Matrix			
A	AOPOLY1	AOPOLY2	AOPOLY5
1	-1.153	0.907	-0.921
2	-0.734	-0.540	1.473
5	0.524	-1.370	-0.921
7	1.363	1.004	0.368

ORTHREF The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=REFERENCE. The design matrix columns for A are as follows.

Design Matrix			
A	AOREF1	AOREF2	AOREF3
1	1.73205	0.00000	0.00000
2	-0.57735	1.63299	0.00000
5	-0.57735	-0.81650	1.41421
7	-0.57735	-0.81650	-1.41421

Link Functions and the Corresponding Distributions

Four link functions are available in the SURVEYLOGISTIC procedure. The logit function is the default. To specify a different link function, use the **LINK=** option in the MODEL statement. The link functions and the corresponding distributions are as follows:

- The **logit** function

$$g(p) = \log\left(\frac{p}{1-p}\right)$$

is the inverse of the cumulative logistic distribution function, which is

$$F(x) = \frac{1}{1 + e^{-x}}$$

- The **probit** (or normit) function

$$g(p) = \Phi^{-1}(p)$$

is the inverse of the cumulative standard normal distribution function, which is

$$F(x) = \Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-\frac{1}{2}z^2} dz$$

Traditionally, the probit function includes an additive constant 5, but throughout PROC SURVEYLOGISTIC, the terms probit and normit are used interchangeably, previously defined as $g(p)$.

- The **complementary log-log** function

$$g(p) = \log(-\log(1-p))$$

is the inverse of the cumulative extreme-value function (also called the Gompertz distribution), which is

$$F(x) = 1 - e^{-e^x}$$

- The **generalized logit** function extends the binary logit link to a vector of levels $(\pi_1, \dots, \pi_{k+1})$ by contrasting each level with a fixed level

$$g(\pi_i) = \log\left(\frac{\pi_i}{\pi_{k+1}}\right) \quad i = 1, \dots, k$$

The variances of the normal, logistic, and extreme-value distributions are not the same. Their respective means and variances are

Distribution	Mean	Variance
Normal	0	1
Logistic	0	$\pi^2/3$
Extreme-value	$-\gamma$	$\pi^2/6$

where γ is the Euler constant. In comparing parameter estimates that use different link functions, you need to take into account the different scalings of the corresponding distributions and, for the complementary log-log function, a possible shift in location. For example, if the fitted probabilities are in the neighborhood of 0.1 to 0.9, then the parameter estimates from using the logit link function should be about $\pi/\sqrt{3} \approx 1.8$ larger than the estimates from the probit link function.

Model Fitting

Determining Observations for Likelihood Contributions

If you use the events/trials syntax, each observation is split into two observations. One has the response value 1 with a frequency equal to the value of the *events* variable. The other observation has the response value 2 and a frequency equal to the value of $(\text{trials} - \text{events})$. These two observations have the same explanatory variable values and the same WEIGHT values as the original observation.

For either the single-trial or the events/trials syntax, let j index all observations. In other words, for the single-trial syntax, j indexes the actual observations. And, for the events/trials syntax, j indexes the observations after splitting (as described previously). If your data set has 30 observations and you use the single-trial syntax, j has values from 1 to 30; if you use the events/trials syntax, j has values from 1 to 60.

Suppose the response variable in a cumulative response model can take on the ordered values $1, \dots, k, k+1$, where k is an integer ≥ 1 . The likelihood for the j th observation with ordered response value y_j and explanatory variables vector (row vectors) \mathbf{x}_j is given by

$$L_j = \begin{cases} F(\alpha_1 + \mathbf{x}_j \boldsymbol{\beta}) & y_j = 1 \\ F(\alpha_i + \mathbf{x}_j \boldsymbol{\beta}) - F(\alpha_{i-1} + \mathbf{x}_j \boldsymbol{\beta}) & 1 < y_j = i \leq k \\ 1 - F(\alpha_k + \mathbf{x}_j \boldsymbol{\beta}) & y_j = k + 1 \end{cases}$$

where $F(\cdot)$ is the logistic, normal, or extreme-value distribution function; $\alpha_1, \dots, \alpha_k$ are ordered intercept parameters; and $\boldsymbol{\beta}$ is the slope parameter vector.

For the generalized logit model, letting the $k+1$ st level be the reference level, the intercepts $\alpha_1, \dots, \alpha_k$ are unordered and the slope vector $\boldsymbol{\beta}_i$ varies with each logit. The likelihood for the j th observation with ordered response value y_j and explanatory variables vector \mathbf{x}_j (row vectors) is given by

$$L_j = \Pr(Y = y_j | \mathbf{x}_j) = \begin{cases} \frac{e^{\alpha_i + \mathbf{x}_j \boldsymbol{\beta}_i}}{1 + \sum_{i=1}^k e^{\alpha_i + \mathbf{x}_j \boldsymbol{\beta}_i}} & 1 \leq y_j = i \leq k \\ \frac{1}{1 + \sum_{i=1}^k e^{\alpha_i + \mathbf{x}_j \boldsymbol{\beta}_i}} & y_j = k + 1 \end{cases}$$

Iterative Algorithms for Model Fitting

Two iterative maximum likelihood algorithms are available in PROC SURVEYLOGISTIC to obtain the pseudo-estimate $\hat{\boldsymbol{\theta}}$ of the model parameter $\boldsymbol{\theta}$. The default is the Fisher scoring method, which is equivalent to fitting by iteratively reweighted least squares. The alternative algorithm is the Newton-Raphson method. Both algorithms give the same parameter estimates; the covariance matrix of $\hat{\boldsymbol{\theta}}$ is estimated in the section “Variance Estimation” on page 7738. For a generalized logit model, only the Newton-Raphson technique is available. You can use the **TECHNIQUE=** option in the MODEL statement to select a fitting algorithm.

Iteratively Reweighted Least Squares Algorithm (Fisher Scoring)

Let Y be the response variable that takes values $1, \dots, k, k+1$ ($k \geq 1$). Let j index all observations and Y_j be the value of response for the j th observation. Consider the multinomial variable $\mathbf{Z}_j = (Z_{1j}, \dots, Z_{kj})'$ such that

$$Z_{ij} = \begin{cases} 1 & \text{if } Y_j = i \\ 0 & \text{otherwise} \end{cases}$$

and $Z_{(k+1)j} = 1 - \sum_{i=1}^k Z_{ij}$. With π_{ij} denoting the probability that the j th observation has response value i , the expected value of \mathbf{Z}_j is $\boldsymbol{\pi}_j = (\pi_{1j}, \dots, \pi_{kj})'$, and $\pi_{(k+1)j} = 1 - \sum_{i=1}^k \pi_{ij}$. The covariance matrix of \mathbf{Z}_j is \mathbf{V}_j , which is the covariance matrix of a multinomial random variable for one trial with parameter vector $\boldsymbol{\pi}_j$. Let $\boldsymbol{\theta}$ be the vector of regression parameters—for example, $\boldsymbol{\theta} = (\alpha_1, \dots, \alpha_k, \boldsymbol{\beta}')'$ for cumulative logit model. Let \mathbf{D}_j be the matrix of partial derivatives of $\boldsymbol{\pi}_j$ with respect to $\boldsymbol{\theta}$. The estimating equation for the regression parameters is

$$\sum_j \mathbf{D}_j' \mathbf{W}_j (\mathbf{Z}_j - \boldsymbol{\pi}_j) = \mathbf{0}$$

where $\mathbf{W}_j = w_j f_j \mathbf{V}_j^{-1}$, and w_j and f_j are the WEIGHT and FREQ values of the j th observation.

With a starting value of $\boldsymbol{\theta}^{(0)}$, the pseudo-estimate of $\boldsymbol{\theta}$ is obtained iteratively as

$$\boldsymbol{\theta}^{(i+1)} = \boldsymbol{\theta}^{(i)} + \left(\sum_j \mathbf{D}_j' \mathbf{W}_j \mathbf{D}_j \right)^{-1} \sum_j \mathbf{D}_j' \mathbf{W}_j (\mathbf{Z}_j - \boldsymbol{\pi}_j)$$

where \mathbf{D}_j , \mathbf{W}_j , and $\boldsymbol{\pi}_j$ are evaluated at the i th iteration $\boldsymbol{\theta}^{(i)}$. The expression after the plus sign is the step size. If the log likelihood evaluated at $\boldsymbol{\theta}^{(i+1)}$ is less than that evaluated at $\boldsymbol{\theta}^{(i)}$, then $\boldsymbol{\theta}^{(i+1)}$ is recomputed by step-halving or ridging. The iterative scheme continues until convergence is obtained—that is, until $\boldsymbol{\theta}^{(i+1)}$ is sufficiently close to $\boldsymbol{\theta}^{(i)}$. Then the maximum likelihood estimate of $\boldsymbol{\theta}$ is $\hat{\boldsymbol{\theta}} = \boldsymbol{\theta}^{(i+1)}$.

By default, starting values are zero for the slope parameters, and starting values are the observed cumulative logits (that is, logits of the observed cumulative proportions of response) for the intercept parameters. Alternatively, the starting values can be specified with the **INEST=** option in the PROC SURVEYLOGISTIC statement.

Newton-Raphson Algorithm

Let

$$\begin{aligned} \mathbf{g} &= \sum_j w_j f_j \frac{\partial l_j}{\partial \boldsymbol{\theta}} \\ \mathbf{H} &= \sum_j -w_j f_j \frac{\partial^2 l_j}{\partial \boldsymbol{\theta}^2} \end{aligned}$$

be the gradient vector and the Hessian matrix, where $l_j = \log L_j$ is the log likelihood for the j th observation. With a starting value of $\boldsymbol{\theta}^{(0)}$, the pseudo-estimate $\hat{\boldsymbol{\theta}}$ of $\boldsymbol{\theta}$ is obtained iteratively until convergence is obtained:

$$\boldsymbol{\theta}^{(i+1)} = \boldsymbol{\theta}^{(i)} + \mathbf{H}^{-1} \mathbf{g}$$

where \mathbf{H} and \mathbf{g} are evaluated at the i th iteration $\boldsymbol{\theta}^{(i)}$. If the log likelihood evaluated at $\boldsymbol{\theta}^{(i+1)}$ is less than that evaluated at $\boldsymbol{\theta}^{(i)}$, then $\boldsymbol{\theta}^{(i+1)}$ is recomputed by step-halving or ridging. The iterative scheme continues until convergence is obtained—that is, until $\boldsymbol{\theta}^{(i+1)}$ is sufficiently close to $\boldsymbol{\theta}^{(i)}$. Then the maximum likelihood estimate of $\boldsymbol{\theta}$ is $\hat{\boldsymbol{\theta}} = \boldsymbol{\theta}^{(i+1)}$.

Convergence Criteria

Four convergence criteria are allowed: `ABSFCNV=`, `FCONV=`, `GCONV=`, and `XCONV=`. If you specify more than one convergence criterion, the optimization is terminated as soon as one of the criteria is satisfied. If none of the criteria is specified, the default is `GCONV=1E-8`.

Existence of Maximum Likelihood Estimates

The likelihood equation for a logistic regression model does not always have a finite solution. Sometimes there is a nonunique maximum on the boundary of the parameter space, at infinity. The existence, finiteness, and uniqueness of pseudo-estimates for the logistic regression model depend on the patterns of data points in the observation space (Albert and Anderson 1984; Santner and Duffy 1986).

Consider a binary response model. Let Y_j be the response of the i th subject, and let \mathbf{x}_j be the row vector of explanatory variables (including the constant 1 associated with the intercept). There are three mutually exclusive and exhaustive types of data configurations: complete separation, quasi-complete separation, and overlap.

Complete separation There is a complete separation of data points if there exists a vector \mathbf{b} that correctly allocates all observations to their response groups; that is,

$$\begin{cases} \mathbf{x}_j \mathbf{b} > 0 & Y_j = 1 \\ \mathbf{x}_j \mathbf{b} < 0 & Y_j = 2 \end{cases}$$

This configuration gives nonunique infinite estimates. If the iterative process of maximizing the likelihood function is allowed to continue, the log likelihood diminishes to zero, and the dispersion matrix becomes unbounded.

Quasi-complete separation The data are not completely separable, but there is a vector \mathbf{b} such that

$$\begin{cases} \mathbf{x}_j \mathbf{b} \geq 0 & Y_j = 1 \\ \mathbf{x}_j \mathbf{b} \leq 0 & Y_j = 2 \end{cases}$$

and equality holds for at least one subject in each response group. This configuration also yields nonunique infinite estimates. If the iterative process of maximizing the likelihood function is allowed to continue, the dispersion matrix becomes unbounded and the log likelihood diminishes to a nonzero constant.

Overlap If neither complete nor quasi-complete separation exists in the sample points, there is an overlap of sample points. In this configuration, the pseudo-estimates exist and are unique.

Complete separation and quasi-complete separation are problems typically encountered with small data sets. Although complete separation can occur with any type of data, quasi-complete separation is not likely with truly continuous explanatory variables.

The SURVEYLOGISTIC procedure uses a simple empirical approach to recognize the data configurations that lead to infinite parameter estimates. The basis of this approach is that any convergence method of maximizing the log likelihood must yield a solution that gives complete separation, if such a solution exists. In maximizing the log likelihood, there is no checking for complete or quasi-complete separation if convergence is attained in eight or fewer iterations. Subsequent to the eighth iteration, the probability of the observed response is computed for each observation. If the probability of the observed response is one for all observations, there is a complete separation of data points and the iteration process is stopped. If the complete separation of data has not been determined and an observation is identified to have an extremely large probability (≥ 0.95) of the observed response, there are two possible situations. First, there is overlap in the data set, and the observation is an atypical observation of its own group. The iterative process, if allowed to continue, stops when a maximum is reached. Second, there is quasi-complete separation in the data set, and the asymptotic dispersion matrix is unbounded. If any of the diagonal elements of the dispersion matrix for the standardized observations vectors (all explanatory variables standardized to zero mean and unit variance) exceeds 5,000, quasi-complete separation is declared and the iterative process is stopped. If either complete separation or quasi-complete separation is detected, a warning message is displayed in the procedure output.

Checking for quasi-complete separation is less foolproof than checking for complete separation. The **NOCHECK** option in the MODEL statement turns off the process of checking for infinite parameter estimates. In cases of complete or quasi-complete separation, turning off the checking process typically results in the procedure failing to converge.

Model Fitting Statistics

Suppose the model contains s explanatory effects. For the j th observation, let $\hat{\pi}_j$ be the estimated probability of the observed response. The three criteria displayed by the SURVEYLOGISTIC procedure are calculated as follows:

- $-2 \log$ likelihood:

$$-2 \text{ Log L} = -2 \sum_j w_j f_j \log(\hat{\pi}_j)$$

where w_j and f_j are the weight and frequency values, respectively, of the j th observation. For binary response models that use the events/trials syntax, this is equivalent to

$$-2 \text{ Log L} = -2 \sum_j w_j f_j \{r_j \log(\hat{\pi}_j) + (n_j - r_j) \log(1 - \hat{\pi}_j)\}$$

where r_j is the number of events, n_j is the number of trials, and $\hat{\pi}_j$ is the estimated event probability.

- Akaike information criterion:

$$\text{AIC} = -2 \text{ Log L} + 2p$$

where p is the number of parameters in the model. For cumulative response models, $p = k + s$, where k is the total number of response levels minus one, and s is the number of explanatory effects. For the generalized logit model, $p = k(s + 1)$.

- Schwarz criterion:

$$SC = -2 \text{ Log } L + p \log\left(\sum_j f_j\right)$$

where p is the number of parameters in the model. For cumulative response models, $p = k + s$, where k is the total number of response levels minus one, and s is the number of explanatory effects. For the generalized logit model, $p = k(s + 1)$.

The $-2 \log$ likelihood statistic has a chi-square distribution under the null hypothesis (that all the explanatory effects in the model are zero), and the procedure produces a p -value for this statistic. The AIC and SC statistics give two different ways of adjusting the $-2 \log$ likelihood statistic for the number of terms in the model and the number of observations used.

Generalized Coefficient of Determination

Cox and Snell (1989, pp. 208–209) propose the following generalization of the coefficient of determination to a more general linear model:

$$R^2 = 1 - \left\{ \frac{L(\mathbf{0})}{L(\hat{\boldsymbol{\theta}})} \right\}^{\frac{2}{n}}$$

where $L(\mathbf{0})$ is the likelihood of the intercept-only model, $L(\hat{\boldsymbol{\theta}})$ is the likelihood of the specified model, and n is the sample size. The quantity R^2 achieves a maximum of less than 1 for discrete models, where the maximum is given by

$$R_{\max}^2 = 1 - \{L(\mathbf{0})\}^{\frac{2}{n}}$$

Nagelkerke (1991) proposes the following adjusted coefficient, which can achieve a maximum value of 1:

$$\tilde{R}^2 = \frac{R^2}{R_{\max}^2}$$

Properties and interpretation of R^2 and \tilde{R}^2 are provided in Nagelkerke (1991). In the “Testing Global Null Hypothesis: BETA=0” table, R^2 is labeled as “RSquare” and \tilde{R}^2 is labeled as “Max-rescaled RSquare.” Use the **RSQUARE** option to request R^2 and \tilde{R}^2 .

INest= Data Set

You can specify starting values for the iterative algorithm in the **INest=** data set.

The **INest=** data set contains one observation for each **BY** group. The **INest=** data set must contain the intercept variables (named **Intercept** for binary response models and **Intercept**, **Intercept2**, **Intercept3**, and so forth, for ordinal response models) and all explanatory variables in the **MODEL** statement. If **BY** processing is used, the **INest=** data set should also include the **BY** variables, and there must be one observation for each **BY** group. If the **INest=** data set also contains the **_TYPE_** variable, only observations with **_TYPE_** value ‘PARMS’ are used as starting values.

Survey Design Information

Specification of Population Totals and Sampling Rates

To include a finite population correction (*fpc*) in Taylor series variance estimation, you can input either the sampling rate or the population total by using the **RATE=** or **TOTAL=** option in the PROC SURVEYLOGISTIC statement. (You cannot specify both of these options in the same PROC SURVEYLOGISTIC statement.) The **RATE=** and **TOTAL=** options apply only to Taylor series variance estimation. The procedure does not use a finite population correction for BRR or jackknife variance estimation.

If you do not specify the **RATE=** or **TOTAL=** option, the Taylor series variance estimation does not include a finite population correction. For fairly small sampling fractions, it is appropriate to ignore this correction. See Cochran (1977) and Kish (1965) for more information.

If your design has multiple stages of selection and you are specifying the **RATE=** option, you should input the first-stage sampling rate, which is the ratio of the number of PSUs in the sample to the total number of PSUs in the study population. If you are specifying the **TOTAL=** option for a multistage design, you should input the total number of PSUs in the study population. See the section “**Primary Sampling Units (PSUs)**” on page 7734 for more details.

For a nonstratified sample design, or for a stratified sample design with the same sampling rate or the same population total in all strata, you can use the **RATE=value** or **TOTAL=value** option. If your sample design is stratified with different sampling rates or population totals in different strata, use the **RATE=SAS-data-set** or **TOTAL=SAS-data-set** option to name a SAS data set that contains the stratum sampling rates or totals. This data set is called a *secondary data set*, as opposed to the *primary data set* that you specify with the **DATA=** option.

The secondary data set must contain all the stratification variables listed in the **STRATA** statement and all the variables in the **BY** statement. If there are formats associated with the **STRATA** variables and the **BY** variables, then the formats must be consistent in the primary and the secondary data sets. If you specify the **TOTAL=SAS-data-set** option, the secondary data set must have a variable named **_TOTAL_** that contains the stratum population totals. Or if you specify the **RATE=SAS-data-set** option, the secondary data set must have a variable named **_RATE_** that contains the stratum sampling rates. If the secondary data set contains more than one observation for any one stratum, then the procedure uses the first value of **_TOTAL_** or **_RATE_** for that stratum and ignores the rest.

The *value* in the **RATE=** option or the values of **_RATE_** in the secondary data set must be nonnegative numbers. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC SURVEYLOGISTIC converts that number to a proportion. The procedure treats the value 1 as 100% instead of 1%.

If you specify the **TOTAL=value** option, *value* must not be less than the sample size. If you provide stratum population totals in a secondary data set, these values must not be less than the corresponding stratum sample sizes.

Primary Sampling Units (PSUs)

When you have clusters, or primary sampling units (PSUs), in your sample design, the procedure estimates variance from the variation among PSUs when the Taylor series variance method is used. See the section “**Taylor Series (Linearization)**” on page 7739 for more information.

BRR or jackknife variance estimation methods draw multiple replicates (or subsamples) from the full sample by following a specific resampling scheme. These subsamples are constructed by deleting PSUs from the full sample.

If you use a **REPWEIGHTS** statement to provide replicate weights for BRR or jackknife variance estimation, you do not need to specify a **CLUSTER** statement. Otherwise, you should specify a **CLUSTER** statement whenever your design includes clustering at the first stage of sampling. If you do not specify a **CLUSTER** statement, then PROC SURVEYLOGISTIC treats each observation as a PSU.

Logistic Regression Models and Parameters

The SURVEYLOGISTIC procedure fits a logistic regression model and estimates the corresponding regression parameters. Each model uses the link function you specified in the **LINK=** option in the **MODEL** statement. There are four types of model you can use with the procedure: cumulative logit model, complementary log-log model, probit model, and generalized logit model.

Notation

Let Y be the response variable with categories $1, 2, \dots, D, D + 1$. The p covariates are denoted by a p -dimension row vector \mathbf{x} .

For a stratified clustered sample design, each observation is represented by a row vector, $(w_{hij}, \mathbf{y}'_{hij}, y_{hij(D+1)}, \mathbf{x}_{hij})$, where

- $h = 1, 2, \dots, H$ is the stratum index
- $i = 1, 2, \dots, n_h$ is the cluster index within stratum h
- $j = 1, 2, \dots, m_{hi}$ is the unit index within cluster i of stratum h
- w_{hij} denotes the sampling weight
- \mathbf{y}_{hij} is a D -dimensional column vector whose elements are indicator variables for the first D categories for variable Y . If the response of the j th unit of the i th cluster in stratum h falls in category d , the d th element of the vector is one, and the remaining elements of the vector are zero, where $d = 1, 2, \dots, D$.
- $y_{hij(D+1)}$ is the indicator variable for the $(D + 1)$ category of variable Y
- \mathbf{x}_{hij} denotes the k -dimensional row vector of explanatory variables for the j th unit of the i th cluster in stratum h . If there is an intercept, then $x_{hij1} \equiv 1$.
- $\tilde{n} = \sum_{h=1}^H n_h$ is the total number of clusters in the sample
- $n = \sum_{h=1}^H \sum_{i=1}^{n_h} m_{hi}$ is the total sample size

The following notations are also used:

- f_h denotes the sampling rate for stratum h
- π_{hij} is the expected vector of the response variable:

$$\begin{aligned}\pi_{hij} &= E(y_{hij} | \mathbf{x}_{hij}) \\ &= (\pi_{hij1}, \pi_{hij2}, \dots, \pi_{hijD})' \\ \pi_{hij(D+1)} &= E(y_{hij(D+1)} | \mathbf{x}_{hij})\end{aligned}$$

Note that $\pi_{hij(D+1)} = 1 - \mathbf{1}'\pi_{hij}$, where $\mathbf{1}$ is a D -dimensional column vector whose elements are 1.

Logistic Regression Models

If the response categories of the response variable Y can be restricted to a number of ordinal values, you can fit cumulative probabilities of the response categories with a cumulative logit model, a complementary log-log model, or a probit model. Details of cumulative logit models (or proportional odds models) can be found in McCullagh and Nelder (1989). If the response categories of Y are nominal responses without natural ordering, you can fit the response probabilities with a generalized logit model. Formulation of the generalized logit models for nominal response variables can be found in Agresti (2002). For each model, the procedure estimates the model parameter θ by using a pseudo-log-likelihood function. The procedure obtains the pseudo-maximum likelihood estimator $\hat{\theta}$ by using iterations described in the section “[Iterative Algorithms for Model Fitting](#)” on page 7729 and estimates its variance described in the section “[Variance Estimation](#)” on page 7738.

Cumulative Logit Model

A cumulative logit model uses the **logit** function

$$g(t) = \log\left(\frac{t}{1-t}\right)$$

as the link function.

Denote the cumulative sum of the expected proportions for the first d categories of variable Y by

$$F_{hijd} = \sum_{r=1}^d \pi_{hijr}$$

for $d = 1, 2, \dots, D$. Then the cumulative logit model can be written as

$$\log\left(\frac{F_{hijd}}{1 - F_{hijd}}\right) = \alpha_d + \mathbf{x}_{hij}\boldsymbol{\beta}$$

with the model parameters

$$\begin{aligned}\boldsymbol{\beta} &= (\beta_1, \beta_2, \dots, \beta_k)' \\ \boldsymbol{\alpha} &= (\alpha_1, \alpha_2, \dots, \alpha_D)', \quad \alpha_1 < \alpha_2 < \dots < \alpha_D \\ \boldsymbol{\theta} &= (\boldsymbol{\alpha}', \boldsymbol{\beta}')'\end{aligned}$$

Complementary Log-Log Model

A complementary log-log model uses the **complementary log-log** function

$$g(t) = \log(-\log(1 - t))$$

as the link function. Denote the cumulative sum of the expected proportions for the first d categories of variable Y by

$$F_{hijd} = \sum_{r=1}^d \pi_{hijr}$$

for $d = 1, 2, \dots, D$. Then the complementary log-log model can be written as

$$\log(-\log(1 - F_{hijd})) = \alpha_d + \mathbf{x}_{hij}\boldsymbol{\beta}$$

with the model parameters

$$\begin{aligned}\boldsymbol{\beta} &= (\beta_1, \beta_2, \dots, \beta_k)' \\ \boldsymbol{\alpha} &= (\alpha_1, \alpha_2, \dots, \alpha_D)', \quad \alpha_1 < \alpha_2 < \dots < \alpha_D \\ \boldsymbol{\theta} &= (\boldsymbol{\alpha}', \boldsymbol{\beta}')'\end{aligned}$$

Probit Model

A probit model uses the **probit** (or normit) function, which is the inverse of the cumulative standard normal distribution function,

$$g(t) = \Phi^{-1}(t)$$

as the link function, where

$$\Phi(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^t e^{-\frac{1}{2}z^2} dz$$

Denote the cumulative sum of the expected proportions for the first d categories of variable Y by

$$F_{hijd} = \sum_{r=1}^d \pi_{hijr}$$

for $d = 1, 2, \dots, D$. Then the probit model can be written as

$$F_{hijd} = \Phi(\alpha_d + \mathbf{x}_{hij}\boldsymbol{\beta})$$

with the model parameters

$$\begin{aligned}\boldsymbol{\beta} &= (\beta_1, \beta_2, \dots, \beta_k)' \\ \boldsymbol{\alpha} &= (\alpha_1, \alpha_2, \dots, \alpha_D)', \quad \alpha_1 < \alpha_2 < \dots < \alpha_D \\ \boldsymbol{\theta} &= (\boldsymbol{\alpha}', \boldsymbol{\beta}')'\end{aligned}$$

Generalized Logit Model

For nominal response, a generalized logit model is to fit the ratio of the expected proportion for each response category over the expected proportion of a reference category with a logit link function.

Without loss of generality, let category $D + 1$ be the reference category for the response variable Y . Denote the expected proportion for the d th category by $\pi_{hij d}$ as in the section “Notation” on page 7735. Then the generalized logit model can be written as

$$\log \left(\frac{\pi_{hij d}}{\pi_{hij(D+1)}} \right) = \mathbf{x}_{hij} \boldsymbol{\beta}_d$$

for $d = 1, 2, \dots, D$, with the model parameters

$$\begin{aligned} \boldsymbol{\beta}_d &= (\beta_{d1}, \beta_{d2}, \dots, \beta_{dk})' \\ \boldsymbol{\theta} &= (\boldsymbol{\beta}'_1, \boldsymbol{\beta}'_2, \dots, \boldsymbol{\beta}'_D)' \end{aligned}$$

Likelihood Function

Let $g(\cdot)$ be a link function such that

$$\boldsymbol{\pi} = g(\mathbf{x}, \boldsymbol{\theta})$$

where $\boldsymbol{\theta}$ is a column vector for regression coefficients. The pseudo-log likelihood is

$$l(\boldsymbol{\theta}) = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} \left((\log(\boldsymbol{\pi}_{hij}))' \mathbf{y}_{hij} + \log(\pi_{hij(D+1)}) y_{hij(D+1)} \right)$$

Denote the pseudo-estimator as $\hat{\boldsymbol{\theta}}$, which is a solution to the estimating equations:

$$\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} \mathbf{D}_{hij} \left(\text{diag}(\boldsymbol{\pi}_{hij}) - \boldsymbol{\pi}_{hij} \boldsymbol{\pi}_{hij}' \right)^{-1} (\mathbf{y}_{hij} - \boldsymbol{\pi}_{hij}) = \mathbf{0}$$

where \mathbf{D}_{hij} is the matrix of partial derivatives of the link function g with respect to $\boldsymbol{\theta}$.

To obtain the pseudo-estimator $\hat{\boldsymbol{\theta}}$, the procedure uses iterations with a starting value $\boldsymbol{\theta}^{(0)}$ for $\boldsymbol{\theta}$. See the section “Iterative Algorithms for Model Fitting” on page 7729 for more details.

Variance Estimation

Due to the variability of characteristics among items in the population, researchers apply scientific sample designs in the sample selection process to reduce the risk of a distorted view of the population, and they make inferences about the population based on the information from the sample survey data. In order to make statistically valid inferences for the population, they must incorporate the sample design in the data analysis.

The SURVEYLOGISTIC procedure fits linear logistic regression models for discrete response survey data by using the maximum likelihood method. In the variance estimation, the procedure uses the Taylor series

(linearization) method or replication (resampling) methods to estimate sampling errors of estimators based on complex sample designs, including designs with stratification, clustering, and unequal weighting (Binder 1981, 1983; Roberts, Rao, and Kumar 1987; Skinner, Holt, and Smith 1989; Binder and Roberts 2003; Morel 1989; Lehtonen and Pahkinen 1995; Woodruff 1971; Fuller 1975; Särndal, Swensson, and Wretman 1992; Fuller 2009; Wolter 2007; Rust 1985; Dippo, Fay, and Morganstein 1984; Rao and Shao 1999; Rao, Wu, and Yue 1992; Rao and Shao 1996).

You can use the **VARMETHOD=** option to specify a variance estimation method to use. By default, the Taylor series method is used. However, replication methods have recently gained popularity for estimating variances in complex survey data analysis. One reason for this popularity is the relative simplicity of replication-based estimates, especially for nonlinear estimators; another is that modern computational capacity has made replication methods feasible for practical survey analysis.

Replication methods draw multiple replicates (also called subsamples) from a full sample according to a specific resampling scheme. The most commonly used resampling schemes are the *balanced repeated replication* (BRR) method and the *jackknife* method. For each replicate, the original weights are modified for the PSUs in the replicates to create replicate weights. The parameters of interest are estimated by using the replicate weights for each replicate. Then the variances of parameters of interest are estimated by the variability among the estimates derived from these replicates. You can use the **REPWEIGHTS** statement to provide your own replicate weights for variance estimation.

The following sections provide details about how the variance-covariance matrix of the estimated regression coefficients is estimated for each variance estimation method.

Taylor Series (Linearization)

The Taylor series (linearization) method is the most commonly used method to estimate the covariance matrix of the regression coefficients for complex survey data. It is the default variance estimation method used by PROC SURVEYLOGISTIC.

Using the notation described in the section “**Notation**” on page 7735, the estimated covariance matrix of model parameters $\hat{\theta}$ by the Taylor series method is

$$\widehat{V}(\hat{\theta}) = \widehat{Q}^{-1} \widehat{G} \widehat{Q}^{-1}$$

where

$$\begin{aligned} \widehat{Q} &= \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} \widehat{D}_{hij} \left(\text{diag}(\hat{\pi}_{hij}) - \hat{\pi}_{hij} \hat{\pi}_{hij}' \right)^{-1} \widehat{D}_{hij}' \\ \widehat{G} &= \frac{n-1}{n-p} \sum_{h=1}^H \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (\mathbf{e}_{hi\cdot} - \bar{\mathbf{e}}_{h\cdot\cdot})(\mathbf{e}_{hi\cdot} - \bar{\mathbf{e}}_{h\cdot\cdot})' \\ \mathbf{e}_{hi\cdot} &= \sum_{j=1}^{m_{hi}} w_{hij} \widehat{D}_{hij} \left(\text{diag}(\hat{\pi}_{hij}) - \hat{\pi}_{hij} \hat{\pi}_{hij}' \right)^{-1} (\mathbf{y}_{hij} - \hat{\pi}_{hij}) \\ \bar{\mathbf{e}}_{h\cdot\cdot} &= \frac{1}{n_h} \sum_{i=1}^{n_h} \mathbf{e}_{hi\cdot} \end{aligned}$$

and \mathbf{D}_{hij} is the matrix of partial derivatives of the link function g with respect to θ and \widehat{D}_{hij} and the response probabilities $\hat{\pi}_{hij}$ are evaluated at $\hat{\theta}$.

If you specify the **TECHNIQUE=NEWTON** option in the MODEL statement to request the **Newton-Raphson algorithm**, the matrix $\widehat{\mathbf{Q}}$ is replaced by the negative (expected) Hessian matrix when the estimated covariance matrix $\widehat{\mathbf{V}}(\hat{\boldsymbol{\theta}})$ is computed.

Adjustments to the Variance Estimation

The factor $(n - 1)/(n - p)$ in the computation of the matrix $\widehat{\mathbf{G}}$ reduces the small sample bias associated with using the estimated function to calculate deviations (Morel 1989; Hidioglou, Fuller, and Hickman 1980). For simple random sampling, this factor contributes to the degrees-of-freedom correction applied to the residual mean square for ordinary least squares in which p parameters are estimated. By default, the procedure uses this adjustment in Taylor series variance estimation. It is equivalent to specifying the **VADJUST=DF** option in the MODEL statement. If you do not want to use this multiplier in the variance estimation, you can specify the **VADJUST=NONE** option in the MODEL statement to suppress this factor.

In addition, you can specify the **VADJUST=MOREL** option to request an adjustment to the variance estimator for the model parameters $\hat{\boldsymbol{\theta}}$, introduced by Morel (1989):

$$\widehat{\mathbf{V}}(\hat{\boldsymbol{\theta}}) = \widehat{\mathbf{Q}}^{-1} \widehat{\mathbf{G}} \widehat{\mathbf{Q}}^{-1} + \kappa \lambda \widehat{\mathbf{Q}}^{-1}$$

where for given nonnegative constants δ and ϕ ,

$$\begin{aligned} \kappa &= \max\left(\delta, p^{-1} \text{tr}\left(\widehat{\mathbf{Q}}^{-1} \widehat{\mathbf{G}}\right)\right) \\ \lambda &= \min\left(\phi, \frac{p}{\tilde{n} - p}\right) \end{aligned}$$

The adjustment $\kappa \lambda \widehat{\mathbf{Q}}^{-1}$ does the following:

- reduces the small sample bias reflected in inflated Type I error rates
- guarantees a positive-definite estimated covariance matrix provided that $\widehat{\mathbf{Q}}^{-1}$ exists
- is close to zero when the sample size becomes large

In this adjustment, κ is an estimate of the design effect, which has been bounded below by the positive constant δ . You can use **DEFFBOUND= δ** in the **VADJUST=MOREL** option in the MODEL statement to specify this lower bound; by default, the procedure uses $\delta = 1$. The factor λ converges to zero when the sample size becomes large, and λ has an upper bound ϕ . You can use **ADJBOUND= ϕ** in the **VADJUST=MOREL** option in the MODEL statement to specify this upper bound; by default, the procedure uses $\phi = 0.5$.

Balanced Repeated Replication (BRR) Method

The balanced repeated replication (BRR) method requires that the full sample be drawn by using a stratified sample design with two primary sampling units (PSUs) per stratum. Let H be the total number of strata. The total number of replicates R is the smallest multiple of 4 that is greater than H . However, if you prefer a larger number of replicates, you can specify the **REPS=number** option. If a $\text{number} \times \text{number}$ **Hadamard matrix** cannot be constructed, the number of replicates is increased until a Hadamard matrix becomes available.

Each replicate is obtained by deleting one PSU per stratum according to the corresponding **Hadamard matrix** and adjusting the original weights for the remaining PSUs. The new weights are called replicate weights.

Replicates are constructed by using the first H columns of the $R \times R$ **Hadamard matrix**. The r th ($r = 1, 2, \dots, R$) replicate is drawn from the full sample according to the r th row of the Hadamard matrix as follows:

- If the (r, h) element of the Hadamard matrix is 1, then the first PSU of stratum h is included in the r th replicate and the second PSU of stratum h is excluded.
- If the (r, h) element of the Hadamard matrix is -1 , then the second PSU of stratum h is included in the r th replicate and the first PSU of stratum h is excluded.

Note that the “first” and “second” PSUs are determined by data order in the input data set. Thus, if you reorder the data set and perform the same analysis by using BRR method, you might get slightly different results, because the contents in each replicate sample might change.

The replicate weights of the remaining PSUs in each half-sample are then doubled to their original weights. For more details about the BRR method, see Wolter (2007) and Lohr (2010).

By default, an appropriate Hadamard matrix is generated automatically to create the replicates. You can request that the Hadamard matrix be displayed by specifying the **VARMETHOD=BRR(PRINTH)** *method-option*. If you provide a Hadamard matrix by specifying the **VARMETHOD=BRR(HADAMARD=)** *method-option*, then the replicates are generated according to the provided Hadamard matrix.

You can use the **VARMETHOD=BRR(OUTWEIGHTS=)** *method-option* to save the replicate weights into a SAS data set.

Let $\hat{\theta}$ be the estimated regression coefficients from the full sample for θ , and let $\hat{\theta}_r$ be the estimated regression coefficient from the r th replicate by using replicate weights. PROC SURVEYLOGISTIC estimates the covariance matrix of $\hat{\theta}$ by

$$\widehat{V}(\hat{\theta}) = \frac{1}{R} \sum_{r=1}^R (\hat{\theta}_r - \hat{\theta}) (\hat{\theta}_r - \hat{\theta})'$$

with H degrees of freedom, where H is the number of strata.

Fay's BRR Method

Fay's method is a modification of the **BRR** method, and it requires a stratified sample design with two primary sampling units (PSUs) per stratum. The total number of replicates R is the smallest multiple of 4 that is greater than the total number of strata H . However, if you prefer a larger number of replicates, you can specify the **REPS=** *method-option*.

For each replicate, Fay's method uses a Fay coefficient $0 \leq \epsilon < 1$ to impose a perturbation of the original weights in the full sample that is gentler than using only half-samples, as in the traditional BRR method. The Fay coefficient $0 \leq \epsilon < 1$ can be set by specifying the **FAY = ϵ** *method-option*. By default, $\epsilon = 0.5$ if the **FAY** *method-option* is specified without providing a value for ϵ (Judkins 1990; Rao and Shao 1999). When $\epsilon = 0$, Fay's method becomes the traditional **BRR** method. For more details, see Dippo, Fay, and Morganstein (1984); Fay (1984, 1989); Judkins (1990).

Let H be the number of strata. Replicates are constructed by using the first H columns of the $R \times R$ Hadamard matrix, where R is the number of replicates, $R > H$. The r th ($r = 1, 2, \dots, R$) replicate is created from the full sample according to the r th row of the Hadamard matrix as follows:

- If the (r, h) element of the Hadamard matrix is 1, then the full sample weight of the first PSU in stratum h is multiplied by ϵ and the full sample weight of the second PSU is multiplied by $2 - \epsilon$ to obtain the r th replicate weights.
- If the (r, h) element of the Hadamard matrix is -1 , then the full sample weight of the first PSU in stratum h is multiplied by $2 - \epsilon$ and the full sample weight of the second PSU is multiplied by ϵ to obtain the r th replicate weights.

You can use the **VARMETHOD=BRR(OUTWEIGHTS=)** *method-option* to save the replicate weights into a SAS data set.

By default, an appropriate Hadamard matrix is generated automatically to create the replicates. You can request that the Hadamard matrix be displayed by specifying the **VARMETHOD=BRR(PRINTH)** *method-option*. If you provide a Hadamard matrix by specifying the **VARMETHOD=BRR(HADAMARD=)** *method-option*, then the replicates are generated according to the provided Hadamard matrix.

Let $\hat{\theta}$ be the estimated regression coefficients from the full sample for θ . Let $\hat{\theta}_r$ be the estimated regression coefficient obtained from the r th replicate by using replicate weights. PROC SURVEYLOGISTIC estimates the covariance matrix of $\hat{\theta}$ by

$$\widehat{V}(\hat{\theta}) = \frac{1}{R(1 - \epsilon)^2} \sum_{r=1}^R (\hat{\theta}_r - \hat{\theta}) (\hat{\theta}_r - \hat{\theta})'$$

with H degrees of freedom, where H is the number of strata.

Jackknife Method

The jackknife method of variance estimation deletes one PSU at a time from the full sample to create replicates. The total number of replicates R is the same as the total number of PSUs. In each replicate, the sample weights of the remaining PSUs are modified by the jackknife coefficient α_r . The modified weights are called replicate weights.

The jackknife coefficient and replicate weights are described as follows.

Without Stratification If there is no stratification in the sample design (no **STRATA** statement), the jackknife coefficients α_r are the same for all replicates:

$$\alpha_r = \frac{R - 1}{R} \quad \text{where } r = 1, 2, \dots, R$$

Denote the original weight in the full sample for the j th member of the i th PSU as w_{ij} . If the i th PSU is included in the r th replicate ($r = 1, 2, \dots, R$), then the corresponding replicate weight for the j th member of the i th PSU is defined as

$$w_{ij}^{(r)} = w_{ij} / \alpha_r$$

With Stratification If the sample design involves stratification, each stratum must have at least two PSUs to use the jackknife method.

Let stratum \tilde{h}_r be the stratum from which a PSU is deleted for the r th replicate. Stratum \tilde{h}_r is called the *donor stratum*. Let $n_{\tilde{h}_r}$ be the total number of PSUs in the donor stratum \tilde{h}_r . The jackknife coefficients are defined as

$$\alpha_r = \frac{n_{\tilde{h}_r} - 1}{n_{\tilde{h}_r}} \quad \text{where } r = 1, 2, \dots, R$$

Denote the original weight in the full sample for the j th member of the i th PSU as w_{ij} . If the i th PSU is included in the r th replicate ($r = 1, 2, \dots, R$), then the corresponding replicate weight for the j th member of the i th PSU is defined as

$$w_{ij}^{(r)} = \begin{cases} w_{ij} & \text{if } i\text{th PSU is not in the donor stratum } \tilde{h}_r \\ w_{ij}/\alpha_r & \text{if } i\text{th PSU is in the donor stratum } \tilde{h}_r \end{cases}$$

You can use the `VARMETHOD=JACKKNIFE(OUTJKCOEFS=)` *method-option* to save the jackknife coefficients into a SAS data set and use the `VARMETHOD=JACKKNIFE(OUTWEIGHTS=)` *method-option* to save the replicate weights into a SAS data set.

If you provide your own replicate weights with a `REPWEIGHTS` statement, then you can also provide corresponding jackknife coefficients with the `JKCOEFS=` option.

Let $\hat{\theta}$ be the estimated regression coefficients from the full sample for θ . Let $\hat{\theta}_r$ be the estimated regression coefficient obtained from the r th replicate by using replicate weights. PROC SURVEYLOGISTIC estimates the covariance matrix of $\hat{\theta}$ by

$$\hat{V}(\hat{\theta}) = \sum_{r=1}^R \alpha_r (\hat{\theta}_r - \hat{\theta}) (\hat{\theta}_r - \hat{\theta})'$$

with $R - H$ degrees of freedom, where R is the number of replicates and H is the number of strata, or $R - 1$ when there is no stratification.

Hadamard Matrix

A Hadamard matrix \mathbf{H} is a square matrix whose elements are either 1 or -1 such that

$$\mathbf{H}\mathbf{H}' = k\mathbf{I}$$

where k is the dimension of \mathbf{H} and \mathbf{I} is the identity matrix of order k . The order k is necessarily 1, 2, or a positive integer that is a multiple of 4.

For example, the following matrix is a Hadamard matrix of dimension $k = 8$:

$$\begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\ 1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \end{bmatrix}$$

Domain Analysis

A **DOMAIN** statement requests that the procedure perform logistic regression analysis for each domain.

For a domain Ω , let I_Ω be the corresponding indicator variable:

$$I_\Omega(h, i, j) = \begin{cases} 1 & \text{if observation } (h, i, j) \text{ belongs to } \Omega \\ 0 & \text{otherwise} \end{cases}$$

Let

$$v_{hij} = w_{hij} I_\Omega(h, i, j) = \begin{cases} w_{hij} & \text{if observation } (h, i, j) \text{ belongs to } \Omega \\ 0 & \text{otherwise} \end{cases}$$

The regression in domain Ω uses v as the weight variable.

Hypothesis Testing and Estimation

Score Statistics and Tests

To understand the general form of the score statistics, let $\mathbf{g}(\boldsymbol{\theta})$ be the vector of first partial derivatives of the log likelihood with respect to the parameter vector $\boldsymbol{\theta}$, and let $\mathbf{H}(\boldsymbol{\theta})$ be the matrix of second partial derivatives of the log likelihood with respect to $\boldsymbol{\theta}$. That is, $\mathbf{g}(\boldsymbol{\theta})$ is the gradient vector, and $\mathbf{H}(\boldsymbol{\theta})$ is the Hessian matrix. Let $\mathbf{I}(\boldsymbol{\theta})$ be either $-\mathbf{H}(\boldsymbol{\theta})$ or the expected value of $-\mathbf{H}(\boldsymbol{\theta})$. Consider a null hypothesis H_0 . Let $\hat{\boldsymbol{\theta}}$ be the MLE of $\boldsymbol{\theta}$ under H_0 . The chi-square score statistic for testing H_0 is defined by

$$\mathbf{g}'(\hat{\boldsymbol{\theta}}) \mathbf{I}^{-1}(\hat{\boldsymbol{\theta}}) \mathbf{g}(\hat{\boldsymbol{\theta}})$$

It has an asymptotic χ^2 distribution with r degrees of freedom under H_0 , where r is the number of restrictions imposed on $\boldsymbol{\theta}$ by H_0 .

Testing the Parallel Lines Assumption

For an ordinal response, PROC SURVEYLOGISTIC performs a test of the parallel lines assumption. In the displayed output, this test is labeled “Score Test for the Equal Slopes Assumption” when the **LINK=** option is **NORMIT** or **CLOGLOG**. When **LINK=LOGIT**, the test is labeled as “Score Test for the Proportional Odds Assumption” in the output. This section describes the methods used to calculate the test.

For this test, the number of response levels, $D + 1$, is assumed to be strictly greater than 2. Let Y be the response variable taking values $1, \dots, D, D + 1$. Suppose there are k explanatory variables. Consider the general cumulative model without making the parallel lines assumption:

$$g(\Pr(Y \leq d \mid \mathbf{x})) = (1, \mathbf{x}) \boldsymbol{\theta}_d, \quad 1 \leq d \leq D$$

where $g(\cdot)$ is the link function, and $\boldsymbol{\theta}_d = (\alpha_d, \beta_{d1}, \dots, \beta_{dk})'$ is a vector of unknown parameters consisting of an intercept α_d and k slope parameters $\beta_{k1}, \dots, \beta_{kd}$. The parameter vector for this general cumulative model is

$$\boldsymbol{\theta} = (\boldsymbol{\theta}'_1, \dots, \boldsymbol{\theta}'_D)'$$

Under the null hypothesis of parallelism $H_0: \beta_{1i} = \beta_{2i} = \dots = \beta_{Di}, 1 \leq i \leq k$, there is a single common slope parameter for each of the s explanatory variables. Let β_1, \dots, β_k be the common slope parameters. Let $\hat{\alpha}_1, \dots, \hat{\alpha}_D$ and $\hat{\beta}_1, \dots, \hat{\beta}_D$ be the MLEs of the intercept parameters and the common slope parameters. Then, under H_0 , the MLE of θ is

$$\hat{\theta} = (\hat{\theta}'_1, \dots, \hat{\theta}'_D)' \quad \text{with} \quad \hat{\theta}_d = (\hat{\alpha}_d, \hat{\beta}_1, \dots, \hat{\beta}_k)', \quad 1 \leq d \leq D$$

and the chi-square score statistic $\mathbf{g}'(\hat{\theta})\mathbf{I}^{-1}(\hat{\theta})\mathbf{g}(\hat{\theta})$ has an asymptotic chi-square distribution with $k(D - 1)$ degrees of freedom. This tests the parallel lines assumption by testing the equality of separate slope parameters simultaneously for all explanatory variables.

Wald Confidence Intervals for Parameters

Wald confidence intervals are sometimes called normal confidence intervals. They are based on the asymptotic normality of the parameter estimators. The $100(1 - \alpha)\%$ Wald confidence interval for θ_j is given by

$$\hat{\theta}_j \pm z_{1-\alpha/2} \hat{\sigma}_j$$

where $z_{1-\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the standard normal distribution, $\hat{\theta}_j$ is the pseudo-estimate of θ_j , and $\hat{\sigma}_j$ is the standard error estimate of $\hat{\theta}_j$ in the section “[Variance Estimation](#)” on page 7738.

Testing Linear Hypotheses about the Regression Coefficients

Linear hypotheses for θ are expressed in matrix form as

$$H_0: \mathbf{L}\theta = \mathbf{c}$$

where \mathbf{L} is a matrix of coefficients for the linear hypotheses and \mathbf{c} is a vector of constants. The vector of regression coefficients θ includes slope parameters as well as intercept parameters. The Wald chi-square statistic for testing H_0 is computed as

$$\chi^2_W = (\mathbf{L}\hat{\theta} - \mathbf{c})'[\mathbf{L}\hat{\mathbf{V}}(\hat{\theta})\mathbf{L}']^{-1}(\mathbf{L}\hat{\theta} - \mathbf{c})$$

where $\hat{\mathbf{V}}(\hat{\theta})$ is the estimated covariance matrix in the section “[Variance Estimation](#)” on page 7738. Under H_0 , χ^2_W has an asymptotic chi-square distribution with r degrees of freedom, where r is the rank of \mathbf{L} .

Odds Ratio Estimation

Consider a dichotomous response variable with outcomes *event* and *nonevent*. Let a dichotomous risk factor variable X take the value 1 if the risk factor is present and 0 if the risk factor is absent. According to the logistic model, the log odds function, $g(X)$, is given by

$$g(X) \equiv \log\left(\frac{\Pr(\text{event} | X)}{\Pr(\text{nonevent} | X)}\right) = \beta_0 + \beta_1 X$$

The odds ratio ψ is defined as the ratio of the odds for those with the risk factor ($X = 1$) to the odds for those without the risk factor ($X = 0$). The log of the odds ratio is given by

$$\log(\psi) \equiv \log(\psi(X = 1, X = 0)) = g(X = 1) - g(X = 0) = \beta_1$$

The parameter, β_1 , associated with X represents the change in the log odds from $X = 0$ to $X = 1$. So the odds ratio is obtained by simply exponentiating the value of the parameter associated with the risk factor. The odds ratio indicates how the odds of *event* change as you change X from 0 to 1. For instance, $\psi = 2$ means that the odds of an event when $X = 1$ are twice the odds of an event when $X = 0$.

Suppose the values of the dichotomous risk factor are coded as constants a and b instead of 0 and 1. The odds when $X = a$ become $\exp(\beta_0 + a\beta_1)$, and the odds when $X = b$ become $\exp(\beta_0 + b\beta_1)$. The odds ratio corresponding to an increase in X from a to b is

$$\psi = \exp[(b - a)\beta_1] = [\exp(\beta_1)]^{b-a} \equiv [\exp(\beta_1)]^c$$

Note that for any a and b such that $c = b - a = 1$, $\psi = \exp(\beta_1)$. So the odds ratio can be interpreted as the change in the odds for any increase of one unit in the corresponding risk factor. However, the change in odds for some amount other than one unit is often of greater interest. For example, a change of one pound in body weight might be too small to be considered important, while a change of 10 pounds might be more meaningful. The odds ratio for a change in X from a to b is estimated by raising the odds ratio estimate for a unit change in X to the power of $c = b - a$, as shown previously.

For a polytomous risk factor, the computation of odds ratios depends on how the risk factor is parameterized. For illustration, suppose that **Race** is a risk factor with four categories: White, Black, Hispanic, and Other.

For the effect parameterization scheme (PARAM=EFFECT) with White as the reference group, the design variables for **Race** are as follows.

Race	Design Variables		
	X_1	X_2	X_3
Black	1	0	0
Hispanic	0	1	0
Other	0	0	1
White	-1	-1	-1

The log odds for Black is

$$\begin{aligned} g(\text{Black}) &= \beta_0 + \beta_1(X_1 = 1) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) \\ &= \beta_0 + \beta_1 \end{aligned}$$

The log odds for White is

$$\begin{aligned} g(\text{White}) &= \beta_0 + \beta_1(X_1 = -1) + \beta_2(X_2 = -1) + \beta_3(X_3 = -1) \\ &= \beta_0 - \beta_1 - \beta_2 - \beta_3 \end{aligned}$$

Therefore, the log odds ratio of Black versus White becomes

$$\begin{aligned} \log(\psi(\text{Black, White})) &= g(\text{Black}) - g(\text{White}) \\ &= 2\beta_1 + \beta_2 + \beta_3 \end{aligned}$$

For the reference cell parameterization scheme (PARAM=REF) with White as the reference cell, the design variables for race are as follows.

Race	Design Variables		
	X_1	X_2	X_3
Black	1	0	0
Hispanic	0	1	0
Other	0	0	1
White	0	0	0

The log odds ratio of Black versus White is given by

$$\begin{aligned}
 \log(\psi(\text{Black}, \text{White})) &= g(\text{Black}) - g(\text{White}) \\
 &= (\beta_0 + \beta_1(X_1 = 1) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0)) - \\
 &\quad (\beta_0 + \beta_1(X_1 = 0) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0)) \\
 &= \beta_1
 \end{aligned}$$

For the GLM parameterization scheme (PARAM=GLM), the design variables are as follows.

Race	Design Variables			
	X_1	X_2	X_3	X_4
Black	1	0	0	0
Hispanic	0	1	0	0
Other	0	0	1	0
White	0	0	0	1

The log odds ratio of Black versus White is

$$\begin{aligned}
 \log(\psi(\text{Black}, \text{White})) &= g(\text{Black}) - g(\text{White}) \\
 &= (\beta_0 + \beta_1(X_1 = 1) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) + \beta_4(X_4 = 0)) - \\
 &\quad (\beta_0 + \beta_1(X_1 = 0) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) + \beta_4(X_4 = 1)) \\
 &= \beta_1 - \beta_4
 \end{aligned}$$

Consider the hypothetical example of heart disease among race in Hosmer and Lemeshow (2000, p. 51). The entries in the following contingency table represent counts.

Disease Status	Race			
	White	Black	Hispanic	Other
Present	5	20	15	10
Absent	20	10	10	10

The computation of odds ratio of Black versus White for various parameterization schemes is shown in Table 91.9.

Table 91.9 Odds Ratio of Heart Disease Comparing Black to White

PARAM=	Parameter Estimates				Odds Ratio Estimates
	$\hat{\beta}_1$	$\hat{\beta}_2$	$\hat{\beta}_3$	$\hat{\beta}_4$	
EFFECT	0.7651	0.4774	0.0719		$\exp(2 \times 0.7651 + 0.4774 + 0.0719) = 8$
REF	2.0794	1.7917	1.3863		$\exp(2.0794) = 8$
GLM	2.0794	1.7917	1.3863	0.0000	$\exp(2.0794) = 8$

Since the log odds ratio ($\log(\psi)$) is a linear function of the parameters, the Wald confidence interval for $\log(\psi)$ can be derived from the parameter estimates and the estimated covariance matrix. Confidence intervals for the odds ratios are obtained by exponentiating the corresponding confidence intervals for the log odds ratios. In the displayed output of PROC SURVEYLOGISTIC, the “Odds Ratio Estimates” table contains the odds ratio estimates and the corresponding 95% Wald confidence intervals computed by using the covariance matrix in the section “Variance Estimation” on page 7738. For continuous explanatory variables, these odds ratios correspond to a unit increase in the risk factors.

To customize odds ratios for specific units of change for a continuous risk factor, you can use the **UNITS** statement to specify a list of relevant units for each explanatory variable in the model. Estimates of these customized odds ratios are given in a separate table. Let (L_j, U_j) be a confidence interval for $\log(\psi)$. The corresponding lower and upper confidence limits for the customized odds ratio $\exp(c\beta_j)$ are $\exp(cL_j)$ and $\exp(cU_j)$, respectively, (for $c > 0$); or $\exp(cU_j)$ and $\exp(cL_j)$, respectively, (for $c < 0$). You use the **CLODDS** option in the MODEL statement to request confidence intervals for the odds ratios.

For a generalized logit model, odds ratios are computed similarly, except D odds ratios are computed for each effect, corresponding to the D logits in the model.

Rank Correlation of Observed Responses and Predicted Probabilities

The predicted mean score of an observation is the sum of the Ordered Values (shown in the “Response Profile” table) minus one, weighted by the corresponding predicted probabilities for that observation; that is, the predicted mean score is $\sum_{d=1}^{D+1} (d-1)\hat{\pi}_d$, where $D+1$ is the number of response levels and $\hat{\pi}_d$ is the predicted probability of the d th (ordered) response.

A pair of observations with different observed responses is said to be *concordant* if the observation with the lower ordered response value has a lower predicted mean score than the observation with the higher ordered response value. If the observation with the lower ordered response value has a higher predicted mean score than the observation with the higher ordered response value, then the pair is *discordant*. If the pair is neither concordant nor discordant, it is a *tie*. Enumeration of the total numbers of concordant and discordant pairs is carried out by categorizing the predicted mean score into intervals of length $D/500$ and accumulating the corresponding frequencies of observations.

Let N be the sum of observation frequencies in the data. Suppose there are a total of t pairs with different responses, n_c of them are concordant, n_d of them are discordant, and $t - n_c - n_d$ of them are tied. PROC SURVEYLOGISTIC computes the following four indices of rank correlation for assessing the predictive ability of a model:

$$c = (n_c + 0.5(t - n_c - n_d))/t$$

$$\text{Somers' } D = (n_c - n_d)/t$$

$$\text{Goodman-Kruskal Gamma} = (n_c - n_d)/(n_c + n_d)$$

$$\text{Kendall's Tau-}a = (n_c - n_d)/(0.5N(N - 1))$$

Note that c also gives an estimate of the area under the receiver operating characteristic (ROC) curve when the response is binary (Hanley and McNeil 1982).

For binary responses, the predicted mean score is equal to the predicted probability for Ordered Value 2. As such, the preceding definition of concordance is consistent with the definition used in previous releases for the binary response model.

Linear Predictor, Predicted Probability, and Confidence Limits

This section describes how predicted probabilities and confidence limits are calculated by using the pseudo-estimates (MLEs) obtained from PROC SURVEYLOGISTIC. For a specific example, see the section “[Getting Started: SURVEYLOGISTIC Procedure](#)” on page 7685. Predicted probabilities and confidence limits can be output to a data set with the OUTPUT statement.

Cumulative Response Models

For a row vector of explanatory variables \mathbf{x} , the linear predictor

$$\eta_i = g(\Pr(Y \leq i | \mathbf{x})) = \alpha_i + \mathbf{x}\boldsymbol{\beta}, \quad 1 \leq i \leq k$$

is estimated by

$$\hat{\eta}_i = \hat{\alpha}_i + \mathbf{x}\hat{\boldsymbol{\beta}}$$

where $\hat{\alpha}_i$ and $\hat{\boldsymbol{\beta}}$ are the MLEs of α_i and $\boldsymbol{\beta}$. The estimated standard error of η_i is $\hat{\sigma}(\hat{\eta}_i)$, which can be computed as the square root of the quadratic form $(1, \mathbf{x}')\hat{\mathbf{V}}_{\mathbf{b}}(1, \mathbf{x})'$, where $\hat{\mathbf{V}}_{\mathbf{b}}$ is the estimated covariance matrix of the parameter estimates. The asymptotic $100(1 - \alpha)\%$ confidence interval for η_i is given by

$$\hat{\eta}_i \pm z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i)$$

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile point of a standard normal distribution.

The predicted value and the $100(1 - \alpha)\%$ confidence limits for $\Pr(Y \leq i | \mathbf{x})$ are obtained by back-transforming the corresponding measures for the linear predictor.

Link	Predicted Probability	100(1 - α) Confidence Limits
LOGIT	$1/(1 + e^{-\hat{\eta}_i})$	$1/(1 + e^{-\hat{\eta}_i \pm z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i)})$
PROBIT	$\Phi(\hat{\eta}_i)$	$\Phi(\hat{\eta}_i \pm z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i))$
CLOGLOG	$1 - e^{-e^{\hat{\eta}_i}}$	$1 - e^{-e^{\hat{\eta}_i \pm z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i)}}$

Generalized Logit Model

For a vector of explanatory variables \mathbf{x} , let π_i denote the probability of obtaining the response value i :

$$\pi_i = \begin{cases} \frac{\pi_{k+1} e^{\alpha_i + \mathbf{x}\boldsymbol{\beta}_i}}{1 + \sum_{j=1}^k e^{\alpha_j + \mathbf{x}\boldsymbol{\beta}_j}} & 1 \leq i \leq k \\ 1 & i = k + 1 \end{cases}$$

By the *delta method*,

$$\sigma^2(\pi_i) = \left(\frac{\partial \pi_i}{\partial \boldsymbol{\theta}} \right)' \mathbf{V}(\boldsymbol{\theta}) \frac{\partial \pi_i}{\partial \boldsymbol{\theta}}$$

A $100(1-\alpha)\%$ confidence level for π_i is given by

$$\hat{\pi}_i \pm z_{\alpha/2} \hat{\sigma}(\hat{\pi}_i)$$

where $\hat{\pi}_i$ is the estimated expected probability of response i and $\hat{\sigma}(\hat{\pi}_i)$ is obtained by evaluating $\sigma(\pi_i)$ at $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$.

Output Data Sets

You can use the Output Delivery System (ODS) to create a SAS data set from any piece of PROC SURVEYLOGISTIC output. See the section “[ODS Table Names](#)” on page 7757 for more information. For a more detailed description of using ODS, see Chapter 20, “[Using the Output Delivery System](#).”

PROC SURVEYLOGISTIC also provides an **OUTPUT** statement to create a data set that contains estimated linear predictors, the estimates of the cumulative or individual response probabilities, and their confidence limits.

If you use BRR or jackknife variance estimation, PROC SURVEYLOGISTIC provides an output data set that stores the replicate weights and an output data set that stores the jackknife coefficients for jackknife variance estimation.

OUT= Data Set in the OUTPUT Statement

The OUT= data set in the **OUTPUT** statement contains all the variables in the input data set along with statistics you request by using *keyword=name* options or the PREDPROBS= option in the OUTPUT statement. In addition, if you use the single-trial syntax and you request any of the XBETA=, STDXBETA=, PREDICTED=, LCL=, and UCL= options, the OUT= data set contains the automatic variable _LEVEL_. The value of _LEVEL_ identifies the response category upon which the computed values of XBETA=, STDXBETA=, PREDICTED=, LCL=, and UCL= are based.

When there are more than two response levels, only variables named by the XBETA=, STDXBETA=, PREDICTED=, LOWER=, and UPPER= options and the variables given by PREDPROBS=(INDIVIDUAL CUMULATIVE) have their values computed; the other variables have missing values. If you fit a generalized logit model, the cumulative predicted probabilities are not computed.

When there are only two response categories, each input observation produces one observation in the OUT= data set.

If there are more than two response categories and you specify only the `PREDPROBS=` option, then each input observation produces one observation in the `OUT=` data set. However, if you fit an ordinal (cumulative) model and specify options other than the `PREDPROBS=` options, each input observation generates as many output observations as one fewer than the number of response levels, and the predicted probabilities and their confidence limits correspond to the cumulative predicted probabilities. If you fit a generalized logit model and specify options other than the `PREDPROBS=` options, each input observation generates as many output observations as the number of response categories; the predicted probabilities and their confidence limits correspond to the probabilities of individual response categories.

For observations in which only the response variable is missing, values of the `XBETA=`, `STDXBETA=`, `PREDICTED=`, `UPPER=`, `LOWER=`, and `PREDPROBS=` options are computed even though these observations do not affect the model fit. This enables, for instance, predicted probabilities to be computed for new observations.

Replicate Weights Output Data Set

If you specify the `OUTWEIGHTS= method-option` for `VARMETHOD=BRR` or `VARMETHOD=JACKKNIFE`, PROC SURVEYLOGISTIC stores the replicate weights in an output data set. The `OUTWEIGHTS=` output data set contains all observations from the `DATA=` input data set that are valid (used in the analysis). (A valid observation is an observation that has a positive value of the `WEIGHT` variable. Valid observations must also have nonmissing values of the `STRATA` and `CLUSTER` variables, unless you specify the `MISSING` option.)

The `OUTWEIGHTS=` data set contains the following variables:

- all variables in the `DATA=` input data set
- `RepWt_1`, `RepWt_2`, ..., `RepWt_n`, which are the replicate weight variables

where n is the total number of replicates in the analysis. Each replicate weight variable contains the replicate weights for the corresponding replicate. Replicate weights equal zero for those observations not included in the replicate.

After the procedure creates replicate weights for a particular input data set and survey design, you can use the `OUTWEIGHTS= method-option` to store these replicate weights and then use them again in subsequent analyses, either in PROC SURVEYLOGISTIC or in the other survey procedures. You can use the `REPWEIGHTS` statement to provide replicate weights for the procedure.

Jackknife Coefficients Output Data Set

If you specify the `OUTJKCOEFS= method-option` for `VARMETHOD=JACKKNIFE`, PROC SURVEYLOGISTIC stores the jackknife coefficients in an output data set. The `OUTJKCOEFS=` output data set contains one observation for each replicate. The `OUTJKCOEFS=` data set contains the following variables:

- `Replicate`, which is the replicate number for the jackknife coefficient
- `JKCoefficient`, which is the jackknife coefficient
- `DonorStratum`, which is the stratum of the PSU that was deleted to construct the replicate, if you specify a `STRATA` statement

After the procedure creates jackknife coefficients for a particular input data set and survey design, you can use the `OUTJKCOEFS= method-option` to store these coefficients and then use them again in subsequent analyses, either in PROC SURVEYLOGISTIC or in the other survey procedures. You can use the `JKCOEFS=` option in the `REPWEIGHTS` statement to provide jackknife coefficients for the procedure.

Displayed Output

The SURVEYLOGISTIC procedure produces output that is described in the following sections.

Output that is generated by the `EFFECT`, `ESTIMATE`, `LSMEANS`, `LSMESTIMATE`, and `SLICE` statements are not listed below. For information about the output that is generated by these statements, see the corresponding sections of Chapter 19, “[Shared Concepts and Topics](#).”

Model Information

By default, PROC SURVEYLOGISTIC displays the following information in the “Model Information” table:

- name of the input Data Set
- name and label of the Response Variable if the single-trial syntax is used
- number of Response Levels
- name of the Events Variable if the events/trials syntax is used
- name of the Trials Variable if the events/trials syntax is used
- name of the Offset Variable if the `OFFSET=` option is specified
- name of the Frequency Variable if the `FREQ` statement is specified
- name(s) of the Stratum Variable(s) if the `STRATA` statement is specified
- total Number of Strata if the `STRATA` statement is specified
- name(s) of the Cluster Variable(s) if the `CLUSTER` statement is specified
- total Number of Clusters if the `CLUSTER` statement is specified
- name of the Weight Variable if the `WEIGHT` statement is specified
- Variance Adjustment method
- Upper Bound `ADJBOUND` parameter used in the `VADJUST=MOREL(ADJBOUND=)` option
- Lower Bound `DEFFBOUND` parameter used in the `VADJUST=MOREL(DEFFBOUND=)` option
- whether FPC (finite population correction) is used

Variance Estimation

By default, PROC SURVEYLOGISTIC displays the following variance estimation information in the “Variance Estimation” table:

- Method, which is the variance estimation method
- Variance Adjustment method
- Upper Bound ADJBOUND parameter specified in the `VADJUST=MOREL(ADJBOUND=)` option
- Lower Bound DEFFBOUND parameter specified in the `VADJUST=MOREL(DEFFBOUND=)` option
- whether FPC (finite population correction) is used
- Number of Replicates, if you specify the `VARMETHOD=BRR` or `VARMETHOD=JACKKNIFE` option
- Number of Replicates Used, if you specify the `VARMETHOD=BRR` or `VARMETHOD=JACKKNIFE` option and some of the replicates are excluded due to unattained convergence
- Hadamard Data Set name, if you specify the `VARMETHOD=BRR(HADAMARD=) method-option`
- Fay Coefficient, if you specify the `VARMETHOD=BRR(FAY) method-option`
- Replicate Weights input data set name, if you use a `REPWEIGHTS` statement
- whether Missing Levels are created for categorical variables by the `MISSING` option
- whether observations with Missing Values are included in the analysis by the `NOMCAR` option

Data Summary

By default, PROC SURVEYLOGISTIC displays the following information for the entire data set:

- Number of Observations read from the input data set
- Number of Observations used in the analysis

If there is a DOMAIN statement, PROC SURVEYLOGISTIC also displays the following:

- Number of Observations in the current domain
- Number of Observations not in the current domain

If there is a FREQ statement, PROC SURVEYLOGISTIC also displays the following:

- Sum of Frequencies of all the observations read from the input data set
- Sum of Frequencies of all the observations used in the analysis

If there is a WEIGHT statement, PROC SURVEYLOGISTIC also displays the following:

- Sum of Weights of all the observations read from the input data set
- Sum of Weights of all the observations used in the analysis
- Sum of Weights of all the observations in the current domain, if DOMAIN statement is also specified.

Response Profile

By default, PROC SURVEYLOGISTIC displays a “Response Profile” table, which gives, for each response level, the ordered value (an integer between one and the number of response levels, inclusive); the value of the response variable if the single-trial syntax is used or the values “EVENT” and “NO EVENT” if the events/trials syntax is used; the count or frequency; and the sum of weights if the WEIGHT statement is specified.

Class Level Information

If you use a CLASS statement to name classification variables, PROC SURVEYLOGISTIC displays a "Class Level Information" table. This table contains the following information for each classification variable:

- Class, which lists each CLASS variable name
- Value, which lists the values of the classification variable. The values are separated by a white space character; therefore, to avoid confusion, you should not include a white space character within a classification variable value.
- Design Variables, which lists the parameterization used for the classification variables

Stratum Information

When you specify the LIST option in the STRATA statement, PROC SURVEYLOGISTIC displays a "Stratum Information" table, which provides the following information for each stratum:

- Stratum Index, which is a sequential stratum identification number
- STRATA variable(s), which lists the levels of STRATA variables for the stratum
- Population Total, if you specify the TOTAL= option
- Sampling Rate, if you specify the TOTAL= or RATE= option. If you specify the TOTAL= option, the sampling rate is based on the number of nonmissing observations in the stratum.
- N Obs, which is the number of observations
- number of Clusters, if you specify a CLUSTER statement

Maximum Likelihood Iteration History

The “Maximum Likelihood Iterative Phase” table gives the iteration number, the step size (in the scale of 1.0, 0.5, 0.25, and so on) or the ridge value, $-2 \log$ likelihood, and parameter estimates for each iteration. Also displayed are the last evaluation of the gradient vector and the last change in the $-2 \log$ likelihood. You need to use the ITPRINT option in the MODEL statement to obtain this table.

Score Test

The “Score Test” table displays the score test result for testing the parallel lines assumption, if an ordinal response model is fitted. If LINK=CLOGLOG or LINK=PROBIT, this test is labeled “Score Test for the Parallel Slopes Assumption.” The proportion odds assumption is a special case of the parallel lines assumption when LINK=LOGIT. In this case, the test is labeled “Score Test for the Proportional Odds Assumption.”

Model Fit Statistics

By default, PROC SURVEYLOGISTIC displays the following information in the “Model Fit Statistics” table:

- “Model Fit Statistics” and “Testing Global Null Hypothesis: BETA=0” tables, which give the various criteria ($-2 \log L$, AIC, SC) based on the likelihood for fitting a model with intercepts only and for fitting a model with intercepts and explanatory variables. If you specify the NOINT option, these statistics are calculated without considering the intercept parameters. The third column of the table gives the chi-square statistics and p -values for the $-2 \log L$ statistic and for the Score statistic. These test the joint effect of the explanatory variables included in the model. The Score criterion is always missing for the models identified by the first two columns of the table. Note also that the first two rows of the Chi-Square column are always missing, since tests cannot be performed for AIC and SC.
- generalized R^2 measures for the fitted model if you specify the RSQUARE option in the MODEL statement

Type III Analysis of Effects

PROC SURVEYLOGISTIC displays the “Type III Analysis of Effects” table if the model contains an effect involving a CLASS variable. This table gives the degrees of freedom, the Wald Chi-square statistic, and the p -value for each effect in the model.

Analysis of Maximum Likelihood Estimates

By default, PROC SURVEYLOGISTIC displays the following information in the “Analysis of Maximum Likelihood Estimates” table:

- the degrees of freedom for Wald chi-square test
- maximum likelihood estimate of the parameter
- estimated standard error of the parameter estimate, computed as the square root of the corresponding diagonal element of the estimated covariance matrix

- Wald chi-square statistic, computed by squaring the ratio of the parameter estimate divided by its standard error estimate
- p -value of the Wald chi-square statistic with respect to a chi-square distribution with one degree of freedom
- standardized estimate for the slope parameter, given by $\hat{\beta}_i / (s/s_i)$, where s_i is the total sample standard deviation for the i th explanatory variable and

$$s = \begin{cases} \pi/\sqrt{3} & \text{logistic} \\ 1 & \text{normal} \\ \pi/\sqrt{6} & \text{extreme-value} \end{cases}$$

You need to specify the STB option in the MODEL statement to obtain these estimates. Standardized estimates of the intercept parameters are set to missing.

- value of $(e^{\hat{\beta}_i})$ for each slope parameter β_i if you specify the EXPB option in the MODEL statement. For continuous variables, this is equivalent to the estimated odds ratio for a one-unit change.
- label of the variable (if space permits) if you specify the PARMLABEL option in the MODEL statement. Due to constraints on the line size, the variable label might be suppressed in order to display the table in one panel. Use the SAS system option LINESIZE= to specify a larger line size to accommodate variable labels. A shorter line size can break the table into two panels, allowing labels to be displayed.

Odds Ratio Estimates

The “Odds Ratio Estimates” table displays the odds ratio estimates and the corresponding 95% Wald confidence intervals. For continuous explanatory variables, these odds ratios correspond to a unit increase in the risk factors.

Association of Predicted Probabilities and Observed Responses

The “Association of Predicted Probabilities and Observed Responses” table displays measures of association between predicted probabilities and observed responses, which include a breakdown of the number of pairs with different responses, and four rank correlation indexes: Somers’ D , Goodman-Kruskal Gamma, and Kendall’s Tau- a , and c .

Wald Confidence Interval for Parameters

The “Wald Confidence Interval for Parameters” table displays confidence intervals for all the parameters if you use the CLPARM option in the MODEL statement.

Wald Confidence Interval for Odds Ratios

The “Wald Confidence Interval for Odds Ratios” table displays confidence intervals for all the odds ratios if you use the CLODDS option in the MODEL statement.

Estimated Covariance Matrix

PROC SURVEYLOGISTIC displays the following information in the “Estimated Covariance Matrix” table:

- estimated covariance matrix of the parameter estimates if you use the COVB option in the MODEL statement
- estimated correlation matrix of the parameter estimates if you use the CORRB option in the MODEL statement

Linear Hypotheses Testing Results

The “Linear Hypothesis Testing” table gives the result of the Wald test for each TEST statement (if specified).

Hadamard Matrix

If you specify the **VARMETHOD=BRR(PRINTH)** *method-option* in the PROC SURVEYLOGISTIC statement, the procedure displays the Hadamard matrix.

When you provide a Hadamard matrix with the **VARMETHOD=BRR(HADAMARD=)** *method-option*, the procedure displays only used rows and columns of the Hadamard matrix.

ODS Table Names

PROC SURVEYLOGISTIC assigns a name to each table it creates; these names are listed in [Table 91.10](#). You can use these names to refer the table when using the Output Delivery System (ODS) to select tables and create output data sets. The EFFECT, ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements also create tables, which are not listed in [Table 91.10](#). For information about these tables, see the corresponding sections of Chapter 19, “Shared Concepts and Topics.”

For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 91.10 ODS Tables Produced by PROC SURVEYLOGISTIC

ODS Table Name	Description	Statement	Option
Association	Association of predicted probabilities and observed responses	MODEL	Default
ClassLevelInfo	Class variable levels and design variables	MODEL	Default (with CLASS variables)
CLOddsWald	Wald’s confidence limits for odds ratios	MODEL	CLODDS
CLparmWald	Wald’s confidence limits for parameters	MODEL	CLPARM
ContrastCoeff	L matrix from CONTRAST	CONTRAST	E
ContrastEstimate	Estimates from CONTRAST	CONTRAST	ESTIMATE=
ContrastTest	Wald test for CONTRAST	CONTRAST	Default
ConvergenceStatus	Convergence status	MODEL	Default

Table 91.10 *continued*

ODS Table Name	Description	Statement	Option
CorrB	Estimated correlation matrix of parameter estimators	MODEL	CORRB
CovB	Estimated covariance matrix of parameter estimators	MODEL	COVB
CumulativeModelTest	Test of the cumulative model assumption	MODEL	(Ordinal response)
DomainSummary	Domain summary	DOMAIN	Default
FitStatistics	Model fit statistics	MODEL	Default
GlobalTests	Test for global null hypothesis	MODEL	Default
HadamardMatrix	Hadamard matrix	PROC	PRINTH
IterHistory	Iteration history	MODEL	ITPRINT

VarianceEstimation	Variance estimation	PROC	Default

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS.](#)”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

When ODS Graphics is enabled, then the ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements can produce plots that are associated with their analyses. For information about these plots, see the corresponding sections of Chapter 19, “[Shared Concepts and Topics](#).”

Examples: SURVEYLOGISTIC Procedure

Example 91.1: Stratified Cluster Sampling

A market research firm conducts a survey among undergraduate students at a certain university to evaluate three new Web designs for a commercial Web site targeting undergraduate students at the university.

The sample design is a stratified sample where the strata are students’ classes. Within each class, 300 students are randomly selected by using simple random sampling without replacement. The total number of students in each class in the fall semester of 2001 is shown in the following table:

Class	Enrollment
1 - Freshman	3,734
2 - Sophomore	3,565
3 - Junior	3,903
4 - Senior	4,196

This total enrollment information is saved in the SAS data set Enrollment by using the following SAS statements:

```
proc format;
  value Class
    1='Freshman' 2='Sophomore'
    3='Junior'   4='Senior';
run;

data Enrollment;
  format Class Class.;
  input Class _TOTAL_;
  datalines;
1 3734
2 3565
3 3903
4 4196
;
```

In the data set Enrollment, the variable `_TOTAL_` contains the enrollment figures for all classes. They are also the population size for each stratum in this example.

Each student selected in the sample evaluates one randomly selected Web design by using the following scale:

1	Dislike very much
2	Dislike
3	Neutral
4	Like
5	Like very much

The survey results are collected and shown in the following table, with the three different Web designs coded as A, B, and C.

Evaluation of New Web Designs						
Strata	Design	Rating Counts				
		1	2	3	4	5
Freshman	A	10	34	35	16	15
	B	5	6	24	30	25
	C	11	14	20	34	21
Sophomore	A	19	12	26	18	25
	B	10	18	32	23	26
	C	15	22	34	9	20
Junior	A	8	21	23	26	22
	B	1	4	15	33	47
	C	16	19	30	23	12
Senior	A	11	14	24	33	18
	B	8	15	25	30	22
	C	2	34	30	18	16

The survey results are stored in a SAS data set WebSurvey by using the following SAS statements:

```
proc format;
  value Design 1='A' 2='B' 3='C';
  value Rating
    1='dislike very much'
    2='dislike'
    3='neutral'
    4='like'
    5='like very much';
run;

data WebSurvey;
  format Class Class. Design Design. Rating Rating.;
  do Class=1 to 4;
    do Design=1 to 3;
      do Rating=1 to 5;
        input Count @@;
        output;
      end;
    end;
  end;
end;
```

```

datalines;
10 34 35 16 15      8 21 23 26 22      5 10 24 30 21
1 14 25 23 37      11 14 20 34 21      16 19 30 23 12
19 12 26 18 25      11 14 24 33 18      10 18 32 23 17
8 15 35 30 12      15 22 34 9 20      2 34 30 18 16
;

data WebSurvey;
  set WebSurvey;
  if Class=1 then Weight=3734/300;
  if Class=2 then Weight=3565/300;
  if Class=3 then Weight=3903/300;
  if Class=4 then Weight=4196/300;
run;

```

The data set WebSurvey contains the variables Class, Design, Rating, Count, and Weight. The variable class is the stratum variable, with four strata: freshman, sophomore, junior, and senior. The variable Design specifies the three new Web designs: A, B, and C. The variable Rating contains students' evaluations of the new Web designs. The variable counts gives the frequency with which each Web design received each rating within each stratum. The variable weight contains the sampling weights, which are the reciprocals of selection probabilities in this example.

Output 91.1.1 shows the first 20 observations of the data set.

Output 91.1.1 Web Design Survey Sample (First 20 Observations)

Obs	Class	Design	Rating	Count	Weight
1	Freshman	A	dislike very much	10	12.4467
2	Freshman	A	dislike	34	12.4467
3	Freshman	A	neutral	35	12.4467
4	Freshman	A	like	16	12.4467
5	Freshman	A	like very much	15	12.4467
6	Freshman	B	dislike very much	8	12.4467
7	Freshman	B	dislike	21	12.4467
8	Freshman	B	neutral	23	12.4467
9	Freshman	B	like	26	12.4467
10	Freshman	B	like very much	22	12.4467
11	Freshman	C	dislike very much	5	12.4467
12	Freshman	C	dislike	10	12.4467
13	Freshman	C	neutral	24	12.4467
14	Freshman	C	like	30	12.4467
15	Freshman	C	like very much	21	12.4467
16	Sophomore	A	dislike very much	1	11.8833
17	Sophomore	A	dislike	14	11.8833
18	Sophomore	A	neutral	25	11.8833
19	Sophomore	A	like	23	11.8833
20	Sophomore	A	like very much	37	11.8833

The following SAS statements perform the logistic regression:

```
proc surveylogistic data=WebSurvey total=Enrollment;
  stratum Class;
  freq Count;
  class Design;
  model Rating (order=internal) = design;
  weight Weight;
run;
```

The PROC SURVEYLOGISTIC statement invokes the procedure. The TOTAL= option specifies the data set Enrollment, which contains the population totals in the strata. The population totals are used to calculate the finite population correction factor in the variance estimates. The response variable Rating is in the ordinal scale. A cumulative logit model is used to investigate the responses to the Web designs. In the MODEL statement, rating is the response variable, and Design is the effect in the regression model. The ORDER=INTERNAL option is used for the response variable Rating to sort the ordinal response levels of Rating by its internal (numerical) values rather than by the formatted values (for example, 'like very much'). Because the sample design involves stratified simple random sampling, the STRATA statement is used to specify the stratification variable Class. The WEIGHT statement specifies the variable Weight for sampling weights.

The sample and analysis summary is shown in [Output 91.1.2](#). There are five response levels for the Rating, with 'dislike very much' as the lowest ordered value. The regression model is modeling lower cumulative probabilities by using logit as the link function. Because the TOTAL= option is used, the finite population correction is included in the variance estimation. The sampling weight is also used in the analysis.

Output 91.1.2 Web Design Survey, Model Information

The SURVEYLOGISTIC Procedure	
Model Information	
Data Set	WORK.WEBSURVEY
Response Variable	Rating
Number of Response Levels	5
Frequency Variable	Count
Stratum Variable	Class
Number of Strata	4
Weight Variable	Weight
Model	Cumulative Logit
Optimization Technique	Fisher's Scoring
Variance Adjustment	Degrees of Freedom (DF)
Finite Population Correction	Used

Output 91.1.2 *continued*

Response Profile			
Ordered Value	Rating	Total Frequency	Total Weight
1	dislike very much	116	1489.0733
2	dislike	227	2933.0433
3	neutral	338	4363.3767
4	like	283	3606.8067
5	like very much	236	3005.7000
Probabilities modeled are cumulated over the lower Ordered Values.			

In [Output 91.1.3](#), the score chi-square for testing the proportional odds assumption is 98.1957, which is highly significant. This indicates that the cumulative logit model might not adequately fit the data.

Output 91.1.3 Web Design Survey, Testing the Proportional Odds Assumption

Score Test for the Proportional Odds Assumption		
Chi-Square	DF	Pr > ChiSq
98.1957	6	<.0001

An alternative model is to use the generalized logit model with the LINK=GLOGIT option, as shown in the following SAS statements:

```
proc surveylogistic data=WebSurvey total=Enrollment;
  stratum Class;
  freq Count;
  class Design;
  model Rating (ref='neutral') = Design /link=glogit;
  weight Weight;
run;
```

The REF='neutral' option is used for the response variable Rating to indicate that all other response levels are referenced to the level 'neutral.' The option LINK=GLOGIT option requests that the procedure fit a generalized logit model.

The summary of the analysis is shown in [Output 91.1.4](#), which indicates that the generalized logit model is used in the analysis.

Output 91.1.4 Web Design Survey, Model Information

The SURVEYLOGISTIC Procedure			
Model Information			
Data Set		WORK.WEBSURVEY	
Response Variable		Rating	
Number of Response Levels		5	
Frequency Variable		Count	
Stratum Variable		Class	
Number of Strata		4	
Weight Variable		Weight	
Model		Generalized Logit	
Optimization Technique		Newton-Raphson

Design B vs C	like	1.218	0.838	1.768
Design B vs C	like very much	1.389	0.925	2.086

Example 91.2: The Medical Expenditure Panel Survey (MEPS)

The U.S. Department of Health and Human Services conducts the Medical Expenditure Panel Survey (MEPS) to produce national and regional estimates of various aspects of health care. The MEPS has a complex sample design that includes both stratification and clustering. The sampling weights are adjusted for nonresponse and raked with respect to population control totals from the Current Population Survey. See the MEPS Survey Background (2006) and Machlin, Yu, and Zodet (2005) for details.

In this example, the 1999 full-year consolidated data file HC-038 (MEPS HC-038, 2002) from the MEPS is used to investigate the relationship between medical insurance coverage and the demographic variables. The data can be downloaded directly from the Agency for Healthcare Research and Quality (AHRQ) Web site at http://www.meps.ahrq.gov/mepsweb/data_stats/download_data_files_detail.jsp?cboPufNumber=HC-038 in either ASCII format or SAS transport format. The Web site includes a detailed description of the data as well as the SAS program used to access and format it.

For this example, the SAS transport format data file for HC-038 is downloaded to 'C:H38.ssp' on a Windows-based PC. The instructions on the Web site lead to the following SAS statements for creating

a SAS data set MEPS, which contains only the sample design variables and other variables necessary for this analysis.

```
proc format;
  value racex
    -9 = 'NOT ASCERTAINED'
    -8 = 'DK'
    -7 = 'REFUSED'
    -1 = 'INAPPLICABLE'
    1 = 'AMERICAN INDIAN'
    2 = 'ALEUT, ESKIMO'
    3 = 'ASIAN OR PACIFIC ISLANDER'
    4 = 'BLACK'
    5 = 'WHITE'
    91 = 'OTHER'
  ;
  value sex
    -9 = 'NOT ASCERTAINED'
    -8 = 'DK'
    -7 = 'REFUSED'
    -1 = 'INAPPLICABLE'
    1 = 'MALE'
    2 = 'FEMALE'
  ;
  value povcat9h
    1 = 'NEGATIVE OR POOR'
    2 = 'NEAR POOR'
    3 = 'LOW INCOME'
    4 = 'MIDDLE INCOME'
    5 = 'HIGH INCOME'
  ;
  value inscov9f
    1 = 'ANY PRIVATE'
    2 = 'PUBLIC ONLY'
    3 = 'UNINSURED'
  ;
run;

libname mylib '';
filename in1 'H38.SSP';
proc xcopy in=in1 out=mylib import;
run;

data meps;
  set mylib.H38;
  label racex= sex= inscov99= povcat99=
    varstr99= varpsu99= perwt99f= totexp99=;
  format racex racex. sex sex.
    povcat99 povcat9h. inscov99 inscov9f.;
  keep inscov99 sex racex povcat99 varstr99
    varpsu99 perwt99f totexp99;
run;
```

There are a total of 24,618 observations in this SAS data set. Each observation corresponds to a person in the survey. The stratification variable is VARSTR99, which identifies the 143 strata in the sample. The variable VARPSU99 identifies the 460 PSUs in the sample. The sampling weights are stored in the variable PERWT99F. The response variable is the health insurance coverage indicator variable, INSCOV99, which has three values:

-
- | | |
|---|--|
| 1 | The person had any private insurance coverage any time during 1999 |
| 2 | The person had only public insurance coverage during 1999 |
| 3 | The person was uninsured during all of 1999 |
-

The demographic variables include gender (SEX), race (RACEX), and family income level as a percent of the poverty line (POVCAT99). The variable RACEX has five categories:

-
- | | |
|---|---------------------------|
| 1 | American Indian |
| 2 | Aleut, Eskimo |
| 3 | Asian or Pacific Islander |
| 4 | Black |
| 5 | White |
-

The variable POVCAT99 is constructed by dividing family income by the applicable poverty line (based on family size and composition), with the resulting percentages grouped into five categories:

-
- | | |
|---|---|
| 1 | Negative or poor (less than 100%) |
| 2 | Near poor (100% to less than 125%) |
| 3 | Low income (125% to less than 200%) |
| 4 | Middle income (200% to less than 400%) |
| 5 | High income (greater than or equal to 400%) |
-

The data set also contains the total health care expenditure in 1999, TOTEXP99, which is used as a covariate in the analysis.

Output 91.2.1 displays the first 30 observations of this data set.

Output 91.2.1 1999 Full-Year MEPS (First 30 Observations)

30	MALE	BLACK	NEGATIVE OR POOR	PUBLIC ONLY		0	4574.73	73	12

The following SAS statements fit a generalized logit model for the 1999 full-year consolidated MEPS data:

```
proc surveylogistic data=meps;
  stratum VARSTR99;
  cluster VARPSU99;
  weight PERWT99F;
  class SEX RACEX POVCAT99;
  model INSCOV99 = TOTEXP99 SEX RACEX POVCAT99 / link=glogit;
run;
```

The STRATUM statement specifies the stratification variable VARSTR99. The CLUSTER statement specifies the PSU variable VARPSU99. The WEIGHT statement specifies the sample weight variable PERWT99F. The demographic variables SEX, RACEX, and POVCAT99 are listed in the CLASS statement to indicate that they are categorical independent variables in the MODEL statement. In the MODEL statement, the response variable is INSCOV99, and the independent variables are TOTEXP99 along with the selected demographic variables. The LINK= option requests that the procedure fit the generalized logit model because the response variable INSCOV99 has nominal responses.

The results of this analysis are shown in the following outputs.

PROC SURVEYLOGISTIC lists the model fitting information and sample design information in [Output 91.2.2](#).

Output 91.2.2 MEPS, Model Information

The SURVEYLOGISTIC Procedure	
Model Information	
Data Set	WORK.MEPS
Response Variable	INSCOV99
Number of Response Levels	3
Stratum Variable	VARSTR99
Number of Strata	143
Cluster Variable	VARPSU99
Number of Clusters	460
Weight Variable	PERWT99F
Model	Generalized Logit
Optimization Technique	Newton-Raphson
Variance Adjustment	Degrees of Freedom (DF)

[Output 91.2.3](#) displays the number of observations and the total of sampling weights both in the data set and used in the analysis. Only the observations with positive person-level weight are used in the analysis. Therefore, 1,053 observations with zero person-level weights were deleted.

Output 91.2.3 MEPS, Number of Observations

Number of Observations Read	24618
Number of Observations Used	23565
Sum of Weights Read	2.7641E8
Sum of Weights Used	2.7641E8

[Output 91.2.4](#) lists the three insurance coverage levels for the response variable INSCOV99. The “UNINSURED” category is used as the reference category in the model.

Output 91.2.4 MEPS, Response Profile

Response Profile			
Ordered Value	INSCOV99	Total Frequency	Total Weight
1	ANY PRIVATE	16130	204403997
2	PUBLIC ONLY	4241	41809572
3	UNINSURED	3194	30197198

Logits modeled use INSCOV99='UNINSURED' as the reference category.

Output 91.2.5 shows the parameterization in the regression model for each categorical independent variable.

Output 91.2.5 MEPS, Classification Levels

Class Level Information						
Class	Value		Design Variables			
SEX	FEMALE	1				
	MALE	-1				
RACEX	ALEUT, ESKIMO	1	0	0	0	
	AMERICAN INDIAN	0	1	0	0	
	ASIAN OR PACIFIC ISLANDER	0	0	1	0	
	BLACK	0	0	0	1	
	WHITE	-1	-1	-1	-1	
POVCAT99	HIGH INCOME	1	0	0	0	
	LOW INCOME	0	1	0	0	
	MIDDLE INCOME	0	0	1	0	
	NEAR POOR	0	0	0	1	
	NEGATIVE OR POOR	-1	-1	-1	-1	

Output 91.2.6 displays the parameter estimates and their standard errors.

Output 91.2.7 displays the odds ratio estimates and their standard errors.

For example, after adjusting for the effects of sex, race, and total health care expenditures, a person with high income is estimated to be 11.595 times more likely than a poor person to choose private health care insurance over no insurance, but only 0.274 times as likely to choose public health insurance over no insurance.

Output 91.2.6 MEPS, Parameter Estimates

Overview: SURVEYMEANS Procedure

The SURVEYMEANS procedure estimates characteristics of a survey population by using statistics computed from a survey sample. It enables you to estimate statistics such as means, totals, proportions, quantiles, geometric means, and ratios. PROC SURVEYMEANS also provides domain analysis, which computes estimates for subpopulations or domains. The procedure also estimates variances and confidence limits and performs t tests for these statistics. PROC SURVEYMEANS uses either the Taylor series (linearization) method or replication (subsampling) methods to estimate sampling errors of estimators based on complex sample designs. The sample design can be a complex survey sample design with stratification, clustering, and unequal weighting. For more information, see Fuller (2009); Lohr (2010); Särndal, Swensson, and Wretman (1992); Wolter (2007).

Getting Started: SURVEYMEANS Procedure

This section demonstrates how you can use the SURVEYMEANS procedure to produce descriptive statistics from sample survey data. For a complete description of PROC SURVEYMEANS, see the section “[Syntax: SURVEYMEANS Procedure](#)” on page 7785. The section “[Examples: SURVEYMEANS Procedure](#)” on page 7839 provides more complicated examples to illustrate the applications of PROC SURVEYMEANS.

Simple Random Sampling

This example illustrates how you can use PROC SURVEYMEANS to estimate population means and proportions from sample survey data. The study population is a junior high school with a total of 4,000 students in grades 7, 8, and 9. Researchers want to know how much these students spend weekly for ice cream, on average, and what percentage of students spend at least \$10 weekly for ice cream.

To answer these questions, 40 students were selected from the entire student population by using simple random sampling (SRS). Selection by simple random sampling means that all students have an equal chance of being selected and no student can be selected more than once. Each student selected for the sample was asked how much he or she spends for ice cream per week, on average. The SAS data set IceCream saves the responses of the 40 students:

```
data IceCream;
  input Grade Spending @@;
  if (Spending < 10) then Group='less';
  else Group='more';
  datalines;
7 7 7 7 8 12 9 10 7 1 7 10 7 3 8 20 8 19 7 2
7 2 9 15 8 16 7 6 7 6 7 6 9 15 8 17 8 14 9 8
9 8 9 7 7 3 7 12 7 4 9 14 8 18 9 9 7 2 7 1
7 4 7 11 9 8 8 10 8 13 7 2 9 6 9 11 7 2 7 9
;
```

The variable Grade contains a student's grade. The variable Spending contains a student's response regarding how much he spends per week for ice cream, in dollars. The variable Group is created to indicate

whether a student spends at least \$10 weekly for ice cream: Group='more' if a student spends at least \$10, or Group='less' if a student spends less than \$10.

You can use PROC SURVEYMEANS to produce estimates for the entire student population, based on this random sample of 40 students:

```
title1 'Analysis of Ice Cream Spending';
title2 'Simple Random Sample Design';
proc surveymeans data=IceCream total=4000;
  var Spending Group;
run;
```

The PROC SURVEYMEANS statement invokes the procedure. The TOTAL=4000 option specifies the total number of students in the study population, or school. The procedure uses this total to adjust variance estimates for the effects of sampling from a finite population. The VAR statement names the variables to analyze, Spending and Group.

Figure 92.1 displays the results from this analysis. There are a total of 40 observations used in the analysis. The “Class Level Information” table lists the two levels of the variable Group. This variable is a character variable, and so PROC SURVEYMEANS provides a categorical analysis for it, estimating the relative frequency or proportion for each level. If you want a categorical analysis for a numeric variable, you can name that variable in the CLASS statement.

Figure 92.1 Analysis of Ice Cream Spending

Analysis of Ice Cream Spending						
Simple Random Sample Design						
The SURVEYMEANS Procedure						
Data Summary						
Number of Observations			40			
Class Level Information						
Class						
Variable		Levels	Values			
Group		2	less more			
Statistics						
Variable	Level	N	Mean	Std Error of Mean	95% CL for Mean	

Spending		40	8.750000	0.845139	7.04054539	10.4594546
Group	less	23	0.575000	0.078761	0.41568994	0.7343101
	more	17	0.425000	0.078761	0.26568994	0.5843101

The “Statistics” table displays the estimates for each analysis variable. By default, PROC SURVEYMEANS displays the number of observations, the estimate of the mean, its standard error, and the 95% confidence limits for the mean. You can obtain other statistics by specifying the corresponding *statistic-keywords* in the PROC SURVEYMEANS statement.

The estimate of the average weekly ice cream expense is \$8.75 for students at this school. The standard error of this estimate is \$0.85, and the 95% confidence interval for weekly ice cream expense is from \$7.04 to \$10.46. The analysis variable Group is a character variable, and so PROC SURVEYMEANS analyzes it as categorical, estimating the relative frequency or proportion for each level or category. These estimates are displayed in the Mean column of the “Statistics” table. It is estimated that 57.5% of all students spend less than \$10 weekly on ice cream, while 42.5% of the students spend at least \$10 weekly. The standard error of each estimate is 7.9%.

Stratified Sampling

Suppose that the sample of students described in the previous section was actually selected by using stratified random sampling. In stratified sampling, the study population is divided into nonoverlapping strata, and samples are selected from each stratum independently.

The list of students in this junior high school was stratified by grade, yielding three strata: grades 7, 8, and 9. A simple random sample of students was selected from each grade. Table 92.1 shows the total number of students in each grade.

Table 92.1 Number of Students by Grade

Grade	Number of Students
7	1,824
8	1,025
9	1,151
Total	4,000

To analyze this stratified sample, you need to provide the population totals for each stratum to PROC SURVEYMEANS. The SAS data set StudentTotals contains the information from Table 92.1:

```
data StudentTotals;
    input Grade _total_;
    datalines;
7 1824
8 1025
9 1151
;
```

The variable Grade is the stratum identification variable, and the variable _TOTAL_ contains the total number of students for each stratum. PROC SURVEYMEANS requires you to use the variable name _TOTAL_ for the stratum population totals.

The procedure uses the stratum population totals to adjust variance estimates for the effects of sampling from a finite population. If you do not provide population totals or sampling rates, then the procedure assumes

that the proportion of the population in the sample is very small, and the computation does not involve a finite population correction.

In a stratified sample design, when the sampling rates in the strata are unequal, you need to use sampling weights to reflect this information in order to produce an unbiased mean estimator. In this example, the appropriate sampling weights are reciprocals of the probabilities of selection. You can use the following DATA step to create the sampling weights:

```
data IceCream;
  set IceCream;
  if Grade=7 then Prob=20/1824;
  if Grade=8 then Prob=9/1025;
  if Grade=9 then Prob=11/1151;
  Weight=1/Prob;
run;
```

When you use PROC SURVEYSELECT to select your sample, the procedure creates these sampling weights for you.

The following SAS statements perform the stratified analysis of the survey data:

```
title1 'Analysis of Ice Cream Spending';
title2 'Stratified Sample Design';
proc surveymeans data=IceCream total=StudentTotals;
  stratum Grade / list;
  var Spending Group;
  weight Weight;
run;
```

The PROC SURVEYMEANS statement invokes the procedure. The DATA= option names the SAS data set IceCream as the input data set to be analyzed. The TOTAL= option names the data set StudentTotals as the input data set that contains the stratum population totals. Comparing this to the analysis in the section “[Simple Random Sampling](#)” on page 7779, notice that the TOTAL=StudentTotals option is used here instead of the TOTAL=4000 option. In this stratified sample design, the population totals are different for different strata, and so you need to provide them to PROC SURVEYMEANS in a SAS data set.

The STRATA statement identifies the stratification variable Grade. The LIST option in the STRATA statement requests that the procedure display stratum information. The WEIGHT statement tells the procedure that the variable Weight contains the sampling weights.

[Figure 92.2](#) displays information about the input data set. There are three strata in the design and 40 observations in the sample. The categorical variable Group has two levels, ‘less’ and ‘more.’

[Figure 92.3](#) displays information for each stratum. The table displays a stratum index and the values of the STRATA variable. The stratum index identifies each stratum by a sequentially assigned number. For each stratum, the table gives the population total (total number of students), the sampling rate, and the sample size. The stratum sampling rate is the ratio of the number of students in the sample to the number of students in the population for that stratum. The table also lists each analysis variable and the number of stratum observations for that variable. For categorical variables, the table lists each level and the number of sample observations in that level.

Figure 92.4 shows the following:

- The estimate of average weekly ice cream expense is \$9.14 for students in this school, with a standard error of \$0.53, and a 95% confidence interval from \$8.06 to \$10.22.
- An estimate of 54.5% of all students spend less than \$10 weekly on ice cream, and 45.5% spend more, with a standard error of 5.8%.

Figure 92.4 Analysis of Ice Cream Spending

Statistics						
Variable	Level	N	Mean	Std Error of Mean	95% CL for Mean	
Spending		40	9.141298	0.531799	8.06377052	10.2188254
Group	less	23	0.544555	0.058424	0.42617678	0.6629323

Output Data Sets

PROC SURVEYMEANS uses the Output Delivery System (ODS) to create output data sets. This is a departure from older SAS procedures that provide OUTPUT statements for similar functionality. For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

For example, to save the “Statistics” table shown in Figure 92.4 in the previous section in an output data set, you use the ODS OUTPUT statement as follows:

```

title1 'Analysis of Ice Cream Spending';
title2 'Stratified Sample Design';
proc surveymeans data=IceCream total=StudentTotals;
    stratum Grade / list;
    var Spending Group;
    weight Weight;
    ods output Statistics=MyStat;
run;

```

The statement

```
ods output Statistics=MyStat;
```

requests that the “Statistics” table that appears in Figure 92.4 be placed in a SAS data set MyStat.

The PRINT procedure displays observations of the data set MyStat:

```

proc print data=MyStat;
run;

```

Figure 92.5 displays the data set MyStat. The section “ODS Table Names” on page 7838 gives the complete list of tables produced by PROC SURVEYMEANS.

Figure 92.5 Output Data Set MyStat

Analysis of Ice Cream Spending Stratified Sample Design							
Obs	VarName	Var Level	N	Mean	StdErr	Lower CLMean	Upper CLMean

Syntax: SURVEYMEANS Procedure

The following statements are available in the SURVEYMEANS procedure:

```
PROC SURVEYMEANS < options > < statistic-keywords > ;
  BY variables ;
  CLASS variables ;
  CLUSTER variables ;
  DOMAIN variables < variable*variable variable*variable*variable ... > < / option > ;
  POSTSTRATA variables / PSTOTAL= < option > ;
  POSTSTRATA variables / PSPCT= < option > ;
  RATIO < 'label' > variables / variables ;
  REPWEIGHTS variables < / options > ;
  STRATA variables < / option > ;
  VAR variables ;
  WEIGHT variable ;
```

The PROC SURVEYMEANS statement invokes the procedure. It optionally names the input data sets, specifies statistics for the procedure to compute, and specifies the variance estimation method. The PROC SURVEYMEANS statement is required.

The VAR statement identifies the variables to be analyzed. The CLASS statement identifies numeric variables that are to be analyzed as categorical variables. The STRATA statement lists the variables that form the strata in a stratified sample design. The CLUSTER statement specifies cluster identification variables in a clustered sample design. The DOMAIN statement lists the variables that define domains for subpopulation analysis. The RATIO statement requests ratio analysis for means or proportions of analysis variables. The WEIGHT statement names the sampling weight variable. The POSTSTRATA statement lists the variables that are used to form poststrata for poststratification. The REPWEIGHTS statement names replicate weight variables for BRR or jackknife variance estimation. You can use a BY statement with PROC SURVEYMEANS to obtain separate analyses for groups defined by the BY variables.

All statements can appear multiple times except the PROC SURVEYMEANS statement, POSTSTRATA statement, and WEIGHT statement, which can appear only once.

The rest of this section gives detailed syntax information for the BY, CLASS, CLUSTER, DOMAIN, POSTSTRATA, RATIO, REPWEIGHTS, STRATA, VAR, and WEIGHT statements in alphabetical order after the description of the PROC SURVEYMEANS statement.

PROC SURVEYMEANS Statement

PROC SURVEYMEANS <options> *statistic-keywords* ;

The PROC SURVEYMEANS statement invokes the SURVEYMEANS procedure. In this statement, you identify the data set to be analyzed, specify the variance estimation method, and provide sample design information. The DATA= option names the input data set to be analyzed. The VARMETHOD= option specifies the variance estimation method, which is the Taylor series method by default. For Taylor series variance estimation, you can include a finite population correction factor in the analysis by providing either the sampling rate or population total with the RATE= or TOTAL= option. If your design is stratified, with different sampling rates or totals for different strata, then you can input these stratum rates or totals in a SAS data set that contains the stratification variables.

In the PROC SURVEYMEANS statement, you also can use *statistic-keywords* to specify statistics, such as population mean and population total, for the procedure to compute. You can also request data set summary information and sample design information.

Table 92.2 summarizes the options available in the PROC SURVEYMEANS statement.

Table 92.2 PROC SURVEYMEANS Statement Options

Option	Description
ALPHA=	Sets the confidence level for confidence limits
DATA=	Specifies the SAS data set to be analyzed
MISSING	Treats missing values as a valid
NOMCAR	Computes variance estimates by analyzing the nonmissing values as a domain
NONSYMCL	Requests nonsymmetric confidence limits for quantiles
NOSPARSE	Suppresses the display of analysis variables with zero frequency
ORDER=	Specifies the order in which to report the values of the categorical variables
PERCENTILE=	Specifies percentiles that you want the procedure to compute
QUANTILE=	Specifies quantiles that you want the procedure to compute
RATE=	Specifies the sampling rate
STACKING	Produces the output data sets by using a stacking table structure
TOTAL=	Specifies the total number of primary sampling units
VARMETHOD=	Specifies the variance estimation method

You can specify the following options in the PROC SURVEYMEANS statement:

ALPHA= α

sets the confidence level for confidence limits. The value of the ALPHA= option must be between 0 and 1, and the default value is 0.05. A confidence level of α produces $100(1 - \alpha)\%$ confidence limits. The default of ALPHA=0.05 produces 95% confidence limits.

DATA=SAS-data-set

specifies the SAS data set to be analyzed by PROC SURVEYMEANS. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

MISSING

treats missing values as a valid (nonmissing) category for all categorical variables, which include [CLASS](#), [STRATA](#), [CLUSTER](#), [DOMAIN](#), and [POSTSTRATA](#) variables.

By default, if you do not specify the MISSING option, an observation is excluded from the analysis if it has a missing value. For more information, see the section “[Missing Values](#)” on page 7804.

NOMCAR

requests that the procedure treat missing values in the variance computation as *not missing completely at random* (NOMCAR) for Taylor series variance estimation. When you specify the NOMCAR option, PROC SURVEYMEANS computes variance estimates by analyzing the nonmissing values as a domain (subpopulation), where the entire population includes both nonmissing and missing domains. See the section “[Missing Values](#)” on page 7804 for more details.

By default, PROC SURVEYMEANS completely excludes an observation from analysis if that observation has a missing value, unless you specify the [MISSING](#) option for categorical variables. Note that the NOMCAR option has no effect on a categorical variable when you specify the MISSING option, which treats missing values as a valid nonmissing level.

The NOMCAR option applies only to Taylor series variance estimation. The replication methods, which you request with the [VARMETHOD=BRR](#) and [VARMETHOD=JACKKNIFE](#) options, do not use the NOMCAR option.

The NOMCAR option is not available for geometric means or poststratification.

NONSYMCL

requests nonsymmetric confidence limits for quantiles when you request quantiles with [PERCENTILE=](#) or [QUANTILE=](#) option. See the section “[Confidence Limits](#)” on page 7818 for more details. This option applies only to the default [VARMETHOD=TAYLOR](#) option.

NOSPARSE

suppresses the display of analysis variables with zero frequency. By default, the procedure displays all continuous variables and all levels of categorical variables.

ORDER=DATA | FORMATTED | INTERNAL

specifies the order in which the values of the categorical variables are to be reported.

This option also determines the sort order for the levels of [CIUSTER](#) and [DOMAIN](#) variables and controls [STRATA](#) variable levels in the “Stratum Information” table.

The following shows how PROC SURVEYMEANS interprets values of the ORDER= option:

DATA	orders values according to their order in the input data set.
FORMATTED	orders values by their formatted values. This order is operating environment dependent. By default, the order is ascending.
INTERNAL	orders values by their unformatted values, which yields the same order that the SORT procedure does. This order is operating environment dependent.

By default, ORDER=INTERNAL. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent.

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PERCENTILE=(values)

specifies percentiles you want the procedure to compute. You can separate values with blanks or commas. Each value must be between 0 and 100. You can also use the *statistic-keywords* DECILES, MEDIAN, Q1, Q3, and QUARTILES to request common percentiles.

PROC SURVEYMEANS uses Woodruff's method (Dorfman and Valliant 1993; Särndal, Swensson, and Wretman 1992; Francisco and Fuller 1991) to estimate the variances of quantiles. See the section "Quantiles" on page 7817 for more details.

QUANTILE=(values)

specifies quantiles you want the procedure to compute. You can separate values with blanks or commas. Each value must be between 0 and 1. You can also use the *statistic-keywords* DECILES, MEDIAN, Q1, Q3, and QUARTILES to request common quantiles.

PROC SURVEYMEANS uses Woodruff's method (Dorfman and Valliant 1993; Särndal, Swensson, and Wretman 1992; Francisco and Fuller 1991) to estimate the variances of quantiles. See the section "Quantiles" on page 7817 for more details.

RATE=value | SAS-data-set

R=value | SAS-data-set

specifies the sampling rate as a nonnegative *value*, or specifies an input data set that contains the stratum sampling rates. The procedure uses this information to compute a finite population correction for Taylor series variance estimation. The procedure does not use the RATE= option for BRR or jackknife variance estimation, which you request with the **VARMETHOD=BRR** or **VARMETHOD=JACKKNIFE** option.

If your sample design has multiple stages, you should specify the *first-stage sampling rate*, which is the ratio of the number of PSUs selected to the total number of PSUs in the population.

For a nonstratified sample design, or for a stratified sample design with the same sampling rate in all strata, you should specify a nonnegative *value* for the RATE= option. If your design is stratified with different sampling rates in the strata, then you should name a SAS data set that contains the stratification variables and the sampling rates. See the section "Specification of Population Totals and Sampling Rates" on page 7805 for more details.

The *value* in the RATE= option or the values of `_RATE_` in the secondary data set must be nonnegative numbers. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC SURVEYMEANS converts that number to a proportion. The procedure treats the value 1 as 100% instead of 1%.

If you do not specify the **TOTAL=** or RATE= option, then the Taylor series variance estimation does not include a finite population correction. You cannot specify both the TOTAL= and RATE= options.

STACKING

requests that the procedure produce the output data sets by using a stacking table structure, which was the default before SAS 9. The new default is to produce a rectangular table structure in the output data sets.

A rectangular structure creates one observation for each analysis variable in the data set. A stacking structure creates only one observation in the output data set for all analysis variables.

The STACKING option affects the following tables:

- Domain
- Ratio
- Statistics
- StrataInfo

See the section “[Rectangular and Stacking Structures in an Output Data Set](#)” on page 7831 for more details.

TOTAL=*value* | *SAS-data-set*

N=*value* | *SAS-data-set*

specifies the total number of primary sampling units in the study population as a positive *value*, or specifies an input data set that contains the stratum population totals. The procedure uses this information to compute a finite population correction for Taylor series variance estimation. The procedure does not use the TOTAL= option for BRR or jackknife variance estimation, which you request with the [VARMETHOD=BRR](#) or [VARMETHOD=JACKKNIFE](#) option.

For a nonstratified sample design, or for a stratified sample design with the same population total in all strata, you should specify a positive *value* for the TOTAL= option. If your sample design is stratified with different population totals in the strata, then you should name a SAS data set that contains the stratification variables and the population totals. See the section “[Specification of Population Totals and Sampling Rates](#)” on page 7805 for more details.

If you do not specify the TOTAL= or [RATE=](#) option, then the Taylor series variance estimation does not include a finite population correction. You cannot specify both the TOTAL= and RATE= options.

statistic-keywords

specifies the statistics for the procedure to compute. If you do not specify any *statistic-keywords*, PROC SURVEYMEANS computes the NOBS, MEAN, STDERR, and CLM statistics by default.

The statistics produced depend on the type of the analysis variable. If you name a numeric variable in the CLASS statement, then the procedure analyzes that variable as a categorical variable. The procedure always analyzes character variables as categorical. See the section “[CLASS Statement](#)” on page 7796 for more information.

PROC SURVEYMEANS computes MIN, MAX, and RANGE for numeric variables but not for categorical variables. For numeric variables, the keyword MEAN produces the mean, but for categorical variables it produces the proportion in each category or level. Also, for categorical variables, the keyword NOBS produces the number of observations for each variable level, and the keyword NMISS produces the number of missing observations for each level. If you request the keyword NCLUSTER for a categorical variable, PROC SURVEYMEANS displays for each level the number of clusters with observations in that level. PROC SURVEYMEANS computes SUMWGT in the same way for both categorical and numeric variables, as the sum of the weights over all nonmissing observations.

PROC SURVEYMEANS performs univariate analysis, analyzing each variable separately. Thus the number of nonmissing and missing observations might not be the same for all analysis variables. See the section “[Missing Values](#)” on page 7804 for more information.

The following statistics are available for ratios (which you request with a **RATIO** statement): N, NCLU, SUMWGT, RATIO, STDERR, DF, T, PROBT, and CLM, as shown in the following list. If no statistics are requested, the procedure computes the ratio and its standard error by default.

The valid *statistic-keywords* are as follows:

ALL	all available statistics except those associated with geometric means
ALLGEO	all available statistics associated with geometric means
CLM	$100(1 - \alpha)\%$ two-sided confidence limits for the MEAN, where α is determined by the ALPHA= option; the default is $\alpha = 0.05$
CLSUM	$100(1 - \alpha)\%$ two-sided confidence limits for the SUM, where α is determined by the ALPHA= option; the default is $\alpha = 0.05$
CV	coefficient of variation for MEAN
CVSUM	coefficient of variation for SUM
DECILES	the 10th, the 20th, . . . , and the 90th percentiles including their standard errors and confidence limits
DF	degrees of freedom for the <i>t</i> test
GEOMEAN	geometric mean of a numeric variable that contains positive values
GMCLM	$100(1 - \alpha)\%$ two-sided confidence limits for the GEOMEAN, where α is determined by the ALPHA= option; the default is $\alpha = 0.05$
GMSTDERR	standard error of the GEOMEAN. When you request GEOMEAN, the procedure computes GMSTDERR by default.
LCLM	$100(1 - \alpha)\%$ one-sided lower confidence limit for the MEAN, where α is determined by the ALPHA= option; the default is $\alpha = 0.05$
LCLSUM	$100(1 - \alpha)\%$ one-sided lower confidence limit for the SUM, where α is determined by the ALPHA= option; the default is $\alpha = 0.05$
LGMCLM	$100(1 - \alpha)\%$ one-sided lower confidence limit for the GEOMEAN, where α is determined by the ALPHA= option; the default is $\alpha = 0.05$
MAX	maximum value
MEAN	mean for a numeric variable, or the proportion in each category for a categorical variable
MEDIAN	median for a numeric variable
MIN	minimum value
NCLUSTER	number of clusters
NMISS	number of missing observations
NOBS	number of nonmissing observations
Q1	lower quartile
Q3	upper quartile
QUARTILES	lower quartile (25%th percentile), median (50%th percentile), and upper quartile (75%th percentile), including their standard errors and confidence limits

RANGE	range, MAX–MIN
STD	standard deviation of the SUM. When you request SUM, the procedure computes STD by default.
STDERR	standard error of the MEAN or RATIO. When you request MEAN or RATIO, the procedure computes STDERR by default.
SUM	weighted sum, $\sum w_i y_i$, or estimated population total when the appropriate sampling weights are used
SUMWGT	sum of the weights, $\sum w_i$
T	t -value and its corresponding p -value with DF degrees of freedom for $H_0 : \theta = 0$, where θ is a requested statistic
UCLM	$100(1 - \alpha)\%$ one-sided upper confidence limit for the MEAN, where α is determined by the ALPHA= option; the default is $\alpha = 0.05$
UCLSUM	$100(1 - \alpha)\%$ one-sided upper confidence limit for the SUM, where α is determined by the ALPHA= option; the default is $\alpha = 0.05$
UGMCLM	$100(1 - \alpha)\%$ one-sided upper confidence limit for the GEOMEAN, where α is determined by the ALPHA= option; the default is $\alpha = 0.05$
VAR	variance of the MEAN or RATIO
VARSUM	variance of the SUM

See the section “[Statistical Computations](#)” on page 7807 for details about how PROC SURVEYMEANS computes these statistics.

VARMETHOD=BRR <(method-options)>

VARMETHOD=JACKKNIFE | **JK** <(method-options)>

VARMETHOD=TAYLOR

specifies the variance estimation method. VARMETHOD=TAYLOR requests the Taylor series method, which is the default if you do not specify the VARMETHOD= option or the REPWEIGHTS statement. VARMETHOD=BRR requests variance estimation by balanced repeated replication (BRR), and VARMETHOD=JACKKNIFE requests variance estimation by the delete-1 jackknife method.

For VARMETHOD=BRR and VARMETHOD=JACKKNIFE you can specify *method-options* in parentheses. [Table 92.3](#) summarizes the available *method-options*.

Table 92.3 Variance Estimation Options

VARMETHOD=	Variance Estimation Method	Method-Options
BRR	Balanced repeated replication	DFADJ FAY <=value> HADAMARD=SAS-data-set OUTWEIGHTS=SAS-data-set PRINTH REPS=number
JACKKNIFE	Jackknife	DFADJ OUTJKCOEFS=SAS-data-set OUTWEIGHTS=SAS-data-set
TAYLOR	Taylor series linearization	None

Method-options must be enclosed in parentheses following the method keyword. For example:

```
varmethod=BRR (reps=60 outweights=myReplicateWeights)
```

The following values are available for the VARMETHOD= option:

BRR <(method-options)>

requests **balanced repeated replication** (BRR) variance estimation. The BRR method requires a stratified sample design with two primary sampling units (PSUs) per stratum. See the section “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7824 for more information.

You can specify the following *method-options* in parentheses following VARMETHOD=BRR:

DFADJ

computes the degrees of freedom as the number of nonmissing strata for an analysis variable. The degrees of freedom for VARMETHOD=BRR equal the number of strata, which by default is based on all valid observations in the data set. But if you specify the DFADJ *method-option*, PROC SURVEYMEANS does not count any empty strata that are due to all observations containing missing values for an analysis variable.

See the section “[Degrees of Freedom](#)” on page 7810 for more information. See the section “[Data and Sample Design Summary](#)” on page 7832 for details about valid observations.

The DFADJ *method-option* has no effect on categorical variables when you specify the **MISSING** option, which treats missing values as a valid nonmissing level.

The DFADJ *method-option* cannot be used when you provide replicate weights with a **REPWEIGHTS** statement. When you use a REPWEIGHTS statement, the degrees of freedom equal the number of REPWEIGHTS variables (or replicates), unless you specify an alternative value in the DF= option in the REPWEIGHTS statement.

FAY <=value>

requests **Fay’s method**, a modification of the **BRR** method, for variance estimation. See the section “[Fay’s BRR Method](#)” on page 7825 for more information.

You can specify the *value* of the Fay coefficient, which is used in converting the original sampling weights to replicate weights. The Fay coefficient must be a nonnegative number less than 1. By default, the value of the Fay coefficient equals 0.5.

HADAMARD=SAS-data-set

H=SAS-data-set

names a SAS data set that contains the **Hadamard matrix** for BRR replicate construction. If you do not provide a Hadamard matrix with the

HADAMARD= *method-option*, PROC SURVEYMEANS generates an appropriate Hadamard matrix for replicate construction. See the sections “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7824 and “[Hadamard Matrix](#)” on page 7827 for details.

If a Hadamard matrix of a given dimension exists, it is not necessarily unique. Therefore, if you want to use a specific Hadamard matrix, you must provide the matrix as a SAS data set in the HADAMARD= *method-option*.

In the HADAMARD= input data set, each variable corresponds to a column of the Hadamard matrix, and each observation corresponds to a row of the matrix. You can use any variable names in the HADAMARD= data set. All values in the data set must equal either 1 or –1. You must ensure that the matrix you provide is indeed a Hadamard matrix—that is, $\mathbf{A}'\mathbf{A} = R\mathbf{I}$, where \mathbf{A} is the Hadamard matrix of dimension R and \mathbf{I} is an identity matrix. PROC SURVEYMEANS does not check the validity of the Hadamard matrix that you provide.

The HADAMARD= input data set must contain at least H variables, where H denotes the number of first-stage strata in your design. If the data set contains more than H variables, the procedure uses only the first H variables. Similarly, the HADAMARD= input data set must contain at least H observations.

If you do not specify the REPS= *method-option*, then the number of replicates is taken to be the number of observations in the HADAMARD= input data set. If you specify the number of replicates—for example, REPS= $nreps$ —then the first $nreps$ observations in the HADAMARD= data set are used to construct the replicates.

You can specify the PRINTH option to display the Hadamard matrix that the procedure uses to construct replicates for BRR.

OUTWEIGHTS=SAS-data-set

names a SAS data set that contains replicate weights. See the section “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7824 for information about replicate weights. See the section “[Replicate Weights Output Data Set](#)” on page 7829 for more details about the contents of the OUTWEIGHTS= data set.

The OUTWEIGHTS= *method-option* is not available when you provide replicate weights with the REPWEIGHTS statement.

PRINTH

displays the Hadamard matrix.

When you provide your own Hadamard matrix with the HADAMARD= *method-option*, only the rows and columns of the Hadamard matrix that are used by the procedure are displayed. See the sections “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7824 and “[Hadamard Matrix](#)” on page 7827 for details.

The `PRINTH method-option` is not available when you provide replicate weights with the `REPWEIGHTS` statement because the procedure does not use a Hadamard matrix in this case.

REPS=*number*

specifies the number of replicates for BRR variance estimation. The value of *number* must be an integer greater than 1.

If you do not provide a Hadamard matrix with the `HADAMARD= method-option`, the number of replicates should be greater than the number of strata and should be a multiple of 4. See the section “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7824 for more information. If a Hadamard matrix cannot be constructed for the `REPS=` value that you specify, the value is increased until a Hadamard matrix of that dimension can be constructed. Therefore, it is possible for the actual number of replicates used to be larger than the `REPS=` value that you specify.

If you provide a Hadamard matrix with the `HADAMARD= method-option`, the value of `REPS=` must not be less than the number of rows in the Hadamard matrix. If you provide a Hadamard matrix and do not specify the `REPS= method-option`, the number of replicates equals the number of rows in the Hadamard matrix.

If you do not specify the `REPS=` or `HADAMARD= method-option` and do not include a `REPWEIGHTS` statement, the number of replicates equals the smallest multiple of 4 that is greater than the number of strata.

If you provide replicate weights with the `REPWEIGHTS` statement, the procedure does not use the `REPS= method-option`. With a `REPWEIGHTS` statement, the number of replicates equals the number of `REPWEIGHTS` variables.

JACKKNIFE | JK <(method-options)>

requests variance estimation by the delete-1 jackknife method. See the section “[Jackknife Method](#)” on page 7826 for details. If you provide replicate weights with a `REPWEIGHTS` statement, `VARMETHOD=JACKKNIFE` is the default variance estimation method.

You can specify the following *method-options* in parentheses following `VARMETHOD=JACKKNIFE`:

DFADJ

computes the degrees of freedom as the number of nonmissing strata for an analysis variable. The degrees of freedom for `VARMETHOD=JACKKNIFE` equal the number of clusters (or number of observations if there is no clusters) minus the number of strata (or one if there is no strata). By default, the number of strata is based on all valid observations in the data set. But if you specify the `DFADJ method-option`, PROC SURVEYMEANS does not count any empty strata that are due to all observations containing missing values for an analysis variable.

See the section “[Degrees of Freedom](#)” on page 7810 for more information. See the section “[Data and Sample Design Summary](#)” on page 7832 for details about valid observations.

The `DFADJ` *method-option* has no effect on categorical variables when you specify the `MISSING` option, which treats missing values as a valid nonmissing level.

The `DFADJ` *method-option* cannot be used when you provide replicate weights with a `REPWEIGHTS` statement. When you use a `REPWEIGHTS` statement, the degrees of freedom equal the number of `REPWEIGHTS` variables (or replicates), unless you specify an alternative value in the `DF=` option in the `REPWEIGHTS` statement.

OUTJKCOEFS=SAS-data-set

names a SAS data set that contains jackknife coefficients. See the section “[Jackknife Method](#)” on page 7826 for information about [jackknife coefficients](#). See the section “[Jackknife Coefficients Output Data Set](#)” on page 7830 for more details about the contents of the `OUTJKCOEFS=` data set.

OUTWEIGHTS=SAS-data-set

names a SAS data set that contains replicate weights. See the section “[Jackknife Method](#)” on page 7826 for information about replicate weights. See the section “[Replicate Weights Output Data Set](#)” on page 7829 for more details about the contents of the `OUTWEIGHTS=` data set.

The `OUTWEIGHTS=` *method-option* is not available when you provide replicate weights with the `REPWEIGHTS` statement.

TAYLOR

requests Taylor series variance estimation. This is the default method if you do not specify the `VARMETHOD=` option or a `REPWEIGHTS` statement. See the section “[Taylor Series Method](#)” on page 7809 for more information.

BY Statement

BY variables ;

You can specify a `BY` statement with `PROC SURVEYMEANS` to obtain separate analyses of observations in groups that are defined by the `BY` variables. When a `BY` statement appears, the procedure expects the input data set to be sorted in order of the `BY` variables. If you specify more than one `BY` statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the `SORT` procedure with a similar `BY` statement.
- Specify the `NOTSORTED` or `DESCENDING` option in the `BY` statement for the `SURVEYMEANS` procedure. The `NOTSORTED` option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the `BY` variables) and that these groups are not necessarily in alphabetical or increasing numeric order.

- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

Note that using a BY statement provides completely separate analyses of the BY groups. It does not provide a statistically valid domain (subpopulation) analysis, where the total number of units in the subpopulation is not known with certainty. You should use the DOMAIN statement to obtain domain analysis. For more information about subpopulation analysis for sample survey data, see Cochran (1977).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* ;

The CLASS statement names variables to be analyzed as categorical variables. For categorical variables, PROC SURVEYMEANS estimates the proportion in each category or level, instead of the overall mean. PROC SURVEYMEANS always analyzes character variables as categorical. If you want categorical analysis for a numeric variable, you must include that variable in the CLASS statement.

The CLASS *variables* are one or more variables in the DATA= input data set. These variables can be either character or numeric. The formatted values of the CLASS variables determine the categorical variable levels. Thus, you can use formats to group values into levels. See the FORMAT procedure in the *Base SAS Procedures Guide* and the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference* for more information.

When determining levels of a CLASS variable, an observation with missing values for this CLASS variable is excluded, unless you specify the MISSING option. For more information, see the section “Missing Values” on page 7804.

You can use multiple CLASS statements to specify categorical variables.

When you specify classification variables, you can use the SAS system option SUMSIZE= to limit (or to specify) the amount of memory that is available for data analysis. See the chapter on SAS system options in *SAS System Options: Reference* for a description of the SUMSIZE= option.

CLUSTER Statement

CLUSTER *variables* ;

The CLUSTER statement names variables that identify the clusters in a clustered sample design. The combinations of categories of CLUSTER variables define the clusters in the sample. If there is a STRATA statement, clusters are nested within strata.

If you provide replicate weights for BRR or jackknife variance estimation with the REPWEIGHTS statement, you do not need to specify a CLUSTER statement.

If your sample design has clustering at multiple stages, you should identify only the first-stage clusters (primary sampling units (PSUs)), in the CLUSTER statement. See the section “Primary Sampling Units (PSUs)” on page 7806 for more information.

The CLUSTER *variables* are one or more variables in the DATA= input data set. These variables can be either character or numeric. The formatted values of the CLUSTER variables determine the CLUSTER variable levels. Thus, you can use formats to group values into levels. See the FORMAT procedure in the *Base SAS Procedures Guide* and the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference* for more information.

When determining levels of a CLUSTER variable, an observation with missing values for this CLUSTER variable is excluded, unless you specify the **MISSING** option. For more information, see the section “[Missing Values](#)” on page 7804.

You can use multiple CLUSTER statements to specify cluster variables. The procedure uses variables from all CLUSTER statements to create clusters.

DOMAIN Statement

DOMAIN *variables* < *variable*variable variable*variable*variable . . .* > < / *option* > ;

The DOMAIN statement requests analysis for domains (subpopulations) in addition to analysis for the entire study population. The DOMAIN statement names the variables that identify domains, which are called domain variables.

It is common practice to compute statistics for domains. The formation of these domains might be unrelated to the sample design. Therefore, the sample sizes for the domains are random variables. Use a DOMAIN statement to incorporate this variability into the variance estimation.

Note that a DOMAIN statement is different from a **BY** statement. In a BY statement, you treat the sample sizes as fixed in each subpopulation, and you perform analysis within each BY group independently. See the section “[Domain Analysis](#)” on page 7806 for more details.

Use the DOMAIN statement on the entire data set to perform a domain analysis. Creating a new data set from a single domain and analyzing that with PROC SURVEYMEANS yields inappropriate estimates of variance.

A domain variable can be either character or numeric. The procedure treats domain variables as categorical variables. If a variable appears by itself in a DOMAIN statement, each level of this variable determines a domain in the study population. If two or more variables are joined by asterisks (*), then every possible combination of levels of these variables determines a domain. The procedure performs a descriptive analysis within each domain that is defined by the domain variables.

When determining levels of a DOMAIN variable, an observation with missing values for this DOMAIN variable is excluded, unless you specify the **MISSING** option. For more information, see the section “[Missing Values](#)” on page 7804.

The formatted values of the domain variables determine the categorical variable levels. Thus, you can use formats to group values into levels. See the FORMAT procedure in the *Base SAS Procedures Guide* and the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference* for more information.

You can specify the following option in the DOMAIN statement after a slash (/):

DFADJ

computes the degrees of freedom by using the number of non-empty strata for an analysis variable in a domain.

In a domain analysis, it is possible that some strata contain no sampling units for a specific domain. Or some strata in the domain might be empty due to missing values. By default, the procedure counts these empty strata when computing the degrees of freedom.

However, if you specify the DFADJ option, the procedure excludes any empty strata when computing the degrees of freedom. Prior to SAS 9.2, the procedure excluded empty strata by default.

See the section “[Degrees of Freedom](#)” on page 7810 for more information. See the section “[Data and Sample Design Summary](#)” on page 7832 for details about valid observations.

The DFADJ option has no effect on categorical variables when you specify the [MISSING](#) option, which treats missing values as a valid nonmissing level.

POSTSTRATA Statement

POSTSTRATA *variables* / **PSTOTAL=** *< option >* ;

POSTSTRATA *variables* / **PSPCT=** *< option >* ;

The POSTSTRATA statement names variables that form the poststrata to adjust the sampling weight for analyzing the survey. The combinations of categories of POSTSTRATA variables define the poststrata in the sample.

The POSTSTRATA *variables* are one or more variables in the DATA= input data set. These variables can be either character or numeric. The formatted values of the POSTSTRATA *variables* determine the categorical levels. Thus, you can use formats to group values into levels. See the FORMAT procedure in the *Base SAS Procedures Guide* and the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference* for more information.

You must specify either poststratification totals or poststratification proportions, but not both, in the POSTSTRATA statement after a slash (/).

PSTOTAL=*SAS-data-set* | *values*

POSTTOTAL=*SAS-data-set* | *values*

PSCONTROL=*SAS-data-set* | *values*

specifies an input data set that contains the poststratum totals or specifies the population poststratum totals as positive *values*. The SURVEYMEANS procedure uses this information to compute weight adjustment for poststratification.

You can provide poststratification totals by specifying **PSTOTAL=***SAS-data-set*, which names a SAS data set that contains the poststratification variables and the poststratum totals. This data set is called the *poststratum total data set*.

A poststratum total data set must contain all the poststratification variables that are listed in the POSTSTRATA statement and all the variables listed in the BY statement. If there are formats associated with the POSTSTRATA variables and the BY variables, then the formats in the poststratum

total data set for these variables must be consistent with those in the **DATA=** data set in the PROC SURVEYMEANS statement.

A poststratum total data set must have a variable named **_PSTOTAL_** that contains the poststratum totals. The value of **_PSTOTAL_** must be positive.

When poststratum levels are easy to identify, their corresponding poststratum totals can be specified as a list of positive numbers.

ORDER=FORMATTED is used to order the levels of poststratum levels.

You can separate *values* in the **PSTOTAL=** option with blanks or commas. The number of *values* must equal the number of poststrata in the data. List the *values* in the order of the corresponding poststratum level. The sum of the *values* should equal the total sampling weights.

PSPCT=SAS-data-set | values

POSTPCT=SAS-data-set | values

specifies an input data set that contains the population poststratum proportions or specifies the population poststratum proportions as positive *values*. The SURVEYMEANS procedure uses this information to compute weight adjustment for poststratification.

You can provide poststratification proportions by specifying **POSTPCT=SAS-data-set**, which names a SAS data set that contains the poststratification variables and the poststratum poststratification. This data set is called the *poststratum proportion data set*.

A poststratum proportion data set must contain all the poststratification variables that are listed in the POSTSTRATA statement and all the variables listed in the BY statement. If there are formats associated with the POSTSTRATA variables and the BY variables, then the formats in the poststratum proportion data set for these variables must be consistent with those in the **DATA=** data set in the PROC SURVEYMEANS statement.

A poststratum proportion data set must have a variable named **_PSPCT_** that contains the poststratum proportions. The value of **_PSPCT_** must be positive.

You can provide poststratum proportions either as positive decimal numbers between 0 and 1 for all poststrata or as positive percentages that must be less than 100 for all poststrata. If any value of the proportions is greater than 1, the procedure treats all proportions as percentages instead of decimal numbers.

When poststratum levels are easy to identify, their corresponding poststratum proportions can be specified as a list of positive numbers.

ORDER=FORMATTED is used to order the levels of poststratum levels.

You can separate *values* in the **POSTPCT=** option with blanks or commas. The number of *values* must equal the number of poststrata in the data. List the *values* in the order of the corresponding poststratum level.

If you provide the proportions as decimal numbers, then the sum of these values over all poststrata must be 1.

If you provide the proportions as percentages, then the sum of these percentages over all poststrata must be 100.

You can also optionally specify the following option to create an output data set to store the poststratification weights.

OUTPSWGT=SAS-data-set

OUT=SAS-data-set

names a SAS data set to contain poststratification weights. See the section “[Poststratification](#)” on page 7820 for information about poststratification weights.

If you also specify an **OUTWEIGHTS=** *method-option* for **VARMETHOD=BRR** or **VARMETHOD=JACKKNIFE** in the **PROC SURVEYMEANS** statement, the **OUTPSWGT=** option is ignored. The poststratification weights for the full sample and the replication weights adjusted for poststratification are stored in the **OUTWEIGHTS=** data set.

See the section “[Poststratification Weights Output Data Set](#)” on page 7830 for more information about the contents of the **OUTPSWGT=** data set and the section “[Replicate Weights Output Data Set](#)” on page 7829 for more information about the contents of the **OUTWEIGHTS=** data set.

RATIO Statement

RATIO < 'label' > *variables / variables* ;

The **RATIO** statement requests ratio analysis for means or proportions of analysis variables. A ratio statement names the variables whose means are used as numerators or denominators in a ratio. Variables that appear before the slash (/) are called *numerator variables* and are used as numerators. Variables that appear after the slash (/) are called *denominator variables* and are used as denominators. These *variables* can be any number of analysis variables, either continuous or categorical, except those named in the **BY**, **CLUSTER**, **STRATA**, **DOMAIN**, **POSTSTRATA**, **REPWEIGHTS**, and **WEIGHT** statements.

You can optionally specify a label for each **RATIO** statement to identify the ratios in the output. Labels must be enclosed in single quotes.

The computation of ratios depends on whether the numerator and denominator variables are continuous or categorical.

For continuous variables, ratios are calculated from the variable means. For example, for continuous variables *X*, *Y*, *Z*, and *T*, the following **RATIO** statement requests that the procedure analyze the ratios \bar{x}/\bar{z} , \bar{x}/\bar{t} , \bar{y}/\bar{z} , and \bar{y}/\bar{t} :

```
ratio x y / z t;
```

If a continuous variable appears as both a numerator and a denominator variable, the ratio of this variable to itself is ignored.

For categorical variables, ratios are calculated with the proportions for the categories. For example, if the categorical variable *Gender* has the values ‘Male’ and ‘Female,’ with the proportions $p_m = \text{Pr}(\text{Gender}=\text{‘Male’})$ and $p_f = \text{Pr}(\text{Gender}=\text{‘Female’})$, and *Y* is a continuous variable, then the following **RATIO** statement requests that the procedure analyze the ratios p_m/p_f , p_f/p_m , \bar{y}/p_m , and \bar{y}/p_f :

```
ratio Gender y / Gender;
```

If a categorical variable appears as both a numerator and denominator variable, then the ratios of the proportions for all categories are computed, except the ratio of each category to itself.

You can have more than one RATIO statement. Each RATIO statement produces ratios independently by using its own numerator and denominator variables. Each RATIO statement also produces its own ratio analysis table.

Available statistics for a ratio are as follows:

- N, number of observations used to compute the ratio
- NCLU, number of clusters
- SUMWGT, sum of weights
- RATIO, ratio
- STDERR, standard error of ratio
- VAR, variance of ratio
- T, *t*-value of ratio
- PROBT, *p*-value of *t*
- DF, degrees of freedom of *t*
- CLM, two-sided confidence limits for ratio
- UCLM, one-sided upper confidence limit for ratio
- LCLM, one-sided lower confidence limit for ratio

The procedure calculates these statistics based on the *statistic-keywords* that you specify in the PROC SURVEYMEANS statement. If a *statistic-keyword* is not appropriate for a RATIO statement, that *statistic-keyword* is ignored for the ratios. If no valid statistics are requested for a RATIO statement, the procedure computes the ratio and its standard error by default.

When the means or proportions for the numerator and denominator variables in a ratio are calculated, an observation is excluded if it has a missing value for a continuous numerator or denominator variable. The procedure also excludes an observation with a missing value for a categorical numerator or denominator variable unless you specify the MISSING option.

When the denominator for a ratio is zero, then the value of the ratio is displayed as ‘-Infy’, ‘Infy’, or a missing value, depending on whether the numerator is negative, positive, or zero, respectively, and the corresponding internal value is the special missing value ‘.M’, the special missing value ‘.I’, or the usual missing value, respectively.

REPWEIGHTS Statement

REPWEIGHTS *variables* < / options > ;

The REPWEIGHTS statement names variables that provide replicate weights for BRR or jackknife variance estimation, which you request with the **VARMETHOD=BRR** or **VARMETHOD=JACKKNIFE** option in the PROC SURVEYMEANS statement. If you do not provide replicate weights for these methods by using a

REPWEIGHTS statement, then the procedure constructs replicate weights for the analysis. See the sections “Balanced Repeated Replication (BRR) Method” on page 7824 and “Jackknife Method” on page 7826 for information about replicate weights.

Each REPWEIGHTS variable should contain the weights for a single replicate, and the number of replicates equals the number of REPWEIGHTS variables. The REPWEIGHTS variables must be numeric, and the variable values must be nonnegative numbers.

If you provide replicate weights with a REPWEIGHTS statement, you do not need to specify a CLUSTER or STRATA statement. If you use a REPWEIGHTS statement and do not specify the VARMETHOD= option in the PROC SURVEYMEANS statement, the procedure uses VARMETHOD=JACKKNIFE by default.

If you specify a REPWEIGHTS statement but do not include a WEIGHT statement, the procedure uses the average of replicate weights of each observation as the observation’s weight.

You can specify the following options in the REPWEIGHTS statement after a slash (/):

DF=*df*

specifies the degrees of freedom for the analysis. The value of *df* must be a positive number. By default, the degrees of freedom equals the number of REPWEIGHTS variables.

JKCOEFS=*value*

specifies a jackknife coefficient for VARMETHOD=JACKKNIFE. The coefficient *value* must be a nonnegative number. See the section “Jackknife Method” on page 7826 for details about jackknife coefficients.

You can use this option to specify a single value of the jackknife coefficient, which the procedure uses for all replicates. To specify different coefficients for different replicates, use the JKCOEFS=*values* or JKCOEFS=SAS-data-set option.

JKCOEFS=*values*

specifies jackknife coefficients for VARMETHOD=JACKKNIFE, where each coefficient corresponds to an individual replicate that is identified by a REPWEIGHTS variable. You can separate *values* with blanks or commas. The coefficient *values* must be nonnegative numbers. The number of *values* must equal the number of replicate weight variables named in the REPWEIGHTS statement. List these values in the same order in which you list the corresponding replicate weight variables in the REPWEIGHTS statement.

See the section “Jackknife Method” on page 7826 for details about jackknife coefficients.

To specify different coefficients for different replicates, you can also use the JKCOEFS=SAS-data-set option. To specify a single jackknife coefficient for all replicates, use the JKCOEFS=*value* option.

JKCOEFS=SAS-data-set

names a SAS data set that contains the jackknife coefficients for VARMETHOD=JACKKNIFE. You provide the jackknife coefficients in the JKCOEFS= data set variable JKCoefficient. Each coefficient value must be a nonnegative number. The observations in the JKCOEFS= data set should correspond to the replicates that are identified by the REPWEIGHTS variables. Arrange the coefficients or observations in the JKCOEFS= data set in the same order in which you list the corresponding replicate weight variables in the REPWEIGHTS statement. The number of observations in the JKCOEFS= data set must not be less than the number of REPWEIGHTS variables.

See the section “Jackknife Method” on page 7826 for details about jackknife coefficients.

To specify different coefficients for different replicates, you can also use the **JKCOEFS=values** option. To specify a single jackknife coefficient for all replicates, use the **JKCOEFS=value** option.

STRATA Statement

STRATA *variables* < / *option* > ;

The STRATA statement specifies variables that form the strata in a stratified sample design. The combinations of categories of STRATA variables define the strata in the sample.

If your sample design has stratification at multiple stages, you should identify only the first-stage strata in the STRATA statement. See the section “[Specification of Population Totals and Sampling Rates](#)” on page 7805 for more information.

If you provide replicate weights for BRR or jackknife variance estimation with the **REPWEIGHTS** statement, you do not need to specify a STRATA statement.

The STRATA *variables* are one or more variables in the DATA= input data set. These variables can be either character or numeric. The formatted values of the STRATA variables determine the levels. Thus, you can use formats to group values into levels. See the FORMAT procedure in the *Base SAS Procedures Guide* and the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference* for more information.

When determining levels of a STRATA variable, an observation with missing values for this STRATA variable is excluded, unless you specify the **MISSING** option. For more information, see the section “[Missing Values](#)” on page 7804.

You can use multiple STRATA statements to specify stratum variables.

You can specify the following option in the STRATA statement after a slash (/):

LIST

displays a “Stratum Information” table, which includes values of the STRATA variables and the number of observations, number of clusters, population total, and sampling rate for each stratum. See the section “[Stratum Information](#)” on page 7833 for more details.

VAR Statement

VAR *variables* ;

The VAR statement names the variables to be analyzed.

A *variable* in the VAR statement should not appear in any of the **BY**, **CLUSTER**, **DOMAIN**, **POSTSTRATA**, **REPWEIGHTS**, **STRATA**, and **WEIGHT** statements.

If you want a categorical analysis for a numeric variable, you must also name that variable in the **CLASS** statement. For categorical variables, PROC SURVEYMEANS estimates the proportion in each category or level, instead of the overall mean. Character variables are always analyzed as categorical variables. See the section “[CLASS Statement](#)” on page 7796 for more information.

When you specify a variable in a **RATIO** statement but not in a VAR statement, PROC SURVEYMEANS includes this variable as an analysis variable.

If you do not specify a VAR statement, then PROC SURVEYMEANS analyzes all variables in the DATA= input data set, except those named in the **BY**, **CLUSTER**, **DOMAIN**, **POSTSTRATA**, **REPWEIGHTS**, **STRATA**, and **WEIGHT** statements.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement names the variable that contains the sampling weights. This variable must be numeric, and the sampling weights must be positive numbers. If an observation has a weight that is nonpositive or missing, then the procedure omits that observation from the analysis. See the section “Missing Values” on page 7804 for more information. If you specify more than one WEIGHT statement, the procedure uses only the first WEIGHT statement and ignores the rest.

If you do not specify a WEIGHT statement but provide replicate weights with a **REPWEIGHTS** statement, PROC SURVEYMEANS uses the average of replicate weights of each observation as the observation’s weight.

If you do not specify a WEIGHT statement or a **REPWEIGHTS** statement, PROC SURVEYMEANS assigns all observations a weight of one.

Details: SURVEYMEANS Procedure

Missing Values

If you have missing values in your survey data for any reason, such as nonresponse, this can compromise the quality of your survey results. If the respondents are different from the nonrespondents with regard to a survey effect or outcome, then survey estimates might be biased and cannot accurately represent the survey population. There are a variety of techniques in sample design and survey operations that can reduce nonresponse. After data collection is complete, you can use imputation to replace missing values with acceptable values, and/or you can use sampling weight adjustments to compensate for nonresponse. You should complete this data preparation and adjustment before you analyze your data with PROC SURVEYMEANS. For more information, see Cochran (1977); Kalton and Kaspyzyk (1986); Brick and Kalton (1996).

If an observation has a missing value or a nonpositive value for the **WEIGHT** variable, then that observation is excluded from the analysis.

An observation is also excluded from the analysis if it has a missing value for any design (**STRATA**, **CLUSTER**, **DOMAIN**, or **POSTSTRATA**) variable, unless you specify the **MISSING** option in the PROC SURVEYMEANS statement. If you specify the **MISSING** option, the procedure treats missing values as a valid (nonmissing) category for all categorical variables.

By default, when computing statistics for an analysis variable, PROC SURVEYMEANS omits observations with missing values for that analysis variable. The procedure computes statistics for each variable based only on observations that have nonmissing values for that variable. This treatment is based on the assumption that the missing values are missing completely at random (MCAR). However, this assumption is sometimes

not true. For example, evidence from other surveys might suggest that observations with missing values are systematically different from observations without missing values. If you believe that missing values are not missing completely at random, then you can specify the **NOMCAR** option to let variance estimation include these observations with missing values in the analysis variables.

Whether or not you specify the **NOMCAR** option, the procedure always excludes observations with missing or invalid values for the **WEIGHT**, **STRATA**, **CLUSTER**, and **DOMAIN** variables, unless you specify the **MISSING** option.

When you specify the **NOMCAR** option, the procedure treats observations with and without missing values for analysis variables as two different domains, and it performs a domain analysis in the domain of nonmissing observations.

The procedure performs univariate analysis and analyzes each **VAR** variable separately. Thus, the number of missing observations might be different for different variables. You can specify the keyword **NMISS** in the **PROC SURVEYMEANS** statement to display the number of missing values for each analysis variable in the “Statistics” table.

When you specify a **RATIO** statement, the procedure excludes any observation that has a missing value for a continuous numerator or denominator variable. The procedure also excludes an observation with a missing value for a categorical numerator or denominator variable unless you specify the **MISSING** option.

If you use a **REPWEIGHTS** statement, all **REPWEIGHTS** variables must contain nonmissing values.

Survey Data Analysis

Specification of Population Totals and Sampling Rates

To include a finite population correction (*fpc*) in Taylor series variance estimation, you can input either the sampling rate or the population total by using the **RATE=** or **TOTAL=** option in the **PROC SURVEYMEANS** statement. (You cannot specify both of these options in the same **PROC SURVEYMEANS** statement.) The **RATE=** and **TOTAL=** options apply only to Taylor series variance estimation. The procedure does not use a finite population correction for **BRR** or jackknife variance estimation.

If you do not specify the **RATE=** or **TOTAL=** option, the Taylor series variance estimation does not include a finite population correction. For fairly small sampling fractions, it is appropriate to ignore this correction. For more information, see Cochran (1977); Kish (1965).

If your design has multiple stages of selection and you are specifying the **RATE=** option, you should input the first-stage sampling rate, which is the ratio of the number of PSUs in the sample to the total number of PSUs in the study population. If you are specifying the **TOTAL=** option for a multistage design, you should input the total number of PSUs in the study population. See the section “**Primary Sampling Units (PSUs)**” on page 7806 for more details.

For a nonstratified sample design, or for a stratified sample design with the same sampling rate or the same population total in all strata, you can use the **RATE=value** or **TOTAL=value** option. If your sample design is stratified with different sampling rates or population totals in different strata, use the **RATE=SAS-data-set** or **TOTAL=SAS-data-set** option to name a SAS data set that contains the stratum sampling rates or totals. This data set is called a *secondary data set*, as opposed to the *primary data set* that you specify with the **DATA=** option.

The secondary data set must contain all the stratification variables listed in the STRATA statement and all the variables in the BY statement. If there are formats associated with the STRATA variables and the BY variables, then the formats must be consistent in the primary and the secondary data sets. If you specify the TOTAL=SAS-data-set option, the secondary data set must have a variable named `_TOTAL_` that contains the stratum population totals. Or if you specify the RATE=SAS-data-set option, the secondary data set must have a variable named `_RATE_` that contains the stratum sampling rates. If the secondary data set contains more than one observation for any one stratum, then the procedure uses the first value of `_TOTAL_` or `_RATE_` for that stratum and ignores the rest.

The *value* in the RATE= option or the values of `_RATE_` in the secondary data set must be nonnegative numbers. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC SURVEYMEANS converts that number to a proportion. The procedure treats the value 1 as 100% instead of 1%.

If you specify the TOTAL=*value* option, *value* must not be less than the sample size. If you provide stratum population totals in a secondary data set, these values must not be less than the corresponding stratum sample sizes.

Primary Sampling Units (PSUs)

When you have clusters, or primary sampling units (PSUs), in your sample design, the procedure estimates variance from the variation among PSUs when the Taylor series variance method is used. See the section “Variance and Standard Error of the Mean” on page 7809 and the section “Variance and Standard Deviation of the Total” on page 7812 for more information.

BRR or jackknife variance estimation methods draw multiple replicates (or subsamples) from the full sample by following a specific resampling scheme. These subsamples are constructed by deleting PSUs from the full sample.

If you use a **REPWEIGHTS** statement to provide replicate weights for BRR or jackknife variance estimation, you do not need to specify a **CLUSTER** statement. Otherwise, you should specify a **CLUSTER** statement whenever your design includes clustering at the first stage of sampling. If you do not specify a **CLUSTER** statement, then PROC SURVEYMEANS treats each observation as a PSU.

Domain Analysis

It is common practice to compute statistics for domains (subpopulations), in addition to computing statistics for the entire study population. Analysis for domains that uses the entire sample is called *domain analysis* (also called subgroup analysis, subpopulation analysis, or subdomain analysis). The formation of these subpopulations of interest might be unrelated to the sample design. Therefore, the sample sizes for the subpopulations might actually be random variables.

Use a **DOMAIN** statement to incorporate this variability into the variance estimation. Note that using a **BY** statement provides completely separate analyses of the BY groups. It does not provide a statistically valid subpopulation or domain analysis, where the total number of units in the subpopulation is not known with certainty.

For more detailed information about domain analysis, see Kish (1965).

Statistical Computations

The SURVEYMEANS procedure uses the Taylor series (linearization) method or replication (resampling) methods to estimate sampling errors of estimators based on complex sample designs. For more information, see Fuller (2009); Wolter (2007); Lohr (2010); Kalton (1983); Hidiroglou, Fuller, and Hickman (1980); Fuller et al. (1989); Lee, Forthoffer, and Lorimor (1989); Cochran (1977); Kish (1965); Hansen, Hurwitz, and Madow (1953); Rust (1985); Dippo, Fay, and Morganstein (1984); Rao and Shao (1999); Rao, Wu, and Yue (1992); Rao and Shao (1996). You can use the **VARMETHOD=** option to specify a variance estimation method to use. By default, the Taylor series method is used.

The Taylor series method obtains a linear approximation for the estimator and then uses the variance estimate for this approximation to estimate the variance of the estimate itself (Woodruff 1971; Fuller 1975). When there are clusters, or PSUs, in the sample design, the procedure estimates variance from the variation among PSUs. When the design is stratified, the procedure pools stratum variance estimates to compute the overall variance estimate. For *t* tests of the estimates, the degrees of freedom equal the number of clusters minus the number of strata in the sample design.

For a multistage sample design, the Taylor series estimation depends only on the first stage of the sample design. Therefore, the required input includes only first-stage cluster (PSU) and first-stage stratum identification. You do not need to input design information about any additional stages of sampling. This variance estimation method assumes that the first-stage sampling fraction is small, or that the first-stage sample is drawn with replacement, as it often is in practice.

Quite often in complex surveys, respondents have unequal weights, which reflect unequal selection probabilities and adjustments for nonresponse. In such surveys, the appropriate sampling weights must be used to obtain valid estimates for the study population.

However, replication methods have recently gained popularity for estimating variances in complex survey data analysis. One reason for this popularity is the relative simplicity of replication-based estimates, especially for nonlinear estimators; another is that modern computational capacity has made replication methods feasible for practical survey analysis.

Replication methods draw multiple replicates (also called subsamples) from a full sample according to a specific resampling scheme. The most commonly used resampling schemes are the *balanced repeated replication* (BRR) method and the *jackknife* method. For each replicate, the original weights are modified for the PSUs in the replicates to create replicate weights. The population parameters of interest are estimated by using the replicate weights for each replicate. Then the variances of parameters of interest are estimated by the variability among the estimates derived from these replicates. You can use a **REPWEIGHTS** statement to provide your own replicate weights for variance estimation. For more information about using replication methods to analyze sample survey data, see the section “Replication Methods for Variance Estimation” on page 7824.

Definitions and Notation

For a stratified clustered sample design, together with the sampling weights, the sample can be represented by an $n \times (P + 1)$ matrix

$$\begin{aligned} (\mathbf{w}, \mathbf{Y}) &= (w_{hij}, y_{hij}) \\ &= (w_{hij}, y_{hij}^{(1)}, y_{hij}^{(2)}, \dots, y_{hij}^{(P)}) \end{aligned}$$

where

- $h = 1, 2, \dots, H$ is the stratum index
- $i = 1, 2, \dots, n_h$ is the cluster index within stratum h
- $j = 1, 2, \dots, m_{hi}$ is the unit index within cluster i of stratum h
- $p = 1, 2, \dots, P$ is the analysis variable number, with a total of P variables
- $n = \sum_{h=1}^H \sum_{i=1}^{n_h} m_{hi}$ is the total number of observations in the sample
- w_{hij} denotes the sampling weight for unit j in cluster i of stratum h
- $y_{hij} = (y_{hij}^{(1)}, y_{hij}^{(2)}, \dots, y_{hij}^{(P)})$ are the observed values of the analysis variables for unit j in cluster i of stratum h , including both the values of numerical variables and the values of indicator variables for levels of categorical variables.

For a categorical variable C , let l denote the number of levels of C , and denote the level values as c_1, c_2, \dots, c_l . Let $y_{hij}^{(q)}$ ($q \in \{1, 2, \dots, P\}$) be an indicator variable for the category $C = c_k$ ($k = 1, 2, \dots, l$) with the observed value in unit j in cluster i of stratum h :

$$y_{hij}^{(q)} = I_{\{C=c_k\}}(h, i, j) = \begin{cases} 1 & \text{if } C_{hij} = c_k \\ 0 & \text{otherwise} \end{cases}$$

Note that the indicator variable $y_{hij}^{(q)}$ is set to missing when C_{hij} is missing. Therefore, the total number of analysis variables, P , is the total number of numerical variables plus the total number of levels of all categorical variables.

The sampling rate f_h for stratum h , which is used in Taylor series variance estimation, is the fraction of first-stage units (PSUs) selected for the sample. You can use the TOTAL= or RATE= option to input population totals or sampling rates. See the section “[Specification of Population Totals and Sampling Rates](#)” on page 7805 for details. If you input stratum totals, PROC SURVEYMEANS computes f_h as the ratio of the stratum sample size to the stratum total. If you input stratum sampling rates, PROC SURVEYMEANS uses these values directly for f_h . If you do not specify the TOTAL= or RATE= option, then the procedure assumes that the stratum sampling rates f_h are negligible, and a finite population correction is not used when computing variances. Replication methods specified by the [VARMETHOD=BRR](#) or the [VARMETHOD=JACKKNIFE](#) option do not use this finite population correction f_h .

Mean

When you specify the keyword MEAN, the procedure computes the estimate of the mean (mean per element) from the survey data. Also, the procedure computes the mean by default if you do not specify any *statistic-keywords* in the PROC SURVEYMEANS statement.

PROC SURVEYMEANS computes the estimate of the mean as

$$\hat{Y} = \left(\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} y_{hij} \right) / w_{..}$$

where

$$w_{...} = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij}$$

is the sum of the weights over all observations in the sample.

Variance and Standard Error of the Mean

When you specify the keyword `STDERR`, the procedure computes the standard error of the mean. Also, the procedure computes the standard error by default if you specify the keyword `MEAN`, or if you do not specify any *statistic-keywords* in the `PROC SURVEYMEANS` statement. The keyword `VAR` requests the variance of the mean.

Taylor Series Method

When you use `VARMETHOD=TAYLOR`, or by default if you do not specify the `VARMETHOD=` option, `PROC SURVEYMEANS` uses the Taylor series method to estimate the variance of the mean \hat{Y} . The procedure computes the estimated variance as

$$\hat{V}(\hat{Y}) = \sum_{h=1}^H \hat{V}_h(\hat{Y})$$

where, if $n_h > 1$, then

$$\begin{aligned} \hat{V}_h(\hat{Y}) &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (e_{hi\cdot} - \bar{e}_{h..})^2 \\ e_{hi\cdot} &= \left(\sum_{j=1}^{m_{hi}} w_{hij} (y_{hij} - \hat{Y}) \right) / w_{...} \\ \bar{e}_{h..} &= \left(\sum_{i=1}^{n_h} e_{hi\cdot} \right) / n_h \end{aligned}$$

and if $n_h = 1$, then

$$\hat{V}_h(\hat{Y}) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

Replication Methods

When you specify `VARMETHOD=BRR` or `VARMETHOD=JACKKNIFE`, the procedure computes the variance $\hat{V}(\hat{Y})$ with replication methods by using the variability among replicate estimates to estimate the overall variance. See the section “Replication Methods for Variance Estimation” on page 7824 for more details.

Standard Error

The standard error of the mean is the square root of the estimated variance.

$$\text{StdErr}(\hat{Y}) = \sqrt{\hat{V}(\hat{Y})}$$

t Test for the Mean

If you specify the keyword T, PROC SURVEYMEANS computes the t -value for testing that the population mean equals zero, $H_0 : \bar{Y} = 0$. The test statistic equals

$$t(\hat{Y}) = \hat{Y} / \text{StdErr}(\hat{Y})$$

The two-sided p -value for this test is

$$\text{Prob}(|T| > |t(\hat{Y})|)$$

where T is a random variable with the t distribution with df degrees of freedom.

Degrees of Freedom

PROC SURVEYMEANS computes degrees of freedom df to obtain the $100(1 - \alpha)\%$ confidence limits for means, proportions, totals, ratios, and other statistics. The degrees of freedom computation depends on the variance estimation method that you request. Missing values can affect the degrees of freedom computation. See the section “[Missing Values](#)” on page 7804 for details.

Taylor Series Variance Estimation

For the Taylor series method, PROC SURVEYMEANS calculates the degrees of freedom for the t test as the number of clusters minus the number of strata. If there are no clusters, then the degrees of freedom equal the number of observations minus the number of strata. If the design is not stratified, then the degrees of freedom equal the number of PSUs minus one.

If all observations in a stratum are excluded from the analysis due to missing values, then that stratum is called an *empty stratum*. Empty strata are not counted in the total number of strata for the table. Similarly, empty clusters and missing observations are not included in the total counts of cluster and observations that are used to compute the degrees of freedom for the analysis.

If you specify the MISSING option, missing values are treated as valid nonmissing levels for a categorical variable and are included in computing degrees of freedom. If you specify the NOMCAR option for Taylor series variance estimation, observations with missing values for an analysis variable are included in computing degrees of freedom.

Replicate-Based Variance Estimation

When there is a REPWEIGHTS statement, the degrees of freedom equal the number of REPWEIGHTS variables, unless you specify an alternative in the DF= option in a REPWEIGHTS statement.

For BRR or jackknife variance estimation without a REPWEIGHT statement, by default PROC SURVEYMEANS computes the degrees of freedom by using all valid observations in the input data set. A valid observation is an observation that has a positive value of the WEIGHT variable and nonmissing values of the STRATA and CLUSTER variables unless you specify the MISSING option. See the section “[Data and Sample Design Summary](#)” on page 7832 for details about valid observations.

For BRR variance estimation (including [Fay's method](#)) without a REPWEIGHTS statement, PROC SURVEYMEANS calculates the degrees of freedom as the number of strata. PROC SURVEYMEANS bases the number of strata on all valid observations in the data set, unless you specify the [DFADJ method-option](#) for [VARMETHOD=BRR](#). When you specify the DFADJ option, the procedure computes the degrees of freedom as the number of nonmissing strata for an analysis variable. This excludes any empty strata that occur when observations with missing values of that analysis variable are removed.

For jackknife variance estimation without a REPWEIGHTS statement, PROC SURVEYMEANS calculates the degrees of freedom as the number of clusters (or number of observations if there are no clusters) minus the number of strata (or one if there are no strata). For jackknife variance estimation, PROC SURVEYMEANS bases the number of strata and clusters on all valid observations in the data set, unless you specify the [DFADJ method-option](#) for [VARMETHOD=JACKKNIFE](#). When you specify the DFADJ option, the procedure computes the degrees of freedom from the number of nonmissing strata and clusters for an analysis variable. This excludes any empty strata or clusters that occur when observations with missing values of an analysis variable are removed.

The procedure displays the degrees of freedom for the t test if you specify the keyword DF in the PROC SURVEYMEANS statement.

Confidence Limits for the Mean

If you specify the keyword CLM, the procedure computes two-sided confidence limits for the mean. Also, the procedure includes the confidence limits by default if you do not specify any [statistic-keywords](#) in the PROC SURVEYMEANS statement.

The confidence coefficient is determined by the value of the ALPHA= option, which by default equals 0.05 and produces 95% confidence limits. The confidence limits are computed as

$$\hat{Y} \pm \text{StdErr}(\hat{Y}) \cdot t_{df, \alpha/2}$$

where \hat{Y} is the estimate of the mean, $\text{StdErr}(\hat{Y})$ is the standard error of the mean, and $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df calculated as in the section “[t Test for the Mean](#)” on page 7810.

If you specify the keyword UCLM, the procedure computes the one-sided upper $100(1 - \alpha)\%$ confidence limit for the mean:

$$\hat{Y} + \text{StdErr}(\hat{Y}) \cdot t_{df, \alpha}$$

If you specify the keyword LCLM, the procedure computes the one-sided lower $100(1 - \alpha)\%$ confidence limit for the mean:

$$\hat{Y} - \text{StdErr}(\hat{Y}) \cdot t_{df, \alpha}$$

Coefficient of Variation

If you specify the keyword CV, PROC SURVEYMEANS computes the coefficient of variation, which is the ratio of the standard error of the mean to the estimated mean:

$$cv(\bar{Y}) = \text{StdErr}(\bar{Y}) / \bar{Y}$$

If you specify the keyword CVSUM, PROC SURVEYMEANS computes the coefficient of variation for the estimated total, which is the ratio of the standard deviation of the sum to the estimated total:

$$cv(Y) = \text{Std}(\hat{Y}) / \hat{Y}$$

Proportions

If you specify the keyword MEAN for a categorical variable, PROC SURVEYMEANS estimates the proportion, or relative frequency, for each level of the categorical variable. If you do not specify any *statistic-keywords* in the PROC SURVEYMEANS statement, the procedure estimates the proportions for levels of the categorical variables, together with their standard errors and confidence limits.

The procedure estimates the proportion in level c_k for variable C as

$$\hat{p} = \frac{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} y_{hij}^{(q)}}{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij}}$$

where $y_{hij}^{(q)}$ is the value of the indicator function for level $C = c_k$, defined in the section “Definitions and Notation” on page 7807, and $y_{hij}^{(q)}$ equals 1 if the observed value of variable C equals c_k , and $y_{hij}^{(q)}$ equals 0 otherwise. Since the proportion estimator is actually an estimator of the mean for an indicator variable, the procedure computes its variance and standard error according to the method outlined in the section “Variance and Standard Error of the Mean” on page 7809. Similarly, the procedure computes confidence limits for proportions as in the section “Confidence Limits for the Mean” on page 7811.

Total

If you specify the keyword SUM, the procedure computes the estimate of the population total from the survey data. The estimate of the total is the weighted sum over the sample:

$$\hat{Y} = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} y_{hij}$$

For a categorical variable level, \hat{Y} estimates its total frequency in the population.

Variance and Standard Deviation of the Total

When you specify the keyword STD or the keyword SUM, the procedure estimates the standard deviation of the total. The keyword VARSUM requests the variance of the total.

Taylor Series Method

When you use `VARMETHOD=TAYLOR`, or by default, PROC SURVEYMEANS uses the Taylor series method to estimate the variance of the total as

$$\hat{V}(\hat{Y}) = \sum_{h=1}^H \hat{V}_h(\hat{Y})$$

where, if $n_h > 1$, then

$$\begin{aligned}\widehat{V}_h(\widehat{Y}) &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (y_{hi\cdot} - \bar{y}_{h..})^2 \\ y_{hi\cdot} &= \sum_{j=1}^{m_{hi}} w_{hij} y_{hij} \\ \bar{y}_{h..} &= \left(\sum_{i=1}^{n_h} y_{hi\cdot} \right) / n_h\end{aligned}$$

and if $n_h = 1$, then

$$\widehat{V}_h(\widehat{Y}) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

Replication Methods

When you specify **VARMETHOD=BRR** or **VARMETHOD=JACKKNIFE** option, the procedure computes the variance $\widehat{V}(\widehat{Y})$ with replication methods by measuring the variability among the estimates derived from these replicates. See the section “[Replication Methods for Variance Estimation](#)” on page 7824 for more details.

Standard Deviation

The standard deviation of the total equals

$$\text{Std}(\widehat{Y}) = \sqrt{\widehat{V}(\widehat{Y})}$$

Confidence Limits for the Total

If you specify the keyword **CLSUM**, the procedure computes confidence limits for the total. The confidence coefficient is determined by the value of the **ALPHA=** option, which by default equals 0.05 and produces 95% confidence limits. The confidence limits are computed as

$$\widehat{Y} \pm \text{Std}(\widehat{Y}) \cdot t_{df, \alpha/2}$$

where \widehat{Y} is the estimate of the total, $\text{Std}(\widehat{Y})$ is the estimated standard deviation, and $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df calculated as described in the section “[t Test for the Mean](#)” on page 7810.

If you specify the keyword **UCLSUM**, the procedure computes the one-sided upper $100(1 - \alpha)\%$ confidence limit for the sum:

$$\widehat{Y} + \text{Std}(\widehat{Y}) \cdot t_{df, \alpha}$$

If you specify the keyword **LCLSUM**, the procedure computes the one-sided lower $100(1 - \alpha)\%$ confidence limit for the sum:

$$\widehat{Y} - \text{Std}(\widehat{Y}) \cdot t_{df, \alpha}$$

Ratio

When you use a **RATIO** statement, the procedure produces statistics requested by the *statistic-keywords* in the PROC SURVEYMEANS statement.

Suppose that you want to calculate the ratio of variable Y to variable X . Let x_{hij} be the value of variable X for the j th member in cluster i in the h th stratum.

The ratio of Y to X is

$$\hat{R} = \frac{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} y_{hij}}{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} x_{hij}}$$

PROC SURVEYMEANS uses the Taylor series method to estimate the variance of the ratio \hat{R} as

$$\hat{V}(\hat{R}) = \sum_{h=1}^H \hat{V}_h(\hat{R})$$

where, if $n_h > 1$, then

$$\begin{aligned} \hat{V}_h(\hat{R}) &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (g_{hi\cdot} - \bar{g}_{h\cdot\cdot})^2 \\ g_{hi\cdot} &= \frac{\sum_{j=1}^{m_{hi}} w_{hij} (y_{hij} - x_{hij} \hat{R})}{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} x_{hij}} \\ \bar{g}_{h\cdot\cdot} &= \left(\sum_{i=1}^{n_h} g_{hi\cdot} \right) / n_h \end{aligned}$$

and if $n_h = 1$, then

$$\hat{V}_h(\hat{R}) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

The standard error of the ratio is the square root of the estimated variance:

$$\text{StdErr}(\hat{R}) = \sqrt{\hat{V}(\hat{R})}$$

When the denominator for a ratio is zero, then the value of the ratio is displayed as ‘-Infy’, ‘Infy’, or a missing value, depending on whether the numerator is negative, positive, or zero, respectively; and the corresponding internal value is the special missing value ‘.M’, the special missing value ‘.I’, or the usual missing value, respectively.

Domain Statistics

When you use a **DOMAIN** statement to request a domain analysis, the procedure computes the requested statistics for each domain.

For a domain D , let I_D be the corresponding indicator variable:

$$I_D(h, i, j) = \begin{cases} 1 & \text{if observation } (h, i, j) \text{ belongs to } D \\ 0 & \text{otherwise} \end{cases}$$

Let

$$v_{hij} = w_{hij} I_D(h, i, j) = \begin{cases} w_{hij} & \text{if observation } (h, i, j) \text{ belongs to } D \\ 0 & \text{otherwise} \end{cases}$$

The requested statistics for variable y in domain D are computed by using the new weights v .

Domain Mean

The estimated mean of y in the domain D is

$$\widehat{\bar{Y}}_D = \left(\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} v_{hij} y_{hij} \right) / v_{\dots}$$

where

$$v_{\dots} = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} v_{hij}$$

The variance of $\widehat{\bar{Y}}_D$ is estimated by

$$\widehat{V}(\widehat{\bar{Y}}_D) = \sum_{h=1}^H \widehat{V}_h(\widehat{\bar{Y}}_D)$$

where, if $n_h > 1$, then

$$\begin{aligned} \widehat{V}_h(\widehat{\bar{Y}}_D) &= \frac{n_h(1 - f_h)}{n_h - 1} \sum_{i=1}^{n_h} (r_{hi\cdot} - \bar{r}_{h\cdot\cdot})^2 \\ r_{hi\cdot} &= \left(\sum_{j=1}^{m_{hi}} v_{hij} (y_{hij} - \widehat{\bar{Y}}_D) \right) / v_{\dots} \\ \bar{r}_{h\cdot\cdot} &= \left(\sum_{i=1}^{n_h} r_{hi\cdot} \right) / n_h \end{aligned}$$

and if $n_h = 1$, then

$$\widehat{V}_h(\widehat{\bar{Y}}_D) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

Domain Total

The estimated total in domain D is

$$\hat{Y}_D = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} v_{hij} y_{hij}$$

and its estimated variance is

$$\hat{V}(\hat{Y}_D) = \sum_{h=1}^H \hat{V}_h(\hat{Y}_D)$$

where, if $n_h > 1$, then

$$\begin{aligned} \hat{V}_h(\hat{Y}_D) &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (z_{hi\cdot} - \bar{z}_{h\cdot\cdot})^2 \\ z_{hi\cdot} &= \sum_{j=1}^{m_{hi}} v_{hij} z_{hij} \\ \bar{z}_{h\cdot\cdot} &= \left(\sum_{i=1}^{n_h} z_{hi\cdot} \right) / n_h \end{aligned}$$

and if $n_h = 1$, then

$$\hat{V}_h(\hat{Y}_D) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

Domain Ratio

The estimated ratio of Y to X in domain D is

$$\hat{R}_D = \frac{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} v_{hij} y_{hij}}{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} v_{hij} x_{hij}}$$

and its estimated variance is

$$\hat{V}(\hat{R}_D) = \sum_{h=1}^H \hat{V}_h(\hat{R}_D)$$

where, if $n_h > 1$, then

$$\begin{aligned} \hat{V}_h(\hat{R}_D) &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (g_{hi\cdot} - \bar{g}_{h\cdot\cdot})^2 \\ g_{hi\cdot} &= \frac{\sum_{j=1}^{m_{hi}} v_{hij} (y_{hij} - x_{hij} \hat{R}_D)}{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} v_{hij} x_{hij}} \\ \bar{g}_{h\cdot\cdot} &= \left(\sum_{i=1}^{n_h} g_{hi\cdot} \right) / n_h \end{aligned}$$

and if $n_h = 1$, then

$$\widehat{V}_h(\widehat{R}_D) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

Quantiles

Let Y be the variable of interest in a complex survey. Denote $F(t) = \Pr(Y \leq t)$ as the cumulative distribution for Y . For $0 < p < 1$, the p th quantile of the population cumulative distribution function is

$$Y_p = \inf\{y : F(y) \geq p\}$$

Estimate of Quantile

Let $\{y_{hij}, w_{hij}\}$ be the observed values for variable Y associated with sampling weights, where (h, i, j) are the stratum index, cluster index, and member index, respectively, as shown in the section “Definitions and Notation” on page 7807. Let $y_{(1)} < y_{(2)} < \dots < y_{(d)}$ denote the sample order statistics for variable Y .

An estimate of quantile Y_p is

$$\hat{Y}_p = \begin{cases} y_{(1)} & \text{if } p < \hat{F}(y_{(1)}) \\ y_{(k)} + \frac{p - \hat{F}(y_{(k)})}{\hat{F}(y_{(k+1)}) - \hat{F}(y_{(k)})} (y_{(k+1)} - y_{(k)}) & \text{if } \hat{F}(y_{(k)}) \leq p < \hat{F}(y_{(k+1)}) \\ y_{(d)} & \text{if } p = 1 \end{cases}$$

where $\hat{F}(t)$ is the estimated cumulative distribution for Y :

$$\hat{F}(t) = \frac{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} I(y_{hij} \leq t)}{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij}}$$

and $I(\cdot)$ is the indicator function.

Standard Error

When you use **VARMETHOD=TAYLOR**, or by default if you do not specify the **VARMETHOD=** option, PROC SURVEYMEANS uses Woodruff’s method (Dorfman and Valliant 1993; Särndal, Swensson, and Wretman 1992; Francisco and Fuller 1991) to estimate the variances of quantiles. This method first constructs a confidence interval on a quantile. Then it uses the width of the confidence interval to estimate the standard error of a quantile.

In order to estimate the variance for \hat{Y}_p , first the procedure estimates the variance of the estimated distribution function $\hat{F}(\hat{Y}_p)$ by

$$\hat{V}(\hat{F}(\hat{Y}_p)) = \sum_{h=1}^H \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (d_{hi\cdot} - \bar{d}_{h\cdot\cdot})^2$$

where

$$d_{hi\cdot} = \left(\sum_{j=1}^{m_{hi}} w_{hij} (I(y_{hij} \leq \hat{Y}_p) - \hat{F}(\hat{Y}_p)) \right) / w_{\dots}$$

$$\bar{d}_{h\cdot\cdot} = \left(\sum_{i=1}^{n_h} d_{hi\cdot} \right) / n_h$$

Then $100(1 - \alpha)\%$ confidence limits for $\hat{F}(\hat{Y}_p)$ can be constructed by

$$(\hat{p}_L, \hat{p}_U) = \left(\hat{F}(\hat{Y}_p) - t_{df, \alpha/2} \sqrt{\hat{V}(\hat{F}(\hat{Y}_p))}, \quad \hat{F}(\hat{Y}_p) + t_{df, \alpha/2} \sqrt{\hat{V}(\hat{F}(\hat{Y}_p))} \right)$$

where $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df degrees of freedom, described in the section “[Degrees of Freedom](#)” on page 7810.

When (\hat{p}_L, \hat{p}_U) is out of the range of $[0, 1]$, the procedure does not compute the standard error.

The \hat{p}_L th quantile is defined as

$$\hat{Y}_{\hat{p}_L} = \begin{cases} y_{(1)} & \text{if } \hat{p}_L < \hat{F}(y_{(1)}) \\ y_{(k_L)} + \frac{\hat{p}_L - \hat{F}(y_{(k_L)})}{\hat{F}(y_{(k_L+1)}) - \hat{F}(y_{(k_L)})} (y_{(k_L+1)} - y_{(k_L)}) & \text{if } \hat{F}(y_{(k_L)}) \leq \hat{p}_L < \hat{F}(y_{(k_L+1)}) \\ y_{(d)} & \text{if } \hat{p}_L = 1 \end{cases}$$

and the \hat{p}_U th quantile is defined as

$$\hat{Y}_{\hat{p}_U} = \begin{cases} y_{(1)} & \text{if } \hat{p}_U < \hat{F}(y_{(1)}) \\ y_{(k_U)} + \frac{\hat{p}_U - \hat{F}(y_{(k_U)})}{\hat{F}(y_{(k_U+1)}) - \hat{F}(y_{(k_U)})} (y_{(k_U+1)} - y_{(k_U)}) & \text{if } \hat{F}(y_{(k_U)}) \leq \hat{p}_U < \hat{F}(y_{(k_U+1)}) \\ y_{(d)} & \text{if } \hat{p}_U = 1 \end{cases}$$

The standard error of \hat{Y}_p then is estimated by

$$\text{sd}(\hat{Y}_p) = \frac{\hat{Y}_{\hat{p}_U} - \hat{Y}_{\hat{p}_L}}{2t_{df, \alpha/2}}$$

where $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution with df degrees of freedom.

When you use the replication method, PROC SURVEYMEANS uses the usual variance estimates for a quantile as described in the section “[Replication Methods for Variance Estimation](#)” on page 7824. However, you should proceed cautiously because this variance estimator can have poor properties (Dorfman and Valliant 1993).

Confidence Limits

Symmetric $100(1 - \alpha)\%$ confidence limits are computed as

$$\left(\hat{Y}_p - \text{sd}(\hat{Y}_p) \cdot t_{df, \alpha/2}, \quad \hat{Y}_p + \text{sd}(\hat{Y}_p) \cdot t_{df, \alpha/2} \right)$$

If you specify the [NONSYMCL](#) option in the SURVEYMEANS statement when you use [VARMETHOD=TAYLOR](#) option, the procedure computes $100(1 - \alpha)\%$ nonsymmetric confidence limits:

$$(\hat{Y}_{\hat{p}_L}, \hat{Y}_{\hat{p}_U})$$

Geometric Mean

For a continuous variable Y that has positive values, the SURVEYMEANS procedure can compute its geometric mean and associated standard error and confidence limits. To request these statistics, you can specify *statistic-keywords* such as GEOMEAN, GEOSTDERR, and GEOMLCLM.

The geometric mean of Y from a sample is computed as

$$\begin{aligned}\hat{Y}_G &= \left(\prod_{h=1}^H \prod_{i=1}^{n_h} \prod_{j=1}^{m_{hi}} y_{hij}^{w_{hij}} \right)^{\frac{1}{w_{...}}} \\ &= \exp \left(\frac{1}{w_{...}} \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} \ln(y_{hij}) \right)\end{aligned}$$

where

$$w_{...} = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij}$$

is the sum of the weights over all observations in the data set.

When you use the Taylor series method, the variance estimation for the geometric mean is computed as

$$\hat{V}(\hat{Y}_G) = (\hat{Y}_G)^2 \sum_{h=1}^H \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (r_{hi\cdot} - \bar{r}_{h..})^2$$

where

$$\begin{aligned}r_{hi\cdot} &= \left(\sum_{j=1}^{m_{hi}} w_{hij} (\ln(y_{hij}) - \ln(\hat{Y}_G)) \right) / w_{...} \\ \bar{r}_{h..} &= \left(\sum_{i=1}^{n_h} r_{hi\cdot} \right) / n_h\end{aligned}$$

The standard error of the geometric mean is the square root of the estimated variance:

$$\text{StdErr}(\hat{Y}_G) = \sqrt{\hat{V}(\hat{Y}_G)}$$

The confidence limits for the geometric means are computed based on the confidence limits for the log transformation of the Y variable as

$$\left(\exp(\ln(\hat{Y}_G) - \gamma), \quad \exp(\ln(\hat{Y}_G) + \gamma) \right)$$

where

$$\gamma = t_{df, \alpha/2} * \text{StdErr}(\widehat{Y}_G) / \widehat{Y}_G$$

and $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution, with df calculated as in the section “[t Test for the Mean](#)” on page 7810.

If you use replication methods to estimate the variance by specifying `VARMETHOD=BRR` or `VARMETHOD=JACKKNIFE`, the procedure computes the variance of a geometric means $\widehat{V}_R(\widehat{Y}_G)$ by using the variability among replicate estimates to estimate the overall variance. See the section “[Replication Methods for Variance Estimation](#)” on page 7824 for more information.

Then the standard error is the square root of the estimated variance:

$$\text{StdErr}_R(\widehat{Y}_G) = \sqrt{\widehat{V}_R(\widehat{Y}_G)}$$

The confidence limits for the geometric means are computed based on the confidence limits for the log transformation of the variable Y as

$$\left(\exp(\ln(\widehat{Y}_G) - \lambda), \quad \exp(\ln(\widehat{Y}_G) + \lambda) \right)$$

where

$$\lambda = t_{df, \alpha/2} * \text{StdErr}_R(\widehat{Y}_G) / \widehat{Y}_G$$

and $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the t distribution, with df calculated as in the section “[t Test for the Mean](#)” on page 7810.

Poststratification

After a probability sample is drawn and survey data are collected, researchers sometimes want to stratify the sample according to auxiliary information about the sampled population. This process is often called *poststratification*.

When poststratification is done properly, it can improve efficiency. It can also be used to adjust the sampling weights such that the marginal distribution of the sampling weights is in agreement with known auxiliary information from other resources, such as the census. The adjusted weight is often called the *poststratification weight*. It is quite common for researchers to use poststratification techniques in survey data analysis.

Poststratification is also used by epidemiologists, who frequently analyze health survey data. They often compute statistics based on a process called *direct standardization*, a form of poststratification. For example, certain diseases, such as cancer, are more common among older populations. Therefore, to compare the prevalence rates among geographic regions that are populated with different age groups, it is necessary to make adjustments according to such demographic categories and to compute relative prevalence rates of the diseases.

For more information about poststratification, see Fuller (2009); Lohr (2010); Wolter (2007); Rao, Yung, and Hidioglou (2002).

After you provide the population controls for each poststratum that is defined by the poststratification variables, the SURVEYMEANS procedure creates the poststratification weights accordingly. Then the procedure computes statistics that you request by using poststratification weights.

You can save the poststratification weights in an `OUTPSWGT=` data to be used in subsequent analyses.

For a select sample, let $p = 1, 2, \dots, P$ be the poststratum index; let Z_1, Z_2, \dots, Z_P be the population totals for each corresponding poststratum; and let I_p be a corresponding indicator variable for the poststratum p defined by

$$I_p(h, i, j) = \begin{cases} 1 & \text{if observation } (h, i, j) \text{ belongs to } p\text{th poststratum} \\ 0 & \text{otherwise} \end{cases}$$

Denote the total sum of original weights in the sample for each poststratum as

$$\psi_p = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} w_{hij} I_p(h, i, j)$$

Then the poststratification weight for the observation (h, i, j) is

$$\tilde{w}_{hij} = w_{hij} \frac{Z_p}{\psi_p}$$

The SURVEYMEANS procedure computes statistics by using the poststratification weights \tilde{w}_{hij} instead of the original weights w_{hij} .

The standard error and confidence intervals of computed statistics are based on the estimated variance, using either a replication method or the Taylor series method.

Replication Methods

When you specify `VARMETHOD=BRR` or `VARMETHOD=JACKKNIFE`, PROC SURVEYMEANS computes the variance of a statistic by using replication methods, as described in the section “[Replication Methods for Variance Estimation](#)” on page 7824. However, with poststratification, an extra step is needed to adjust the weights.

First, PROC SURVEYMEANS constructs a replicate and computes appropriate replicate weights for the replicate. Then, by using the poststratification control totals, the procedure adjusts these replicate weights in the same way as described previously for constructing the poststratification weights for the full sample. Finally, PROC SURVEYMEANS computes the estimate for a desired statistics by using the poststratification weights that are adjusted from the replicate weights in the current replicate. Then the final variance is estimated by the variability among replicate estimates, as described in the section “[Replication Methods for Variance Estimation](#)” on page 7824.

Taylor Series Method

When you specify **VARMETHOD=TAYLOR**, or by default when you do not specify the **VARMETHOD=** option, PROC SURVEYMEANS uses the Taylor series method to estimate the variances of requested statistics.

Variance of the Mean The mean of variable Y under poststratification is

$$\hat{Y}_{PS} = \left(\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \tilde{w}_{hij} y_{hij} \right) / \tilde{w}_{...}$$

where

$$\tilde{w}_{...} = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \tilde{w}_{hij}$$

is the sum of the poststratification weights over all observations in the sample.

For each poststratum $p = 1, 2, \dots, P$, let the mean of variable Y in each poststratum be

$$\hat{Y}^{(p)} = \left(\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} I_p(h, i, j) \tilde{w}_{hij} y_{hij} \right) / \tilde{w}_{...}^{(p)}$$

where

$$\tilde{w}_{...}^{(p)} = \sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} I_p(h, i, j) \tilde{w}_{hij}$$

is the total of the poststratification weights in poststratum p .

For observation (h, i, j) , let p be the poststratum to which it belongs. Let

$$\tilde{y}_{hij} = y_{hij} - \hat{Y}^{(p)}$$

PROC SURVEYMEANS estimates the variance of \hat{Y}_{PS} as

$$\hat{V}(\hat{Y}_{PS}) = \sum_{h=1}^H \hat{V}_h$$

where, if $n_h > 1$, then

$$\begin{aligned}\hat{V}_h &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (e_{hi\cdot} - \bar{e}_{h\cdot\cdot})^2 \\ e_{hi\cdot} &= \left(\sum_{j=1}^{m_{hi}} \tilde{w}_{hij} \tilde{y}_{hij} \right) / \tilde{w}_{h\cdot\cdot} \\ \bar{e}_{h\cdot\cdot} &= \left(\sum_{i=1}^{n_h} e_{hi\cdot} \right) / n_h\end{aligned}$$

and if $n_h = 1$, then

$$\hat{V}_h = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

Variance of the Ratio Suppose you want to calculate the ratio of variable Y to variable X. Let x_{hij} and y_{hij} be the values of variable X and variable Y, respectively, for observation (h, i, j) .

The ratio of Y to X after poststratification is

$$\hat{R}_{PS} = \frac{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \tilde{w}_{hij} y_{hij}}{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \tilde{w}_{hij} x_{hij}}$$

where \tilde{w}_{hij} is the poststratification weight for observation (h, i, j) .

Let

$$\begin{aligned}\tilde{y}_{hij} &= y_{hij} - \hat{\bar{Y}}^{(p)} \\ \tilde{x}_{hij} &= x_{hij} - \hat{\bar{X}}^{(p)}\end{aligned}$$

where $\hat{\bar{Y}}^{(p)}$ and $\hat{\bar{X}}^{(p)}$ are the means of variable Y and variable X, respectively, in poststratum p .

The variance of \hat{R}_{PS} is estimated by

$$\hat{V}(\hat{R}_{PS}) = \sum_{h=1}^H \hat{V}_h(\hat{R}_{PS})$$

where, if $n_h > 1$, then

$$\begin{aligned}\hat{V}_h(\hat{R}_{PS}) &= \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (g_{hi\cdot} - \bar{g}_{h\cdot\cdot})^2 \\ g_{hi\cdot} &= \frac{\sum_{j=1}^{m_{hi}} \tilde{w}_{hij} (\tilde{y}_{hij} - \tilde{x}_{hij} \hat{R}_{PS})}{\sum_{h=1}^H \sum_{i=1}^{n_h} \sum_{j=1}^{m_{hi}} \tilde{w}_{hij} x_{hij}} \\ \bar{g}_{h\cdot\cdot} &= \left(\sum_{i=1}^{n_h} g_{hi\cdot} \right) / n_h\end{aligned}$$

and if $n_h = 1$, then

$$\hat{V}_h(\hat{R}_{PS}) = \begin{cases} \text{missing} & \text{if } n_{h'} = 1 \text{ for } h' = 1, 2, \dots, H \\ 0 & \text{if } n_{h'} > 1 \text{ for some } 1 \leq h' \leq H \end{cases}$$

Replication Methods for Variance Estimation

Recently replication methods have gained popularity for estimating variances in complex survey data analysis. One reason for this popularity is the relative simplicity of replication-based estimates, especially for nonlinear estimators; another is that modern computational capacity has made replication methods feasible for practical survey analysis. For more information, see Lohr (2010); Wolter (2007); Rust (1985); Dippo, Fay, and Morganstein (1984); Rao and Shao (1999); Rao, Wu, and Yue (1992); Rao and Shao (1996).

Replication methods draw multiple replicates (also called subsamples) from a full sample according to a specific resampling scheme. The most commonly used resampling schemes are the *balanced repeated replication* (BRR) method and the *jackknife* method. For each replicate, the original weights are modified for the PSUs in the replicates to create replicate weights. The statistics of interest are estimated by using the replicate weights for each replicate. Then the variances of parameters of interest are estimated by the variability among the estimates derived from these replicates. You can use the **REPWEIGHTS** statement to provide your own replicate weights for variance estimation.

Balanced Repeated Replication (BRR) Method

The balanced repeated replication (BRR) method requires that the full sample be drawn by using a stratified sample design with two primary sampling units (PSUs) per stratum. Let H be the total number of strata. The total number of replicates R is the smallest multiple of 4 that is greater than H . However, if you prefer a larger number of replicates, you can specify the **REPS=number** option. If a $\text{number} \times \text{number}$ Hadamard matrix cannot be constructed, the number of replicates is increased until a Hadamard matrix becomes available.

Each replicate is obtained by deleting one PSU per stratum according to the corresponding Hadamard matrix and adjusting the original weights for the remaining PSUs. The new weights are called replicate weights.

Replicates are constructed by using the first H columns of the $R \times R$ Hadamard matrix. The r th ($r = 1, 2, \dots, R$) replicate is drawn from the full sample according to the r th row of the Hadamard matrix as follows:

- If the (r, h) element of the Hadamard matrix is 1, then the first PSU of stratum h is included in the r th replicate and the second PSU of stratum h is excluded.
- If the (r, h) element of the Hadamard matrix is -1 , then the second PSU of stratum h is included in the r th replicate and the first PSU of stratum h is excluded.

Note that the “first” and “second” PSUs are determined by data order in the input data set. Thus, if you reorder the data set and perform the same analysis by using BRR method, you might get slightly different results, because the contents in each replicate sample might change.

The replicate weights of the remaining PSUs in each half-sample are then doubled to their original weights. For more details about the BRR method, see Wolter (2007) and Lohr (2010).

By default, an appropriate Hadamard matrix is generated automatically to create the replicates. You can request that the Hadamard matrix be displayed by specifying the **VARMETHOD=BRR(PRINTH)** *method-option*. If you provide a Hadamard matrix by specifying the **VARMETHOD=BRR(HADAMARD=)** *method-option*, then the replicates are generated according to the provided Hadamard matrix.

You can use the **VARMETHOD=BRR(OUTWEIGHTS=)** *method-option* to save the replicate weights into a SAS data set.

Suppose that θ is a population parameter of interest. Let $\hat{\theta}$ be the estimate from the full sample for θ . Let $\hat{\theta}_r$ be the estimate from the r th replicate subsample by using replicate weights. PROC SURVEYMEANS estimates the variance of $\hat{\theta}$ by

$$\hat{V}(\hat{\theta}) = \frac{1}{R} \sum_{r=1}^R (\hat{\theta}_r - \hat{\theta})^2$$

with H degrees of freedom, where H is the number of strata.

If a parameter cannot be computed from one or more replicates, then the variance estimate is computed by using those replicates from which the parameter can be estimated. For example, suppose the parameter is a ratio. If a replicate r contains observations such that the denominator of the ratio is zero, then the ratio cannot be computed from replicate r . In this case, the BRR variance estimate is computed as

$$\hat{V}(\hat{\theta}) = \frac{1}{R'} \sum_{r=1}^{R'} (\hat{\theta}_r - \hat{\theta})^2$$

where the summation is over the replicates where the parameter θ can be computed, and R' is the number of those replicates.

Fay's BRR Method

Fay's method is a modification of the **BRR** method, and it requires a stratified sample design with two primary sampling units (PSUs) per stratum. The total number of replicates R is the smallest multiple of 4 that is greater than the total number of strata H . However, if you prefer a larger number of replicates, you can specify the **REPS=** *method-option*.

For each replicate, Fay's method uses a Fay coefficient $0 \leq \epsilon < 1$ to impose a perturbation of the original weights in the full sample that is gentler than using only half-samples, as in the traditional BRR method. The Fay coefficient $0 \leq \epsilon < 1$ can be set by specifying the **FAY = ϵ** *method-option*. By default, $\epsilon = 0.5$ if the **FAY** *method-option* is specified without providing a value for ϵ (Judkins 1990; Rao and Shao 1999). When $\epsilon = 0$, Fay's method becomes the traditional **BRR** method. For more details, see Dippo, Fay, and Morganstein (1984); Fay (1984, 1989); Judkins (1990).

Let H be the number of strata. Replicates are constructed by using the first H columns of the $R \times R$ **Hadamard matrix**, where R is the number of replicates, $R > H$. The r th ($r = 1, 2, \dots, R$) replicate is created from the full sample according to the r th row of the Hadamard matrix as follows:

- If the (r, h) element of the Hadamard matrix is 1, then the full sample weight of the first PSU in stratum h is multiplied by ϵ and the full sample weight of the second PSU is multiplied by $2 - \epsilon$ to obtain the r th replicate weights.

- If the (r, h) element of the Hadamard matrix is -1 , then the full sample weight of the first PSU in stratum h is multiplied by $2 - \epsilon$ and the full sample weight of the second PSU is multiplied by ϵ to obtain the r th replicate weights.

You can use the **VARMETHOD=BRR(OUTWEIGHTS=)** *method-option* to save the replicate weights into a SAS data set.

By default, an appropriate Hadamard matrix is generated automatically to create the replicates. You can request that the Hadamard matrix be displayed by specifying the **VARMETHOD=BRR(PRINTH)** *method-option*. If you provide a Hadamard matrix by specifying the **VARMETHOD=BRR(HADAMARD=)** *method-option*, then the replicates are generated according to the provided Hadamard matrix.

Suppose that θ is a population parameter of interest. Let $\hat{\theta}$ be the estimate from the full sample for θ . Let $\hat{\theta}_r$ be the estimate from the r th replicate subsample by using replicate weights. PROC SURVEYMEANS estimates the variance of $\hat{\theta}$ by

$$\widehat{V}(\hat{\theta}) = \frac{1}{R(1 - \epsilon)^2} \sum_{r=1}^R (\hat{\theta}_r - \hat{\theta})^2$$

with H degrees of freedom, where H is the number of strata.

Jackknife Method

The jackknife method of variance estimation deletes one PSU at a time from the full sample to create replicates. The total number of replicates R is the same as the total number of PSUs. In each replicate, the sample weights of the remaining PSUs are modified by the jackknife coefficient α_r . The modified weights are called replicate weights.

The jackknife coefficient and replicate weights are described as follows.

Without Stratification If there is no stratification in the sample design (no **STRATA** statement), the jackknife coefficients α_r are the same for all replicates:

$$\alpha_r = \frac{R - 1}{R} \quad \text{where } r = 1, 2, \dots, R$$

Denote the original weight in the full sample for the j th member of the i th PSU as w_{ij} . If the i th PSU is included in the r th replicate ($r = 1, 2, \dots, R$), then the corresponding replicate weight for the j th member of the i th PSU is defined as

$$w_{ij}^{(r)} = w_{ij} / \alpha_r$$

With Stratification If the sample design involves stratification, each stratum must have at least two PSUs to use the jackknife method.

Let stratum \tilde{h}_r be the stratum from which a PSU is deleted for the r th replicate. Stratum \tilde{h}_r is called the *donor stratum*. Let $n_{\tilde{h}_r}$ be the total number of PSUs in the donor stratum \tilde{h}_r . The jackknife coefficients are defined as

$$\alpha_r = \frac{n_{\tilde{h}_r} - 1}{n_{\tilde{h}_r}} \quad \text{where } r = 1, 2, \dots, R$$

Denote the original weight in the full sample for the j th member of the i th PSU as w_{ij} . If the i th PSU is included in the r th replicate ($r = 1, 2, \dots, R$), then the corresponding replicate weight for the j th member of the i th PSU is defined as

$$w_{ij}^{(r)} = \begin{cases} w_{ij} & \text{if } i\text{th PSU is not in the donor stratum } \tilde{h}_r \\ w_{ij}/\alpha_r & \text{if } i\text{th PSU is in the donor stratum } \tilde{h}_r \end{cases}$$

You can use the `VARMETHOD=JACKKNIFE(OUTJKCOEFS=)` *method-option* to save the jackknife coefficients into a SAS data set and use the `VARMETHOD=JACKKNIFE(OUTWEIGHTS=)` *method-option* to save the replicate weights into a SAS data set.

If you provide your own replicate weights with a `REPWEIGHTS` statement, then you can also provide corresponding jackknife coefficients with the `JKCOEFS=` option.

Suppose that θ is a population parameter of interest. Let $\hat{\theta}$ be the estimate from the full sample for θ . Let $\hat{\theta}_r$ be the estimate from the r th replicate subsample by using replicate weights. PROC SURVEYMEANS estimates the variance of $\hat{\theta}$ by

$$\hat{V}(\hat{\theta}) = \sum_{r=1}^R \alpha_r (\hat{\theta}_r - \hat{\theta})^2$$

with $R - H$ degrees of freedom, where R is the number of replicates and H is the number of strata, or $R - 1$ when there is no stratification.

Hadamard Matrix

A Hadamard matrix \mathbf{H} is a square matrix whose elements are either 1 or -1 such that

$$\mathbf{H}\mathbf{H}' = k\mathbf{I}$$

where k is the dimension of \mathbf{H} and \mathbf{I} is the identity matrix of order k . The order k is necessarily 1, 2, or a positive integer that is a multiple of 4.

For example, the following matrix is a Hadamard matrix of dimension $k = 8$:

$$\begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\ 1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \end{bmatrix}$$

Computational Resources

Due to the complex nature of survey data analysis, the SURVEYMEANS procedure usually requires more memory than an analysis by the MEANS procedure for the same analysis variables. PROC SURVEYMEANS requires memory resources to keep a copy of each unique value of the STRATUM, CLUSTER, and DOMAIN variables in addition to the memory needed for the categorical analysis variables and other computations.

The estimated memory needed by the SURVEYMEANS procedure is described as follows.

Let:

- T_{str} be the total number of STRATUM variables
- $L_{\text{str}}(t)$ be the number of unique values for the t th STRATUM variable, where $t = 1, 2, \dots, T_{\text{str}}$
- H be the total number of strata
- T_{clu} be the total number of CLUSTER variables
- $L_{\text{clu}}(t)$ be the number of unique values for the t th CLUSTER variable, where $t = 1, 2, \dots, T_{\text{clu}}$
- T_{dom} be the total number of DOMAIN variables in a domain (you might have multiple domains defined in a DOMAIN statement)
- $L_{\text{dom}}(t)$ be the number of unique values for the t th DOMAIN variable, where $t = 1, 2, \dots, T_{\text{dom}}$
- D be the total number of domains
- T_{cont} be the total number of continuous analysis variables
- T_{clas} be the total number of categorical analysis variables (CLASS variable)
- $L_{\text{clas}}(t)$ be the number of unique values for the t th CLASS variable, where $t = 1, 2, \dots, T_{\text{clas}}$
- T_{ratio} be the total number of ratios
- T_{pctl} be the total number of percentiles
- c be a constant on the order of 32 bytes (64 for 64-bit architectures) plus the maximum combined unformatted and formatted length among all the STRATUM, CLUSTER, DOMAIN, and CLASS variables

If all combinations of levels of categorical variables exist, the maximum potential memory (in bytes) requirements for the analysis is estimated by

$$c * P * Q + 2000 * (H + 1) * (D + 1) * Q$$

where

$$P = \prod_{t=1}^{T_{\text{str}}} L_{\text{str}}(t) \prod_{t=1}^{T_{\text{clu}}} L_{\text{clu}}(t) \prod_{t=1}^{T_{\text{dom}}} L_{\text{dom}}(t)$$

$$Q = T_{\text{cont}} + \sum_{t=1}^{T_{\text{clas}}} L_{\text{clas}}(t) + T_{\text{ratio}} + T_{\text{pctl}}$$

A relatively small amount of memory, compared to the memory usage described in the preceding calculation, is also needed for the analysis.

When the data-dependent memory usage overwhelms what is available in the computer system, the procedure might open one or more utility files to complete the analysis. This process can be controlled by the SAS system option `SUMSIZE=`, which sets the memory threshold where utility file operations begin. For best results, set `SUMSIZE=` to be less than the amount of real memory that is likely to be available for the task. See the chapter on SAS system options in *SAS System Options: Reference* for a description of the `SUMSIZE=` option.

If PROC SURVEYMEANS reports that there is insufficient memory, increase `SUMSIZE=`. A `SUMSIZE=` value greater than `MEMSIZE=` has no effect. Therefore, you might also need to increase `MEMSIZE=`.

The `MEMSIZE` option can be specified at system invocation, on the SAS command line, or in a configuration file. However, the `MEMSIZE` system option is not available in some operating environments. See the *SAS Companion* for your operating environment for more information and for the syntax specification.

To report a procedure's memory consumption, you can use the `FULLTIMER` option. The syntax is described in the *SAS Companion* for your operating environment.

Also see the *SAS System Options: Reference* for more information about how to adjust your computation resource parameters for your operating environment.

For additional information about the memory usage for categorical variables, see the section “Computational Resources” in the chapter “The MEANS Procedure” in the *Base SAS Procedures Guide: Statistical Procedures*.

Output Data Sets

You can use the Output Delivery System to create a SAS data set from any piece of PROC SURVEYMEANS output. See the section “[ODS Table Names](#)” on page 7838 for more information.

PROC SURVEYMEANS also provides an output data set that stores the replicate weights for BRR or jackknife variance estimation and an output data set that stores the jackknife coefficients for jackknife variance estimation.

Replicate Weights Output Data Set

If you specify the `OUTWEIGHTS= method-option` for `VARMETHOD=BRR` or `VARMETHOD=JACKKNIFE`, PROC SURVEYMEANS stores the replicate weights in an output data set. The `OUTWEIGHTS=` output data set contains all observations from the `DATA=` input data set that are valid (used in the analysis). (A valid observation is an observation that has a positive value of the `WEIGHT` variable. Valid observations must also have nonmissing values of the `STRATA` and `CLUSTER` variables, unless you specify the `MISSING` option. See the section “[Data and Sample Design Summary](#)” on page 7832 for details about valid observations.)

The `OUTWEIGHTS=` data set contains the following variables:

- all variables in the `DATA=` input data set
- `RepWt_1`, `RepWt_2`, ..., `RepWt_n`, which are the replicate weight variables

where n is the total number of replicates in the analysis. Each replicate weight variable contains the replicate weights for the corresponding replicate. Replicate weights equal zero for those observations not included in the replicate.

After the procedure creates replicate weights for a particular input data set and survey design, you can use the `OUTWEIGHTS= method-option` to store these replicate weights and then use them again in subsequent analyses, either in PROC SURVEYMEANS or in the other survey procedures. You can use the `REPWEIGHTS` statement to provide replicate weights for the procedure.

Jackknife Coefficients Output Data Set

If you specify the `OUTJKCOEFS= method-option` for `VARMETHOD=JACKKNIFE`, PROC SURVEYMEANS stores the jackknife coefficients in an output data set. The `OUTJKCOEFS=` output data set contains one observation for each replicate. The `OUTJKCOEFS=` data set contains the following variables:

- Replicate, which is the replicate number for the jackknife coefficient
- JKCoefficient, which is the jackknife coefficient
- DonorStratum, which is the stratum of the PSU that was deleted to construct the replicate, if you specify a `STRATA` statement

After the procedure creates jackknife coefficients for a particular input data set and survey design, you can use the `OUTJKCOEFS= method-option` to store these coefficients and then use them again in subsequent analyses, either in PROC SURVEYMEANS or in the other survey procedures. You can use the `JKCOEFS=` option in the `REPWEIGHTS` statement to provide jackknife coefficients for the procedure.

Poststratification Weights Output Data Set

If you specify the `OUTPSWGT=` option in the `POSTSTRATA` statement, PROC SURVEYMEANS stores the poststratification weights in an output data set. The `OUTPSWGT=` output data set contains all observations from the `DATA=` input data set that are valid (used in the analysis). (A valid observation is an observation that has a positive value of the `WEIGHT` variable. Valid observations must also have non-missing values of the `STRATA` and `CLUSTER` variables, unless you specify the `MISSING` option. See the section “Data and Sample Design Summary” on page 7832 for more information about valid observations.)

For `VARMETHOD=TAYLOR`, the `OUTPSWGT=` data set contains the following variables:

- all variables in the `DATA=` input data set
- `_PSWt_`, which contains poststratification weights

For `VARMETHOD=BRR` and `VARMETHOD=JACKKNIFE`, the `OUTPSWGT=` option is the same `OUTWEIGHTS= method-option` that you specify in the PROC SURVEYMEANS statement, except that it also contains the variable `_PSWt_`, which contains poststratification weights for the full sample. The replication weights, adjusted for poststratification, are stored in the `OUTWEIGHTS=` data set. See the section “Replicate Weights Output Data Set” on page 7829 for the contents of the `OUTWEIGHTS=` data set.

However, if you also specify an `OUTWEIGHTS= method-option` in the PROC SURVEYMEANS statement and use a different data set name, the data set in `OUTPSWGT=` option is ignored.

If you provide your own replicate weights by using a `REPWEIGHTS` statement for `VARMETHOD=BRR` or `VARMETHOD=JACKKNIFE`, the poststratification replicate weights replace the original replicate weights in the `OUTPSWGT=` data set.

Rectangular and Stacking Structures in an Output Data Set

When you use an ODS output statement to create SAS data sets for certain tables in PROC SURVEYMEANS, there are two possible types of table structure for the output data sets: *rectangular* and *stacking*. A rectangular structure creates one observation for each analysis variable in the data set. A stacking structure creates only one observation in the output data set for all analysis variables.

Before SAS 9, the stacking table structure, similar to the table structure in PROC MEANS, was the default in PROC SURVEYMEANS. Since SAS 9, the new default is to produce a rectangular table in the output data sets. You can use the **STACKING** option to request that the procedure produce the output data sets by using a stacking table structure.

The STACKING option affects the following tables:

- Domain
- Ratio
- Statistics
- StrataInfo

Figure 92.6 and Figure 92.7 shows these two structures for analyzing the following data set:

```
data new;
  input sex$ x;
  datalines;
M 12
F 5
M 13
F 23
F 11
;
```

The following statements request the default rectangular structure of the output data set for the statistics table:

```
proc surveymeans data=new mean;
  ods output statistics=rectangle;
run;

proc print data=rectangle;
run;
```

Figure 92.6 shows the rectangular structure.

Figure 92.6 Rectangular Structure in the Output Data Set

Rectangular Structure in the Output Data Set				
Obs	Var Name	Var Level	Mean	StdErr
1	x		12.800000	2.905168
2	sex	F	0.600000	0.244949
3	sex	M	0.400000	0.244949

The following statements specify the **STACKING** option to request that the output data set have a stacking structure:

```
proc surveymeans data=new mean stacking;
  ods output statistics=stacking;
run;

proc print data=stacking;
run;
```

Figure 92.7 shows the stacking structure of the output data set for the statistics table requested by the **STACKING** option.

Figure 92.7 Stacking Structure in the Output Data Set Requested by the STACKING option

Stacking Structure in the Output Data Set					
Obs	x	x_Mean	x_StdErr	sex_F	sex_F_Mean
1	x	12.800000	2.905168	sex=F	0.600000
Obs	sex_F_StdErr	sex_M	sex_M_Mean	sex_M_StdErr	
1	0.244949	sex=M	0.400000		0.244949

Displayed Output

The SURVEYMEANS procedure produces output that is described in the following sections.

Data and Sample Design Summary

The “Data Summary” table provides information about the input data set and the sample design. This table displays the total number of valid observations, where an observation is considered *valid* if it has nonmissing values for all procedure variables other than the analysis variables—that is, for all specified

STRATA, **CLUSTER**, **DOMAIN**, **POSTSTRATA**, and **WEIGHT** variables. This number might differ from the number of nonmissing observations for an individual analysis variable, which the procedure displays in the “Statistics” table. See the section “[Missing Values](#)” on page 7804 for more information.

PROC SURVEYMEANS displays the following information in the “Data Summary” table:

- Number of Strata, if you specify a STRATA statement
- Number of Poststrata, if you specify a POSTSTRATA statement
- Number of Clusters, if you specify a CLUSTER statement
- Number of Observations, which is the total number of valid observations
- Sum of Weights, which is the sum over all valid observations, if you specify a WEIGHT statement

Class Level Information

If you use a **CLASS** statement to name classification variables for categorical analysis, or if you list any character variables in the VAR statement, then PROC SURVEYMEANS displays a “Class Level Information” table. This table contains the following information for each classification variable:

- Class Variable, which lists each CLASS variable name
- Levels, which is the number of values or levels of the classification variable
- Values, which lists the values of the classification variable. The values are separated by a white space character; therefore, to avoid confusion, you should not include a white space character within a classification variable value.

Stratum Information

If you specify the **LIST** option in the STRATA statement, PROC SURVEYMEANS displays a “Stratum Information” table. This table displays the number of valid observations in each stratum, as well as the number of nonmissing stratum observations for each analysis variable. The “Stratum Information” table provides the following for each stratum:

- Stratum Index, which is a sequential stratum identification number
- STRATA variable(s), which lists the levels of **STRATA** variables for the stratum
- Population Total, if you specify the **TOTAL=** option
- Sampling Rate, if you specify the **TOTAL=** or **RATE=** option. If you specify the **TOTAL=** option, the sampling rate is based on the number of valid observations in the stratum.
- N Obs, which is the number of valid observations
- Variable, which lists each analysis variable name
- Levels, which identifies each level for categorical variables

- N, which is the number of nonmissing observations for the analysis variable
- Clusters, which is the number of clusters, if you specify a **CLUSTER** statement

Variance Estimation

If the variance method is not Taylor series or if the **NOMCAR** option is used, by default, PROC SURVEYMEANS displays the following variance estimation specifications in the “Variance Estimation” table:

- Method, which is the variance estimation method
- Replicate Weights Data Set, which is the name of the SAS data set that contains the replicate weights
- Number of Replicates, which is the number of replicates if you specify the **VARMETHOD=BRR** or **VARMETHOD=JACKKNIFE** option
- Hadamard Data Set, which is the name of the SAS data set for the HADAMARD matrix if you specify the **VARMETHOD=BRR(HADAMARD=)** *method-option*
- Fay Coefficient, which is the value of the FAY coefficient if you specify the **VARMETHOD=BRR(FAY)** *method-option*
- Missing Levels Included (MISSING), if you specify the **MISSING** option
- Missing Levels Included (NOMCAR), if you specify the **NOMCAR** option

Statistics

The “Statistics” table displays all of the statistics that you request with *statistic-keywords* in the PROC SURVEYMEANS statement, except DECILES, MEDIAN, Q1, Q3, and QUARTILES, which are displayed in the “Quantiles” table. If you do not specify any *statistic-keywords*, then by default this table displays the following information for each analysis variable: the sample size, the mean, the standard error of the mean, and the confidence limits for the mean. The “Statistics” table can contain the following information for each analysis variable, depending on which *statistic-keywords* you request:

- Variable name
- Variable Label
- Level, which identifies each level for categorical variables
- N, which is the number of nonmissing observations
- N Miss, which is the number of missing observations
- Minimum
- Maximum
- Range

- Number of Clusters
- Sum of Weights
- DF, which is the degrees of freedom for the t test
- Mean
- Std Error of Mean, which is the standard error of the mean
- Var of Mean, which is the variance of the mean
- t Value, for testing H_0 : population MEAN = 0
- $\Pr > |t|$, which is the two-sided p -value for the t test
- $100(1 - \alpha)\%$ CL for Mean, which are two-sided confidence limits for the mean
- $100(1 - \alpha)\%$ Upper CL for Mean, which is a one-sided upper confidence limit for the mean
- $100(1 - \alpha)\%$ Lower CL for Mean, which is a one-sided lower confidence limit for the mean
- Coeff of Variation, which is the coefficient of variation for the mean
- Sum
- Std Dev, which is the standard deviation of the sum
- Var of Sum, which is the variance of the sum
- $100(1 - \alpha)\%$ CL for Sum, which are two-sided confidence limits for the sum
- $100(1 - \alpha)\%$ Upper CL for Sum, which is a one-sided upper confidence limit for the sum
- $100(1 - \alpha)\%$ Lower CL for Sum, which is a one-sided lower confidence limit for the Sum
- Coeff of Variation for sum, which is the coefficient of variation for the sum

Quantiles

The “Quantiles” table displays all the quantiles that you request with either *statistic-keywords* such as DECILES, MEDIAN, Q1, Q3, and QUARTILES, or the **PERCENTILE=** option, or the **QUANTILE=** option in the PROC SURVEYMEANS statement.

The “Quantiles” table contains the following information for each quantile:

- Variable name
- Variable Label
- Percentile, which is the requested quantile in the format of %
- Percentile Label, which is the corresponding common name for a percentile if it exists—for example, *Median* for 50th percentile

- Estimate, which is the estimate for a requested quantile with respect to the population distribution
- Std Error, which is the standard error of the quantile
- $100(1 - \alpha)\%$ Confidence Limits, which are two-sided confidence limits for the quantile

Domain Analysis

If you specify a **DOMAIN** statement, the procedure displays domain statistics in a “Domain Analysis” table. A “Domain Analysis” table displays all the requested statistics for each level of the domain request. The procedure produces a separate “Domain Analysis” for each separate domain request. For example, the **DOMAIN** statement

```
domain A B*C*D A*C C;
```

specifies four domain requests:

- A: all the levels of A
- C: all the levels of C
- A*C: all the interactive levels of A and C
- B*C*D: all the interactive levels of B, C, and D

The procedure displays four “Domain Analysis” tables, one for each domain definition. If you use an **ODS OUTPUT** statement to create an output data set for domain analysis, the output data set contains a variable **Domain** whose values are these domain definitions. It contains all the columns in the “Statistics” table plus columns of domain variable values.

Ratio Analysis

The “Ratio Analysis” table displays statistics for all the ratios that you request in the **RATIO** statement. If you do not specify any *statistic-keywords* in the **PROC SURVEYMEANS** statement, then by default this table displays the ratios and standard errors. The “Ratio Analysis” table can contain the following information for each ratio, depending on which *statistic-keywords* you request:

- Numerator, which identifies the numerator variable of the ratio
- Denominator, which identifies the denominator variable of the ratio
- N, which is the number of observations used in the ratio analysis
- number of Clusters
- Sum of Weights
- DF, which is the degrees of freedom for the *t* test
- Ratio
- Std Err of Ratio, which is the standard error of the ratio

- Var, which is the variance of the ratio
- t Value, for testing $H_0 : \text{population RATIO} = 0$
- $\Pr > |t|$, which is the two-sided p -value for the t test
- $100(1 - \alpha)\%$ CL for Ratio, which are two-sided confidence limits for the Ratio
- Upper $100(1 - \alpha)\%$ CL for Ratio, which are one-sided upper confidence limits for the Ratio
- Lower $100(1 - \alpha)\%$ CL for Ratio, which are one-sided lower confidence limits for the Ratio

When you use the ODS OUTPUT statement to create an output data set, if you use labels for your RATIO statement, these labels are saved in the variable Ratio Statement in the output data set.

Domain Ratio Analysis

If you specify a **DOMAIN** statement with a **RATIO** statement, the procedure displays domain ratios in a “Domain Ratio Analysis” table. A “Domain Ratio Analysis” table displays all the ratio statistics for each level of the domain request. It contains all the columns in the “Ratio Analysis” table plus columns of domain variable values.

Hadamard Matrix

If you specify the **VARMETHOD=BRR(PRINTH)** *method-option* in the PROC SURVEYMEANS statement, PROC SURVEYMEANS displays the Hadamard matrix that is used to construct replicates for BRR variance estimation.

If you provide a Hadamard matrix with the **VARMETHOD=BRR(HADAMARD=)** *method-option* but the procedure does not use the entire matrix, the procedure displays only the rows and columns that are actually used to construct replicates.

Geometric Means

The “Geometric Means” table displays all the statistics related to geometric mean that you request with *statistic-keywords* in the PROC SURVEYMEANS statement. The “Geometric Means” table can contain the following information for each analysis variable, depending on which *statistic-keywords* you request:

- Variable Name
- Variable Label
- Geometric Mean
- Std Error of Geometric Mean
- $100(1 - \alpha)\%$ CL for Geometric Mean, which are two-sided confidence limits for the geometric mean
- $100(1 - \alpha)\%$ Lower CL for Geometric Mean, which is a one-sided lower confidence limit for the geometric mean
- $100(1 - \alpha)\%$ Upper CL for Geometric Mean, which is a one-sided upper confidence limit for the geometric mean

Domain Geometric Means

If you specify a **DOMAIN** statement and request any statistics related to geometric mean with *statistic-keywords* in the PROC SURVEYMEANS statement, the procedure displays these statistics for each domain level in a “Domain Geometric Means” table. It contains all the columns in the “Geometric Means” table plus columns of domain variable values.

ODS Table Names

PROC SURVEYMEANS assigns a name to each table it creates; these names are listed in Table 92.4. You can use these names to refer to tables when you use the Output Delivery System (ODS) to select tables and create output data sets. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 92.4 ODS Tables Produced by PROC SURVEYMEANS

ODS Table Name	Description	Statement	Option
ClassVarInfo	Class level information	CLASS	Default
Domain	Statistics in domains	DOMAIN	Default
DomainRatio	Statistics for ratios in domains	DOMAIN and RATIO	Default
DomainGeoMeans	Statistics related to geometric means in domains	PROC and DOMAIN	Keywords
GeoMeans	Statistics related to geometric means	PROC	Keywords
HadamardMatrix	Hadamard matrix	PROC	PRINTH
Ratio	Statistics for ratios	RATIO	Default
Quantiles	Quantiles	PROC	Default
Statistics	Statistics	PROC	Default
StrataInfo	Stratum information	STRATA	LIST
Summary	Data summary	PROC	Default
VarianceEstimation	Variance estimation	PROC	VARMETHOD=JK BRR or NOMCAR

For example, the following statements create an output data set MyStrata, which contains the “StrataInfo” table, and an output data set MyStat, which contains the “Statistics” table for the ice cream study discussed in the section “Stratified Sampling” on page 7781:

```

title1 'Analysis of Ice Cream Spending';
proc surveymeans data=IceCream total=StudentTotals;
  strata Grade / list;
  var Spending Group;
  weight Weight;
  ods output
    StrataInfo = MyStrata
    Statistics = MyStat;
run;

```

Examples: SURVEYMEANS Procedure

The section “Getting Started: SURVEYMEANS Procedure” on page 7779 contains examples of analyzing data from simple random sampling and stratified simple random sample designs. This section provides more examples that illustrate how to use PROC SURVEYMEANS.

Example 92.1: Stratified Cluster Sample Design

Consider the example in the section “Stratified Sampling” on page 7781. The study population is a junior high school with a total of 4,000 students in grades 7, 8, and 9. Researchers want to know how much these students spend weekly for ice cream, on the average, and what percentage of students spend at least \$10 weekly for ice cream.

The example in the section “Stratified Sampling” on page 7781 assumes that the sample of students was selected using a stratified simple random sample design. This example shows analysis based on a more complex sample design.

Suppose that every student belongs to a study group and that study groups are formed within each grade level. Each study group contains between two and four students. Table 92.5 shows the total number of study groups for each grade.

Table 92.5 Study Groups and Students by Grade

Grade	Number of Study Groups	Number of Students
7	608	1,824
8	252	1,025
9	403	1,151
Total	1263	4,000

It is quicker and more convenient to collect data from students in the same study group than to collect data from students individually. Therefore, this study uses a stratified clustered sample design. The primary sampling units, or clusters, are study groups. The list of all study groups in the school is stratified by grade level. From each grade level, a sample of study groups is randomly selected, and all students in each selected study group are interviewed. The sample consists of eight study groups from the 7th grade, three groups from the 8th grade, and five groups from the 9th grade.

The SAS data set IceCreamStudy saves the responses of the selected students:

```
data IceCreamStudy;
  input Grade StudyGroup Spending @@;
  if (Spending < 10) then Group='less';
  else Group='more';
  datalines;
7 34 7      7 34 7      7 412 4      9 27 14
7 34 2      9 230 15     9 27 15     7 501 2
9 230 8     9 230 7      7 501 3      8 59 20
7 403 4     7 403 11     8 59 13     8 59 17
```

```

8 143 12      8 143 16      8 59 18      9 235 9
8 143 10      9 312 8      9 235 6      9 235 11
9 312 10      7 321 6      8 156 19      8 156 14
7 321 3      7 321 12      7 489 2      7 489 9
7 78 1      7 78 10      7 489 2      7 156 1
7 78 6      7 412 6      7 156 2      9 301 8
;

```

In the data set `IceCreamStudy`, the variable `Grade` contains a student's grade. The variable `StudyGroup` identifies a student's study group. It is possible for students from different grades to have the same study group number because study groups are sequentially numbered within each grade. The variable `Spending` contains a student's response regarding how much he spends per week for ice cream, in dollars. The variable `GROUP` indicates whether a student spends at least \$10 weekly for ice cream. It is not necessary to store the data in order of grade and study group.

The SAS data set `StudyGroup` is created to provide PROC SURVEYMEANS with the sample design information shown in [Table 92.5](#):

```

data StudyGroups;
    input Grade _total_;
    datalines;
7 608
8 252
9 403
;

```

The variable `Grade` identifies the strata, and the variable `_TOTAL_` contains the total number of study groups in each stratum. As discussed in the section “[Specification of Population Totals and Sampling Rates](#)” on page 7805, the population totals stored in the variable `_TOTAL_` should be expressed in terms of the primary sampling units (PSUs), which are study groups in this example. Therefore, the variable `_TOTAL_` contains the total number of study groups for each grade, rather than the total number of students.

In order to obtain unbiased estimates, you create sampling weights by using the following SAS statements:

```

data IceCreamStudy;
    set IceCreamStudy;
    if Grade=7 then Prob=8/608;
    if Grade=8 then Prob=3/252;
    if Grade=9 then Prob=5/403;
    Weight=1/Prob;
run;

```

The sampling weights are the reciprocals of the probabilities of selections. The variable `Weight` contains the sampling weights. Because the sampling design is clustered and all students from each selected cluster are interviewed, the sampling weights equal the inverse of the cluster (or study group) selection probabilities.

The following SAS statements perform the analysis for this sample design:

```

title1 'Analysis of Ice Cream Spending';
proc surveymeans data=IceCreamStudy total=StudyGroups;
  strata Grade / list;
  cluster StudyGroup;
  var Spending Group;
  weight Weight;
run;

```

[Output 92.1.1](#) provides information about the sample design and the input data set. There are three strata in the sample design, and the sample contains 16 clusters and 40 observations. The variable `Group` has two levels, 'less' and 'more.'

Output 92.1.1 Data Summary and Class Information

Analysis of Ice Cream Spending		
The SURVEYMEANS Procedure		
Data Summary		
Number of Strata		3
Number of Clusters		16
Number of Observations		40
Sum of Weights		3162.6
Class Level Information		
Class		
Variable	Levels	Values
Group	2	less more

[Output 92.1.2](#) displays information for each stratum. Since the primary sampling units in this design are study groups, the population totals shown in [Output 92.1.2](#) are the total numbers of study groups for each stratum or grade. This differs from [Output 92.3](#), which provides the population totals in terms of students since students were the primary sampling units for that design. [Output 92.1.2](#) also displays the number of clusters for each stratum and analysis variable.

Output 92.1.2 Stratum Information

Stratum Information						
Stratum Index	Grade	Population Total	Sampling Rate	N Obs	Variable	Level
1	7	608	1.32%	20	Spending Group	less more
2	8	252	1.19%	9	Spending Group	less more
3	9	403	1.24%	11	Spending Group	less more

Stratum Information						
Stratum Index	Grade	Population Total	Sampling Rate	N Obs	Variable	N
1	7	608	1.32%	20	Spending Group	20 17 3
2	8	252	1.19%	9	Spending Group	9 0 9
3	9	403	1.24%	11	Spending Group	11 6 5

Stratum Information						
Stratum Index	Grade	Population Total	Sampling Rate	N Obs	Variable	Clusters
1	7	608	1.32%	20	Spending Group	8 8 3
2	8	252	1.19%	9	Spending Group	3 0 3
3	9	403	1.24%	11	Spending Group	5 4 4

Output 92.1.3 displays the estimates of the average weekly ice cream expenditure and the percentage of students spending at least \$10 weekly for ice cream.

Output 92.1.3 Statistics

Statistics						
Variable	Level	N	Mean	Std Error of Mean	95% CL for Mean	
Spending Group		40	8.923860	0.650859	7.51776370	10.3299565
	less	23	0.561437	0.056368	0.43966057	0.6832130
	more	17	0.438563	0.056368	0.31678698	0.5603394

Example 92.2: Domain Analysis

Suppose that you are studying profiles of 800 top-performing companies to provide information about their impact on the economy. You are also interested in the company profiles within each market type. A sample of 66 companies is selected with unequal probability across market types. However, market type is not included in the sample design. Thus, the number of companies within each market type is a random variable in your sample. To obtain statistics within each market type, you should use domain analysis. The data of the 66 companies are saved in the following data set:

```
data Company;
  length Type $14;
  input Type$ Asset Sale Value Profit Employee Weight;
  datalines;
Other      2764.0  1828.0  1850.3  144.0  18.7  9.6

;

For each company in your sample, the variables are defined as follows:

- Type identifies the type of market for the company.
- Asset contains the company's assets, in millions of dollars.
- Sale contains sales, in millions of dollars.
- Value contains the market value of the company, in millions of dollars.
- Profit contains the profit, in millions of dollars.

- Employee contains the number of employees, in thousands.
- Weight contains the sampling weight.

The following SAS statements use PROC SURVEYMEANS to perform the domain analysis, estimating means, and other statistics for the overall population and also for the subpopulations (or domain) defined by market type. The DOMAIN statement specifies Type as the domain variable:

```
title 'Top Companies Profile Study';
proc surveymeans data=Company total=800 mean sum;
  var Asset Sale Value Profit Employee;
  weight Weight;
  domain Type;
run;
```

Output 92.2.1 shows that there are 66 observations in the sample. The sum of the sampling weights equals 799.8, which is close to the total number of companies in the study population.

Output 92.2.1 Company Profile Study

Top Companies Profile Study				
The SURVEYMEANS Procedure				
Data Summary				
Number of Observations		66		
Sum of Weights		799.8		
Statistics				
Variable	Mean	Std Error of Mean	Sum	Std Dev
Asset	6523.488510	720.557075	5217486	1073829
Sale	4215.995799	839.132506	3371953	847885
Value	2145.935121	342.531720	1716319	359609
Profit	188.788210	25.057876	150993	30144
Employee	36.874869	7.787857	29493	7148.003298

The “Statistics” table in Output 92.2.1 displays the estimates of the mean and total for all analysis variables for the entire set of 800 companies, while Output 92.2.2 shows the mean and total estimates for each company type.

Output 92.2.2 Domain Analysis for Company Profile Study

Example 92.3: Ratio Analysis

Suppose you are interested in the profit per employee and the sale per employee among the 800 top-performing companies in the data in the previous example. The following SAS statements illustrate how you can use PROC SURVEYMEANS to estimate these ratios:

```
title 'Ratio Analysis in Top Companies Profile Study';
proc surveymeans data=Company total=800 ratio;
  var Profit Sale Employee;
  weight Weight;
  ratio Profit Sale / Employee;
run;
```

The RATIO statement requests the ratio of the profit and the sales to the number of employees.

Output 92.3.1 shows the estimated ratios and their standard errors. Because the profit and the sales figures are in millions of dollars, and the employee numbers are in thousands, the profit per employee is estimated as \$5,120 with a standard error of \$1,059, and the sales per employee are \$114,332 with a standard error of \$20,503.

Output 92.3.1 Estimate Ratios

Ratio Analysis in Top Companies Profile Study			
The SURVEYMEANS Procedure			
Ratio Analysis			
Numerator	Denominator	Ratio	Std Err
Sale	Employee	114.332497	20.502742
Profit	Employee	5.119698	1.058939

Example 92.4: Analyzing Survey Data with Missing Values

As described in the section “[Missing Values](#)” on page 7804, the SURVEYMEANS procedure excludes an observation from the analysis if it has a missing value for the analysis variable or a nonpositive value for the WEIGHT variable.

However, if there is evidence indicating that the nonrespondents are different from the respondents for your study, you can use the NOMCAR option to compute descriptive statistics among respondents while still counting the number of nonrespondents.

We use the ice cream example in the section “[Stratified Sampling](#)” on page 7781 to illustrate how to perform similar analysis when there are missing values.

Suppose that some of the students failed to provide the amounts spent on ice cream, as shown in the following data set, IceCream:

```

data IceCream;
  input Grade Spending @@;
  if Grade=7 then Prob=20/1824;
  if Grade=8 then Prob=9/1025;
  if Grade=9 then Prob=11/1151;
  Weight=1/Prob;
  datalines;
7 7 7 7 8 . 9 10 7 . 7 10 7 3 8 20 8 19 7 2
7 . 9 15 8 16 7 6 7 6 7 6 9 15 8 17 8 14 9 .
9 8 9 7 7 3 7 12 7 4 9 14 8 18 9 9 7 2 7 1
7 4 7 11 9 8 8 . 8 13 7 . 9 . 9 11 7 2 7 9
;

data StudentTotals;
  input Grade _total_;
  datalines;
7 1824
8 1025
9 1151
;

```

Considering the possibility that those students who did not respond spend differently than those students who did respond, you can use the NOMCAR option to request the analysis to treat the respondents as a domain rather than exclude the nonrespondents.

The following SAS statements produce the desired analysis:

```

title 'Analysis of Ice Cream Spending';
proc surveymeans data=IceCream total=StudentTotals nomcar mean sum;
  strata Grade;
  var Spending;
  weight Weight;
run;

```

Output 92.4.1 summarizes the analysis including the variance estimation method.

Output 92.4.1 Analysis of Incomplete Ice Cream Data Excluding Observations with Missing Values

Analysis of Ice Cream Spending	
The SURVEYMEANS Procedure	
Data Summary	
Number of Strata	3
Number of Observations	40
Sum of Weights	4000
Variance Estimation	
Method	Taylor Series
Missing Values	NOMCAR

Output 92.4.2 shows the mean and total estimates when treating respondents as a domain in the student population. Although the point estimates are the same as the analysis without the NOMCAR option, for this particular example, the variance estimations are slightly higher when you assume that the missingness is not completely at random.

Output 92.4.2 Analysis of Incomplete Ice Cream Data Excluding Observations with Missing Values

Statistics				
Variable	Mean	Std Error of Mean	Sum	Std Dev
Spending	9.770542	0.652347	32139	3515.126876

Example 92.5: Variance Estimation Using Replication Methods

In order to improve service, the San Francisco Municipal Railway (MUNI) conducts a survey to estimate passenger's average waiting time for MUNI's subway system.

The study uses a stratified cluster sample design. Each MUNI subway line is a stratum. The subway lines included in the study are 'J-Church,' 'K-Ingleside,' 'L-Taraval,' 'M-Ocean View,' 'N-Judah,' and the street car 'F-Market & Wharves.' The MUNI vehicles in service for these lines during a day are primary sampling units. Within each stratum, two vehicles (PSUs) are randomly selected. Then the waiting times of passengers for a selected MUNI vehicle are collected.

Table 92.6 shows the number of passengers that are interviewed in each of the selected MUNI vehicles.

Table 92.6 The Sample of the MUNI Waiting Time Study

MUNI Line	Vehicle	Number of Passengers
F-Market & Wharves	1	65
	2	102
J-Church	1	101
	2	142
K-Ingleside	1	145
	2	180
L-Taraval	1	135
	2	185
M-Ocean View	1	139
	2	203
N-Judah	1	306
	2	234

The collected data are saved in the SAS data set MUNIsurvey. The variable Line indicates which MUNI line a passenger is riding. The variable vehicle identifies the vehicle that a passenger is boarding. The variable

Waittime is the time (in minutes) that a passenger waited. The variable weight contains the sampling weights, which are determined by selection probabilities within each stratum.

Output 92.5.1 displays the first 10 observations of the data set MUNIsurvey.

Output 92.5.1 First 10 Observations in the Data Set from the MUNI Subway Survey

MUNI Subway Passenger Waiting Time Survey Data					
Obs	line	vehicle	passenger	waittime	weight
1	F-Market & Wharves	1	1	18	59
2	F-Market & Wharves	1	2	0	59
3	F-Market & Wharves	1	3	16	59
4	F-Market & Wharves	1	4	13	59
5	F-Market & Wharves	1	5	5	59
6	F-Market & Wharves	1	6	13	59
7	F-Market & Wharves	1	7	7	59
8	F-Market & Wharves	1	8	5	59
9	F-Market & Wharves	1	9	16	59
10	F-Market & Wharves	1	10	5	59

Using the VARMETHOD=BRR option, the following SAS statements analyze the MUNI subway survey by using the BRR method to estimate the variance:

```

title 'MUNI Passenger Waiting Time Analysis Using BRR';
proc surveymeans data=MUNIsurvey mean varmethod=brr mean clm;
  strata line;
  cluster vehicle;
  var waittime;
  weight weight;
run;

```

The STRATUM variable is line, which corresponds to MUNI lines. The two clusters within each stratum are identified by the variable vehicle. The sampling weights are stored in the variable weight. The mean and confident limits for passenger waiting time (in minutes) are requested statistics.

Output 92.5.2 summarizes the data and indicates that the variance estimation method is BRR with 8 replicates.

Output 92.5.2 MUNI Passenger Waiting Time Analysis Using the BRR Method

MUNI Passenger Waiting Time Analysis Using BRR	
The SURVEYMEANS Procedure	
Data Summary	
Number of Strata	6
Number of Clusters	12
Number of Observations	1937
Sum of Weights	143040
Variance Estimation	
Method	BRR
Number of Replicates	8

Output 92.5.3 reports that the average passenger waiting time for a MUNI vehicle is 7.33 minutes, with an estimated standard of 0.24 minutes, using the BRR method. The 95% confident limits for the mean are estimated as 6.75 to 7.91 minutes.

Output 92.5.3 MUNI Passenger Waiting Time Analysis Using the BRR Method

Statistics			
Variable	Mean	Std Error of Mean	95% CL for Mean
waittime	7.333012	0.237557	6.75172983 7.91429366

Alternatively, the variance can be estimated using the jackknife method if the VARMETHOD=JACKKNIFE option is used. The following SAS statements analyze the MUNI subway survey by using the jackknife method to estimate the variance:

```

title 'MUNI Passenger Waiting Time Analysis Using Jackknife';
proc surveymeans data=MUNISurvey mean varmethod=jackknife mean clm;
  strata line;
  cluster vehicle;
  var waittime;
  weight weight;
run;

```

Output 92.5.4 summarizes the data and indicates that the variance estimation method is jackknife with 12 replicates.

Output 92.5.4 MUNI Passenger Waiting Time Analysis Using the Jackknife Method

MUNI Passenger Waiting Time Analysis Using Jackknife	
The SURVEYMEANS Procedure	
Data Summary	
Number of Strata	6
Number of Clusters	12
Number of Observations	1937
Sum of Weights	143040
Variance Estimation	
Method	Jackknife
Number of Replicates	12

Output 92.5.5 reports the statistics computed using the jackknife method. Although the average passenger waiting time remains the same (7.33 minutes), the standard error is slightly smaller 0.23 minutes when the jackknife method is used, as opposed to 0.24 minutes when the BRR method is used. The 95% confidence limits are between 6.76 and 7.90 minutes when the jackknife method is used.

Output 92.5.5 MUNI Passenger Waiting Time Analysis Using the Jackknife Method

Statistics			
Variable	Mean	Std Error of Mean	95% CL for Mean
waittime	7.333012	0.232211	6.76481105 7.90121244

Overview: SURVEYPHREG Procedure

The SURVEYPHREG procedure performs regression analysis based on the Cox proportional hazards model for sample survey data. Cox’s semiparametric model is widely used in the analysis of survival data to estimate hazard rates when adequate explanatory variables are available. The procedure provides design-based variance estimates, confidence intervals, and hypothesis tests concerning the parameters and model effects. See Chapter 3, “Introduction to Statistical Modeling with SAS/STAT Software,” and Chapter 14, “Introduction to Survey Procedures,” for an introduction to the basic concepts of survey data analysis; see Chapter 13, “Introduction to Survival Analysis Procedures,” for an introduction to the basic concepts of survival analysis.

The survival time of each member of a finite population is assumed to follow its own hazard function, $\lambda_i(t)$, expressed as

$$\lambda_i(t) = \lambda(t; \mathbf{Z}_i(t)) = \lambda_0(t) \exp(\mathbf{Z}_i'(t)\boldsymbol{\beta})$$

where $\lambda_0(t)$ is an arbitrary and unspecified baseline hazard function, $\mathbf{Z}_i(t)$ is the vector of explanatory variables for the i th population unit at time t , and $\boldsymbol{\beta}$ is the vector of unknown regression parameters.

The finite population regression parameter $\boldsymbol{\beta}_N$ is defined as the maximizer of the partial log likelihood when the entire finite population is observed. The SURVEYPHREG procedure produces a sample-based estimate $\hat{\boldsymbol{\beta}}$ of the proportional hazards regression parameters $\boldsymbol{\beta}_N$ for the finite population by maximizing the partial pseudo-log-likelihood $l_\pi(\boldsymbol{\beta}; \mathbf{Z}_i(t), t_i)$ based on observed covariates $\mathbf{Z}_i(t)$ and observed survival time t_i . The procedure also produces an estimate of the sampling variance $V(\hat{\boldsymbol{\beta}}|\mathcal{F}_N)$, which assumes that the values of

the finite population \mathcal{F}_N are fixed. For statistical inference, PROC SURVEYPHREG incorporates complex survey sample designs, including designs with stratification, clustering, and unequal weighting.

The procedure also allows time-dependent explanatory variables. An explanatory variable is time-dependent if its value for any given individual can change over time. Time-dependent variables have many useful applications in survival analysis. You can include time-dependent variables such as blood pressure or blood chemistry measures that vary with time during the course of a study. You can also use time-dependent variables to test the validity of the proportional hazards model.

Several optimization techniques are available in SURVEYPHREG to maximize the log likelihood. Hazard ratio estimates can also be obtained along with parameter estimates. Sampling errors of the regression parameters and hazard ratios are computed by using either the Taylor series (linearization) method or one of the replication (resampling) methods that are based on complex sample designs (Binder 1983; Wolter 2007; Särndal, Swensson, and Wretman 1992; Binder 1992; Lohr 2010; Fuller 2009). These variance estimators essentially assume the finite population as fixed and estimate the variability due to the random sample selection mechanism.

The remaining sections of this chapter contain information about how to use PROC SURVEYPHREG, information about the underlying statistical methodology, and some applications of the procedure. The section “[Getting Started: SURVEYPHREG Procedure](#)” on page 7857 introduces PROC SURVEYPHREG with an example. The section “[Syntax: SURVEYPHREG Procedure](#)” on page 7861 describes the syntax of the procedure. The section “[Details: SURVEYPHREG Procedure](#)” on page 7884 summarizes the statistical techniques employed in PROC SURVEYPHREG. The section “[Examples: SURVEYPHREG Procedure](#)” on page 7913 includes some additional examples of useful applications. Experienced SAS/STAT software users might decide to proceed to the “Syntax” section, while other users might choose to read both the “Getting Started” and “Examples” sections before proceeding to “Syntax” and “Details.”

Getting Started: SURVEYPHREG Procedure

This section uses a data set that is obtained by stratified random sampling from a simulated finite population to illustrate some of the basic features of PROC SURVEYPHREG.

Suppose the library system for a small county wants to study the length of time that books are borrowed over a specified study period, adjusting for the age of the borrower and accounting for the fact that some books are never returned. Suppose there are 10 branch libraries in the county. Assume that a list of 11,617 (simulated) transactions is available for the study period October 1, 2008, to December 31, 2008, and assume that this list can be used as the sampling frame. A stratified random sample with replacement is used to select 100 transactions, where branch libraries are the strata. The total number of transactions within branches range from 510 to 2,011 for the study period. The total sample size of 100 transactions is allocated proportionally across branches based on the number of transactions. For each selected transaction, telephone interviews were conducted to find out additional characteristics of the borrower. The data set LibrarySurvey contains the following variables for all units (transactions) in the sample:

- Branch, the library branch from which the book was borrowed
- SampleWeight, the survey sampling weight for the transaction
- CheckOut, the date the book was borrowed

- CheckIn, the date the book was returned, with a missing value if the book was not returned by December 31, 2008
- Age, the age of the borrower

    lenBorrow = CheckIn          - CheckOut;
  else
    lenBorrow = input('31Dec2008',date9.) - CheckOut;
run;
```

PROC SURVEYPHREG can be used to estimate the regression parameters of a proportional hazards model and the design-based variance of the estimated coefficients. The design-based variance is useful when the finite population is considered fixed, as in this example. See Lohr (2010) and Särndal, Swensson, and Wretman (1992) for details.

The following statements request a proportional hazards regression of lenBorrow on Age with Returned as the censor indicator. A transaction is considered to be censored if its check-in date is missing. The WEIGHT statement specifies the sampling weight variable (SamplingWeight), and the STRATA statement specifies the stratification variable (Branch).

```

proc surveyphreg data = LibrarySurvey;
  weight SamplingWeight;
  strata Branch;
  model lenBorrow*Returned(0) = Age;
run;

```

Summary information about the model, number of observations, survey design, censored values, and variance estimation method are shown in [Output 93.1](#). The “Model Information” table summarizes the model you fit. The “Number of Observations” table displays the number of observations read and used by the procedure. This table also displays the sum of weights read and used. The sum of weights read (11,616.79) can be used as an estimator of the population size, and the sum of weights used can be used as an estimator of the respondent size in the population. The “Design Summary” table displays survey design information such as stratification and clustering. This example implements a stratified design with 10 strata. The “Censored Summary” and “Weighted Censored Summary” tables display the (weighted) number of censored and event units. Weighted counts can be used as estimators of the corresponding finite population quantities. For example, [Output 93.1](#) shows that 10% of the sampled units are censored and an estimated 10.05% of the population units are censored.

Figure 93.1 Summary Statistics

The SURVEYPHREG Procedure			
Model Information			
Data Set	WORK.LIBRARYSURVEY

11616.79	10449.22	1167.57	10.05
Variance Estimation			
Method	Taylor Series		

Parameter estimates and their standard errors are shown in [Output 93.2](#). The estimated regression coefficient is highly significant with a value of 0.062, indicating a positive association between age and the length of time books are borrowed (recall that these are simulated data). In this example, the procedure uses the STRATA and WEIGHT statements to incorporate stratification and unequal weighting, respectively, into variance estimation. The degrees of freedom are calculated as the number of sampling units (100) minus the number of strata (10). Note that the estimated variance reported in [Output 93.2](#) ignores the finite population correction (*fpc*). You can use the TOTAL= or RATE= option in the PROC statement to include an *fpc* in your variance estimator.

Syntax: SURVEYPHREG Procedure

The following statements are available in the SURVEYPHREG procedure. Items within < > are optional.

```

PROC SURVEYPHREG < options > ;
  BY variables ;
  CLASS variable < (options) > < ... variable < (options) > > < / options > ;
  CLUSTER variables ;
  DOMAIN variables < variable* variable variable* variable* variable ... > ;
  ESTIMATE < 'label' > estimate-specification < / options > ;
  FREQ variable ;
  LSMEANS < model-effects > < / options > ;
  LSMESTIMATE model-effect lsmestimate-specification < / options > ;
  MODEL response < * censor(list) > = effects < / options > ;
  NLOPTIONS < options > ;
  OUTPUT < OUT=SAS-data-set > < keyword=name ... keyword=name > < / options > ;
  Programming statements ;
  REPWEIGHTS variables < / options > ;
  SLICE model-effect < / options > ;
  STRATA variables < / option > ;
  STORE < OUT= > item-store-name < / LABEL= 'label' > ;
  TEST < model-effects > < / options > ;
  WEIGHT variable ;

```

The PROC SURVEYPHREG and MODEL statements are required. The CLASS statement, if present, must precede the MODEL statement.

The MODEL statement specifies the analysis model. The CLASS statement specifies the categorical variables. The STRATA statement lists the variables that form the strata in a stratified sample design. The CLUSTER statement specifies cluster identification variables in a clustered sample design. The WEIGHT statement names the sampling weight variable. The NLOPTIONS statement specifies the optimization techniques. The REPWEIGHTS statement names replicate weight variables for BRR or jackknife variance estimation. The DOMAIN statement lists the variables that define domains for subpopulation analysis. The BY statement requests completely separate analyses of groups defined by the BY variables.

The rest of this section provides detailed syntax information for each statement, beginning with the PROC SURVEYPHREG statement. The remaining statements are covered in alphabetical order.

The **ESTIMATE**, **LSMEANS**, **LSMESTIMATE**, **SLICE**, **STORE**, and **TEST** statements are also available in other procedures. Summary descriptions of functionality and syntax for these statements are provided in this chapter, and you can find full documentation about them in Chapter 19, “[Shared Concepts and Topics](#).”

PROC SURVEYPHREG Statement

PROC SURVEYPHREG <options> ;

The PROC SURVEYPHREG statement invokes the SURVEYPHREG procedure. It also identifies the data set to be analyzed. Table 93.1 summarizes the options available in the PROC SURVEYPHREG statement.

Table 93.1 PROC SURVEYPHREG Statement Options

Option	Description
DATA=	Names the input SAS data set
MISSING	Treats missing values as a valid category
NOPRINT	Suppresses all displayed output
NOMCAR	Uses missing observations specified as <i>not missing completely at random</i>
ORDER=	Specifies the sort order of CLASS variables
RATE=	Specifies the sampling rate
TOTAL=	Specifies the total number of primary sampling units
VARMETHOD=	Specifies the variance estimation method

You can specify the following options in the PROC SURVEYPHREG statement:

DATA=SAS-data-set

names the SAS data set that contains the data to be analyzed. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

MISSING

treats missing values as a valid (nonmissing) category for all categorical variables, which include CLASS, STRATA, CLUSTER, and DOMAIN variables. By default, if you do not specify the MISSING option, an observation is excluded from the analysis if it has a missing value for any of these categorical variables. For more information, see the section “Missing Values” on page 7893.

NOPRINT

suppresses all displayed output. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, “Using the Output Delivery System,” for more information.

NOMCAR

includes observations with missing values of the analysis variables that are specified in the MODEL statement as *not missing completely at random* (NOMCAR) for Taylor series variance estimation. When you specify the NOMCAR option, PROC SURVEYPHREG computes variance estimates by analyzing the nonmissing values as a domain (subpopulation), where the entire population includes both nonmissing and missing domains. See the section “Missing Values” on page 7893 for details.

By default, PROC SURVEYPHREG excludes an observation from analyses (and the corresponding variance computations) if that observation has a missing value for any of the variables in the MODEL statement. Note that if you specify the MISSING option for classification variables, then the procedure treats the missing values as a valid nonmissing level.

The NOMCAR option applies only to Taylor series variance estimation. The replication methods, which you request with the VARMETHOD=BRR and VARMETHOD=JACKKNIFE options, do not use the NOMCAR option.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of the classification variables (which are specified in the [CLASS](#) statement). This option applies to the levels for all classification variables, except when you use the (default) ORDER=FORMATTED option with numeric classification variables that have no explicit format. With this option, the levels of such variables are ordered by their internal value.

The ORDER= option can take the following values:

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent. For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

RATE=value | SAS-data-set**R=value | SAS-data-set**

specifies the sampling rate as a nonnegative *value*, or identifies an input data set that gives the stratum sampling rates in a variable named `_RATE_`. PROC SURVEYPHREG uses this information to compute a finite population correction for Taylor series variance estimation. The procedure does not use the RATE= option for BRR or jackknife variance estimation, which you request with the [VARMETHOD=BRR](#) or [VARMETHOD=JACKKNIFE](#) option.

If your sample design has multiple stages, you should specify the *first-stage sampling rate*, which is the ratio of the number of primary sampling units (PSUs) that are selected to the total number of PSUs in the population.

For a nonstratified sample design, or for a stratified sample design with the same sampling rate in all strata, you should specify a nonnegative *value* for the RATE= option. If your design is stratified with different sampling rates in different strata, then you should name a SAS data set that contains the stratification variables and the stratum sampling rates. See the section “[Population Totals and Sampling Rates](#)” on page 7892 for details.

The sampling rate *value* must be a nonnegative number. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC SURVEYPHREG converts that number to a proportion. The procedure treats the value 1 as 100% instead of 1%.

If you do not specify the RATE= or [TOTAL=](#) option, then the Taylor series variance estimation does not include a finite population correction. You cannot specify both the TOTAL= option and the RATE= option in the same PROC SURVEYPHREG statement.

TOTAL=*value* | *SAS-data-set*

N=*value* | *SAS-data-set*

specifies the total number of primary sampling units (PSUs) in the study population as a positive *value*, or identifies an input data set that gives the stratum population totals in a variable named `_TOTAL_`. PROC SURVEYPHREG uses this information to compute a finite population correction for Taylor series variance estimation. The procedure does not use the TOTAL= option for BRR or jackknife variance estimation, which you request with the **VARMETHOD=BRR** or **VARMETHOD=JACKKNIFE** option.

For a nonstratified sample design, or for a stratified sample design with the same population total in all strata, you should specify a positive *value* for the TOTAL= option, which refers to the total number of PSUs in each stratum. If your sample design is stratified with different population totals in different strata, then you should name a SAS data set that contains the stratification variables and the stratum totals. See the section “[Population Totals and Sampling Rates](#)” on page 7892 for details.

If you do not specify the TOTAL= or **RATE=** option, then the Taylor series variance estimation does not include a finite population correction. You cannot specify both the TOTAL= option and the RATE= option in the same PROC SURVEYPHREG statement.

VARMETHOD=BRR < (*method-options*) > | **JACKKNIFE** < (*method-options*) > | **TAYLOR**

specifies the variance estimation method. **VARMETHOD=TAYLOR** requests the Taylor series method, which is the default if you do not specify the **VARMETHOD=** option or a **REPWEIGHTS** statement. **VARMETHOD=BRR** requests variance estimation by balanced repeated replication (BRR), and **VARMETHOD=JACKKNIFE** requests variance estimation by the delete-1 jackknife method.

For **VARMETHOD=BRR** and **VARMETHOD=JACKKNIFE**, you can specify *method-options* in parentheses following the variance method name. [Table 93.2](#) summarizes the available *method-options*.

Table 93.2 Variance Estimation Options

VARMETHOD=	Variance Estimation Method	<i>Method-Options</i>
BRR	Balanced repeated replication	CENTER=FULLSAMPLE REPLICATES FAY <= <i>value</i> > HADAMARD=SAS-data-set OUTWEIGHTS=SAS-data-set PRINTH REPS=number
JACKKNIFE	Jackknife	CENTER=FULLSAMPLE REPLICATES OUTJKCOEFS=SAS-data-set OUTWEIGHTS=SAS-data-set
TAYLOR	Taylor series linearization	None

The following values are available for the VARMETHOD= option:

BRR < (*method-options*) >

requests variance estimation by balanced repeated replication (BRR). The BRR method requires a stratified sample design with two primary sampling units (PSUs) in each stratum. If you specify the VARMETHOD=BRR option, you must also specify a **STRATA** statement unless you provide replicate weights with a **REPWEIGHTS** statement. See the section “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7896 for details.

You can specify the following *method-options* in parentheses after the VARMETHOD=BRR option:

CENTER=FULLSAMPLE | REPLICATES

defines how to compute the deviations for the BRR method. CENTER=FULLSAMPLE is the default, which computes the deviations of the replicate estimates from the full sample estimate. Alternatively, you can specify CENTER=REPLICATES to compute the deviations of the replicate estimates from the average of the replicate estimates. See the section “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7896 for details.

FAY <=*value*>

requests Fay’s method, which is a modification of the BRR method. See the section “[Fay’s BRR Method](#)” on page 7898 for details.

You can specify the *value* of the Fay coefficient, which is used in converting the original sampling weights to replicate weights. The Fay coefficient must be a nonnegative number less than 1. By default, the value of the Fay coefficient equals 0.5.

HADAMARD=SAS-data-set

H=SAS-data-set

names a SAS data set that contains the Hadamard matrix for BRR replicate construction. If you do not provide a Hadamard matrix with the HADAMARD= *method-option*, PROC SURVEYPHREG generates an appropriate Hadamard matrix for replicate construction. See the sections “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7896 and “[Hadamard Matrix](#)” on page 7898 for details.

If a Hadamard matrix of a given dimension exists, it is not necessarily unique. Therefore, if you want to use a specific Hadamard matrix, you must provide the matrix as a SAS data set in the HADAMARD= *method-option*.

In the HADAMARD= input data set, each variable corresponds to a column of the Hadamard matrix, and each observation corresponds to a row of the matrix. You can use any variable names in the HADAMARD= data set. All values in the data set must equal either 1 or –1. You must ensure that the matrix you provide is indeed a Hadamard matrix—that is, $\mathbf{A}'\mathbf{A} = R\mathbf{I}$, where \mathbf{A} is the Hadamard matrix of dimension R and \mathbf{I} is an identity matrix. PROC SURVEYPHREG does not check the validity of the Hadamard matrix that you provide.

The HADAMARD= input data set must contain at least H variables, where H denotes the number of first-stage strata in your design. If the data set contains more than H variables, PROC SURVEYPHREG uses only the first H variables. Similarly, the HADAMARD= input data set must contain at least H observations.

If you do not specify the REPS= *method-option*, then the number of replicates is taken to be the number of observations in the HADAMARD= input data set. If you specify the number of replicates—for example, REPS= $nreps$ —then the first $nreps$ observations in the HADAMARD= data set are used to construct the replicates.

You can specify the PRINTH *method-option* to display the Hadamard matrix that the procedure uses to construct replicates for BRR.

OUTWEIGHTS=SAS-data-set

names an output SAS data set to store the replicate weights that PROC SURVEYPHREG creates for BRR variance estimation. See the section “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7896 for information about replicate weights. See the section “[Replicate Weights Output Data Set](#)” on page 7908 for details about the contents of the OUTWEIGHTS= data set.

The OUTWEIGHTS= *method-option* is not available when you provide replicate weights with a REPWEIGHTS statement.

PRINTH

displays the Hadamard matrix used to construct replicates for BRR. When you provide the Hadamard matrix in the HADAMARD= *method-option*, PROC SURVEYPHREG displays only the rows and columns that are actually used to construct replicates. See the sections “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7896 and “[Hadamard Matrix](#)” on page 7898 for more information.

The PRINTH *method-option* is not available when you provide replicate weights with a REPWEIGHTS statement because the procedure does not use a Hadamard matrix in this case.

REPS=number

specifies the number of replicates for BRR variance estimation. The value of *number* must be an integer greater than 1.

If you do not provide a Hadamard matrix with the HADAMARD= *method-option*, the number of replicates should be greater than the number of strata and should be a multiple of 4. See the section “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7896 for more information. If a Hadamard matrix cannot be constructed for the REPS= value that you specify, the value is increased until a Hadamard matrix of that dimension can be constructed. Therefore, it is possible for the actual number of replicates used to be larger than the REPS= value that you specify.

If you provide a Hadamard matrix with the HADAMARD= *method-option*, the value of REPS= must not be less than the number of rows in the Hadamard matrix. If you provide a Hadamard matrix and do not specify the REPS= *method-option*, the number of replicates equals the number of rows in the Hadamard matrix.

If you do not specify the REPS= or HADAMARD= *method-option* and do not include a **REPWEIGHTS** statement, the number of replicates equals the smallest multiple of 4 that is greater than the number of strata.

If you provide replicate weights with a **REPWEIGHTS** statement, the procedure does not use the REPS= *method-option*. With a **REPWEIGHTS** statement, the number of replicates equals the number of **REPWEIGHTS** variables.

JACKKNIFE | JK <(method-options)>

requests variance estimation by the delete-1 jackknife method. See the section “[Jackknife Method](#)” on page 7899 for details. If you provide replicate weights with a **REPWEIGHTS** statement, **VARMETHOD=JACKKNIFE** is the default variance estimation method. The **JACKKNIFE** method requires at least two primary sampling units (PSUs) in each stratum for stratified designs unless you provide replicate weights with a **REPWEIGHTS** statement.

You can specify the following *method-options* in parentheses following **VARMETHOD=JACKKNIFE**:

CENTER=FULLSAMPLE | REPLICATES

defines how to compute the deviations for the jackknife method. **CENTER=FULLSAMPLE** is the default, which computes the deviations of the replicate estimates from the full sample estimate. Alternatively, you can specify **CENTER=REPLICATES** to compute the deviations of the replicate estimates from the average of the replicate estimates. See the section “[Jackknife Method](#)” on page 7899 for details.

OUTWEIGHTS=SAS-data-set

names an output SAS data set that contains replicate weights. See the section “[Jackknife Method](#)” on page 7899 for information about replicate weights. See the section “[Replicate Weights Output Data Set](#)” on page 7908 for more details about the contents of the **OUTWEIGHTS=** data set.

The **OUTWEIGHTS=** *method-option* is not available when you provide replicate weights with the **REPWEIGHTS** statement.

OUTJKCOEFS=SAS-data-set

names an output SAS data set that contains [jackknife coefficients](#). See the section “[Jackknife Coefficients Output Data Set](#)” on page 7909 for more details about the contents of the **OUTJKCOEFS=** data set.

TAYLOR

requests [Taylor series](#) variance estimation. This is the default method if you do not specify the **VARMETHOD=** option or a **REPWEIGHTS** statement. See the section “[Taylor Series Linearization](#)” on page 7895 for more information.

BY Statement

BY *variables* ;

You can specify a **BY** statement with **PROC SURVEYPHREG** to obtain separate analyses of observations in groups that are defined by the **BY** variables. When a **BY** statement appears, the procedure expects the input data set to be sorted in order of the **BY** variables. If you specify more than one **BY** statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the SURVEYPHREG procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

Note that using a BY statement provides completely separate analyses of the BY groups. It does not provide a domain (subpopulation) analysis, where the total number of units in the subpopulation is not known at the time the survey is designed. For such an analysis use the [DOMAIN](#) statement.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* < (*options*) > ... < *variable* < (*options*) > > < / *options* > ;

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. The CLASS statement must precede the [MODEL](#) statement. Most *options* can be specified either as individual variable *options* or as global *options*. You can specify *options* for each variable by enclosing the options in parentheses after the variable name. You can also specify global *options* for the CLASS statement by placing the *options* after a slash (/). Global *options* are applied to all the variables specified in the CLASS statement. If you specify more than one CLASS statement, the global *options* specified in any one CLASS statement apply to all CLASS statements. However, individual CLASS variable *options* override the global *options*. The following *options* are available:

DESCENDING

DESC

reverses the sort order of the classification variable. If both the DESCENDING and [ORDER=](#) options are specified, PROC SURVEYPHREG orders the categories according to the ORDER= option and then reverses that order.

MISSING

treats missing values (“.”, “.A”, ..., “.Z” for numeric variables and blanks for character variables) as valid values for the CLASS variable.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of classification variables. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option can be useful when you use the CONTRAST statement. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent. When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values.

The following table shows how PROC SURVEYPHREG interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted values, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) values
FREQ	Descending frequency count; levels with more observations come earlier in the order
INTERNAL	Unformatted value

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PARAM=keyword

specifies the parameterization method for the classification variable or variables. You can specify any of the *keywords* shown in the following table;

Design matrix columns are created from CLASS variables according to the corresponding coding schemes:

Value of PARAM=	Coding
EFFECT	Effect coding
GLM	Less-than-full-rank reference cell coding (this <i>keyword</i> can be used only in a global option)
ORDINAL THERMOMETER	Cumulative parameterization for an ordinal CLASS variable
POLYNOMIAL POLY	Polynomial coding
REFERENCE REF	Reference cell coding
ORTHEFFECT	Orthogonalizes PARAM=EFFECT coding
ORTHORDINAL ORTHOTHERM	Orthogonalizes PARAM=ORDINAL coding
ORTHPOLY	Orthogonalizes PARAM=POLYNOMIAL coding
ORTHREF	Orthogonalizes PARAM=REFERENCE coding

All parameterizations are full rank, except for the GLM parameterization. The [REF=](#) option in the CLASS statement determines the reference level for EFFECT and REFERENCE coding and for their orthogonal parameterizations. It also indirectly determines the reference level for a singular GLM parameterization through the order of levels.

If PARAM=ORTHPOLY or PARAM=POLY and the classification variable is numeric, then the [ORDER=](#) option in the CLASS statement is ignored, and the internal unformatted values are used. See

the section “[Other Parameterizations](#)” on page 387 of Chapter 19, “[Shared Concepts and Topics](#),” for further details.

REF= *'level' | keyword*

specifies the reference level for [PARAM=EFFECT](#), [PARAM=REFERENCE](#), and their orthogonalizations. For [PARAM=GLM](#), the REF= option specifies a level of the classification variable to be put at the end of the list of levels. This level thus corresponds to the reference level in the usual interpretation of the linear estimates with a singular parameterization.

For an individual variable REF= option (but not for a global REF= option), you can specify the *level* of the variable to use as the reference level. Specify the formatted value of the variable if a format is assigned. For a global or individual variable REF= option, you can use one of the following *keywords*. The default is REF=LAST.

FIRST designates the first ordered level as reference.

LAST designates the last ordered level as reference.

TRUNCATE *<=n>*

specifies the length *n* of CLASS variable values to use in determining CLASS variable levels. The default is to use the full formatted length of the CLASS variable. If you specify TRUNCATE without the length *n*, the first 16 characters of the formatted values are used. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases before SAS 9. The TRUNCATE option is available only as a global option.

CLUSTER Statement

CLUSTER *variables ;*

The CLUSTER statement names variables that identify the first-stage clusters in a clustered sample design. First-stage clusters are also known as primary sampling units (PSUs). The combinations of categories of CLUSTER variables define the clusters in the sample. If there is a [STRATA](#) statement, clusters are nested within strata.

If your sample design has clustering at multiple stages, you should specify only the first-stage clusters (PSUs) in the CLUSTER statement. See the section “[Specifying the Sample Design](#)” on page 7891 for more information.

If you provide replicate weights for BRR or jackknife variance estimation with a [REPWEIGHTS](#) statement, you do not need to specify a CLUSTER statement.

The CLUSTER *variables* are one or more variables in the [DATA=](#) input data set. These variables can be either character or numeric, but the procedure treats them as categorical variables. The formatted values of the CLUSTER variables determine the CLUSTER variable levels. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussions of the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference*.

You can use multiple CLUSTER statements to specify CLUSTER variables. The procedure uses variables from all CLUSTER statements to create clusters. Cluster variables must not occur in the CLASS statement.

DOMAIN Statement

DOMAIN *variables* < *variable** *variable* *variable** *variable** *variable* ... > ;

The DOMAIN statement requests analysis for domains (subpopulations), in addition to analysis for the entire study population. The DOMAIN statement names the variables that identify domains, which are called domain variables.

It is common practice to compute statistics for domains. The formation of these domains might not be known at the design stage. Therefore, the sample sizes for the domains are often random. Use a DOMAIN statement to incorporate this variability into the variance estimation.

Note that a DOMAIN statement is different from a BY statement. In a BY statement, you treat the sample sizes as fixed in each subpopulation, and you perform analysis within each BY group independently.

Use the DOMAIN statement on the entire data set to perform a domain analysis. Creating a new data set from a single domain and analyzing that with PROC SURVEYPHREG yields inappropriate estimates of variance.

A domain variable can be either character or numeric. The procedure treats domain variables as categorical variables. If a variable appears by itself in a DOMAIN statement, each level of this variable determines a domain in the study population. If two or more variables are joined by asterisks (*), then every possible combination of levels of these variables determines a domain. The procedure performs a descriptive analysis within each domain that is defined by the domain variables. Domain variables must not occur in the CLASS statement.

The formatted values of the domain variables determine the categorical variable levels. Thus, you can use formats to group values into levels. For more information, see the FORMAT procedure in the *Base SAS Procedures Guide* and the FORMAT statement and SAS formats in the *SAS Formats and Informats: Reference*.

ESTIMATE Statement

ESTIMATE < '*label*' > *estimate-specification* < (*divisor=n*) >
 < , ... < '*label*' > *estimate-specification* < (*divisor=n*) > >
 < / *options* > ;

The ESTIMATE statement provides a mechanism for obtaining custom hypothesis tests. Estimates are formed as linear estimable functions of the form $\mathbf{L}\boldsymbol{\beta}$. You can perform hypothesis tests for the estimable functions, construct confidence limits, and obtain specific nonlinear transformations.

Table 93.3 summarizes the options available in the ESTIMATE statement.

Table 93.3 ESTIMATE Statement Options

Option	Description
Construction and Computation of Estimable Functions	
DIVISOR=	Specifies a list of values to divide the coefficients
NOFILL	Suppresses the automatic fill-in of coefficients for higher-order effects
SINGULAR=	Tunes the estimability checking difference
Degrees of Freedom and p-values	
ADJUST=	Determines the method for multiple comparison adjustment of estimates
ALPHA= α	Determines the confidence level ($1 - \alpha$)
LOWER	Performs one-sided, lower-tailed inference
STEPPDOWN	Adjusts multiplicity-corrected p -values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits
CORR	Displays the correlation matrix of estimates
COV	Displays the covariance matrix of estimates
E	Prints the L matrix
JOINT	Produces a joint F or chi-square test for the estimable functions
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the ESTIMATE statement, see the section “[ESTIMATE Statement](#)” on page 437 in Chapter 19, “[Shared Concepts and Topics](#).”

FREQ Statement

FREQ *variable* ;

The FREQ statement names a numeric *variable* that provides a frequency for each observation in the input data set. PROC SURVEYPHREG treats each observation as if it appears n times, where n is the value of the FREQ variable for the observation. If not an integer, the frequency value is truncated to an integer. If the frequency value is missing, the observation is not used in the analysis. The FREQ statement allows one frequency variable.

If you use the FREQ statement and request the jackknife or BRR variance estimator by specifying the **VARMETHOD=JACKKNIFE** or **VARMETHOD=BRR** option in the PROC SURVEYPHREG statement, then you must identify the primary sampling units with a **CLUSTER** statement unless you also provide replicate weights with a **REPWEIGHTS** statement.

LSMEANS Statement

LSMEANS < model-effects > < / options > ;

The LSMEANS statement computes and compares least squares means (LS-means) of fixed effects. LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs.

Table 93.4 summarizes the options available in the LSMEANS statement.

Table 93.4 LSMEANS Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies the covariate value in computing LS-means
BYLEVEL	Computes separate margins
DIFF	Requests differences of LS-means
OM=	Specifies the weighting scheme for LS-means computation as determined by the input data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and <i>p</i>-values	
ADJUST=	Determines the method for multiple-comparison adjustment of LS-means differences
ALPHA= α	Determines the confidence level ($1 - \alpha$)
STEPDOWN	Adjusts multiple-comparison <i>p</i> -values further in a step-down fashion
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the L matrix
LINES	Produces a “Lines” display for pairwise LS-means differences
MEANS	Prints the LS-means
PLOTS=	Requests graphs of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the LSMEANS statement, see the section “[LSMEANS Statement](#)” on page 453 in Chapter 19, “[Shared Concepts and Topics](#).”

LSMESTIMATE Statement

```
LSMESTIMATE model-effect < 'label'> values < divisor=n>
              < , ... < 'label'> values < divisor=n> >
              < / options> ;
```

The LSMESTIMATE statement provides a mechanism for obtaining custom hypothesis tests among least squares means.

Table 93.5 summarizes the options available in the LSMESTIMATE statement.

Table 93.5 LSMESTIMATE Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies covariate values in computing LS-means
BYLEVEL	Computes separate margins
DIVISOR=	Specifies a list of values to divide the coefficients
OM=	Specifies the weighting scheme for LS-means computation as determined by a data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and p-values	
ADJUST=	Determines the method for multiple-comparison adjustment of LS-means differences
ALPHA= α	Determines the confidence level $(1 - \alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiple-comparison p -values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the L matrix
ELSM	Prints the K matrix
JOINT	Produces a joint F or chi-square test for the LS-means and LS-means differences
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the LSMESTIMATE statement, see the section “[LSMESTIMATE Statement](#)” on page 470 in Chapter 19, “[Shared Concepts and Topics](#).”

MODEL Statement

MODEL *response* < * *censor* (*list*) > = *effects* < / *options* > ;

The MODEL statement identifies the variable to be used as the failure time variable, the optional censoring variable, and the explanatory effects, including covariates, main effects, and interactions; see the section “[Specification of Effects](#)” on page 3324 of Chapter 42, “[The GLM Procedure](#),” for more information. A note of caution: specifying the effect T*A in the MODEL statement, where T is the time variable and A is a CLASS variable, does not make the effect time-dependent. You must specify exactly one MODEL statement.

The MODEL statement allows one response variable. In the MODEL statement, the failure time variable precedes the equal sign. This can optionally be followed by an asterisk, the name of the censoring variable, and a list of censoring values (separated by blanks or commas if there is more than one) enclosed in parentheses. If the censoring variable takes on one of these values, the corresponding failure time is considered to be censored. The variables following the equal sign are the explanatory variables (sometimes called independent variables or covariates) for the model.

The censoring variable must be numeric. The failure time variable must contain nonnegative values. Any observation with a negative failure time is excluded from the analysis, as is any observation with a missing value for any of the variables listed in the MODEL statement. See “[Missing Values](#)” on page 7893 for details.

Table 93.6 summarizes the options available in the MODEL statement, which can be specified after a slash (/).

Table 93.6 MODEL Statement Options

Option	Description
ALPHA=	Specifies α for the $100(1 - \alpha)\%$ confidence limits
CLPARM	Computes confidence limits for regression parameters
COVB	Displays covariance matrix
DF=	Specifies the denominator degrees of freedom
HESS	Displays the Hessian matrix
INVHESS	Displays the inverse of the Hessian matrix
RISKLIMITS	Computes confidence limits for the exponentials of the regression parameters
SERATIO=	Computes the ratio of two standard errors for the regression coefficients
SINGULAR=	Specifies tolerance for testing singularity
TIES=	Specifies the method of handling ties in failure times
VADJUST=	Specifies a variance adjustment factor
VARRATIO=	Computes the ratio of two variances for the regression coefficients

ALPHA= α

sets the level of the confidence limits for the estimated regression parameters and the hazard ratios. The value of *alpha* must be between 0 and 1, and the default is 0.05. A confidence level of α produces $100(1 - \alpha)\%$ confidence limits. The default of ALPHA=0.05 produces 95% confidence limits.

The ALPHA= option has no effect unless the CLPARM or RISKLIMITS option is also specified.

CLPARM

produces confidence limits for regression parameters of Cox proportional hazards models. The confidence coefficient can be specified with the ALPHA= option. Classification main effects that use parameterizations other than REF, EFFECT, or GLM are ignored. See “[Confidence Intervals](#)” on page 7905 for details.

COVB

displays the estimated covariance matrix of the parameter estimates.

DF=value | keyword

specifies the denominator degrees of freedom for hypothesis tests and the degrees of freedom to use for confidence limits. If a *value* is specified, it must be a nonnegative number. By default, PROC SURVEYPHREG computes the degrees of freedom as described in the section “[Degrees of Freedom](#)” on page 7901. Instead of a *value*, you can specify one of the following key words:

NONE

specifies the denominator degrees of freedom to be infinite. Use this option if you want to compute chi-square tests and normal confidence intervals. This option is applicable to both the Taylor series linearization and the replication methods.

PARMADJ

computes the denominator degrees of freedom as the number of clusters (or observations if no CLUSTER statement is specified) minus the number of strata (or one if no STRATA statement is specified) minus the number of nonsingular parameters plus one in the model. This option can be useful if you are fitting a model with many parameters relative to the number of clusters minus the number of strata. See Korn and Graubard (1999, section 5.2) for further details. This option is applicable only for the Taylor series linearization method.

ALLREPS

computes the denominator degrees of freedom for replication methods by using the total number of replicate samples. By default, PROC SURVEYPHREG computes the denominator degrees of freedom based on the number of replicate samples used. See “[Degrees of Freedom](#)” on page 7901 for details.

HESS

displays the last evaluation of the Hessian matrix.

INVHESS

displays the inverse of the Hessian matrix that is evaluated at the estimated regression parameters.

RISKLIMITS**RL**

produces confidence limits for hazard ratios and related quantities. See the section “[Hazard Ratios](#)” on page 7905 for details. The confidence coefficient can be specified with the **ALPHA=** option. Great care needs to be taken with any interpretation of the estimates and their confidence limits if interaction effects are involved in the model or if parameterizations other than REF, EFFECT, or GLM are used.

SERATIO=ALL | MODEL | IND

computes the ratio of two standard errors for the regression parameters. The standard error in the numerator uses the complete design information that you specify. You can specify the following options to compute different standard errors for the denominator:

ALL

requests both MODEL and IND standard error ratios.

MODEL

computes the standard errors in the denominator as the square root of the diagonals of the inverse Hessian matrix evaluated at the estimated regression parameters. See the section “[Variance Ratios and Standard Error Ratios](#)” on page 7902 for more information.

IND

computes the standard errors in the denominator by ignoring stratification and clustering. See the section “[Variance Ratios and Standard Error Ratios](#)” on page 7902 for more information.

SINGULAR=value

specifies the singularity criterion for determining linear dependencies in the set of explanatory variables. The default value is 10^{-12} .

TIES=method

specifies how to handle ties in the failure time. The available *methods* are as follows:

BRESLOW

uses the approximate partial likelihood of Breslow (1974). This is the default value.

EFRON

uses the approximate partial likelihood of Efron (1977).

If there are no ties, both methods result in the same likelihood and yield identical estimates. The default, TIES=BRESLOW, is the most efficient method when there are no ties.

VADJUST=DF | PARMADJ | NONE | AVGREPSS

specifies variance adjustment factors. You can use the following key words:

DF**PARMADJ**

requests degrees of freedom adjustment $(n - 1)/(n - p)$ in the computation of the matrix **G** for the Taylor series linearization [variance estimation](#). By default, VADJUST=DF.

NONE

excludes the degrees of freedom adjustment $(n - 1)/(n - p)$ from the computation of the matrix **G** for the Taylor series linearization [variance estimation](#).

AVGREPSS

use the average sum of squares from all the usable replicate samples for the unusable replicates. This option is applicable only for the jackknife replication method. AVGREPSS multiplies the default jackknife variance estimator by the factor R/R_a , where R_a is the number of usable replicates and R is the total number of replicates. See the section “[Variance Adjustment Factors](#)” on page 7902 for details.

VARRATIO=ALL | MODEL | IND

computes the ratio of two variances for the regression parameters. The variance in the numerator uses the complete design information. You can specify the following options to compute different variances for the denominator:

ALL

requests both MODEL and IND variance ratios.

MODEL

computes the variances in the denominator as the diagonals of the inverse Hessian matrix evaluated at the estimated regression parameters. See the section “[Variance Ratios and Standard Error Ratios](#)” on page 7902 for more information.

IND

computes the variances in the denominator by ignoring stratification and clustering. See the section “[Variance Ratios and Standard Error Ratios](#)” on page 7902 for more information.

NLOPTIONS Statement

NLOPTIONS <options> ;

The NLOPTIONS statement specifies details of the nonlinear optimization used by PROC SURVEYPHREG to maximize the log likelihood function. By default, the procedure uses the Newton-Raphson optimization technique. For more information about the NLOPTIONS statement, see the section “[NLOPTIONS Statement](#)” on page 482 in Chapter 19, “[Shared Concepts and Topics](#).”

OUTPUT Statement

OUTPUT <OUT=SAS-data-set> <keyword=name ... keyword=name> </options> ;

The OUTPUT statement creates a new SAS data set that contains statistics that are calculated for each observation unit. These statistics can include the estimated linear predictor ($\mathbf{z}'_j \hat{\boldsymbol{\beta}}$) and its standard error, residuals, and influence statistics. In addition, this data set includes all the variables from the DATA= input data set.

Only score residuals are available in the OUTPUT data set if the model contains a time-dependent variable that is defined by means of programming statements.

The following list explains specifications in the OUTPUT statement:

OUT=SAS-data-set

names the output data set. If you omit the OUT= option, the OUTPUT data set is named by using the DATA n convention. See the section “[OUT= Data Set for the OUTPUT statement](#)” on page 7908 for more information.

keyword=name

specifies the statistics to include in the OUTPUT data set and names the new variables that contain the statistics. Specify a keyword for each desired statistic (see the following list of keywords), and optionally an equal sign with either a variable or a list of variables in parentheses to contain the statistics. If you specify a keyword without a variable name, then the procedure uses default names. The keywords that accept a list of variables are RESSCH, RESSCO, and WTRESSCH. For these keywords, you can specify as many names in *name* as the number of explanatory variables in the MODEL statement. If you specify k names and k is less than the total number of explanatory variables, only the first k names are taken from the list; the procedure assigns default names for the rest of the statistics. The keywords and the corresponding statistics are as follows:

ATRISK

specifies the number of subjects at risk at the observation time τ_j .

RESDEV

specifies the deviance residual \hat{D}_j . This is a transform of the martingale residual to achieve a more symmetric distribution.

RESMART

specifies the martingale residual \hat{M}_j . The residual at the observation time τ_j can be interpreted as the difference over $[0, \tau_j]$ in the observed number of events minus the expected number of events given by the model.

RESSCH

specifies the Schoenfeld residuals. These residuals are useful in assessing the proportional hazards assumption.

RESSCO

specifies the score residuals. These residuals are a decomposition of the first partial derivative of the log likelihood. They can be used to assess the leverage that is exerted by each subject in the parameter estimation. They are also useful in constructing design-based variance estimators.

STDXBETA

specifies the standard error of the [estimated linear predictor](#), $\sqrt{\mathbf{z}'_j \hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}|F) \mathbf{z}_j}$.

WTATRISK

specifies the weighted number of subjects at risk at the observation time τ_j .

XBETA

specifies the estimate of the linear predictor, $\mathbf{z}'_j \hat{\boldsymbol{\beta}}$.

Programming Statements

Programming statements are used to create or modify the values of the explanatory variables in the MODEL statement. They are especially useful in fitting models with time-dependent explanatory variables. Programming statements can also be used to create explanatory variables that are not time-dependent. PROC SURVEYPHREG programming statements cannot be used to create or modify the values of the response variable, the censoring variable, the frequency variable, the weight variable, the class variables, the strata variables, the cluster variables, or the domain variables.

The following DATA step statements are available in PROC SURVEYPHREG:

```

ABORT;
ARRAY arrayname < [ dimensions ] > < $ > < variables-and-constants >;
CALL name < (expression < , expression ... >) >;
DELETE;
DO < variable = expression < TO expression > < BY expression > >
    < , expression < TO expression > < BY expression > > ...
    < WHILE expression > < UNTIL expression >;
END;
GOTO statement-label;
IF expression;
IF expression THEN program-statement;
    ELSE program-statement;
variable = expression;
variable + expression;
LINK statement-label;
PUT < variable > < = > ...;
RETURN;
SELECT < (expression) >;
STOP;
SUBSTR(variable, index, length) = expression;
WHEN (expression) program-statement;
    OTHERWISE program-statement;

```

By default, the PUT statement in PROC SURVEYPHREG writes results to the Output window instead of the Log window. If you want the results of the PUT statements to go to the Log window, add the following statement before the PUT statement:

```
FILE LOG;
```

DATA step functions are also available. Use these programming statements the same way you use them in the DATA step. For detailed information, see the *SAS Functions and CALL Routines: Reference*.

Consider the following example of using programming statements in PROC SURVEYPHREG. Suppose blood pressure is measured at multiple times during the course of a study that investigates the effect of blood pressure on some survival time. By treating the blood pressure as a time-dependent explanatory variable, you can use the value of the most recent blood pressure at each specific point of time in the modeling process rather than using the initial blood pressure or the final blood pressure. The values of the following variables are recorded for each patient, if they are available. Otherwise, the variables contain missing values.

Time	survival time
Censor	censoring indicator (with 0 as the censoring value)
BP0	blood pressure on entry to the study
T1	time 1
BP1	blood pressure at T1
T2	time 2
BP2	blood pressure at T2
WT	design weight
PSU	identification of primary sampling units

The following programming statements create a variable BP. At each time T, the value of BP is the blood pressure reading for that time, if available. Otherwise, it is the last blood pressure reading.

```
proc surveyphreg;
  weight WT;
  model Time*Censor(0)=BP;
  cluster PSU;
  BP = BP0;
  if Time>=T1 and T1^=. then BP=BP1;
  if Time>=T2 and T2^=. then BP=BP2;
run;
```

REPWEIGHTS Statement

REPWEIGHTS *variables* </ options> ;

The REPWEIGHTS statement names variables that provide replicate weights for BRR or jackknife variance estimation, which you request with the **VARMETHOD=BRR** or **VARMETHOD=JACKKNIFE** option in the PROC SURVEYPHREG statement. If you do not provide replicate weights for these methods by using a REPWEIGHTS statement, then PROC SURVEYPHREG constructs replicate weights for the analysis. See the sections “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7896 and “[Jackknife Method](#)” on page 7899 for more information.

Each REPWEIGHTS variable should contain the weights for a single replicate, and the number of replicates equals the number of REPWEIGHTS variables. The REPWEIGHTS variables must be numeric, and the variable values must be nonnegative numbers.

If you provide replicate weights with a REPWEIGHTS statement, you do not need to specify a **CLUSTER** or **STRATA** statement. If you use a REPWEIGHTS statement and do not specify the **VARMETHOD=** option in the PROC SURVEYPHREG statement, the procedure uses **VARMETHOD=JACKKNIFE** by default.

If you specify a REPWEIGHTS statement but do not include a **WEIGHT** statement, PROC SURVEYPHREG uses the average of each observation’s replicate weights as the observation’s weight.

You can specify the following options in the REPWEIGHTS statement after a slash (/):

DF=*df*

specifies the degrees of freedom for the analysis. The value of *df* must be a positive number. See the section “[Degrees of Freedom](#)” on page 7901 for details.

PROC SURVEYPHREG also use the DF= value in computing the denominator degrees of freedom for the *F* statistics in Wald type tests and confidence intervals.

JKCOEFS=*jackknife-coefficient-specification*

specifies jackknife coefficients for **VARMETHOD=JACKKNIFE**. The default value for the jackknife coefficient is $(R - 1)/R$, where *R* is the total number of replicates. You can specify an alternative value with one of the following three forms:

JKCOEFS=*value*

specifies a single jackknife coefficient for all replicates. The coefficient *value* must be a non-negative number.

JKCOEFS=(*values*)

specifies jackknife coefficients for **VARMETHOD=JACKKNIFE**, where each coefficient corresponds to an individual replicate identified by a REPWEIGHTS variable. You can separate *values* with blanks or commas. The coefficient *values* must be nonnegative numbers. The number of *values* must equal the number of replicate weight variables named in the REPWEIGHTS statement. List these values in the same order in which you list the corresponding replicate weight variables in the REPWEIGHTS statement.

JKCOEFS=*SAS-data-set*

names a SAS data set that contains the jackknife coefficients for **VARMETHOD=JACKKNIFE**. You provide the jackknife coefficients in the JKCOEFS= data set variable JKCoefficient. Each coefficient value must be a nonnegative number. The observations in the JKCOEFS= data set should correspond to the replicates that are identified by the REPWEIGHTS variables. Arrange the coefficients or observations in the JKCOEFS= data set in the same order in which you list the corresponding replicate weight variables in the REPWEIGHTS statement. The number of observations in the JKCOEFS= data set must not be less than the number of REPWEIGHTS variables.

See the section “[Jackknife Method](#)” on page 7899 for details about jackknife coefficients.

SLICE Statement

SLICE *model-effect* < / *options* > ;

The SLICE statement provides a general mechanism for performing a partitioned analysis of the LS-means for an interaction. This analysis is also known as an analysis of simple effects.

The SLICE statement uses the same options as the **LSMEANS** statement, which are summarized in [Table 19.21](#). For details about the syntax of the SLICE statement, see the section “[SLICE Statement](#)” on page 498 in Chapter 19, “[Shared Concepts and Topics](#).”

STORE Statement

STORE < **OUT=** > *item-store-name* < / **LABEL=** 'label' > ;

The STORE statement requests that the procedure save the context and results of the statistical analysis. The resulting item store has a binary file format that cannot be modified. The contents of the item store can be processed with the PLM procedure.

For details about the syntax of the STORE statement, see the section “[STORE Statement](#)” on page 501 in Chapter 19, “[Shared Concepts and Topics](#).”

STRATA Statement

STRATA *variables* < / *option* > ;

The STRATA statement names variables that form the strata in a stratified sample design. The combinations of levels of STRATA variables define the strata in the sample, where strata are nonoverlapping subgroups that were sampled independently.

If your sample design has stratification at multiple stages, you should identify only the first-stage strata in the STRATA statement. See the section “[Specifying the Sample Design](#)” on page 7891 for more information.

If you provide replicate weights for BRR or jackknife variance estimation with a [REPWEIGHTS](#) statement, you do not need to specify a STRATA statement.

The STRATA *variables* are one or more variables in the DATA= input data set. These variables can be either character or numeric, but the procedure treats them as categorical variables. The formatted values of the STRATA variables determine the STRATA variable levels. Thus, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussions of the FORMAT statement and SAS formats in the *SAS Formats and Informats: Reference*. Strata variables must not occur in the CLASS statement.

The STRATA statement in PROC SURVEYPHREG is different from the STRATA statement in PROC PHREG (Chapter 67, “[The PHREG Procedure](#)”). PROC PHREG fits different baseline hazard functions in different strata, which is useful if the proportional hazards assumption is not satisfied.

You can specify the following option in the STRATA statement after a slash (/):

LIST

displays a “Stratum Information” table, which lists all strata together with the corresponding values of the STRATA variables. This table provides the number of observations and the number of clusters in each stratum, as well as the sampling fraction if you specify the [RATE=](#) or [TOTAL=](#) option.

TEST Statement

TEST < *model-effects* > < / *options* > ;

The TEST statement enables you to perform F tests for model effects that test Type I, Type II, or Type III hypotheses. See Chapter 15, “[The Four Types of Estimable Functions](#),” for details about the construction of Type I, II, and III estimable functions.

Table 93.7 summarizes the options available in the TEST statement.

Table 93.7 TEST Statement Options

Option	Description
CHISQ	Requests chi-square tests
DDF=	Specifies denominator degrees of freedom for fixed effects
E	Requests Type I, Type II, and Type III coefficients
E1	Requests Type I coefficients
E2	Requests Type II coefficients
E3	Requests Type III coefficients
HTYPE=	Indicates the type of hypothesis test to perform
INTERCEPT	Adds a row that corresponds to the overall intercept

For details about the syntax of the TEST statement, see the section “[TEST Statement](#)” on page 502 in Chapter 19, “[Shared Concepts and Topics](#).”

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement names the variable that contains the sampling weights. This variable must be numeric, and the sampling weights must be positive numbers. If an observation has a weight that is nonpositive or missing, then the procedure omits that observation from the analysis. See the section “[Missing Values](#)” on page 7893 for more information. The WEIGHT statement allows one weight variable.

If you do not specify a WEIGHT statement but provide replicate weights with a [REPWEIGHTS](#) statement, PROC SURVEYPHREG uses the average of each observation’s replicate weights as the observation’s weight.

If you specify neither a WEIGHT statement nor a REPWEIGHTS statement, PROC SURVEYPHREG assigns all observations a weight of one.

Details: SURVEYPHREG Procedure

Notation and Estimation

Let $U = \{1, 2, \dots, N\}$ be the set of indices and let \mathcal{F}_N be the set of values for a finite population of size N . The survival time of each member of the finite population is assumed to follow its own hazard function, $\lambda_i(t)$, expressed as

$$\lambda_i(t) = \lambda(t; \mathbf{Z}_i(t)) = \lambda_0(t) \exp(\mathbf{Z}_i'(t)\boldsymbol{\beta})$$

where $\lambda_0(t)$ is an arbitrary and unspecified baseline hazard function, $\mathbf{Z}_i(t)$ is the vector of explanatory variables for the i th unit at time t , and $\boldsymbol{\beta}$ is the vector of unknown regression parameters that are associated with the explanatory variables. The vector $\boldsymbol{\beta}$ is assumed to be the same for all individuals.

The partial likelihood function introduced by Cox (1972, 1975) eliminates the unknown baseline hazard $\lambda_0(t)$ and accounts for censored survival times. If the entire population is observed, then this partial likelihood can be used to estimate β . Let β_N be the desired estimator. Assuming a working model with uncorrelated responses, β_N is obtained by maximizing the partial log likelihood,

$$l(\beta) = \sum_{i \in U} \log \left\{ L(\beta; \mathbf{Z}_i(t), t_i) \right\}$$

with respect to β , where $L(\beta; \mathbf{Z}_i(t), t_i)$ is Cox's partial likelihood function.

Assume that probability sample A is selected from the finite population U and π_i is the selection probability for unit i . Further assume that covariates $\mathbf{Z}_i(t)$ and survival time t_i are available for every unit in the sample A . An estimator of the finite population log likelihood is

$$l_\pi(\beta) = \sum_{i \in A} \pi_i^{-1} \log \left\{ L(\beta; \mathbf{Z}_i(t), t_i) \right\}$$

See “[Partial Likelihood Function for the Cox Model](#)” on page 7890 for more details.

A sample-based estimator $\hat{\beta}$ for the finite population quantity β_N can be obtained by maximizing the partial pseudo-log-likelihood $l_\pi(\beta; \mathbf{Z}_i(t), t_i)$ with respect to β . The design-based variance for $\hat{\beta}$ is obtained by assuming the set of finite population values \mathcal{F}_N as fixed. For more information about maximum pseudo-likelihood estimators and other inferential approaches for survey data, see Kish and Frankel (1974); Godambe and Thompson (1986); Pfeiffermann (1993), Korn and Graubard (1999, chapter 3), Chambers and Skinner (2003, chapter 2), and Fuller (2009, section 6.5). Maximum pseudo-likelihood estimators and their properties for Cox's proportional hazards model for survey data are discussed in Binder (1990, 1992); Lin and Wei (1989); Lin (2000); Boudreau and Lawless (2006).

Without loss of generality, the rest of this section uses indices for stratified clustered designs. For a stratified clustered sample design, observations are represented by a matrix

$$(\mathbf{w}, \mathbf{t}, \mathbf{\Delta}, \mathbf{Z}) = (w_{hij}, t_{hij}, \Delta_{hij}, \mathbf{z}_{hij})$$

where

- \mathbf{w} denotes the vector of sampling weights
- \mathbf{t} denotes the event time variable
- $\mathbf{\Delta}$ denotes the event indicator
- \mathbf{Z} denotes the $n \times p$ matrix of auxiliary information
- $h = 1, 2, \dots, H$ is the stratum index
- $i = 1, 2, \dots, n_h$ is the cluster index within stratum h
- $j = 1, 2, \dots, m_{hi}$ is the unit index within cluster i of stratum h
- p is the total number of parameters
- $n = \sum_{h=1}^H \sum_{i=1}^{n_h} m_{hi}$ is the total number of observations in the sample
- $y_{hij}(t) = I(t_{hij} \geq t)$, where $I(\cdot)$ is an indicator function
- $n_{hij}(t) = I(t_{hij} \leq t)$, where $I(\cdot)$ is an indicator function

Let $\sum_B = \sum_{(h,i,j) \in B}$ denote the summation over the set of indices such that the observation unit j in PSU i and stratum h belongs to the index set B . Typically, B is the set of all population indices that are in the sample, the risk set, or the set of all units with a failure.

The first-stage sampling rate (fraction of PSUs selected for the sample) is denoted by f_h . The first-stage sampling rate is used in Taylor series variance estimation. You can specify the stratum sampling rates with the **RATE=** option. Or if you specify population totals with the **TOTAL=** option, PROC SURVEYFREQ computes f_h as the ratio of stratum sample size to the stratum total, in terms of PSUs. See the section “Population Totals and Sampling Rates” on page 7892 for details. If you do not specify the **RATE=** option or the **TOTAL=** option, then the procedure assumes that the stratum sampling rates f_h are negligible and does not use a finite population correction when computing variances.

Failure Time Distribution

Let T be a nonnegative random variable that represents the failure time of an individual from a homogeneous superpopulation. The survival distribution function (also known as the survivor function) of T is written as

$$S(t) = \Pr(T \geq t)$$

A mathematically equivalent way of specifying the distribution of T is through its hazard function. The hazard function $\lambda(t)$ specifies the instantaneous failure rate at t . If T is a continuous random variable, $\lambda(t)$ is expressed as

$$\lambda(t) = \lim_{\Delta t \rightarrow 0^+} \frac{\Pr(t \leq T < t + \Delta t \mid T \geq t)}{\Delta t} = \frac{f(t)}{S(t)}$$

where $f(t)$ is the probability density function of T .

Time and CLASS Variables Usage

The following DATA step creates an artificial data set, **Test**, to be used in this section. There are six variables in **Test**: the variable **T** contains the failure times; the variable **Status** is the censoring indicator variable with the value 1 for an uncensored failure time and the value 0 for a censored time; the variable **A** is a categorical variable with values 1, 2, and 3 representing three different categories; the variable **MirrorT** is an exact copy of **T**; the variable **W** is the observation weight; and the variable **S** is the strata indicator.

```
data Test;
  input T Status A W S @@;
  MirrorT = T;
  datalines;
23    1    1    10    1    7    0    1    20    2
23    1    1    10    1   10    1    1    20    2
20    0    1    10    1   13    0    1    20    2

;

```

Time Variable on the Right Side of the MODEL Statement

The time variable cannot be used explicitly as an explanatory effect in the MODEL statement. The following statements produce an error message:

```

proc surveyphreg data=Test;
  weight W;
  strata S;
  class A;
  model T*Status(0)=T*A;
run;

```

To use the time variable as an explanatory effect, replace T by MirrorT as an effect, which is an exact copy of T, as in the following statements:

```

proc surveyphreg data=Test;
  weight W;
  strata S;
  class A;
  model T*Status(0)=A*MirrorT;
run;

```

Note that neither T*A nor MirrorT*A in the MODEL statement is time-dependent. The results of fitting this model are shown in [Figure 93.3](#).

Figure 93.3 T*A Effect

The SURVEYPHREG Procedure						
Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Pr > t	Hazard Ratio
MirrorT*A 1	30	-17.560699	0.337239	-52.07	<.0001	0.000
MirrorT*A 2	30	-17.424235	0.331186	-52.61	<.0001	0.000
MirrorT*A 3	30	-17.448672	0.290159	-60.13	<.0001	0.000

CLASS Variables and Programming Statements

In PROC SURVEYPHREG, the levels of CLASS variables are determined by the CLASS statement and the input data and are not affected by user-supplied programming statements. Consider the following state-

ments, which produce the results in Figure 93.4. Variable A is declared as a CLASS variable in the CLASS statement.

```
proc surveyphreg data=Test;
  weight W;
  strata S;
  class A;
  model T*Status(0)=A;
run;
```

Figure 93.4 shows the parameters that correspond to A and their respective regression coefficients estimates.

Figure 93.4 Design Variable and Regression Coefficient Estimates

The SURVEYPHREG Procedure						
Class Level Information						
Class	Levels	Values				
A	3	1	2	3		
Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Pr > t	Hazard Ratio
A 1	30	-1.162184	0.655136	-1.77	0.0862	0.313
A 2	30	-0.616962	0.521841	-1.18	0.2464	0.540
A 3	30	0	.	.	.	1.000

Now consider the programming statement that attempts to change the value of the CLASS variable A as in the following specification:

```
proc surveyphreg data=Test;
  weight W;
  strata S;
  class A;
  model T*Status(0)=A;
  if A=3 then A=2;
run;
```

Results of this analysis are shown in Figure 93.5 and are identical to those in Figure 93.4. The **if A=3 then A=2** programming statement has no effect on the explanatory variable for A, which have already been determined.

Figure 93.5 Design Variable and Regression Coefficient Estimates

The SURVEYPHREG Procedure						
Class Level Information						
Class	Levels	Values				
A	3	1	2	3		
Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Pr > t	Hazard Ratio
A 1	30	-1.162184	0.655136	-1.77	0.0862	0.313
A 2	30	-0.616962	0.521841	-1.18	0.2464	0.540
A 3	30	0	.	.	.	1.000

Additionally any variable used in a programming statement that has already been declared in the CLASS statement is *not* treated as a collection of the corresponding design variables. Consider the following statements:

```
proc surveyphreg data=Test;
  class A;
  model T*Status(0)=A X;
  X=T*A;
run;
```

The CLASS variable A generates two design variables as explanatory variables. The variable X created by the `X=T*A` programming statement is a single time-dependent covariate whose values are evaluated using the exact values of A given in the data, not the dummy coded values that represent A. In the data set Test, A has the values of 1, 2, and 3, and these values are multiplied by the values of T to produce X. If A were a character variable with values 'Bird', 'Cat', and 'Dog', the programming statement `X=T*A` would have produced an error in the attempt to multiply a number with a character value.

Figure 93.6 Single Time-Dependent Variable X*A

The SURVEYPHREG Procedure						
Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Pr > t	Hazard Ratio
A 1	31	0.158010	1.222654	0.13	0.8980	1.171
A 2	31	0.008993	0.674629	0.01	0.9894	1.009
A 3	31	0	.	.	.	1.000
X	31	0.092679	0.073746	1.26	0.2182	1.097

The following statements are not the same as in the preceding program. If you want to create time-dependent covariates from the values of a CLASS variable, you could use syntax like the following:

```
proc surveyphreg data=Test;
  class A;
  model T*Status(0)=A X1 X2;
  X1= T*(A=1);
  X2= T*(A=2);
run;
```

The Boolean parenthetical expressions (A=1) and (A=2) resolve to a value of 1 or 0, depending on whether the expression is true or false, respectively.

Results of this test are shown in Figure 93.7.

Figure 93.7 Simple Test of Proportional Hazards Assumption

The SURVEYPHREG Procedure						
Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Pr > t	Hazard Ratio
A 1	31	-0.007655	1.284875	-0.01	0.9953	0.992
A 2	31	-0.881383	1.834533	-0.48	0.6343	0.414
A 3	31	0	.	.	.	1.000
X1	31	-0.155220	0.172914	-0.90	0.3763	0.856
X2	31	0.011554	0.198796	0.06	0.9540	1.012

In general, when your model contains a categorical explanatory variable that is time-dependent, it might be necessary to use hardcoded dummy variables to represent the categories of the categorical variable.

Partial Likelihood Function for the Cox Model

Let $t_{(1)} < t_{(2)} < \dots < t_{(K)}$ denote the K distinct, ordered event times. Let d_k denote the multiplicity of failures at $t_{(k)}$; that is, d_k is the size of the set \mathcal{D}_k of individuals that fail at $t_{(k)}$. Let w_{hij} be the weight associated with the j th observation unit in the i th cluster in stratum h . Using this notation, the pseudo-likelihood functions used in PROC SURVEYPHREG to estimate β_N are described in the following sections.

Continuous Time Scale

Let \mathcal{R}_k denote the risk set just before the k th ordered event time $t_{(k)}$.

The Breslow likelihood is expressed as

$$L_{\text{Breslow}}(\beta) = \prod_{k=1}^K \frac{\exp(\beta' \sum_{\mathcal{D}_k} w_{hij} \mathbf{Z}_{hij}(t))}{\left\{ \sum_{\mathcal{R}_k} w_{hij} \exp(\beta' \mathbf{Z}_{hij}(t)) \right\}^{\sum_{\mathcal{D}_k} w_{hij}}}$$

The Efron likelihood is expressed as

$$L_{\text{Efron}}(\boldsymbol{\beta}) = \prod_{k=1}^K \frac{\exp(\boldsymbol{\beta}' \sum_{\mathcal{D}_k} w_{hij} \mathbf{Z}_{hij}(t))}{\{\phi(\boldsymbol{\beta}, \mathbf{Z}, \mathbf{w}, k)\}^{\frac{1}{d_k}} \sum_{\mathcal{D}_k} w_{hij}}$$

where $\phi(\boldsymbol{\beta}, \mathbf{Z}, \mathbf{w}, k)$ is

$$\phi(\boldsymbol{\beta}, \mathbf{Z}, \mathbf{w}, k) = \prod_{l=1}^{d_k} \left\{ \sum_{\mathcal{R}_k} w_{hij} \exp(\boldsymbol{\beta}' \mathbf{Z}_{hij}(t)) - \frac{l-1}{d_k} \sum_{\mathcal{D}_k} w_{hij} \exp(\boldsymbol{\beta}' \mathbf{Z}_{hij}(t)) \right\}$$

Specifying the Sample Design

PROC SURVEYPHREG produces statistics that are based on the sample design used to obtain the survey data. PROC SURVEYPHREG can be used for single-stage or multistage designs, with or without stratification, and with or without unequal weighting. To analyze your survey data with PROC SURVEYPHREG, you need to provide sample design information for the procedure. This information can include design (or variance) strata, clusters, and sampling weights. You provide sample design information with the **STRATA**, **CLUSTER**, and **WEIGHT** statements, and with the **RATE=** or **TOTAL=** option in the PROC SURVEYPHREG statement.

If you provide replicate weights for BRR or jackknife variance estimation, you do not need to specify a STRATA or CLUSTER statement. Otherwise, you should specify STRATA and CLUSTER statements whenever your design includes stratification and clustering.

When there are clusters (PSUs) in the sample design, the procedure estimates variance by using the PSUs, as described in the section “[Variance Estimation](#)” on page 7895. For a multistage sample design, PROC SURVEYPHREG uses only the first stage of the sample design for variance estimation. So, the required input includes only first-stage cluster (PSU) and first-stage stratum identification. You do not need to input design information about any additional stages of sampling.

Stratification

If your sample design is stratified at the first stage of sampling, use the **STRATA** statement to name the variables that form the strata. The combinations of categories of STRATA variables define the strata in the sample, where strata are nonoverlapping subgroups that were sampled independently. If your sample design has stratification at multiple stages, you should identify only the first-stage strata in the STRATA statement.

If you use a **REPWEIGHTS** statement to provide replicate weights for BRR or jackknife variance estimation, you do not need to specify a STRATA statement. Otherwise, you should specify a STRATA statement whenever your design includes stratification. If you do not specify a STRATA statement or a REPWEIGHTS statement, then PROC SURVEYPHREG assumes there is no stratification at the first stage. In other words, in this case, the procedure assumes that all observation units are in the same stratum.

Clustering

If your sample design selects clusters at the first stage of sampling, use the **CLUSTER** statement to name the variables that identify the first-stage clusters, which are also called primary sampling units (PSUs). The combinations of categories of CLUSTER variables define the clusters in the sample. If there is a STRATA

statement, clusters are nested within strata. If your sample design has clustering at multiple stages, you should specify only the first-stage clusters (PSUs) in the CLUSTER statement. PROC SURVEYPHREG assumes that each cluster that is defined by the CLUSTER statement variables represents a PSU in the sample.

If you use a REPWEIGHTS statement to provide replicate weights for BRR or jackknife variance estimation, you do not need to specify a CLUSTER statement. Otherwise, you should specify a CLUSTER statement whenever your design includes clustering at the first stage of sampling. If you do not specify a CLUSTER statement, then PROC SURVEYPHREG treats each observation as a PSU.

Weighting

If your sample design includes unequal weighting, use the WEIGHT statement to name the variable that contains the sampling weights. Sampling weights must be positive numbers. If an observation has a weight that is nonpositive or missing, then the procedure omits that observation from the analysis. See the section “Missing Values” on page 7893 for more information.

If you do not specify a WEIGHT statement but include a REPWEIGHTS statement, PROC SURVEYPHREG uses the average of each observation’s replicate weights as the observation’s weight. If you specify neither a WEIGHT statement nor a REPWEIGHTS statement, PROC SURVEYPHREG assumes all observations have a weight of one.

Population Totals and Sampling Rates

To include a finite population correction (*fpc*) in Taylor series variance estimation, you can input either the sampling rate or the population total by using the RATE= or TOTAL= option in the PROC SURVEYPHREG statement. You cannot specify both of these options in the same PROC SURVEYPHREG statement. The RATE= and TOTAL= options apply only to Taylor series variance estimation. The procedure does not use a finite population correction for BRR or jackknife variance estimation.

If you do not specify the RATE= or TOTAL= option, the Taylor series variance estimation does not include a finite population correction. For fairly small sampling fractions, this correction is often ignored. See Cochran (1977) and Kish (1965) for more information.

If your design has multiple stages of selection and you are specifying the RATE= option, you should input the first-stage sampling rate, which is the ratio of the number of PSUs in the sample to the total number of PSUs in the study population. If you are specifying the TOTAL= option for a multistage design, you should input the total number of PSUs in the study population.

For a nonstratified sample design, or for a stratified sample design with the same sampling rate or the same population total in all strata, you can use the RATE=*value* or TOTAL=*value* option. If your sample design is stratified with different sampling rates or population totals in different strata, use the RATE=*SAS-data-set* or TOTAL=*SAS-data-set* option to name a SAS data set that contains the stratum sampling rates or totals. This data set is called a *secondary data set*, as opposed to the *primary data set* that you specify with the DATA= option.

The secondary data set must contain all the stratification variables listed in the STRATA statement and all the variables in the BY statement. Furthermore, the BY groups must appear in the same order as in the primary data set. If there are formats associated with the STRATA variables and the BY variables, then the formats must be consistent in the primary and the secondary data sets. If you specify the TOTAL=*SAS-data-set* option, the secondary data set must have a variable named `_TOTAL_` that contains the stratum population

totals. If you specify the `RATE=SAS-data-set` option, the secondary data set must have a variable named `_RATE_` that contains the stratum sampling rates. If the secondary data set contains more than one observation for any one stratum, the procedure uses the first value of `_TOTAL_` or `_RATE_` for that stratum and ignores the rest.

The *value* in the `RATE=` option or the values of `_RATE_` in the secondary data set must be nonnegative numbers. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC SURVEYPHREG converts that number to a proportion. The procedure treats the value 1 as 100% instead of 1%.

If you specify the `TOTAL=value` option, *value* must not be less than the sample size. If you provide stratum population totals in a secondary data set, these values must not be less than the corresponding stratum sample sizes.

Missing Values

Missing values in your survey data can compromise the quality of your survey results. Some missing values for survey data are because of nonresponses. An observation whose response to every survey item is available is called a *complete respondent*, and an observation whose response to one or more survey items are missing is called an *incomplete respondent*. If the complete respondents are different from the incomplete respondents with regard to a survey effect or outcome, then survey estimates will be biased and will not accurately represent the survey population. There are a variety of techniques in sample design and survey operations that can reduce nonresponse. After data collection is complete, you can use imputation to replace missing values with acceptable values, and you can use sampling weight adjustments to compensate for nonresponse. You should complete this data preparation and adjustment before you analyze your data with PROC SURVEYPHREG. For more details, see Cochran (1977); Kalton and Kaspyzyk (1986); Brick and Kalton (1996).

WEIGHT Variable

If an observation has a missing value or a nonpositive value for the `WEIGHT` variable, then PROC SURVEYPHREG excludes that observation from the analysis.

REPWEIGHTS Variables

If you provide replicate weights with a `REPWEIGHTS` statement for BRR or jackknife variance estimation, all `REPWEIGHTS` variable values must be nonmissing. Similarly, if you provide jackknife coefficients with the `JKCOEFS=` option in the `REPWEIGHTS` statement, all values of the `JKCoefficient` variable must be nonmissing. The procedure does not perform the analysis when any replicate weight or jackknife coefficient value is missing.

CLASS, STRATA, CLUSTER, and DOMAIN Variables

An observation is excluded from the analysis if it has a missing value for any `CLASS`, `STRATA`, `CLUSTER`, or `DOMAIN` variable, unless you specify the `MISSING` option in the PROC SURVEYPHREG statement. If you specify the `MISSING` option, the procedure treats missing values as a valid (nonmissing) category for all categorical variables, which include `STRATA` variables, `CLUSTER` variables, `CLASS` variables, and `DOMAIN` variables.

Analysis Variables

By default, PROC SURVEYPHREG excludes an observation from the likelihood estimation and all associated analyses if the observation has a missing value for any of the variables in the **MODEL** statement, unless you specify the **MISSING** or **NOMCAR** option in the PROC SURVEYPHREG statement. When the procedure excludes observations with missing values from analyses, it displays the total frequency of observations used in the “NObs” table.

If you specify time-dependent covariates by using **programming statements**, the procedure computes the values of the covariates for all observations in the risk set at every event time. If an observation contains missing values for any of the time-dependent covariates at a given event time, then the observation is not used at that event time. However, that same observation can be used at some other event times where it contains no missing values. Therefore, an observation with missing time-dependent covariates can be used at some event times but ignored at other event times, depending on whether any of the corresponding time-dependent covariates are missing.

If you specify the **MISSING** option, the procedure treats missing levels as a valid (nonmissing) level for each categorical analysis variable.

If you specify the **NOMCAR** option for Taylor series variance estimation, the procedure includes observations with missing values of analysis variables in the variance computations.

The NOMCAR Option

When you specify the **NOMCAR** option, PROC SURVEYPHREG computes variance estimates by analyzing the nonmissing values for variables in the regression model as a domain or subpopulation, where the entire population includes both nonmissing and missing domains. By default, if an observation contains missing values for the dependent variable or for any variable used in the independent effects, the observation is excluded from the analysis. See the section “**Missing Values**” on page 7893 for more information.

Note that the **NOMCAR** option has no effect on categorical predictors when you specify the **MISSING** option, which treats missing values as a valid nonmissing level. The **NOMCAR** option does not affect the inclusion of observations with missing values of the **WEIGHT**, **FREQ**, **CLUSTER**, **STRATA**, or **DOMAIN** variables. Observations with missing values of the **WEIGHT** and **FREQ** variables are always excluded from the analysis. Observations with missing values of the **CLUSTER**, **DOMAIN**, or **STRATA** variables are excluded unless you specify the **MISSING** option.

The **NOMCAR** option applies only to Taylor series variance estimation. The replication methods, which you request with the **VARMETHOD=BRR** and **VARMETHOD=JACKKNIFE** options, do not use the **NOMCAR** option.

Degrees of Freedom

PROC SURVEYPHREG computes degrees of freedom to compute confidence limits and *F* statistics. The degrees of freedom computation depends on the variance estimation method that you request. See the section “**Degrees of Freedom**” on page 7901 for details. Missing values can affect the degrees of freedom computation.

Taylor Series Variance Estimation

The degrees of freedom can depend on the number of clusters, the number of strata, and the number of observations. For Taylor series variance estimation, these numbers are based on the observations included

in the analysis. These numbers do not count observations that are excluded from the analysis due to missing values. If all values in a stratum are excluded from the analysis as missing values, then that stratum is called an *empty stratum*. Empty strata are not counted in the total number of strata for the analysis. Similarly, empty clusters and missing observations are not included in the totals counts of clusters and observations that are used to compute the degrees of freedom for the analysis.

If you specify the **MISSING** option, missing values are treated as valid nonmissing levels and are included in computing degrees of freedom. If you specify the **NOMCAR** option for Taylor series variance estimation, observations with missing values for variables in the regression model are included in computing degrees of freedom.

Replicate-Based Variance Estimation

For BRR or jackknife variance estimation, by default PROC SURVEYPHREG computes the degrees of freedom by using all valid observations in the input data set. A valid observation is an observation that has a positive value of the **WEIGHT** variable and nonmissing values of the **STRATA** and **CLUSTER** variables unless you specify the **MISSING** option.

Variance Estimation

PROC SURVEYPHREG uses the Taylor series method or replication (resampling) methods to estimate sampling errors of estimators that are based on complex sample designs (Fuller 1975; Särndal, Swensson, and Wretman 1992; Wolter 2007; Rust 1985; Dippo, Fay, and Morganstein 1984; Rao and Shao 1999, 1996; and Binder 1992). You can use the **VARMETHOD=** option in the PROC statement to specify the variance estimation method. By default, PROC SURVEYPHREG uses the Taylor series method.

However, replication methods have recently gained popularity for estimating variances in complex survey data analysis. One reason for this popularity is the relative simplicity of replication-based estimates, especially for nonlinear estimators; another is that modern computational capacity has made replication methods feasible for practical survey analysis.

Replication methods draw multiple replicates (also called subsamples) from a full sample according to a specific resampling scheme. The most commonly used resampling schemes are the *balanced repeated replication* (BRR) method and the *jackknife* method. For each replicate, the original weights are modified for the PSUs in the replicates to create replicate weights. The parameters of interest are estimated by using the replicate weights for each replicate. Then the variances of parameters of interest are estimated by the variability among the estimates derived from these replicates. The procedure automatically creates replicate weights based on the replication method you specify; alternatively you can use the **REPWEIGHTS** statement to provide your own replicate weights for variance estimation.

The following sections provide details about how the variance-covariance matrix of the estimated regression coefficients is estimated for each variance estimation method.

Taylor Series Linearization

The Taylor series linearization method is the default variance estimation method used by PROC SURVEYPHREG. See the section “**Notation and Estimation**” on page 7884 for definitions of the notation used in this section. Let

$$S^{(r)}(\boldsymbol{\beta}, t) = \sum_A w_{hij} y_{hij}(t) \exp(\boldsymbol{\beta}' \mathbf{Z}_{hij}(t)) \mathbf{Z}_{hij}^{\otimes r}(t)$$

where $r = 0, 1$. Let A be the set of indices in the selected sample. Let

$$\mathbf{a}^{\otimes r} = \begin{cases} \mathbf{a}\mathbf{a}' & , \quad r = 1 \\ I_{\dim(\mathbf{a})} & , \quad r = 0 \end{cases}$$

and let $I_{\dim(\mathbf{a})}$ be the identity matrix of appropriate dimension.

Let $\bar{\mathbf{Z}}(\boldsymbol{\beta}, t) = \frac{S^{(1)}(\boldsymbol{\beta}, t)}{S^{(0)}(\boldsymbol{\beta}, t)}$. The score residual for the (h, i, j) subject is

$$\begin{aligned} \mathbf{L}_{hij}(\boldsymbol{\beta}) &= \Delta_{hij} \left\{ \mathbf{Z}_{hij}(t_{hij}) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, t_{hij}) \right\} \\ &\quad - \sum_{(h', i', j') \in A} \Delta_{h' i' j'} \frac{w_{h' i' j'} Y_{h' i' j'}(t_{h' i' j'}) \exp(\boldsymbol{\beta}' \mathbf{Z}_{h' i' j'}(t_{h' i' j'}))}{S^{(0)}(\boldsymbol{\beta}, t_{h' i' j'})} \left\{ \mathbf{Z}_{h' i' j'}(t_{h' i' j'}) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, t_{h' i' j'}) \right\} \end{aligned}$$

For TIES=EFRON, the computation of the score residuals is modified to comply with the Efron partial likelihood. See the section “[Residuals](#)” on page 7906 for more information.

The Taylor series estimate of the covariance matrix of $\hat{\boldsymbol{\beta}}$ is

$$\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}) = \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \mathbf{G} \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})$$

where $\mathcal{I}(\hat{\boldsymbol{\beta}})$ is the observed information matrix and the $p \times p$ matrix \mathbf{G} is defined as

$$\mathbf{G} = \frac{n-1}{n-p} \sum_{h=1}^H \frac{n_h(1-f_h)}{n_h-1} \sum_{i=1}^{n_h} (\mathbf{e}_{hi+} - \bar{\mathbf{e}}_{h..})' (\mathbf{e}_{hi+} - \bar{\mathbf{e}}_{h..})$$

The observed residuals, their sums and means are defined as follows:

$$\begin{aligned} \mathbf{e}_{hij} &= w_{hij} \mathbf{L}_{hij}(\hat{\boldsymbol{\beta}}) \\ \mathbf{e}_{hi+} &= \sum_{j=1}^{m_{hi}} \mathbf{e}_{hij} \\ \bar{\mathbf{e}}_{h..} &= \frac{1}{n_h} \sum_{i=1}^{n_h} \mathbf{e}_{hi+} \end{aligned}$$

The factor $(n-1)/(n-p)$ in the computation of the matrix \mathbf{G} reduces the small sample bias that is associated with using the estimated function to calculate deviations (Fuller et al. (1989), pp. 77–81). For simple random sampling, this factor contributes to the degrees of freedom correction applied to the residual mean square for ordinary least squares in which p parameters are estimated. By default, the procedure uses this adjustment in the variance estimation. If you do not want to use this multiplier in the variance estimator, then specify the **VADJUST=NONE** option in the **MODEL** statement.

Balanced Repeated Replication (BRR) Method

The balanced repeated replication (BRR) method requires that the full sample be drawn by using a stratified sample design with two primary sampling units (PSUs) per stratum. The BRR method constructs half-sample replicates by deleting one PSU per stratum according to a [Hadamard matrix](#) and doubling the original

weight of the other PSU in that stratum. Let H be the total number of strata. The total number of replicates R is the smallest multiple of 4 that is greater than H . However, if you prefer a larger number of replicates, you can specify the `REPS= n method-option`. If a $n \times n$ Hadamard matrix cannot be constructed, the number of replicates is increased until a Hadamard matrix becomes available.

Each replicate is obtained by deleting one PSU per stratum according to a corresponding Hadamard matrix and adjusting the original weights for the remaining PSUs. The new weights are called replicate weights.

Replicates are constructed by using the first H columns of the $R \times R$ Hadamard matrix. The r th ($r = 1, 2, \dots, R$) replicate is drawn from the full sample according to the r th row of the Hadamard matrix as follows:

- If the (r, h) element of the Hadamard matrix is 1, then the first PSU of stratum h is included in the r th replicate and the second PSU of stratum h is excluded.
- If the (r, h) element of the Hadamard matrix is -1 , then the second PSU of stratum h is included in the r th replicate and the first PSU of stratum h is excluded.

The replicate weights of the remaining PSUs in each half sample are then doubled to their original weights. For more detail about the BRR method, see Wolter (2007) and Lohr (2010).

By default, an appropriate Hadamard matrix is generated automatically to create the replicates. You can display the Hadamard matrix by specifying the `VARMETHOD=BRR(PRINTH) method-option`. If you provide a Hadamard matrix by specifying the `VARMETHOD=BRR(HADAMARD=) method-option`, then the replicates are generated according to the provided Hadamard matrix. You can use the `VARMETHOD=BRR(OUTWEIGHTS=) method-option` to store the replicate weights in a SAS data set.

Let $\hat{\beta}$ be the estimated proportional hazards regression coefficients from the full sample, and let $\hat{\beta}_r$ be the estimated proportional hazards regression coefficients from the r th replicate by using replicate weights. PROC SURVEYPHREG estimates the covariance matrix of $\hat{\beta}$ by

$$\hat{V}(\hat{\beta}) = \frac{1}{R} \sum_{r=1}^R (\hat{\beta}_r - \hat{\beta}) (\hat{\beta}_r - \hat{\beta})'$$

with H degrees of freedom, where H is the number of strata.

If you specify the `CENTER=REPLICATES method-option`, then PROC SURVEYPHREG computes the covariance matrix of $\hat{\beta}$ by

$$\hat{V}(\hat{\beta}) = \frac{1}{R} \sum_{r=1}^R (\hat{\beta}_r - \overline{\hat{\beta}}) (\hat{\beta}_r - \overline{\hat{\beta}})'$$

where $\overline{\hat{\beta}}$ is the average of the replicate estimates as follows:

$$\overline{\hat{\beta}} = \frac{1}{R} \sum_{r=1}^R \hat{\beta}_r$$

If one or more components of $\hat{\beta}_r$ cannot be calculated for some replicates, then the variance estimate is computed by using only the replicates for which the proportional hazards regression coefficients can

be estimated. Estimability and nonconvergence are the two most common reasons why $\hat{\beta}_r$ might not be available for a replicate sample even if $\hat{\beta}$ is defined for the full sample. Let R_a be the number of replicates where $\hat{\beta}_r$ is available, and let $R - R_a$ be the number of replicates where $\hat{\beta}_r$ is not available. Without loss of generality, assume that $\hat{\beta}_r$ is available only for the first R_a replicates; then the BRR variance estimator is

$$\hat{V}(\hat{\beta}) = \frac{1}{R_a} \sum_{r=1}^{R_a} (\hat{\beta}_r - \hat{\beta}) (\hat{\beta}_r - \hat{\beta})'$$

with degrees of freedom equal to the minimum of H and R_a , where H is the number of strata. Alternatively, you can use the `FAY= method-option` to request Fay's BRR method, as discussed in the following section.

Fay's BRR Method

The traditional BRR method constructs half-sample replicates by deleting one PSU per stratum according to a Hadamard matrix and doubling the original weight of the other PSU. Fay's BRR method uses the Fay coefficient, ϵ ($0 \leq \epsilon < 1$), and instead of deleting one PSU per stratum, it multiplies the original weight by the coefficient ϵ . The original weight of the remaining PSU in that stratum is multiplied by $2 - \epsilon$. PROC SURVEYPHREG uses $\epsilon = 0.5$ as the default value; alternatively, you can specify a value for ϵ with the `FAY= method-option`. When $\epsilon = 0$, Fay's method becomes the traditional BRR method. For more details, see Dipppo, Fay, and Morganstein (1984); Fay (1984, 1989); Judkins (1990). Because the traditional BRR method uses only half of the total sample in every replicate, several replicate estimators ($\hat{\beta}_r$) might be undefined even when the full sample estimator ($\hat{\beta}$) is defined. Fay's BRR method is especially useful for this situation because it uses all the sampled units in every replicate.

Let $\hat{\beta}$ be the estimated proportional hazards regression coefficients from the full sample, and let $\hat{\beta}_r$ be the estimated regression coefficients that are obtained from the r th replicate by using replicate weights. PROC SURVEYPHREG estimates the covariance matrix of $\hat{\beta}$ by

$$\hat{V}(\hat{\beta}) = \frac{1}{R(1 - \epsilon)^2} \sum_{r=1}^R (\hat{\beta}_r - \hat{\beta}) (\hat{\beta}_r - \hat{\beta})'$$

with H degrees of freedom, where H is the number of strata.

Hadamard Matrix

PROC SURVEYPHREG uses a Hadamard matrix to construct replicates for BRR variance estimation. You can provide a Hadamard matrix for replicate construction by using the `HADAMARD= method-option` for `VARMETHOD=BRR`. Otherwise, PROC SURVEYPHREG generates an appropriate Hadamard matrix. You can display the Hadamard matrix by specifying the `PRINTH method-option`.

A Hadamard matrix \mathbf{A} of dimension R is a square matrix that has all elements equal to 1 or -1 such that $\mathbf{A}'\mathbf{A} = R\mathbf{I}$, where \mathbf{I} is an identity matrix of appropriate order. The dimension of a Hadamard matrix must equal 1, 2, or a multiple of 4.

For example, the following matrix is a Hadamard matrix of dimension $k = 8$:

$$\begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\ 1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \end{bmatrix}$$

For BRR replicate construction, the dimension of the Hadamard matrix must be at least H , where H denotes the number of first-stage strata in your design. If a Hadamard matrix of a given dimension exists, it is not necessarily unique. Therefore, if you want to use a specific Hadamard matrix, you must provide the matrix as a SAS data set in the `HADAMARD= method-option`. You must ensure that the matrix that you provide is actually a Hadamard matrix; PROC SURVEYPHREG does not check the validity of your Hadamard matrix.

See the section “[Balanced Repeated Replication \(BRR\) Method](#)” on page 7896 for details about how the Hadamard matrix is used to construct replicates for BRR variance estimation.

Jackknife Method

The jackknife method of variance estimation deletes one PSU at a time from the full sample to create replicates. This method is also known as the delete-1 jackknife method because it deletes exactly one PSU in every replicate. The total number of replicates R is the same as the total number of PSUs. In each replicate, the sampling weights of the remaining PSUs are modified by the *jackknife coefficient* α_r . The modified weights are called replicate weights.

Let PSU i in stratum h_r be omitted for the r th replicate; then the jackknife coefficient and replicate weights are computed as

$$\alpha_r = \begin{cases} \frac{n_{hr}-1}{n_{hr}} & \text{for a stratified design} \\ \frac{R-1}{R} & \text{for designs without stratification} \end{cases}$$

and

$$w_{hij}^{(r)} = \begin{cases} w_{hij} & \text{if observation unit } j \text{ is not in donor stratum } h_r \\ 0 & \text{if observation unit } j \text{ is in PSU } i \text{ of donor stratum } h_r \\ w_{hij}/\alpha_r & \text{if observation unit } j \text{ is not in PSU } i \text{ but in donor stratum } h_r \end{cases}$$

You can use the `VARMETHOD=JACKKNIFE(OUTJKCOEFS=) method-option` to store the jackknife coefficients in a SAS data set and use the `VARMETHOD=JACKKNIFE(OUTWEIGHTS=) method-option` to store the replicate weights in a SAS data set.

If you provide your own replicate weights with a `REPWEIGHTS` statement, then you can also provide corresponding jackknife coefficients with the `JKCOEFS=` option. If you provide replicate weights with a `REPWEIGHTS` statement but do not provide jackknife coefficients, then the procedure uses $(R - 1)/R$ as the default jackknife coefficient for every replicate, where R is the total number of replicates.

Let $\hat{\beta}$ be the estimated proportional hazards regression coefficients from the full sample, and let $\hat{\beta}_r$ be the estimated regression coefficients for the r th replicate. PROC SURVEYPHREG estimates the covariance matrix of $\hat{\beta}$ by

$$\widehat{V}(\hat{\beta}) = \sum_{r=1}^R \alpha_r (\hat{\beta}_r - \hat{\beta}) (\hat{\beta}_r - \hat{\beta})'$$

with $R - H$ degrees of freedom, where R is the number of replicates and H is the number of strata, or $R - 1$ when there is no stratification.

If you specify the **CENTER=REPLICATES** *method-option*, then PROC SURVEYPHREG computes the covariance matrix of $\hat{\beta}$ by

$$\widehat{V}(\hat{\beta}) = \sum_{r=1}^R \alpha_r (\hat{\beta}_r - \overline{\hat{\beta}_r}) (\hat{\beta}_r - \overline{\hat{\beta}_r})'$$

where $\overline{\hat{\beta}_r}$ is the average of the replicate estimates as follows:

$$\overline{\hat{\beta}_r} = \frac{1}{R} \sum_{r=1}^R \hat{\beta}_r$$

If one or more components of $\hat{\beta}_r$ cannot be calculated for some replicates, then the variance estimator uses only the replicates for which the proportional hazards regression coefficients can be estimated. Estimability and nonconvergence are two common reasons why $\hat{\beta}_r$ might not be available for a replicate sample even if $\hat{\beta}$ is defined for the full sample. Let R_a be the number of replicates where $\hat{\beta}_r$ are available, and let $R - R_a$ be the number of replicates where $\hat{\beta}_r$ are not available. Without loss of generality, assume that $\hat{\beta}_r$ is available only for the first R_a replicates; then the jackknife variance estimator is

$$\widehat{V}(\hat{\beta}) = \sum_{r=1}^{R_a} \alpha_r (\hat{\beta}_r - \hat{\beta}) (\hat{\beta}_r - \hat{\beta})'$$

with $R_a - H$ degrees of freedom, where H is the number of strata. Alternatively, you can use the **VADJUST=AVGREPSS** option in the MODEL statement to use the average sum of squares for the invalid replicate samples. See “[Variance Adjustment Factors](#)” on page 7902 for details.

Degrees of Freedom

PROC SURVEYPHREG uses the degrees of freedom of the variance estimator to obtain t confidence limits and Wald type F tests. PROC SURVEYPHREG computes the degrees of freedom based on the variance estimation method and the sample design. Alternatively, you can specify the degrees of freedom in the **DF=** option in the **MODEL** statement.

For Taylor series variance estimation, PROC SURVEYPHREG calculates the degrees of freedom (df) as the number of clusters minus the number of strata. If the **CLUSTER** statement is not specified, then the procedure treats each observation as a cluster. If the **STRATA** statement is not specified, then the procedure assumes that all observations are in the same stratum. These numbers are based on the observations included in the analysis. These numbers do not count observations that are excluded from the analysis due to missing values. See the section “[Missing Values](#)” on page 7893 for details. If you specify the **MISSING** option in the **CLASS** statement, missing values are treated as valid nonmissing levels and are included in computing degrees of freedom. If you specify the **NOMCAR** option for Taylor series variance estimation, observations with missing values of the analysis variables are included in computing the degrees of freedom.

If you provide replicate weights with a **REPWEIGHTS** statement, the degrees of freedom is equal the number of replicates used, which is the number of **REPWEIGHTS** variables that provide replicate estimates. Alternatively, you can specify the degrees of freedom in the **DF=** option in the **REPWEIGHTS** or **MODEL** statement.

For BRR variance estimation (when you do not use a **REPWEIGHTS** statement), PROC SURVEYPHREG calculates the degrees of freedom as the number of strata. PROC SURVEYPHREG bases the number of strata on all valid observations in the data set. If some replicate samples are not usable in the sense that these replicate samples cannot be used for parameter estimation (say, for nonconvergence or inestimability), then df equals the minimum of the number of strata and the number of replicates used. Alternatively, you can use the **DF=ALLREPS** option in the **MODEL** statement to specify that df equals the number of strata.

For jackknife variance estimation (when you do not use a **REPWEIGHTS** statement), PROC SURVEYPHREG calculates the degrees of freedom as the number of clusters minus the number of strata. If the **CLUSTER** statement is not specified, then the procedure treats each observation as a cluster. If the **STRATA** statement is not specified, then the procedure assumes that all observations are in the same stratum. For jackknife variance estimation, PROC SURVEYPHREG bases the number of strata and clusters on all valid observations in the data set. If some replicate samples are not usable in the sense that these replicate samples cannot be used for parameter estimation (say, for nonconvergence or inestimability), then df equals the number of clusters (or observations if no **CLUSTER** statement is specified) minus the number of strata (or one in if no **STRATA** statement is specified) minus the number of replicate samples that are not used. Alternatively, you can use the **DF=ALLREPS** option in the **MODEL** statement to specify that df equals the number of clusters minus the number of strata.

Variance Adjustment Factors

PROC SURVEYPHREG provides options for adjustment of the default variance estimators. VADJUST=NONE and VADJUST=DF are available for the Taylor series linearization variance estimator. VADJUST=AVGREPSS is available for the jackknife replication variance estimators.

For models with large number of parameters, it is reasonable to adjust the Taylor series linearized variance estimator by the number of estimable parameters in the analysis model. Fuller et al. (1989, pp. 77–81) use an adjustment factor $(n - 1)/(n - p)$ to estimate the linearized variance for regression coefficients, where n is the total number of observation units and p is the number of estimable parameters in the analysis model. By default, PROC SURVEYPHREG uses this adjustment in the computation of the matrix \mathbf{G} for the Taylor series linearization [variance estimation](#). If you do not want to use this adjustment, then specify VADJUST=NONE.

Variance adjustment factors can be useful for replication variance estimations, especially if some replicate samples are not usable. A replicate sample might not provide useful parameter estimates (replicate estimates) for reasons such as nonconvergence of the optimization or inestimability of some parameters in that subsample. For example, consider the [jackknife variance estimator](#) with R replicates. Suppose that only $R_a (< R)$ replicates are used to obtain replicate estimates and $R - R_a$ replicates cannot be used due to, say, nonconvergence of the optimization. Without loss of generality, assume that the first R_a replicates are used. By default SURVEYPHREG uses

$$\widehat{\mathbf{V}}(\hat{\boldsymbol{\beta}}) = \sum_{r=1}^{R_a} \alpha_r (\hat{\boldsymbol{\beta}}_r - \hat{\boldsymbol{\beta}}) (\hat{\boldsymbol{\beta}}_r - \hat{\boldsymbol{\beta}})'$$

as the jackknife variance estimator. An alternative estimator is

$$\begin{aligned} \widehat{\mathbf{V}}(\hat{\boldsymbol{\beta}}) &= \sum_{r=1}^{R_a} \alpha_r (\hat{\boldsymbol{\beta}}_r - \hat{\boldsymbol{\beta}}) (\hat{\boldsymbol{\beta}}_r - \hat{\boldsymbol{\beta}})' + (R - R_a) \left\{ \frac{1}{R_a} \sum_{r=1}^{R_a} \alpha_r (\hat{\boldsymbol{\beta}}_r - \hat{\boldsymbol{\beta}}) (\hat{\boldsymbol{\beta}}_r - \hat{\boldsymbol{\beta}})' \right\} \\ &= \frac{R}{R_a} \sum_{r=1}^{R_a} \alpha_r (\hat{\boldsymbol{\beta}}_r - \hat{\boldsymbol{\beta}}) (\hat{\boldsymbol{\beta}}_r - \hat{\boldsymbol{\beta}})' \end{aligned}$$

which uses the average replicate sum of squares for the $R - R_a$ unusable replicate samples. If you specify the VADJUST=AVGREPSS option, PROC SURVEYPHREG uses the second variance estimator for the jackknife replication method. Note that you can specify the [FAY method-option](#) for the BRR method to avoid nonconvergence of the optimization or inestimability of some parameters in subsamples.

Variance Ratios and Standard Error Ratios

PROC SURVEYPHREG provides options to compute different variance ratios and standard error ratios.

If you specify the VARRATIO=MODEL option, then the procedure computes the variance ratio of the estimated regression parameter $\hat{\beta}_j$ as $\frac{\hat{V}(\hat{\beta}_j)}{\hat{V}_M(\hat{\beta}_j)}$, where $\hat{V}(\hat{\beta}_j)$, the estimated variance of $\hat{\beta}_j$, uses the complete design information and $\hat{V}_M(\hat{\beta}_j)$ is the j th diagonal element of the observed information matrix $\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})$.

If you specify the VARRATIO=IND option, then the procedure computes the variance ratio of the estimated regression parameter $\hat{\beta}_j$ as $\frac{\hat{V}(\hat{\beta}_j)}{\hat{V}_{\text{IND}}(\hat{\beta}_j)}$, where $\hat{V}(\hat{\beta}_j)$, the estimated variance of $\hat{\beta}_j$, uses the complete design information and $\hat{V}_{\text{IND}}(\hat{\beta}_j)$ is the j th diagonal element of $\hat{V}_{\text{IND}}(\hat{\boldsymbol{\beta}})$. $\hat{V}_{\text{IND}}(\hat{\boldsymbol{\beta}})$ is the sandwich variance

estimator, which ignores the strata and the clusters and is computed as

$$\hat{V}_{\text{IND}}(\hat{\beta}) = \mathcal{I}^{-1}(\hat{\beta}) \left\{ \frac{n}{n-1} (1-f) \sum_h \sum_i \sum_j (e_{hij} - \bar{e}_{...})' (e_{hij} - \bar{e}_{...}) \right\} \mathcal{I}^{-1}(\hat{\beta})$$

where e_{hij} are the weighted score residuals, f is the overall sampling fraction, and n is the number of observation units. The three sums are over the observation units (j) across the PSUs (i) and the strata (h).

For Taylor series variance estimation, PROC SURVEYPHREG determines the value of f , the overall sampling fraction, based on the **RATE=** or **TOTAL=** option. If you do not specify either of these options, PROC SURVEYPHREG assumes that the value of f is negligible and does not use a finite population correction in the analysis. If you specify **RATE=value**, PROC SURVEYPHREG uses *value* as the overall sampling fraction f . If you specify **TOTAL=value**, PROC SURVEYPHREG computes f as the ratio of the number of PSUs in the sample to the specified total.

If you specify stratum sampling rates by using the **RATE=SAS-data-set** option, then PROC SURVEYPHREG computes stratum totals based on these stratum sampling rates and the number of sample PSUs in each stratum. The procedure sums the stratum totals to form the overall total and then computes f as the ratio of the number of sample PSUs to the overall total. Alternatively, if you specify stratum totals with the **TOTAL=SAS-data-set** option, then PROC SURVEYPHREG sums these totals to compute the overall total. The overall sampling fraction f is then computed as the ratio of the number of sample PSUs to the overall total.

The replication methods do not use the finite population correction factor $(1 - f)$ in the denominator.

Standard error ratios are computed as the square root of the variance ratios.

Domain Analysis

Domain analysis refers to the computation of statistics for domains (subpopulations). Formation of subpopulations can be unrelated to the sample design, and so the domain sample sizes can actually be random variables. Domain analysis takes this variability into account to compute variance estimates for estimated model parameters. Domain analysis is also known as subgroup analysis, subpopulation analysis, and subdomain analysis. For more information about domain analysis, see Lohr (2010); Särndal, Swensson, and Wretman (1992); Cochran (1977).

To request domain analysis with PROC SURVEYPHREG, use the **DOMAIN** statement. If your domains are formed by more than one variable, you can specify **DomainVariable_1 * DomainVariable_2** in the **DOMAIN** statement. If you use the **DOMAIN** statement, the procedure performs separate analyses for all domains, in addition to the overall analysis.

Including the domain variables in a **DOMAIN** statement request provides a different analysis from that obtained by using a **BY** statement, which provides completely separate analyses of the **BY** groups. The **BY** statement can also be used to analyze the data set by subgroups, but it is critical to note that this does *not* account for random sample sizes that often occur for domain analyses. The **BY** statement is appropriate only when the number of units in each subgroup is known with certainty. For example, the **BY** statement can be used to obtain stratum level estimates when you have fixed sample sizes for the strata. When the subgroup sample size is random, include the domain variables in **DOMAIN** statement.

Hypothesis Tests, Confidence Intervals, and Residuals

Testing the Global Null Hypothesis

The following statistics can be used to test the global null hypothesis $H_0: \beta = \mathbf{0}$. Let d be the number of clusters (or observations) minus the number of strata (or one) and p be the number of estimable parameters in the analysis model.

The likelihood ratio test is expressed as

$$\chi^2_{LR} = 2 \left[\log \{L(\hat{\beta})\} - \log \{L(\mathbf{0})\} \right]$$

where $L(\cdot)$ denotes the partial pseudo-likelihood described in “[Partial Likelihood Function for the Cox Model](#)” on page 7890. The p -value is computed by using a chi-square distribution with p degrees of freedom. The usual assumptions required for a likelihood ratio test do not hold for the pseudo-likelihood that is used by PROC SURVEYPHREG, leading to other methods for testing the global null hypothesis, such as the Wald test discussed below.

Wald’s test is expressed as

$$W_F = \left(\frac{d - p + 1}{dp} \right) \hat{\beta}' [\widehat{V}(\hat{\beta})]^{-1} \hat{\beta}$$

The p -value is computed by using an F distribution with (p, d) degrees of freedom. For the Taylor series linearization method, the **DF=PARMADJ** option in the MODEL statement computes the p -value by using an F distribution with $(p, d - p + 1)$ degrees of freedom.

If you specify the **DF=NONE** option in the MODEL statement, then the procedure computes

$$W_{\chi^2} = \hat{\beta}' [\widehat{V}(\hat{\beta})]^{-1} \hat{\beta}$$

and the p -value is computed by using a chi-square distribution with p degrees of freedom.

Model Fit Statistics

Suppose the model contains p estimable parameters. Then the following two criteria are displayed for model fit statistics:

- $-2 \log$ likelihood:

$$-2 \text{ Log L} = -2 \log(L(\hat{\beta}))$$

where $L(\cdot)$ is a partial pseudo-likelihood function for the corresponding **TIES=** option as described in the section “[Partial Likelihood Function for the Cox Model](#)” on page 7890, and $\hat{\beta}$ is the maximum pseudo-log-likelihood estimate of the proportional hazards regression coefficients.

- Akaike’s information criterion (AIC):

$$\text{AIC} = -2 \text{ Log L} + 2p$$

The AIC statistics gives a different way of adjusting the $-2 \log$ likelihood statistic for the number of estimable parameters in the model.

Contrasts

For a testable hypothesis $H_0: \mathbf{L}\boldsymbol{\beta} = 0$, the Wald F statistic is computed as

$$F_{\text{Wald}} = \frac{(\mathbf{L}^* \hat{\boldsymbol{\beta}})' (\mathbf{L}^{*'} \hat{\mathbf{V}} \mathbf{L}^*)^{-1} (\mathbf{L}^* \hat{\boldsymbol{\beta}})}{\text{rank}(\mathbf{L})}$$

where \mathbf{L} is a contrast vector or matrix that you specify, $\boldsymbol{\beta}$ is the vector of regression parameters, $\hat{\boldsymbol{\beta}}$ is the estimated regression coefficients, $\hat{\mathbf{V}}$ is the estimated covariance matrix of $\hat{\boldsymbol{\beta}}$, $\text{rank}(\mathbf{L})$ is the rank of \mathbf{L} , and \mathbf{L}^* is a matrix such that

- \mathbf{L}^* has the same number of columns as \mathbf{L}
- \mathbf{L}^* has full row rank
- the rank of \mathbf{L}^* equals the rank of the \mathbf{L} matrix
- all rows of \mathbf{L}^* are estimable functions
- the Wald F statistic computed by using the \mathbf{L}^* matrix is equivalent to the Wald F statistic computed by using the \mathbf{L} matrix with any row deleted that is a linear combination of previous rows

If \mathbf{L} is a full-rank matrix and all rows of \mathbf{L} are estimable functions, then \mathbf{L}^* is the same as \mathbf{L} . It is possible that \mathbf{L} matrix cannot be constructed for a given set of linear contrasts, in which case the contrasts are not testable.

If the **DF=NONE** option in the MODEL statement is specified, then the procedure performs a chi-square significance test.

Confidence Intervals

By default, the SURVEYPHREG procedure computes t confidence limits for the estimated regression coefficients. Alternatively, you can specify the **DF=NONE** option in the MODEL statement to request standard normal confidence intervals. The t confidence interval for a linear combination $\mathbf{l}'\boldsymbol{\beta}$ of the regression coefficients is computed as

$$\left(\mathbf{l}'\hat{\boldsymbol{\beta}} \pm t_{df, \alpha/2} \sqrt{\mathbf{l}'\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{l}} \right)$$

where $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile point of the t distribution with df degrees of freedom. See the section “**Degrees of Freedom**” on page 7901 for more information about df . If you use the **DF=NONE** option in the MODEL statement, then the procedure uses the $100(1 - \alpha/2)$ percentile point of the standard normal distribution.

Hazard Ratios

The hazard ratio for a quantitative effect with regression coefficient $\beta_j = \mathbf{e}_j' \boldsymbol{\beta}$ is defined as $\exp(\beta_j)$, where \mathbf{e}_j denotes the j th unit vector. In general, a log-hazard ratio can be written as $\mathbf{l}'\boldsymbol{\beta}$, a linear combination of the regression coefficients, and the hazard ratio $\exp(\mathbf{l}'\boldsymbol{\beta})$ is obtained by replacing \mathbf{e}_j with \mathbf{l} .

The confidence intervals for hazard ratios are obtained by exponentiating the confidence limits of the corresponding linear combination. Thus, the $100(1 - \alpha)$ confidence limits are

$$\exp \left(\mathbf{e}_j' \hat{\boldsymbol{\beta}} \pm t_{df, \alpha/2} \sqrt{\mathbf{e}_j' \hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}) \mathbf{e}_j} \right)$$

where $t_{df, \alpha/2}$ is the $100(1 - \alpha/2)$ percentile point of the t distribution with df degrees of freedom. See the section “[Degrees of Freedom](#)” on page 7901 for more information about df . If you use the [DF=NONE](#) option in the MODEL statement, then the procedure uses the $100(1 - \alpha/2)$ percentile point of the standard normal distribution.

Residuals

This section describes the computation of residuals (RESMART, RESDEV, RESSCH, and RESSCO in the OUTPUT statement). See the section “[Notation and Estimation](#)” on page 7884 for definition of notation that is used in this section. The residuals are calculated based on the [TIES=](#) option in the MODEL statement.

[TIES=BRESLOW](#)

This is the default option. Let

$$S^{(r)}(\boldsymbol{\beta}, t) = \sum_A w_{hij} y_{hij}(t) \exp(\boldsymbol{\beta}' \mathbf{Z}_{hij}(t)) \mathbf{Z}_{hij}^{\otimes r}(t)$$

$$\bar{\mathbf{Z}}(\boldsymbol{\beta}, t) = \frac{S^{(1)}(\boldsymbol{\beta}, t)}{S^{(0)}(\boldsymbol{\beta}, t)}$$

where $r = 0, 1$; and A be the set of indices in the selected sample.

Further let

$$\begin{aligned} d\Lambda_0(\boldsymbol{\beta}, t) &= \sum_A \frac{w_{hij} dn_{hij}(t)}{S^{(0)}(\boldsymbol{\beta}, t)} \\ dM_{hij}(\boldsymbol{\beta}, t) &= dn_{hij}(t) - y_{hij}(t) \exp(\boldsymbol{\beta}' \mathbf{Z}_{hij}(t)) d\Lambda_0(\boldsymbol{\beta}, t) \end{aligned}$$

The martingale residual at t is defined as

$$\begin{aligned} \hat{M}_{hij}(t) &= \int_0^t dM_{hij}(\hat{\boldsymbol{\beta}}, \tau) \\ &= n_{hij}(t) - \int_0^t y_{hij}(\tau) \exp(\hat{\boldsymbol{\beta}}' \mathbf{Z}_{hij}(\tau)) d\Lambda_0(\hat{\boldsymbol{\beta}}, \tau) \end{aligned}$$

Here $\hat{M}_{hij}(t)$ estimates the difference over $(0, t]$ between the observed number of events for the (h, i, j) observation unit and a conditional expected number of events. The quantity $\hat{M}_{hij} \equiv \hat{M}_{hij}(\infty)$ is referred to as the martingale residual for the (h, i, j) observation unit. For the Cox model with no time-dependent explanatory variables, the martingale residual for the (h, i, j) unit with observation time $t_{(h, i, j)}$ and event status $\Delta_{(h, i, j)}$ is

$$\hat{M}_{(h, i, j)} = \Delta_{(h, i, j)} - e^{\hat{\boldsymbol{\beta}}' \mathbf{Z}_{(h, i, j)}} \int_0^{t_{(h, i, j)}} d\Lambda_0(\hat{\boldsymbol{\beta}}, s)$$

The deviance residual D_{hij} for the (h, i, j) observation unit is a transformation of the corresponding martingale residuals,

$$D_{hij} = \text{sign}(\hat{M}_{hij}) \sqrt{2 \left[-\hat{M}_{hij} - n_{hij}(\infty) \log \left(\frac{n_{hij}(\infty) - \hat{M}_{hij}}{n_{hij}(\infty)} \right) \right]}$$

The square root shrinks large negative martingale residuals, while the logarithmic transformation expands martingale residuals that are close to unity. As such, the deviance residuals are more symmetrically distributed around zero than the martingale residuals. For the Cox model, the deviance residual reduces to the form

$$D_{hij} = \text{sign}(\hat{M}_{hij}) \sqrt{2[-\hat{M}_{hij} - \Delta_{hij} \log(\Delta_{hij} - \hat{M}_{hij})]}$$

The Schoenfeld (1982) residual vector is calculated on a per-event-time basis. At the k th event time $t_{hij,k}$ of the (h, i, j) observation unit, the Schoenfeld residual

$$\hat{\mathbf{U}}_{hij}(t_{hij,k}) = \mathbf{Z}_{hij}(t_{hij,k}) - \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, t_{hij,k})$$

is the difference between the observed covariate vector for the (h, i, j) observation unit and the average of the covariate vectors over the risk set at $t_{hij,k}$. Under the proportional hazards assumption, the Schoenfeld residuals have the sample path of a random walk; therefore, they are useful in assessing time trend or lack of proportionality.

The score process for the (h, i, j) subject at time t is

$$\mathbf{L}_{hij}(\boldsymbol{\beta}, t) = \int_0^t [\mathbf{Z}_{hij}(\tau) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, \tau)] dM_{hij}(\boldsymbol{\beta}, \tau)$$

The vector $\hat{\mathbf{L}}_{hij} \equiv \mathbf{L}_{hij}(\hat{\boldsymbol{\beta}}, \infty)$ is the score residual for the (h, i, j) observation unit.

The score residuals are a decomposition of the first partial derivative of the log likelihood. They are useful in assessing the influence of each subject on individual parameter estimates. They also play an important role in the computation of the variance estimators.

TIES=EFRON

For TIES=EFRON, the preceding computation is modified to comply with the Efron partial likelihood. For a given uncensored time t , let $\delta_{hij}(t) = 1$ if t is an event time for the (h, i, j) observation, and 0 otherwise. Let $d(t) = \sum_{hij \in A} \delta_{hij}(t)$, which is the number of observation units that have an event at t . For $1 \leq l \leq d(t)$, let

$$\begin{aligned} S^{(r)}(\boldsymbol{\beta}, l, t) &= \sum_A w_{hij} y_{hij}(t) \left\{ 1 - \frac{l-1}{d(t)} \delta_{hij}(t) \right\} \exp(\boldsymbol{\beta}' \mathbf{Z}_{hij}(t)) \mathbf{Z}_{hij}^{\otimes r}(t) \\ \bar{\mathbf{Z}}(\boldsymbol{\beta}, l, t) &= \frac{S^{(1)}(\boldsymbol{\beta}, l, t)}{S^{(0)}(\boldsymbol{\beta}, l, t)} \\ d\Lambda_0(\boldsymbol{\beta}, l, t) &= \sum_A \frac{w_{hij} d n_{hij}(t)}{S^{(0)}(\boldsymbol{\beta}, l, t)} \\ dM_{hij}(\boldsymbol{\beta}, l, t) &= d n_{hij}(t) - y_{hij}(t) \left(1 - \delta_{hij}(t) \frac{l-1}{d(t)} \right) \exp(\boldsymbol{\beta}' \mathbf{Z}_{hij}(t)) d\Lambda_0(\boldsymbol{\beta}, l, t) \end{aligned}$$

where $r = 0, 1$, and A are the set of indices in the selected sample.

The martingale residual at t for the (h, i, j) observation unit is defined as

$$\begin{aligned}\hat{M}_{hij}(t) &= \int_0^t \frac{1}{d(\tau)} \sum_{l=1}^{d(\tau)} dM_{hij}(\hat{\beta}, l, \tau) \\ &= n_{hij}(t) - \int_0^t \frac{1}{d(\tau)} \sum_{l=1}^{d(\tau)} y_{hij}(\tau) \left(1 - \delta_{hij}(\tau) \frac{l-1}{d(\tau)}\right) \exp(\hat{\beta}' \mathbf{Z}_{hij}(\tau)) d\Lambda_0(\hat{\beta}, l, \tau)\end{aligned}$$

Deviance residuals are computed by using the same transform on the corresponding martingale residuals as in TIES=BRESLOW.

The Schoenfeld residual vector for the (h, i, j) observation unit at event time $t_{hij,k}$ is

$$\hat{\mathbf{U}}_{hij}(t_{hij,k}) = \mathbf{Z}_{hij}(t_{hij,k}) - \frac{1}{d(t_{hij,k})} \sum_{l=1}^{d(t_{hij,k})} \bar{\mathbf{Z}}(\hat{\beta}, l, t_{hij,k})$$

The score process for the (h, i, j) observation unit at time t is

$$\mathbf{L}_{hij}(\beta, t) = \int_0^t \frac{1}{d(\tau)} \sum_{l=1}^{d(\tau)} \left(\mathbf{Z}_{hij}(\tau) - \bar{\mathbf{Z}}(\beta, l, \tau) \right) dM_{hij}(\beta, l, \tau)$$

Output Data Sets

You can use the Output Delivery System to create a SAS data set from any piece of PROC SURVEYPHREG output. See the section “[ODS Table Names](#)” on page 7912 for more information. PROC SURVEYPHREG also provides an output data set to store observation-level statistics, an output data set to store the replicate weights for BRR or jackknife variance estimation, and an output data set to store the jackknife coefficients for jackknife variance estimation.

OUT= Data Set for the OUTPUT statement

The **OUTPUT** statement can be used to store observation-level statistics, such as the predicted values and their standard errors, the (weighted) number of observation units at risk, martingale residuals, Schoenfeld residuals, score residuals, and deviance residuals. See the section “[Residuals](#)” on page 7906 for details about how these statistics are calculated.

Replicate Weights Output Data Set

If you specify the **OUTWEIGHTS=** *method-option* for **VARMETHOD=BRR** or **JACKKNIFE**, PROC SURVEYPHREG stores the replicate weights in an output data set. The **OUTWEIGHTS=** output data set contains all observations that are used in the analysis or all valid observations in the **DATA=** input data set. See the section “[Missing Values](#)” on page 7893 for details about valid observations.

The OUTWEIGHTS= data set contains the following variables:

- all variables in the DATA= input data set
- RepWt_1, RepWt_2, . . . , RepWt_R, which are the replicate weight variables, where R is the total number of replicates in the analysis

Each replicate weight variable contains the replicate weights for the corresponding replicate. Replicate weights equal zero for those observations not included in the replicate.

After the procedure creates replicate weights for a particular input data set and survey design, you can use the OUTWEIGHTS= *method-option* to store these replicate weights and then use them again in subsequent analyses, either in PROC SURVEYPHREG or in the other survey procedures. You can use a REPWEIGHTS statement to provide replicate weights for the procedure.

Jackknife Coefficients Output Data Set

If you specify the OUTJKCOEFS= *method-option* for VARMETHOD=JACKKNIFE, PROC SURVEYPHREG stores the jackknife coefficients in an output data set. The OUTJKCOEFS= output data set contains one observation for each replicate. The OUTJKCOEFS= data set contains the following variables:

- Replicate, which is the replicate number for the jackknife coefficient
- JKCoefficient, which is the jackknife coefficient for the replicate
- DonorStratum, which is the stratum of the PSU that was deleted to construct the replicate, if you specify a STRATA statement

After the procedure creates jackknife coefficients for a particular input data set and survey design, you can use the OUTJKCOEFS= *method-option* to store these coefficients and then use them again in subsequent analyses, either in PROC SURVEYPHREG or in the other survey procedures. You can use the JKCOEFS= option in the REPWEIGHTS statement to provide jackknife coefficients for the procedure.

Displayed Output

If you use the NOPRINT option in the PROC SURVEYPHREG statement, the procedure does not display any output. Otherwise, PROC SURVEYPHREG displays results of the analysis in a collection of tables.

Model Information

The “Model Information” table displays the two-level name of the input data set, the name and label of the failure time variable, the name and label of the censoring variable and the values that indicate censored times, the model, the name and label of the FREQ variable, the name and label of the WEIGHT variable, the name and label of the STRATA variables, the name and label of the CLUSTER variables, and the method of handling ties in the failure time for the Cox model. The ODS name of the “Model Information” table is “ModelInfo.”

Number of Observations

The “Number of Observations” table displays the number of observations that are read and used, the sum of frequencies read and used, the sum of weights read and used, and the weighted sum of frequencies that are read and used in the analysis. The ODS name of the “Number of Observations” table is “NObs.”

Summary of the Number of Event and Censored Values

The “Summary of the Number of Event and Censored Values” table displays the number of events and censored values. The ODS name of the “Summary of the Number of Event and Censored Values” table is “CensoredSummary.”

Summary of the Weighted Number of Event and Censored Values

The “Summary of the Weighted Number of Event and Censored Values” table displays the weighted number of events and censored values. The ODS name of the “Summary of the Weighted Number of Event and Censored Values” table is “WeightedCensoredSummary.”

Class Level Information

The “Class Level Information” table is displayed when there are CLASS variables in the model. The table lists the categories of every CLASS variable that is used in the model and the corresponding design variable values. The ODS name of the “Class Level Information” table is “ClassLevelInfo.”

Design Summary Table

The “Design Summary” table provides information about the sample design. The table displays the total number of strata that are read and used, and the total number of clusters read and used. The table is displayed only if you specify a STRATA or CLUSTER statement. The ODS name of the “Design Summary” table is “DesignSummary.”

Stratum Information Table

If you specify the LIST option in the STRATA statement, PROC SURVEYPHREG displays a “Stratum Information” table. The ODS name of the “Stratum Information Table” is “StrataInfo.” This table provides the following information for each stratum:

- Stratum Index, which is a sequential stratum identification number
- STRATA variables, which list the levels of STRATA variables for the stratum
- Number of Observations, which is the number of observations used in the stratum
- Population Total for the stratum, if you specify the TOTAL= option
- Sampling Rate for the stratum, if you specify the TOTAL= or RATE= option. If you specify the TOTAL= option, the sampling rate is based on the number of valid observations in the stratum.
- Number of Clusters, which is the number of clusters in the stratum, if you specify a CLUSTER statement

Convergence Status

The “Convergence Status” table displays the convergence status of the optimization routine. The procedure displays this table only when you specify the `NLOPTIONS` statement. The ODS name of the “Convergence Status” table is “ConvergenceStatus.”

Model Fit Statistics

The “Model Fit Statistics” table displays the values of $-2 \log$ likelihood and the AIC for the null model and the fitted model. The ODS name of the “Model Fit Statistics” table is “FitStatistics.”

Testing Global Null Hypothesis: BETA=0

The “Testing Global Null Hypothesis: BETA=0” table displays results of the likelihood ratio test and the Wald test for testing the hypothesis that all parameters are zero. The ODS name of the “Testing Global Null Hypothesis: BETA=0” table is “GlobalTests.”

Analysis of Maximum Likelihood Estimates

The “Analysis of Maximum Likelihood Estimates” table displays the denominator degrees of freedom, which is computed as described in the section “[Degrees of Freedom](#)” on page 7901; the maximum likelihood estimate of the parameter; the estimated standard error, computed as the square root of the corresponding diagonal element of the estimated covariance matrix; the t statistic, computed as the parameter estimate divided by the standard error; the p -value of the t statistic with respect to a t distribution with denominator degrees of freedom; and the hazard ratio estimate. The t confidence limits for the parameter estimates and estimated hazard ratios are displayed if you specify the `CLPARM` or `RISKLIMITS` option in the `MODEL` statement. You can specify the `DF=NONE` option in the `MODEL` statement to request p -values and confidence intervals from a standard normal distribution. If you specify the `VARRATIO=ALL | MODEL | IND` option in the `MODEL` statement, then the variance ratios for model or independence (or both) are displayed. If you specify the `SERATIO=ALL | MODEL | IND` option in the `MODEL` statement, then the standard error ratios for model or independence (or both) are displayed.

The ODS name of the “Analysis of Maximum Likelihood Estimates” table is “ParameterEstimates.”

Covariance Matrix

The “Covariance Matrix” table is displayed if you specify the `COVB` option in the `MODEL` statement. The table contains the estimated covariance matrix for the parameter estimates. The ODS name of the “Covariance Matrix” table is “CovB.”

Hessian Matrix

The “Hessian Matrix” table is displayed if you specify the `HESS` option in the `MODEL` statement. The table contains the Hessian matrix that is evaluated at the estimated regression parameters. The ODS name of the “Hessian Matrix” table is “Hessian.”

Inverse Hessian Matrix

The “Inverse Hessian Matrix” table is displayed if you specify the `INVHESS` option in the `MODEL` statement. The table contains the inverse of the Hessian matrix evaluated at the estimated regression parameters. The ODS name of the “Inverse Hessian Matrix” table is “InvHessian.”

Variance Estimation Table

The “Variance Estimation” table provides the following information:

- Method, which is the variance estimation method—Taylor Series, Balanced Repeated Replication, or Jackknife
- Replicate Weights input data set name, if you provide replicate weights with a **REPWEIGHTS** statement
- Number of Replicates, for **VARMETHOD=BRR** or **VARMETHOD=JACKKNIFE**
- Hadamard Data Set name, if you specify the **HADAMARD=** *method-option* for **VARMETHOD=BRR**
- Fay Coefficient, if you specify the **FAY** *method-option* for **VARMETHOD=BRR**
- Missing Values Included (MISSING), if you specify the **MISSING** option
- Missing Values Included (NOMCAR), if you specify the **NOMCAR** option
- Missing Values Excluded, if you have missing values and you do not specify the **NOMCAR** option

Hadamard Matrix

If you specify the **PRINTH** *method-option* for **VARMETHOD=BRR**, PROC SURVEYPHREG displays the Hadamard matrix that is used to construct replicates for BRR variance estimation. If you provide a Hadamard matrix with the **HADAMARD=** *method-option* for **VARMETHOD=BRR** but the procedure does not use the entire matrix, the procedure displays only the rows and columns that are actually used to construct replicates. The ODS name of the “Hadamard Matrix” table is “HadamardMatrix.”

ODS Table Names

PROC SURVEYPHREG assigns a name to each table it creates. You can use this name to refer to the table when using the Output Delivery System (ODS) to select tables and create output data sets. For more information about ODS, see Chapter 20, “Using the Output Delivery System.” Table 93.8 lists the table names, along with the corresponding analysis options.

Table 93.8 ODS Tables Produced by PROC SURVEYPHREG

ODS Table Name	Description	Statement / Option
CensoredSummary	Summary of event and censored observations	Default
ClassLevelInfo	CLASS variable levels	CLASS
ConvergenceStatus	Convergence status	NLOPTIONS / PALL
CovB	Covariance of parameter estimates	MODEL / COVB
DesignSummary	Design summary	STRATA or CLUSTER
FitStatistics	Model fit statistics	Default
GlobalTests	Tests of the global null hypothesis	Default

Table 93.8 *continued*

ODS Table Name	Description	Statement / Option
Hadamard	Hadamard matrix	VARMETHOD=BRR(PRINTH)
Hessian	Observed Hessian matrix	MODEL / HESSIAN
InvHessian	Inverse of the observed Hessian matrix	MODEL / INVHESS
IterHist	Iteration history	NLOPTIONS / PHISTORY
ModelInfo	Model information	Default
NObs	Number of observations	Default
ParameterEstimates	Maximum likelihood Estimates of model parameters	Default
ParameterEstimatesStart	Initial parameter values for optimization	NLOPTIONS / PALL
StrataInfo	Stratum information	STRATA / LIST
VarianceEstimation	Variance estimation	Default
WeightedCensoredSummary	Summary of weighted number of event and censored observations	WEIGHT

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

When ODS Graphics is enabled, the [ESTIMATE](#), [LSMEANS](#), [LSMESTIMATE](#), and [SLICE](#) statements can produce plots that are associated with their analyses. For information about these plots, see the corresponding sections of Chapter 19, “[Shared Concepts and Topics](#).”

Examples: SURVEYPHREG Procedure

Example 93.1: Analysis of Clustered Data

When experimental units are naturally or artificially clustered, failure times of experimental units within a cluster are correlated. Lee, Wei, and Amato (1992) estimate the regression parameters in the Cox model by maximizing a partial likelihood function under an independent working correlation assumption and estimate

the variance of the estimated regression coefficients by using a robust sandwich variance estimator that accounts for the intracluster dependence.

The Diabetic Retinopathy Study (DRS) is a randomized, controlled clinical trial of more than 1,700 patients across 15 medical centers. One objective of this study was to determine if photocoagulation treatment delays the occurrence of blindness. One eye of each patient was randomly assigned to treatment and the other eye to control. See [Example 67.11](#) in Chapter 67, “The PHREG Procedure,” for more information about the data set and a similar analysis; see <http://www.nei.nih.gov/neitrials/static/study62.asp> for more information about the DRS.

Each patient is a cluster that contributes two observations to the input data set, one for each eye. The following variables are available:

- ID, patient’s identification
- Time, failure time
- Status, event indicator (0=censored, and 1=uncensored)
- Treatment, treatment received (1=laser photocoagulation, and 0=otherwise)
- DiabeticType, type of diabetes (0=juvenile onset with age of onset at 20 or under, and 1= adult onset with age of onset over 20)

The following DATA step creates the data set Blind, which represents 197 diabetic patients from the DRS:

```
data Blind;
  input ID Time Status DiabeticType Treatment @@;
  datalines;
  5 46.23 0 1 1      5 46.23 0 1 0      14 42.50 0 0 1      14 31.30 1 0 0

```

The following SAS statements request a proportional hazards regression of Time on Treatment, DiabeticType, and the Treatment \times DiabeticType interaction, with Status as the censoring indicator. The CLUSTER statement indicates the observations that came from the same patient.

```
proc surveyphreg data=Blind;
  model Time*Status(0) = Treatment DiabeticType Treatment*DiabeticType;
  cluster id;
run;
```

Output 93.1.1 displays some summary information. There are 394 observations and 197 patients (clusters). Almost 61% of the observations are censored. The p -values for the null model are less than 0.0001 for both the likelihood ratio test and the Wald test (Output 93.1.2), which indicates that the survival time is highly dependent on Treatment and DiabeticType. In this example, the likelihood ratio statistic has a chi-square distribution with 3 degrees of freedom and the Wald statistics has the F distribution with the numerator degrees of freedom 3 and the denominator degrees of freedom 196. The denominator degrees of freedom are calculated as the number of clusters (197) minus one.

Output 93.1.1 Summary Information

The SURVEYPHREG Procedure			
Number of Observations Read		394	
Number of Observations Used		394	
Design Summary			
Number of Clusters		197	
Summary of the Number of Event and Censored Values			
Total	Event	Censored	Percent Censored
394	155	239	60.66
Variance Estimation			
Method	Taylor Series		

Output 93.1.2 Global Test Results

Testing Global Null Hypothesis: BETA=0				
Test	Test Statistic	Num DF	Den DF	p-Value
Likelihood Ratio	28.4556	3	Infty	<.0001
Wald	11.3872	3	196	<.0001

Output 93.1.3 displays parameter estimates, standard errors, t statistics, denominator degrees of freedom, p -values, and hazard ratios. In this example data set, Treatment and Treatment \times DiabeticType interaction

are significant with p -values 0.023 and 0.006, respectively. Since the model contains $\text{Treatment} \times \text{DiabeticType}$ interaction, the exponential of the estimated regression coefficient is not the hazard ratio. Use the ESTIMATE statement to calculate the hazard ratios.

Output 93.1.3 Parameter Estimates

Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Pr > t
Treatment	196	-0.424672	0.185912	-2.28	0.0234
DiabeticType	196	0.340841	0.196577	1.73	0.0845
Treatment*DiabeticTy	196	-0.845665	0.305081	-2.77	0.0061
Analysis of Maximum Likelihood Estimates					
Parameter	Hazard Ratio				
Treatment	0.654				
DiabeticType	1.406				
Treatment*DiabeticTy	0.429				

Example 93.2: Stratification, Clustering, and Unequal Weights

This example uses a data set from the National Health and Nutrition Examination Survey I (NHANES I) Epidemiologic Followup Study (NHEFS). The NHEFS is a national longitudinal survey that is conducted by the National Center for Health Statistics, the National Institute on Aging, and some other agencies of the Public Health Service in the United States. Some important objectives of this survey are to determine the relationships between clinical, nutritional, and behavioral factors; to determine mortality and hospital utilizations; and to monitor changes in risk factors for the initial cohort that represents the NHANES I population. A cohort of size 14,407, which includes all persons 25 to 74 years old who completed a medical examination at NHANES I in 1971–1975, was selected for the NHEFS. Personal interviews were conducted for every selected unit during the first wave of data collection from the year 1982 to 1984. Follow-up studies were conducted in 1986, 1987, and 1992. In the year 1986, only nondeceased persons 55 to 74 years old (as reported in the base year survey) were interviewed. The 1987 and 1992 NHEFS contain the entire nondeceased NHEFS cohort. Vital and tracing status data, interview data, health care facility stay data, and mortality data for all four waves are available for public use. See <http://www.cdc.gov/nchs/nhanes/nhefs/nhefs.htm> for more information about the survey and the data sets.

For illustration purposes, 1,018 observations from the 1987 NHEFS public use interview data are used to create the data set cancer. The observations are obtained from 10 strata that contain 596 PSUs. The sum of observation weights for these selected units is over 19 million. Observation weights range from 359 to 129,359 with a mean of 18,747.69 and a median of 11,414. Several observation weights have large values; therefore it is reasonable to rescale the observation weights to facilitate the optimization routine. Different scaling techniques are proposed in the literature. For example, Binder (1992) uses scaled weights such that the sum of weights over the sampled units is one. Without loss of generality, the analysis weights in this example are obtained by dividing each observation weight by a large number (130,000). Because of this rescaling, you must be careful interpreting some results from PROC SURVEYPHREG.

The following variables are used in this example:

- ObsNo, unit identification
- Strata, stratum identification
- PSU, identification for primary sampling units
- ObservationWt, sampling weight associated with each unit
- AnalysisWt, obtained from the sampling weights by dividing each ObservationWt by 130,000
- Smoke, smoking status (−1 = not applicable, 1 = never smoked, 2 = current or former smoker in 1982–1984 follow-up, and 3 = current or former smoker in 1987 follow-up)
- Age, the event-time variable, defined as follows:
 - age of the subject when the first cancer was reported for subjects with reported cancer
 - age of the subject at death for deceased subjects without reported cancer
 - age of the subject as reported in 1987 follow-up (this value is used for nondeceased subjects who never reported cancer)
 - age of the subject for the entry year 1971–1975 survey if the subject has cancer (or is deceased) but the date of incident is not reported
- Cancer, cancer indicator (1 = cancer reported, 0 = cancer not reported)
- BodyWeight, body weight of the subject as reported in the 1987 follow-up, or an imputed body weight based on the subject's age in the entry year 1971–1975 survey

The following SAS statements create the data set cancer. Note that BodyWeight for a few observations (8%) is imputed based on Age by using a deterministic regression imputation model (Särndal and Lundström (2005, chapter 12)). The imputed values are treated as observed values in this example. In other words, this example treats the data set Cancer as the observed data set.

;
```

Suppose you want to study the occurrence of cancer for the base year survey population and its relation to smoking status and body weight. The following statements request a proportional hazards regression of Age on BodyWeight and Smoke with Cancer as the censor indicator. The STRATA, CLUSTER, and WEIGHT statements identify the variance strata, PSUs, and analysis weights respectively. The CLASS statement specifies that Smoke is a categorical variable, and the MODEL statement provides information about the analysis model. The TIES= option in the MODEL statement requests the Efron likelihood to handle tied events. If you do not specify the TIES= option in the MODEL statement, then the procedure uses the Breslow likelihood. The PHISTORY option in the NLOPTIONS statement is used to display the iteration history table. The ESTIMATE statement computes a contrast between subjects who are reported as current (or former) smokers and the others. The EXP option in the ESTIMATE statement requests that the linear contrast be estimated in the exponential scale, which is the hazard ratio. The TEST statement requests the Type 3 test for each effect that is specified in the MODEL statement.

```
proc surveyphreg data = cancer;
    strata strata;
    cluster psu;
    weight analysiswt;
    class smoke;
    model age*cancer(0) = bodyweight smoke / ties = efron;
    nloptions phistory;
    estimate smoke 0.5 0.5 -0.5 -0.5 / exp;
    test ;
run;
```

Some summary statistics are shown in [Output 93.2.1](#). The “Model Information” table contains information about the model such as the names for the dependent and censoring variables, and the likelihood. The “Number of Observations” table displays the number of observations and the sum of weights. A total of 1,018 observations are read from the Cancer data set, but one observation is not used in the analysis because it has a zero sampling weight. The sum of weights is 146.81, which gives an estimated population size of 19,085,105 ($= 146.8085 \times 130,000$). Note that the estimated population size would be 19,085,151 if you use the sampling weights (ObservationWt) instead of the analysis weights (AnalysisWt). The difference is due to the rounding errors in AnalysisWt. For simplicity, analysis weights are rounded at the fifth decimal place. The “Design Summary” table shows that there are 596 PSUs and 10 strata. From the censored summary tables, 11.7% subjects in the sample have reported cancer and an estimated 11.6% subjects in the study population have cancer. The “Variance Estimation” table shows that the Taylor series linearization variance estimation method is used and the observation units with missing values are excluded from the analysis. Note that the only missing unit in this data set has a zero sampling weight and hence it is not included in the analysis.

Output 93.2.1 Model Information, Data Summary, Design Summary, and Information about Variance Estimation

The SURVEYPHREG Procedure

The “Iteration History” table in [Output 93.2.2](#) shows that the procedure converged after four iterations. The “Objective Function” column contains the value of the likelihood after every iteration. The “Objective Function Change” column measures the change in the objective function between iterations; however, this is not the monitored convergence criterion. The SURVEYPHREG procedure monitors several features simultaneously to determine whether to stop an optimization.

Output 93.2.2 Iteration History

Maximum Likelihood Iteration History								
Iter	Rest arts	Func Calls	Act Con	Objective Function	Obj Fun Change	Max Abs Gradient Element	Ridge	Actual Over Pred Change
1	0	4	0	-63.34004	1.6501	21.9620	0	0.916

3	0	8	0	-63.29776	0.000430	0.00293	0	1.012
4	0	10	0	-63.29776	1.528E-7	1.102E-6	0	1.000

Estimates for proportional hazards regression coefficients and their standard errors are shown in [Output 93.2.3](#). The categorical variable Smoke has four levels, and GLM parameterization is used by PROC SURVEYPHREG. You can use the PARAM= option in the CLASS statement to specify other types of parameterizations. The estimated regression coefficient for BodyWeight is 0.012 with a standard error of 0.003. The degrees of freedom for the *t* test are equal to the number of PSUs (596) minus the number of strata (10). The “Estimates” table displays the estimated contrast and the corresponding hypothesis test. The estimated value for the contrast is -0.75. The estimated hazard for the nonsmokers is 0.47 times the estimated hazard for the current or former smokers. In this example data set, the contrast of interest is not significant at 0.05 levels. The “Type III Tests of Model Effects” table displays the Type 3 analysis. The effect variable Smoke has four levels. The F Value for Smoke is 1.49 with three numerator degrees of freedom and 586 denominator degrees of freedom.

Output 93.2.3 Parameter Estimates

Example 93.3: Domain Analysis

This example uses a data set from the NHANES I Epidemiologic Followup Study (NHEFS); see [Example 93.2](#) for more information about the NHEFS.

For illustration purposes, 1,891 observations from the 1992 NHEFS vital and tracing status data set are used to estimate the regression coefficients of a proportional hazards model. The observations are obtained from 22 strata; each stratum contains either two or three primary sampling units. The sum of observation weights for these selected units is almost 103 million. Observation weights range from 1,498 to 470,154 with a mean of 54,457.11 and a median of 45,246. The following variables are used in this example. Although this example uses the observation weights directly, Binder (1992) suggests that a scaled version of the observation weights would be useful to improve the performance of the optimization routine.

The following variables are created in the data set mortality:

- ID, unit identification
- VARSTRATA, stratum identification
- VARPSU, identification for primary sampling units
- SWEIGHT, sampling weight associated with each unit
- AGE, the subject's reported age at the 1992 interview if the subject was alive at that time; otherwise, the subject's age at death
- VITALSTATUS, vital status of subject in 1992 (1 = alive, 3 = dead, 4 = unknown, 5 = traced alive with direct subject contact, 6 = traced alive without direct subject contact)
- POVARIND, indicator for poverty area where subject's household was located at NHANES I (1971–1975) exam, (1 = poverty area, 2 = non-poverty area)
- GENDER, (1 = male, 2 = female)

```
data mortality;
  input ID VARSTRATA VARPSU SWEIGHT AGE VITALSTATUS POVARIND GENDER;
  datalines;
    1 03 1 13312 66 1 1 1
    2 03 1 7941 71 3 1 2
    3 03 1 16048 . 4 1 1
    4 03 3 9298 58 3 1 1
    5 03 2 15336 56 3 1 2
    6 03 1 14744 63 1 1 1
```

```

      7  03  2  83729      70  1  2  2
      8  03  3 106492      57  1  2  1
      9  03  3  78083      81  3  2  2
     10  03  3  55957      79  3  2  1

... more lines ...

    1890  13  1  88939  59  1  2  1
    1891  13  1  59218  75  1  2  2
;

```

Suppose you want to estimate the hazard function for mortality time after adjusting for the poverty area indicator in the base year survey population. The following SAS statements request a proportional hazards regression of age (AGE) on poverty indicator (POVARIND):

```

proc surveyphreg data = mortality nomcar;
  class povarind;
  strata varstrata;
  cluster varpsu;
  weight sweight;
  model age*vitalstatus(1 4 5 6) = povarind;
  domain gender;
run;

```

Subjects with VITALSTATUS 1, 4, 5, or 6 are considered alive. The CLASS statement specifies that POVARIND is a categorical variable, the WEIGHT statement identifies the sampling weights, the STRATA statement identifies variance strata, and the CLUSTER statement identifies variance PSUs. The DOMAIN statement requests three separate analyses: for the overall data set, the male subpopulation, and the female subpopulation respectively. There are 223 observation units with missing values on age. All the units with missing age have vital status 1, 4, 5, or 6. Therefore, these subjects are considered to be alive in the current survey year 1992. Age for every observation unit in the base year survey was known from 1971–1975 NHANES I. One reasonable approach is to determine the age of these 223 units based on their age from the NHANES I data set. However, for illustration purposes, this example does not include the observation units with missing age when estimating the regression coefficients. Instead, an analysis of just the set of respondents is requested by specifying the NOMCAR option in the PROC SURVEYPHREG statement. This option uses a variance estimator that accounts for the random size of the set of respondents.

Output 93.3.1 shows summary statistics for the overall analysis. A total of 1,891 observations are read from the input DATA= data set, but only 1,668 observations are used in the analysis. The remaining 223 observations have missing values in the variable age. The respondent data set represents almost 89.5 million units in the population. There are 22 strata and 55 clusters. Although only 57% observation units in the sample are alive, an estimated 69% observation units in the population are alive. This difference is reasonable because selection probabilities for observation units are not the same. If you do not use the sampling weights, then your sample-based estimators might be biased for the corresponding finite population quantities. The “Variance Estimation” table indicates that the NOMCAR option is used for variance estimation.

Output 93.3.1 Summary Statistics for the Entire Population

The SURVEYPHREG Procedure			
Number of Observations Read	1891		
Number of Observations Used	1668		
Sum of Weights Read	1.0298E8

Missing Values	NOMCAR		

Output 93.3.2 displays the estimated regression coefficients and their standard errors. Poverty index has two levels, and only one level is estimable. By default, PROC SURVEYPHREG estimates the first level (POVARIND 1) and assigns a zero value for the second level. The estimated regression coefficient is 0.385 with a standard error of 0.078. The estimated hazard for the poverty areas is 1.47 times higher than the estimated hazard for the non-poverty areas. The degrees of freedom are equal to the number of PSUs (55) minus the number of strata (22).

Output 93.3.2 Inference for the Entire Population

Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Pr > t	Hazard Ratio
POVARIND 1	33	0.384961	0.077586	4.96	<.0001	1.470
POVARIND 2	33	0	.	.	.	1.000

Output 93.3.3 shows that 813 observation units in the sample are male, and they account for over 42.6 million males in the base year survey population. Approximately half of these observation units in the sample are censored, and an estimated 64.5% observation units are censored for the male subpopulation.

Output 93.3.3 Summary Statistics for the Male Subpopulation

The SURVEYPHREG Procedure			
Domain Analysis for domain GENDER=1			
Number of Observations Read			1891
Number of Observations Used			813
Sum of Weights Read			48887067
Sum of Weights Used			42629905
Summary of the Number of Event and Censored Values			
Total	Event	Censored	Percent Censored
813	404	409	50.31

Output 93.3.6 shows that the estimated proportional hazards regression coefficients for POVARIND for the females subpopulation (0.435) is higher than the estimated proportional hazards regression coefficients for POVARIND for the males subpopulation. The estimated hazard for the females in the poverty areas is 1.54 times higher than the estimated hazard for the females in the non-poverty areas. The degrees of freedom for the t significant test for the female subpopulation are equal to the total number of PSUs (55) minus the total number of strata (22).

Output 93.3.6 Inference for the Female Subpopulation

Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Pr > t	Hazard Ratio
POVARIND 1	33	0.434579	0.115766	3.75	0.0007	1.544
POVARIND 2	33	0	.	.	.	1.000

Example 93.4: Variance Estimation by Using Replicate Weights

Consider the data set LibrarySurvey from “Getting Started: SURVEYPHREG Procedure” on page 7857. The selected sample contains 100 transactions from ten branch libraries. A set of replicate weights and jackknife coefficients are created by randomly assigning observation units in disjoint groups of nearly equal size within each stratum. A total of 46 different groups are created. The data set LibraryRepWeights is

similar to the data set `LibrarySurvey` except that it also contains replicate weights `repwt_1` to `repwt_46`. Each column of replicate weights is obtained by deleting one group of observations and adjusting the sampling weights for the other groups in that stratum (Rust 1985).

The data set `LibraryJKCOEF` contains the jackknife coefficient for every replicate sample. The variable `replicate` denotes the replicate number, `donorstratum` denotes the stratum identification for that replicate, and `jkcoefficient` denotes the jackknife coefficient for that replicate sample.

```
data LibrarySurvey;
    set LibrarySurvey;
    randomorder = ranuni(12345);
run;
proc sort data = LibrarySurvey out = LibrarySurvey;
    by Branch randomorder;
run;
data LibrarySurvey;
    set LibrarySurvey;
    array nGroup{10} (2 2 2 4 4 4 4 8 8 8);
    GroupPSU = mod(_N_, nGroup{Branch});
    drop randomorder nGroup1 nGroup2 nGroup3 nGroup4
        nGroup5 nGroup6 nGroup7 nGroup8 nGroup9 nGroup10;
run;

proc surveymeans data = LibrarySurvey varmethod = jk
    (outweights = LibraryRepWeights outjkcoefs = LibraryJKCOEF);
    weight SamplingWeight;
    strata Branch;
    cluster GroupPSU;
    var Age;
run;
```

It is not necessary to provide replicate weights to compute jackknife variance estimates using the SURVEYPHREG procedure. If you do not specify the replicate weights, then the procedure creates replicate weights for you. For this illustration, assume that `LibraryRepWeights` and `LibraryJKCOEF` are the only two data sets available for analysis.

The following SAS statements request a proportional hazards regression of `lenBorrow` on `Age`. The variable `Returned` is the censor indicator, and the value 0 indicates a censored observation. The `WEIGHT` statement specifies the sampling weight variable, and the `REPWEIGHTS` statement specifies replicate weight variables `RepWt_1` to `RepWt_46`. The `JKCOEFS=` option in the `REPWEIGHTS` statement specifies the jackknife coefficient for each replicate sample. The `VARMETHOD=` option in the `MODEL` statement requests the jackknife variance estimation method. A `STRATA` statement is not required when the `REPWEIGHTS` statement is specified.

```
proc surveypHreg data = LibraryRepWeights varmethod = jk;
    weight SamplingWeight;
    repweights RepWt_: / jkcoefs = LibraryJKCOEF;
    model lenBorrow*Returned(0) = Age;
run;
```

[Output 93.4.1](#) displays some summary information. The “Number of Observations,” “Censored Summary,” and “Weighted Censored Summary” tables are exactly the same as in the example discussed in [“Getting Started: SURVEYPHREG Procedure”](#) on page 7857. The “Variance Estimation” table displays information about the variance estimation, such as the name of the variance estimation method and the number of replicate samples.

Output 93.4.1 Summary Statistics for Overall Analysis

The SURVEYPHREG Procedure			
Number of Observations Read			100
Number of Observations Used			100
Sum of Weights Read			11616.79
Sum of Weights Used			11616.79
Summary of the Number of Event and Censored Values			
Total	Event	Censored	Percent Censored
100	90	10	10.00
Summary of the Weighted Number of Event and Censored Values			
Total	Event	Censored	Percent Censored
11616.79	10449.22	1167.57	10.05
Variance Estimation			
Method			Jackknife
Replicate Weights		WORK.LIBRARYREPWEIGHTS	
Number of Replicates			46

Output 93.4.2 shows that the estimated regression coefficient is 0.0616 with a standard error of 0.009. The denominator degrees of freedom (46) for the t test is equal to the number of replicates used. Note that the estimated proportional hazards regression coefficient is the same as the estimated proportional hazards regression coefficient in the example in “Getting Started: SURVEYPHREG Procedure” on page 7857, but the standard error and the denominator degrees of freedom are different. This is not surprising because these two examples use the same estimator to estimate the regression coefficients but different estimators to estimate the variance.

Output 93.4.2 Inferences Based on Survey Design for Overall Analysis

Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Pr > t	Hazard Ratio
Age	46	0.061593	0.009159	6.73	<.0001	1.064

Example 93.5: A Test of the Proportional Hazards Assumption by Using the Programming Statements

You can use programming statements in PROC SURVEYPHREG to create time-dependent covariates to test the proportional hazards assumption for complex survey data. Consider the data set mortality from [Example 93.3](#). The data set contains 1,891 observations from the 1992 NHANES I Epidemiologic Followup study (NHEFS) vital and tracing status.

Suppose you want to fit a proportional hazards model to this data and construct a test for the proportional hazards assumption on gender. The following statements request a proportional hazards regression of age on gender and x, where the time-dependent covariate x is created using the programming statements. The explanatory variable x assumes the value of the time variable age for the male subgroup. The variable vitalstatus is the censor indicator, and a value of 1, 4, 5, or 6 indicates a censored observation. The WEIGHT statement specifies the sampling weight, and the CLASS statement specifies that gender is a classification variable.

```
proc surveyphreg data = mortality nomcar;
  class gender;
  strata varstrata;
  cluster varpsu;
  weight sweight;
  model age*vitalstatus(1 4 5 6) = gender x;
  x = age*(gender=1);
run;
```

[Output 93.5.1](#) displays some summary information. The “Number of Observations,” “Censored Summary,” and “Weighted Censored Summary” tables are exactly the same as in the example discussed in [“Example 93.3: Domain Analysis”](#) on page 7921.

Output 93.5.1 Data Summary, Censored Summary, and Information about Variance Estimation

The SURVEYPHREG Procedure			
Number of Observations Read			1891
Number of Observations Used			1891
Sum of Weights Read			1.0298E8
Sum of Weights Used			1.0298E8
Summary of the Number of Event and Censored Values			
Total	Event	Censored	Percent Censored
1891	717	1174	62.08
Summary of the Weighted Number of Event and Censored Values			
Total	Event	Censored	Percent Censored
1.0298E8	27650348	75328323	73.15

Output 93.5.1 *continued*

Variance Estimation		
Method	Taylor Series	
Missing Values	NOMCAR	

Output 93.5.2 displays the estimated regression coefficients and their standard errors. The variable **gender** has two levels, and only one level is estimable. By default, PROC SURVEYPHREG estimates the first level (GENDER 1) and assigns a zero value for the second level. The estimated regression coefficient is 1.61 with a standard error of 0.71. The estimated regression coefficient for **x** is -0.02 with a standard error of 0.01. The t statistic for **x** is -1.55 with a p -value of 0.13 on 33 degrees of freedom. This test suggests that an interaction between the time variable **age** and **gender** is not significant. Therefore, there is little evidence of an exponential trend over time in the hazard ratio for **gender**.

Output 93.5.2 Parameter Estimates

Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Pr > t	Hazard Ratio
GENDER 1	33	1.605505	0.709269	2.26	0.0303	4.980
GENDER 2	33	0	.	.	.	1.000
x	33	-0.015648	0.010082	-1.55	0.1302	0.984

Overview: SURVEYREG Procedure

The SURVEYREG procedure performs regression analysis for sample survey data. This procedure can handle complex survey sample designs, including designs with stratification, clustering, and unequal weighting. The procedure fits linear models for survey data and computes regression coefficients and their variance-covariance matrix. The procedure also provides significance tests for the model effects and for any specified estimable linear functions of the model parameters. Using the regression model, the procedure can compute predicted values for the sample survey data.

PROC SURVEYREG uses elementwise regression to compute the regression coefficient estimators by generalized least squares estimation. The procedure assumes that the regression coefficients are the same across strata and primary sampling units (PSUs). To estimate the variance-covariance matrix for the regression coefficients, PROC SURVEYREG uses either the Taylor series (linearization) method or replication (resampling) methods to estimate sampling errors of estimators, based on complex sample designs. For details see Woodruff (1971); Fuller (1975); Särndal, Swensson, and Wretman (1992); Wolter (2007); Rust (1985); Dippo, Fay, and Morganstein (1984); Rao and Shao (1999); Rao, Wu, and Yue (1992); and Rao and Shao (1996).
