BOXWIDTHSCALE=	Specifies that widths of box-and-whiskers plots vary proportionately to group size	✓
CBOXES=	Specifies color for outlines of box-and-whiskers plots	
CBOXFILL=	Specifies fill color for interior of box-and-whiskers plots	

Table 26.6 continued

Option	Description	ODS Graphics
IDCOLOR=	Specifies outlier symbol color in schematic box-and-whiskers plots	
IDTEXT=	Specifies outlier label color in schematic box-and-whiskers plots	
IDFONT=	Specifies outlier label font in schematic box-and-whiskers plots	
IDHEIGHT=	Specifies outlier label height in schematic box-and-whiskers plots	
IDSYMBOL=	Specifies outlier symbol in schematic box-and-whiskers plots	
LBOXES=	Specifies line types for outlines of box-and-whiskers plots	
NOSERIFS	Eliminates serifs from whiskers of box-and-whiskers plots	✓
NOTCHES	Specifies that box-and-whiskers plots be notched	✓
PCTLDEF=	Specifies percentile definition used for box-and-whiskers plots	✓
Options for Plotting and Labeling Points		
ALLLABEL=	Labels means of box-and-whiskers plots	
CLABEL=	Specifies color for labels requested with ALLLABEL= option	
CCONNECT=	Specifies color for line segments requested with BOX-CONNECT= option	
LABELANGLE=	Specifies angle for labels requested with ALLLABEL= option	
SYMBOLLEGEND=	Specifies LEGEND statement for levels of symbol variable	
SYMBOLORDER=	Specifies order in which symbols are assigned for levels of symbol variable	
Reference Line Options		
CHREF=	Specifies color for lines requested by HREF= option	
CVREF=	Specifies color for lines requested by VREF= option	
FRONTREF	Draws reference lines in front of boxes	
HREF=	Requests reference lines perpendicular to horizontal axis	✓
HREFLABELS=	Specifies labels for HREF= lines	✓
HREFLABPOS=	Specifies position of HREFLABELS= labels	
LHREF=	Specifies line type for HREF= lines	
LVREF=	Specifies line type for VREF= lines	
NOBYREF	Specifies that reference line information in a data set be applied uniformly to plots created for all BY groups	✓
VREF=	Requests reference lines perpendicular to vertical axis	✓
VREFLABELS=	Specifies labels for VREF= lines	✓
VREFLABPOS=	Specifies position of VREFLABELS= labels	
Block Variable Legend Options		
BLOCKLABELPOS=	Specifies position of label for block variable legend	
BLOCKLABTYPE=	Specifies text size of block variable legend	
BLOCKPOS=	Specifies vertical position of block variable legend	✓

Table 26.6 continued

Option	Description	ODS Graphics
BLOCKREP	Repeats identical consecutive labels in block variable legend	✓
CBLOCKLAB=	Specifies colors for filling frames enclosing block variable labels	
CBLOCKVAR=	Specifies colors for filling background of block variable legend	
Axis and Axis Label Options		
CAXIS=	Specifies color for axis lines and tick marks	
CFRAME=	Specifies fill color for frame for plot area	
CONTINUOUS	Produces horizontal axis for continuous group variable values (traditional graphics only)	
CTEXT=	Specifies color for tick mark values and axis labels	
HAXIS=	Specifies major tick mark values for horizontal axis	
HEIGHT=	Specifies height of axis label and axis legend text	
HMINOR=	Specifies number of minor tick marks between major tick marks on horizontal axis	
HOFFSET=	Specifies length of offset at both ends of horizontal axis	
NOHLABEL	Suppresses horizontal axis label	✓
NOTICKREP	Specifies that only first occurrence of repeated, adjacent character group values be labeled on horizontal axis	
NOVANGLE	Requests vertical axis labels that are strung out vertically	
SKIPHLABELS=	Specifies thinning factor for tick mark labels on horizontal axis	
TURNHLABELS	Requests horizontal tick labels that are strung out vertically	
VAXIS=	Specifies major tick mark values for vertical axis	✓
VFORMAT=	Specifies format for vertical axis tick marks	✓
VMINOR=	Specifies number of minor tick marks between major tick marks on vertical axis	
VOFFSET=	Specifies length of offset at both ends of vertical axis	
VZERO	Forces origin to be included in vertical axis	
WAXIS=	Specifies width of axis lines	
Input Data Set Options		
MISSBREAK	Specifies that a missing value between identical character group values signify the start of a new group	✓
Output Data Set Options		
OUTBOX=	Produces an output data set containing group summary statistics and outlier values	✓
OUTHISTORY=	Produces an output data set containing group summary statistics	✓
Graphical Enhancement Options		
ANNOTATE=	Specifies annotate data set that adds features to box plot	
BWSLEGEND	Displays a legend identifying the function of group size specified with BOXWIDTHSCALE= option	

Table 26.6 continued

Option	Description	ODS Graphics
DESCRIPTION=	Specifies string that appears in description field of PROC GREPLAY master menu for high-resolution graphics box plot	
FONT=	Specifies font for labels and legends on plots	
HORIZONTAL	Requests a horizontal box plot with ODS Graphics	✓
HTML=	Specifies URLs to be associated with box-and-whiskers plots	
NAME=	Specifies name that appears in name field of PROC GREPLAY master menu for high-resolution graphics box plot	
NLEGEND	Requests legend displaying group sizes	
OUTHIGHHTML=	Specifies URLs to be associated with high outliers on box-and-whiskers plots	
OUTLOWHTML=	Specifies URLs to be associated with low outliers on box-and-whiskers plots	
PAGENUM=	Specifies form of label used in pagination	
PAGENUMPOS=	Specifies position of page number requested with PAGENUM= option	
Grid Options		
CGRID=	Specifies color for grid requested with ENDGRID or GRID option	
ENDGRID	Adds grid after last box-and-whiskers plot	
GRID	Adds grid to box plot	✓
LENDGRID=	Specifies line type for grid requested with ENDGRID option	
LGRID=	Specifies line type for grid requested with GRID option	
WGRID=	Specifies width of grid lines	

Table 26.6 continued

Option	Description	ODS Graphics
Plot Layout Options		
INTERVAL=	Specifies natural time interval between consecutive group positions when time, date, or datetime format is associated with numeric group variable	
INTSTART=	Specifies first major tick mark value on horizontal axis when date, time, or datetime format is associated with numeric group variable	
MAXPANELS=	Specifies maximum number of panels used for box plot	✓
NOCHART	Suppresses creation of box plot	✓
NOFRAME	Suppresses frame for plot area	
NPANELPOS=	Specifies number of group positions per panel	✓
REPEAT	Repeats last group position on panel as first group position of next panel	✓
TOTPANELS=	Specifies number of panels to be used to display box plot	✓
Overlay Options		
CCOVERLAY=	Specifies colors for line segments connecting points on overlays	
COVERLAY=	Specifies colors for points on overlays	
LOVERLAY=	Specifies line types for line segments connecting points on overlays	
NOOVERLAYLEGEND	Suppresses overlay legend	✓
OVERLAY=	Specifies variables to be plotted on overlays	✓
OVERLAYHTML=	Specifies URLs to be associated with overlay plot points	
OVERLAYID=	Specifies labels for overlay plot points	
OVERLAYLEGLAB=	Specifies label for overlay legend	✓
OVERLAYSYM=	Specifies symbols used for overlays	
OVERLAYSYMHT=	Specifies heights for overlay symbols	
WOVERLAY=	Specifies widths for line segments connecting points on overlays	
Clipping Options		
CCLIP=	Specifies color for plot symbol for clipped points	
CLIPFACTOR=	Determines extent to which extreme values are clipped	
CLIPLEGEND=	Specifies text for clipping legend	
CLIPLEGPOS=	Specifies position of clipping legend	
CLIPSUBCHAR=	Specifies substitution character for CLIPLEGEND= text	
CLIPSYMBOL=	Specifies plot symbol for clipped points	
CLIPSYMBOLHT=	Specifies symbol marker height for clipped points	
COVERLAYCLIP=	Specifies color for clipped points on overlays	
OVERLAYCLIPSYM=	Specifies symbol for clipped points on overlays	
OVERLAYCLIPSYMHT=	Specifies symbol height for clipped points on overlays	

Table 26.6 continued

Option	Description	ODS Graphics
Options for Box Plots Produced Using Styles		
BLOCKVAR=	Groups block legends whose backgrounds are filled with colors from style	✓
BOXES=	Groups boxes whose outlines are drawn with colors from style	
BOXFILL=	Groups boxes that are filled with colors from style	

Following are explanations of the options you can specify in the PLOT statement after a slash (/). Only those options marked with † are applicable when ODS Graphics is enabled.

ALLLABEL=VALUE | (variable)

labels the point plotted for the mean of each box-and-whiskers plot with the mean (when ALLLABEL=VALUE) or with the value of the ALLLABEL=variable from the input data set.

ANNOTATE=SAS-data-set

specifies an ANNOTATE= type data set, as described in *SAS/GRAPH: Reference*.

BLOCKLABELPOS=ABOVE | LEFT

specifies the position of a block variable label in the block legend. The keyword ABOVE places the label immediately above the legend, and LEFT places the label to the left of the legend. Use the keyword LEFT with labels that are short enough to fit in the margin of the plot; otherwise, they are truncated. The default keyword is ABOVE.

BLOCKLABTYPE=SCALED | TRUNCATED

BLOCKLABTYPE=height

specifies how lengthy block variable values are treated when there is insufficient space to display them in the block legend. If you specify BLOCKLABTYPE=SCALED, the values are uniformly reduced in height so that they fit. If you specify BLOCKLABTYPE=TRUNCATED, lengthy values are truncated on the right until they fit. You can also specify a text height in vertical percent screen units for the values. By default, lengthy values are not displayed. For more information, see the section “[Displaying Blocks of Data](#)” on page 1016.

† BLOCKPOS=n

specifies the vertical position of the legend for the values of the block variables. Values of *n* and the corresponding positions are as follows. By default, BLOCKPOS=1.

n	Legend Position
1	top of plot, offset from axis frame
2	top of plot, immediately above axis frame
3	bottom of plot, immediately above horizontal axis
4	bottom of plot, below horizontal axis label

† **BLOCKREP**

specifies that block variable values for all groups be displayed. By default, only the first block variable value in any block is displayed, and repeated block variable values are not displayed.

† **BLOCKVAR=***variable* | (*variable-list*)

specifies variables whose values are used to assign colors for filling the background of the legend associated with block variables. A list of BLOCKVAR= variables must be enclosed in parentheses. BLOCKVAR= variables are matched with block variables by their order in the respective variable lists. While the values of a CBLOCKVAR= variable are color names, values of a BLOCKVAR= variable are used to group block legends for assigning fill colors from the ODS style. Block legends with the same BLOCKVAR= variable value are filled with the same color.

† **BOXCONNECT=**MEAN | MEDIAN | MAX | MIN | Q1 | Q3† **BOXCONNECT**

specifies that the points in adjacent box-and-whiskers plots representing group means, medians, maximum values, minimum values, first quartiles, or third quartiles be connected with line segments. If the BOXCONNECT option is specified without a keyword identifying the points to be connected, group means are connected. By default, no points are connected.

BOXES=(*variable*)

specifies a variable whose values are used to assign colors for the outlines of box-and-whiskers plots. While the values of a CBOXES= variable are color names, values of the BOXES= variable are used to group box-and-whiskers plots for assigning outline colors from the ODS style. The outlines of box-and-whiskers plots of groups with the same BOXES= variable value are drawn using the same color.

BOXFILL=(*variable*)

specifies a variable whose values are used to assign fill colors for box-and-whiskers plots. While the values of a CBOXFILL= variable are color names, values of the BOXFILL= variable are used to group box-and-whiskers plots for assigning fill colors from the ODS style. Box-and-whiskers plots of groups with the same BOXFILL= variable value are filled with the same color.

† **BOXSTYLE=***keyword*

specifies the style of the box-and-whiskers plots displayed. If you specify BOXSTYLE=SKELETAL, the whiskers are drawn from the edges of the box to the extreme values of the group. This plot is sometimes referred to as a skeletal box-and-whiskers plot. By default, the whiskers are drawn with serifs. You can specify the NOSERIFS option to draw the whiskers without serifs.

In the following descriptions, the terms *fence* and *far fence* refer to the distance from the first and third quartiles (25th and 75th percentiles, respectively), expressed in terms of the interquartile range (IQR). For example, the lower fence is located at $1.5 \times \text{IQR}$ below the 25th percentile; the upper fence is located at $1.5 \times \text{IQR}$ above the 75th percentile. Similarly, the lower far fence is located at $3 \times \text{IQR}$ below the 25th percentile; the upper far fence is located at $3 \times \text{IQR}$ above the 75th percentile.

If you specify BOXSTYLE=SCHEMATIC, a whisker is drawn from the upper edge of the box to the largest observed value within the upper fence, and another is drawn from the lower edge of the box to the smallest observed value within the lower fence. Serifs are added to the whiskers by default. Observations outside the fences are identified with a special symbol. For traditional graphics you can specify the shape and color for this symbol with the IDSYMBOL= and IDCOLOR= options. The default symbol is a square. This type of plot corresponds to the schematic box-and-whiskers plot

described in Chapter 2 of Tukey (1977). See Figure 26.8 and the discussion in the section “Styles of Box Plots” on page 1007 for more information.

If you specify `BOXSTYLE=SCHEMATICID`, a schematic box-and-whiskers plot is displayed in which an ID variable value is used to label the symbol marking each observation outside the upper and lower fences. A `BOX=` data set can contain a variable named `_ID_` that is used as the ID variable. Otherwise, the first variable listed in the ID statement provides the labels.

If you specify `BOXSTYLE=SCHEMATICIDFAR`, a schematic box-and-whiskers plot is displayed in which the value of the ID variable is used to label the symbol marking each observation outside the lower and upper far fences. Observations between the fences and the far fences are identified with a symbol but are not labeled with the ID variable.

Figure 26.6 illustrates the elements of a skeletal box-and-whiskers plot.

Figure 26.6 Skeletal Box-and-Whiskers Plot

The skeletal style of the box-and-whiskers plot shown in Figure 26.6 is the default.

BOXWIDTH=value

specifies the width (in horizontal percent screen units) of the box-and-whiskers plots.

† BOXWIDTHSCALE=value

specifies that the box-and-whiskers plot width is to vary proportionately to a particular function of the group size n . The function is determined by the *value*.

If you specify a positive value, the widths are proportional to n^{value} . In particular, if you specify `BOXWIDTHSCALE=1`, the widths are proportional to the group size. If you specify `BOXWIDTHSCALE=0.5`, the widths are proportional to \sqrt{n} , as described by McGill, Tukey, and Larsen (1978). If you specify `BOXWIDTHSCALE=0`, the widths are proportional to $\log(n)$. See Example 26.4 for an illustration of the `BOXWIDTHSCALE=` option.

You can specify the **BWSLEGEND** option to display a legend identifying the function of n used to determine the box-and-whiskers plot widths.

By default, the box widths are constant.

BWSLEGEND

displays a legend identifying the function of group size n specified with the **BOXWIDTHSCALE=** option. No legend is displayed if all group sizes are equal. The **BWSLEGEND** option is not applicable unless you also specify the **BOXWIDTHSCALE=** option.

CAXIS=*color*

CAXES=*color*

CA=*color*

specifies the color for the axes and tick marks. This option overrides any **COLOR=** specifications in an **AXIS** statement.

CBLOCKLAB=*color* | (*color-list*)

specifies fill colors for the frames that enclose the block variable labels in a block legend. By default, these areas are not filled. Colors in the **CBLOCKLAB=** list are matched with block variables in the order in which they appear in the **PLOT** statement.

CBLOCKVAR=*variable* | (*variable-list*)

specifies variables whose values are colors for filling the background of the legend associated with block variables. **CBLOCKVAR=** variables are matched with block variables by their order in the respective variable lists. Each **CBLOCKVAR=** variable must be a character variable of no more than eight characters in the input data set, and its values must be valid SAS/GRAPH color names (see *SAS/GRAPH: Reference* for complete details). A list of **CBLOCKVAR=** variables must be enclosed in parentheses.

The procedure matches the **CBLOCKVAR=** variables with block variables in the order specified. That is, each block legend is filled with the color value of the **CBLOCKVAR=** variable of the first observation in each block. In general, values of the i th **CBLOCKVAR=** variable are used to fill the block of the legend corresponding to the i th block variable.

By default, fill colors are not used for the block variable legend. The **CBLOCKVAR=** option is available only when block variables are used in the **PLOT** statement.

CBOXES=*color* | (*variable*)

specifies the colors for the outlines of the box-and-whiskers plots created with the **PLOT** statement. You can use one of the following approaches:

- You can specify **CBOXES=***color* to provide a single outline color for all the box-and-whiskers plots.
- You can specify **CBOXES=**(*variable*) to provide a distinct outline color for each box-and-whiskers plot as the value of the variable. The variable must be a character variable of up to eight characters in the input data set, and its values must be valid SAS/GRAPH color names (see *SAS/GRAPH: Reference* for complete details). The outline color of the plot displayed for a particular group is the value of the variable in the observations corresponding to this group. Note that if there are multiple observations per group in the input data set, the values of the variable should be identical for all the observations in a given group.

CBOXFILL=*color* | (*variable*)

specifies the interior fill colors for the box-and-whiskers plots. You can use one of the following approaches:

- You can specify **CBOXFILL=***color* to provide a single color for all of the box-and-whiskers plots.
- You can specify **CBOXFILL=**(*variable*) to provide a distinct color for each box-and-whiskers plot as the value of the variable. The variable must be a character variable of up to eight characters in the input data set, and its values must be valid SAS/GRAPH color names (or the value **EMPTY**, which you can use to suppress color filling). See *SAS/GRAPH: Reference* for complete details. The interior color of the box displayed for a particular group is the value of the variable in the observations corresponding to this group. Note that if there are multiple observations per group in the input data set, the values of the variable should be identical for all the observations in a given group.

By default, the interiors are not filled.

CCLIP=*color*

specifies a color for the plotting symbol that is specified with the **CLIPSYMBOL=** option to mark clipped values. The default color is the color specified in the **COLOR=** option in the **SYMBOL1** statement.

CCONNECT=*color*

specifies the color for line segments connecting points on the plot. The default color is the color specified in the **COLOR=** option in the **SYMBOL1** statement. This option is not applicable unless you also specify the **BOXCONNECT=** option.

CCOVERLAY=(*color-list*)

specifies the colors for line segments connecting points on overlay plots. Colors in the **CCOVERLAY=** list are matched with variables in the corresponding positions in the **OVERLAY=** list. By default, points are connected by line segments of the same color as the plotted points. You can specify the value **NONE** to suppress the line segments connecting points of an overlay plot.

CFRAME=*color*

specifies the color for filling the rectangle enclosed by the axes and the frame. By default, this area is not filled. The **CFRAME=** option cannot be used in conjunction with the **NOFRAME** option.

CGRID=*color*

specifies the color for the grid requested by the **ENDGRID** or **GRID** option. By default, the grid is the same color as the axes.

CHREF=*color*

specifies the color for the lines requested by the **HREF=** option.

CLABEL=*color*

specifies the color for labels produced by the **ALLLABEL=** option. The default color is the **CTEXT=** color.

CLIPFACTOR=*factor*

requests clipping of extreme values on the box plot. The *factor* that you specify determines the extent to which these values are clipped, and it must be greater than 1.

For examples of the CLIPFACTOR= option, see [Figure 26.17](#) and [Figure 26.18](#). Related clipping options are CCLIP=, CLIPLEGEND=, CLIPLEGPOS=, CLIPSUBCHAR=, and CLIPSYMBOL=.

CLIPLEGEND=*'label'*

specifies the *label* for the legend that indicates the number of clipped boxes when the CLIPFACTOR= option is used. The *label* must be no more than 16 characters and must be enclosed in quotes. For an example, see [Figure 26.18](#).

CLIPLEGPOS= TOP | BOTTOM

specifies the position for the legend that indicates the number of clipped boxes when the CLIPFACTOR= option is used. The keyword TOP or BOTTOM positions the legend at the top or bottom of the chart, respectively. Do not specify CLIPLEGPOS=TOP together with the BLOCKPOS=1 or BLOCKPOS=2 option. By default, CLIPLEGPOS=BOTTOM.

CLIPSUBCHAR=*'character'*

specifies a substitution character (such as '#') for the label provided with the CLIPLEGEND= option. The substitution character is replaced with the number of boxes that are clipped. For example, suppose that the following statements produce a chart in which three boxes are clipped:

```
proc boxplot data=Pistons;
  plot Diameter*Hour /
    clipfactor   = 1.5
    cliplegend   = 'Boxes clipped=#'
    clipsubchar  = '#' ;
run;
```

Then the clipping legend displayed on the chart will be “Boxes clipped=3”.

CLIPSYMBOL=*symbol*

specifies a plot symbol used to identify clipped points on the chart and in the legend when the CLIPFACTOR= option is used. You should use this option in conjunction with the CLIPFACTOR= option. The default *symbol* is CLIPSYMBOL=SQUARE.

CLIPSYMBOLHT=*value*

specifies the height for the symbol marker used to identify clipped points on the chart when the CLIPFACTOR= option is used. The default is the height specified with the H= option in the SYMBOL statement.

For general information about clipping options, see the section “[Clipping Extreme Values](#)” on page 1018.

CONTINUOUS

specifies that numeric group variable values be treated as continuous values. By default, the values of a numeric group variable are considered discrete values unless the HAXIS= option is specified.

NOTE: The CONTINUOUS option is not supported for ODS Graphics output. For more information, see the discussion in the section “[Continuous Group Variables](#)” on page 1009.

COVERLAY=(color-list)

specifies the colors used to plot overlay variables. Colors in the COVERLAY= list are matched with variables in the corresponding positions in the **OVERLAY=** list.

COVERLAYCLIP=color

specifies the color used to plot clipped values on overlay plots when the **CLIPFACTOR=** option is used.

CTEXT=color

specifies the color for tick mark values and axis labels. The default color is the color specified in the CTEXT= option in the most recent GOPTIONS statement.

CVREF=color

specifies the color for the lines requested by the **VREF=** option.

DESCRIPTION='string'**DES='string'**

specifies a description of a box plot produced with high-resolution graphics. The description appears in the PROC GREPLAY master menu and can be no longer than 256 characters. The default description is the analysis variable name.

ENDGRID

adds a grid to the rightmost portion of the plot, beginning with the first labeled major tick mark position that follows the last box-and-whiskers plot. You can use the **HAXIS=** option to force space to be added to the horizontal axis.

FONT=font

specifies a font for labels and legends. You can also specify fonts for axis labels in an **AXIS** statement. The FONT= font takes precedence over the FTEXT= font specified in the GOPTIONS statement. See *SAS/GRAPH: Reference* for more information about the GOPTIONS statement.

FRONTREF

draws reference lines specified with the **HREF=** and **VREF=** options in front of box-and-whiskers plots. By default, reference lines are drawn behind the box-and-whiskers plots and can be obscured by filled boxes.

† GRID

adds a grid to the box plot. Grid lines are horizontal lines positioned at labeled major tick marks, and they cover the length and height of the plotting area.

HAXIS=value-list**HAXIS=AXISn**

specifies tick mark values for the horizontal (group) axis. If the group variable is numeric, the values must be numeric and equally spaced. If the group variable is character, values must be quoted strings of up to 16 characters. Optionally, you can specify an axis name defined in a previous **AXIS** statement. See *SAS/GRAPH: Reference* for more information about the **AXIS** statement.

If you are producing traditional graphics, specifying the **HAXIS=** option with a numeric group variable causes the group variable values to be treated as continuous values. For more information, see the description of the **CONTINUOUS** option and the discussion in the section “Continuous Group Variables” on page 1009. Numeric values can be given in an explicit or implicit list. If a date, time,

or datetime format is associated with a numeric group variable, SAS datetime literals can be used. Examples of HAXIS= lists follow:

- haxis=0 2 4 6 8 10
- haxis=0 to 10 by 2
- haxis='LT12A' 'LT12B' 'LT12C' 'LT15A' 'LT15B' 'LT15C'
- haxis='20MAY88'D to '20AUG88'D by 7
- haxis='01JAN88'D to '31DEC88'D by 30

If the group variable is numeric, the HAXIS= list must span the group variable values. If the group variable is character, the HAXIS= list must include all of the group variable values. You can add group positions to the box plot by specifying HAXIS= values that are not group variable values.

If you specify a large number of HAXIS= values, some of these can be thinned to avoid collisions between tick mark labels. To avoid thinning, use one of the following methods.

- Shorten values of the group variable by eliminating redundant characters. For example, if your group variable has values LOT1, LOT2, LOT3, and so on, you can use the SUBSTR function in a DATA step to eliminate LOT from each value, and you can modify the horizontal axis label to indicate that the values refer to lots.
- Use the [TURNHLABELS](#) option to turn the labels vertically.
- Use the [NPANELPOS=](#) option to force fewer group positions per panel.

HEIGHT=*value*

specifies the height (in vertical screen percent units) of the text for axis labels and legends. This value takes precedence over the HTEXT= value specified in the GOPTIONS statement. This option is recommended for use with fonts specified with the [FONT=](#) option or with the FTEXT= option in the GOPTIONS statement. See *SAS/GRAPH: Reference* for complete information about the GOPTIONS statement.

HMINOR=*n*

HM=*n*

specifies the number of minor tick marks between major tick marks on the horizontal axis. Minor tick marks are not labeled. The default is HMINOR=0.

HOFFSET=*value*

specifies the length (in percent screen units) of the offset at both ends of the horizontal axis. You can eliminate the offset by specifying HOFFSET=0.

† HORIZONTAL

produces a horizontal box plot, with group variable values on the vertical axis and analysis variable values on the horizontal axis. The HORIZONTAL option is supported only with ODS Graphics.

† HREF=*value-list*

HREF=*SAS-data-set*

draws reference lines perpendicular to the horizontal (group) axis on the box plot. You can use this option in the following ways:

- You can specify the values for the lines with an HREF= list. If the group variable is numeric, the values must be numeric. If the group variable is character, the values must be quoted strings of up to 16 characters. If the group variable is formatted, the values must be given as internal values. Examples of HREF= values follow:

```
href=5
href=5 10 15 20 25 30
href='Shift 1' 'Shift 2' 'Shift 3'
```

- You can specify reference line values as the values of a variable named `_REF_` in an HREF= data set. The type and length of `_REF_` must match those of the group variable specified in the PLOT statement. Optionally, you can provide labels for the lines as values of a variable named `_REFLAB_`, which must be a character variable of up to 16 characters. If you want distinct reference lines to be displayed in plots for different analysis variables specified in the PLOT statement, you must include a character variable named `_VAR_`, whose values are the analysis variable names. If you do not include the variable `_VAR_`, all of the lines are displayed in all of the plots. Each observation in an HREF= data set corresponds to a reference line. If BY variables are used in the input data set, the same BY variable structure must be used in the reference line data set unless you specify the **NOBYREF** option.

Unless the **CONTINUOUS** or **HAXIS=** option is specified, numeric group variable values are treated as discrete values, and only HREF= values matching these discrete values are valid. Other values are ignored.

† **HREFLABELS=***'label1' ... 'labeln'*

† **HREFLABEL=***'label1' ... 'labeln'*

† **HREFLAB=***'label1' ... 'labeln'*

specifies labels for the reference lines requested by the **HREF=** option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

HREFLABPOS=*n*

specifies the vertical position of the **HREFLABELS=** label, as described in the following table. By default, *n*=2.

HREFLABPOS=	Label Position
1	along top of plot area
2	staggered from top to bottom of plot area
3	along bottom of plot area
4	staggered from bottom to top of plot area

HTML=*variable*

specifies uniform resource locators (URLs) as values of the specified character variable (or formatted values of a numeric variable). These URLs are associated with box-and-whiskers plots when graphics output is directed into HTML. The value of the **HTML=** variable should be the same for each observation with a given value of the group variable.

IDCOLOR=*color*

specifies the color of the symbol marker used to identify outliers in schematic box-and-whiskers plots (that is, when you specify the keyword SCHEMATIC, SCHEMATICID, or SCHEMATICIDFAR with the **BOXSTYLE=** option). The default color is the color specified with the **CBOXES=** option.

IDTEXT=*color*

specifies the color for the text used to label outliers when you specify the keyword SCHEMATICID or SCHEMATICIDFAR with the **BOXSTYLE=** option. The default value is the color specified with the **CTEXT=** option.

IDFONT=*font*

specifies the font for the text used to label outliers when you specify the keyword SCHEMATICID or SCHEMATICIDFAR with the **BOXSTYLE=** option. The default font is SIMPLEX.

IDHEIGHT=*value*

specifies the height for the text used to label outliers when you specify the keyword SCHEMATICID or SCHEMATICIDFAR with the **BOXSTYLE=** option. The default value is the height specified with the **HTEXT=** option in the **GOPTIONS** statement. See *SAS/GRAPH: Reference* for complete information about the **GOPTIONS** statement.

IDSYMBOL=*symbol*

specifies the symbol marker used to identify outliers in schematic box plots. The default symbol is SQUARE.

INTERVAL=DAY | DTDAY | HOUR | MINUTE | MONTH | QTR | SECOND

specifies the natural time interval between consecutive group positions when a time, date, or datetime format is associated with a numeric group variable. By default, the **INTERVAL=** option uses the number of group positions per panel (screen or page) that you specify with the **NPANELPOS=** option. The default time interval keywords for various time formats are shown in the following table.

Format	Default Keyword	Format	Default Keyword
DATE	DAY	MONYY	MONTH
DATETIME	DTDAY	TIME	SECOND
DDMMYY	DAY	TOD	SECOND
HHMM	HOUR	WEEKDATE	DAY
HOUR	HOUR	WORDDATE	DAY
MMDDYY	DAY	YYMMDD	DAY
MMSS	MINUTE	YYQ	QTR

You can use the **INTERVAL=** option to modify the effect of the **NPANELPOS=** option, which specifies the number of group positions per panel. The **INTERVAL=** option enables you to match the scale of the horizontal axis to the scale of the group variable without having to associate a different format with the group variable.

For example, suppose that your formatted group values span an overall time interval of 100 days and a **DATETIME** format is associated with the group variable. Since the default interval for the **DATETIME** format is **DTDAY** and since **NPANELPOS=25** by default, the plot is displayed with four panels.

Now, suppose that your data span an overall time interval of 100 hours and a DATETIME format is associated with the group variable. The plot for these data is created in a single panel, but the data occupy only a small fraction of the plot since the scale of the data (hours) does not match that of the horizontal axis (days). If you specify `INTERVAL=HOUR`, the horizontal axis is scaled for 25 hours, matching the scale of the data, and the plot is displayed with four panels.

You should use the `INTERVAL=` option only in conjunction with the `CONTINUOUS` or `HAXIS=` option, which produces a horizontal axis of continuous group variable values. For more information, see the descriptions of the `CONTINUOUS` and `HAXIS=` options, and the discussion in the section “Continuous Group Variables” on page 1009.

INTSTART=*value*

specifies the starting value for a numeric horizontal axis when a date, time, or datetime format is associated with the group variable. If the value specified is greater than the first group variable value, this option has no effect.

LABELANGLE=*angle*

specifies the angle at which labels requested with the `ALLLABEL=` option are drawn. A positive angle rotates the labels counterclockwise; a negative angle rotates them clockwise. By default, labels are oriented horizontally.

LBOXES=*linetype*

LBOXES=*(variable)*

specifies the line types for the outlines of the box-and-whiskers plots. You can use one of the following approaches:

- You can specify `LBOXES=linetype` to provide a single linetype for all of the box-and-whiskers plots.
- You can specify `LBOXES=(variable)` to provide a distinct line type for each box-and-whiskers plot. The variable must be a numeric variable in the input data set, and its values must be valid SAS/GRAPH linetype values (numbers ranging from 1 to 46). The line type for the plot displayed for a particular group is the value of the variable in the observations corresponding to this group. Note that if there are multiple observations per group in the input data set, the values of the variable should be identical for all of the observations in a given group.

The default value is 1, which produces solid lines. See the description of the `SYMBOL` statement in *SAS/GRAPH: Reference* for more information about valid linetypes.

LENDGRID=*linetype*

specifies the line type for the grid requested with the `ENDGRID` option. The default value is 1, which produces a solid line. If you use the `LENDGRID=` option, you do not need to specify the `ENDGRID` option. See the description of the `SYMBOL` statement in *SAS/GRAPH: Reference* for more information about valid linetypes.

LGRID=*linetype*

specifies the line type for the grid requested with the `GRID` option. The default value is 1, which produces a solid line. If you use the `LGRID=` option, you do not need to specify the `GRID` option. See the description of the `SYMBOL` statement in *SAS/GRAPH: Reference* for more information about valid linetypes.

LHREF=*linetype*

LH=*linetype*

specifies the line type for reference lines requested with the **HREF=** option. The default value is 2, which produces a dashed line. See the description of the SYMBOL statement in *SAS/GRAPH: Reference* for more information about valid linetypes.

LOVERLAY=(*linetypes*)

specifies line types for the line segments connecting points on overlay plots. Line types in the LOVERLAY= list are matched with variables in the corresponding positions in the **OVERLAY=** list.

LVREF=*linetype*

LV=*linetype*

specifies the line type for reference lines requested by the **VREF=** option. The default value is 2, which produces a dashed line. See the description of the SYMBOL statement in *SAS/GRAPH: Reference* for more information about valid linetypes.

† **MAXPANELS=***n*

specifies the maximum number of panels used to display a box plot. By default, *n* = 20.

† **MISSBREAK**

determines how groups are formed when observations are read from a **DATA=** data set and a character group variable is provided. When you specify the MISSBREAK option, observations with missing values of the group variable are not processed. Furthermore, the next observation with a nonmissing value of the group variable is treated as the beginning observation of a new group even if this value is identical to the most recent nonmissing group value. In other words, by specifying the option MISSBREAK and by inserting an observation with a missing group variable value into a group of consecutive observations with the same group variable value, you can split the group into two distinct groups of observations.

By default (that is, when you omit the MISSBREAK option), observations with missing values of the group variable are not processed, and all remaining observations with the same consecutive value of the group variable are treated as a single group.

NAME='*string*'

specifies a name for the box plot, not more than eight characters, that appears in the PROC GREPLAY master menu.

NLEGEND

requests a legend displaying group sizes. If the size is the same for each group, that number is displayed. Otherwise, the minimum and maximum group sizes are displayed.

† **NOBYREF**

specifies that the reference line information in an **HREF=** or **VREF=** data set be applied uniformly to box plots created for all the BY groups in the input data set. If you specify the NOBYREF option, you do not need to provide BY variables in the reference line data set. By default, you must provide BY variables.

† **NOCHART**

suppresses the creation of the box plot. You typically specify the NOCHART option when you are using the procedure to compute group summary statistics and save them in an output data set.

NOFRAME

suppresses the default frame drawn around the plot.

† NOHLABEL

suppresses the label for the horizontal (group) axis. Use the NOHLABEL option when the meaning of the axis is evident from the tick mark labels, such as when a date format is associated with the group variable.

† NOOVERLAYLEGEND

suppresses the legend for overlay plots that is displayed by default when the **OVERLAY=** option is specified.

† NOSERIFS

eliminates serifs from the whiskers of box-and-whiskers plots.

† NOTCHES

specifies that box-and-whiskers plots be notched. The endpoints of the notches are located at the median plus and minus $1.58(\text{IQR}/\sqrt{n})$, where IQR is the interquartile range and n is the group size. The medians (central lines) of two box-and-whiskers plots are significantly different at approximately the 0.95 confidence level if the corresponding notches do not overlap.

See McGill, Tukey, and Larsen (1978) for more information. Figure 26.7 illustrates the NOTCHES option. Notice the folding effect at the bottom, which happens when the endpoint of a notch is beyond its corresponding quartile. This situation typically occurs when the group size is small.

Figure 26.7 Box Plot: The NOTCHES Option

NOTICKREP

applies to character-valued group variables and specifies that only the first occurrence of repeated, adjacent group values be labeled on the horizontal axis.

NOVANGLE

requests that the vertical axis label be strung out vertically.

† NPANELPOS=*n***NPANEL=*n***

specifies the number of group positions per panel. You typically specify the NPANELPOS= option to display more box-and-whiskers plots on a panel than the default number, which is $n = 25$.

You can specify a positive or negative number for n . The absolute value of n must be at least 5. If n is positive, the number of positions is adjusted so that it is approximately equal to n and so that all panels display approximately the same number of group positions. If n is negative, no balancing is done, and each panel (except possibly the last) displays approximately $|n|$ positions. In this case, the approximation is due only to axis scaling.

You can use the **INTERVAL=** option to change the effect of the NPANELPOS= option when a date or time format is associated with the group variable. The INTERVAL= option enables you to match the scale of the horizontal axis to the scale of the group variable without having to associate a different format with the group variable.

† OUTBOX=*SAS-data-set*

creates an output data set that contains group summary statistics and outlier values for a box plot. You can use an OUTBOX= data set as a **BOX=** input data set in a subsequent run of the procedure. See the section “**OUTBOX= Data Set**” on page 1002 for details.

OUTHIGHTHTML=*variable*

specifies a variable whose values are URLs to be associated with outlier points above the upper fence on a schematic box plot when graphics output is directed into HTML.

† OUTHISTORY=*SAS-data-set*

creates an output data set that contains the group summary statistics. You can use an OUTHISTORY= data set as a **HISTORY=** input data set in a subsequent run of the procedure. See the section “**OUTHISTORY= Data Set**” on page 1003 for details.

OUTLOWHTML=*variable*

specifies a variable whose values are URLs to be associated with outlier points below the lower fence on a schematic box plot when graphics output is directed into HTML.

† OVERLAY=(*variable-list*)

specifies variables to be plotted as overlays on the box plot. One value for each overlay variable is plotted at each group position. If there are multiple observations with the same group variable value in the input data set, the overlay variable values from the first observation in each group are plotted. By default, the points in an overlay plot are connected with line segments.

OVERLAYCLIPSYM=*symbol*

specifies the symbol used to plot clipped values on overlay plots when the **CLIPFACTOR=** option is used.

OVERLAYCLIPSYMHT=*value*

specifies the height for the symbol used to plot clipped values on overlay plots when the **CLIPFACTOR=** option is used.

OVERLAYHTML=(*variable-list*)

specifies variables whose values are URLs to be associated with points on overlay plots when graphics output is directed into HTML. Variables in the **OVERLAYHTML=** list are matched with variables in the corresponding positions in the **OVERLAY=** list.

OVERLAYID=(*variable-list*)

specifies variables whose formatted values are used to label points on overlays. Variables in the **OVERLAYID=** list are matched with variables in the corresponding positions in the **OVERLAY=** list. The value of the **OVERLAYID=** variable should be the same for each observation with a given value of the group variable.

† OVERLAYLEGLAB=*'label'*

specifies the label displayed to the left of the overlay legend produced by the **OVERLAY=** option. The label can be up to 16 characters and must be enclosed in quotes. The default label is “Overlays.”.

OVERLAYSYM=(*symbol-list*)

specifies symbols used to plot overlay variables. Symbols in the **OVERLAYSYM=** list are matched with variables in the corresponding positions in the **OVERLAY=** list.

OVERLAYSYMHT=(*value-list*)

specifies the heights of symbols used to plot overlay variables. Symbol heights in the **OVERLAYSYMHT=** list are matched with variables in the corresponding positions in the **OVERLAY=** list.

PAGENUM=*'string'*

specifies the form of the label used for pagination. The string can be up to 16 characters, and it must include one or two occurrences of the substitution character ‘#’. The first ‘#’ is replaced with the page number, and the optional second ‘#’ is replaced with the total number of pages.

The **PAGENUM=** option is useful when you are working with a large number of groups, resulting in multiple pages of output. For example, suppose that each of the following PLOT statements produces multiple pages:

```
proc boxplot data=Pistons;
  plot Diameter*Hour / pagenum='Page #';
  plot Diameter*Hour / pagenum='Page # of #';
  plot Diameter*Hour / pagenum='#/#';
run;
```

The third page produced by the first statement would be labeled “Page 3”. The third page produced by the second statement would be labeled “Page 3 of 5”. The third page produced by the third statement would be labeled “3/5”.

By default, no page number is displayed.

PAGENUMPOS=TL | TR | BL | BR | TL100 | TR100 | BL0 | BR0

specifies where to position the page number requested with the **PAGENUM=** option. The keywords TL, TR, BL, and BR correspond to the positions top left, top right, bottom left, and bottom right, respectively. You can use the TL100 and TR100 keywords to ensure that the page number appears at the very top of a page when a title is displayed. The BL0 and BR0 keywords ensure that the page number appears at the very bottom of a page when footnotes are displayed.

The default value is BR.

† PCTLDEF=index

specifies one of five definitions used to calculate percentiles in the construction of box-and-whiskers plots. The index can be 1, 2, 3, 4, or 5. The five corresponding percentile definitions are discussed in the section “[Percentile Definitions](#)” on page 1008. The default index is 5.

† REPEAT**† REP**

specifies that the horizontal axis of a plot that spans multiple panels be arranged so that the last group position on a panel is repeated as the first group position on the next panel. The REPEAT option facilitates cutting and pasting panels together. When a SAS DATETIME format is associated with the group variable, the REPEAT option is the default.

SKIPHLABELS=*n***SKIPHLABEL=*n***

specifies the number *n* of consecutive tick mark labels, beginning with the second tick mark label, that are thinned (not displayed) on the horizontal (group) axis. For example, specifying SKIPHLABEL=1 causes every other label to be skipped. Specifying SKIPHLABEL=2 causes the second and third labels to be skipped, the fifth and sixth labels to be skipped, and so forth.

The default value of the SKIPHLABELS= option is the smallest value *n* for which tick mark labels do not collide. A specified *n* will be overridden to avoid collision. To reduce thinning, you can use the [TURNHLABELS](#) option.

SYMBOLLEGEND=LEGEND*n***SYMBOLLEGEND=NONE**

controls the legend for the levels of a symbol variable (see [Example 26.1](#)). You can specify SYMBOLLEGEND=LEGEND*n*, where *n* is the number of a LEGEND statement defined previously. You can specify SYMBOLLEGEND=NONE to suppress the default legend. See *SAS/GRAPH: Reference* for more information about the LEGEND statement.

SYMBOLORDER=DATA | INTERNAL | FORMATTED**SYMORD=DATA | INTERNAL | FORMATTED**

specifies the order in which symbols are assigned for levels of the symbol variable. The DATA keyword assigns symbols to values in the order in which values appear in the input data set. The INTERNAL keyword assigns symbols based on sorted order of internal values of the symbol variable, and the FORMATTED keyword assigns them based on sorted formatted values. The default value is FORMATTED.

† **TOTPANELS**=*n*

specifies the total number of panels to be used to display the plot. This option overrides the **NPANELPOS**= option.

TURNHLABELS**TURNHLABEL**

turns the major tick mark labels for the horizontal (group) axis so that they are arranged vertically. By default, labels are arranged horizontally.

Note that arranging the labels vertically might leave insufficient vertical space on the panel for a plot.

† **VAXIS**=*value-list***VAXIS**=**AXIS***n*

specifies major tick mark values for the vertical axis of a box plot. The values must be listed in increasing order, must be evenly spaced, and must span the range of values displayed in the plot. You can specify the values with an explicit list or with an implicit list, as shown in the following example:

```
proc boxplot;
  plot Width*Hour / vaxis=0 2 4 6 8;
  plot Width*Hour / vaxis=0 to 8 by 2;
run;
```

You can also specify a previously defined **AXIS** statement with the **VAXIS**= option.

† **VFORMAT**=*format*

specifies a format to be used for displaying tick mark labels on the vertical axis of the box plot.

VMINOR=*n***VM**=*n*

specifies the number of minor tick marks between major tick marks on the vertical axis. Minor tick marks are not labeled. By default, **VMINOR**=0.

VOFFSET=*value*

specifies the length in percent screen units of the offset at the ends of the vertical axis.

† **VREF**=*value-list*† **VREF**=**SAS-data-set**

draws reference lines perpendicular to the vertical axis. You can use this option in the following ways:

- Specify the values for the lines with a **VREF**= list:

```
vref=20
vref=20 40 80
```

- Specify the values for the lines as the values of a numeric variable named **_REF_** in a **VREF**= data set. Optionally, you can provide labels for the lines as values of a variable named **_REFLAB_**, which must be a character variable of up to 16 characters. If you want distinct reference lines to be displayed in plots for different analysis variables specified in the **PLOT** statement, you must include a character variable named **_VAR_**, whose values are the names of the analysis variables. If you do not include the variable **_VAR_**, all of the lines are displayed in all of the

plots. Each observation in the VREF= data set corresponds to a reference line. If BY variables are used in the input data set, the same BY-variable structure must be used in the VREF= data set unless you specify the **NOBYREF** option.

† **VREFLABELS**=*'label1' ... 'labeln'*

† **VREFLABEL**=*'label1' ... 'labeln'*

† **VREFLAB**=*'label1' ... 'labeln'*

specifies labels for the reference lines requested by the **VREF=** option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

VREFLABPOS=*n*

specifies the horizontal position of the **VREFLABELS=** label, as described in the following table. By default, *n* = 1.

n	Label Position
1	left-justified in plot area
2	right-justified in plot area
3	left-justified in right margin

VZERO

forces the origin to be included in the vertical axis for a box plot.

WAXIS=*n*

specifies the width in pixels for the axis and frame lines. By default, *n* = 1.

WGRID=*n*

specifies the width in pixels for grid lines requested with the **ENDGRID** and **GRID** options. By default, *n* = 1.

WOVERLAY=(*value-list*)

specifies the widths in pixels for the line segments connecting points on overlay plots. Widths in the **WOVERLAY=** list are matched with variables in the corresponding positions in the **OVERLAY=** list. By default, all overlay widths are 1.

Details: BOXPLOT Procedure

Summary Statistics Represented by Box Plots

Table 26.7 lists the summary statistics represented in each box-and-whiskers plot.

Table 26.7 Summary Statistics Represented by Box Plots

Group Summary Statistic	Feature of Box-and-Whiskers Plot
maximum	endpoint of upper whisker
third quartile (75th percentile)	upper edge of box
median (50th percentile)	line inside box
mean	symbol marker
first quartile (25th percentile)	lower edge of box
minimum	endpoint of lower whisker

Note that you can request different box plot styles, as discussed in the section “[Styles of Box Plots](#)” on page 1007, and as illustrated in [Example 26.2](#).

Output Data Sets

OUTBOX= Data Set

The OUTBOX= data set saves group summary statistics and outlier values. The following variables can be saved:

- the group variable
- the variable `_VAR_`, containing the analysis variable name
- the variable `_TYPE_`, identifying features of box-and-whiskers plots
- the variable `_VALUE_`, containing values of box-and-whiskers plot features
- the variable `_ID_`, containing labels for outliers
- the variable `_HTML_`, containing URLs associated with plot features

`_ID_` is included in the OUTBOX= data set only if the keyword `SCHEMATICID` or `SCHEMATICIDFAR` is specified with the `BOXSTYLE=` option. `_HTML_` is present only if one or more of the `HTML=`, `OUT-HIGHHTML=`, and `OUTLOWHTML=` options are specified.

Each observation in an OUTBOX= data set records the value of a single feature of one group’s box-and-whiskers plot, such as its mean. The `_TYPE_` variable identifies the feature whose value is recorded in `_VALUE_`. [Table 26.8](#) lists valid `_TYPE_` variable values.

Table 26.8 Valid _TYPE_ Values in an OUTBOX= Data Set

TYPE	Description
N	group size
MIN	minimum group value
Q1	group first quartile
MEDIAN	group median
MEAN	group mean
Q3	group third quartile
MAX	group maximum value
STDDEV	group standard deviation
LOW	low outlier value
HIGH	high outlier value
LOWHISKR	low whisker value, if different from MIN
HIWHISKR	high whisker value, if different from MAX
FARLOW	low far outlier value
FARHIGH	high far outlier value

Additionally, the following variables, if specified, are included:

- block variables
- symbol variable
- BY variables
- ID variables

OUTHISTORY= Data Set

The OUTHISTORY= data set saves group summary statistics. The following variables are saved:

- the group variable
- group minimum variables named by *analysis-variable* suffixed with *L*
- group first-quartile variables named by *analysis-variable* suffixed with *1*
- group mean variables named by *analysis-variable* suffixed with *X*
- group median variables named by *analysis-variable* suffixed with *M*
- group third-quartile variables named by *analysis-variable* suffixed with *3*
- group maximum variables named by *analysis-variable* suffixed with *H*
- group standard deviation variables named by *analysis-variable* suffixed with *S*
- group size variables named by *analysis-variable* suffixed with *N*

If an analysis variable name has the maximum length of 32 characters, PROC BOXPLOT forms summary statistic names from its first 16 characters, its last 15 characters, and the appropriate suffix.

Subgroup summary variables are created for each analysis variable specified in the PLOT statement. For example, consider the following statements:

```
proc boxplot data=Steel;
    plot (Width Diameter)*Lot / outhistory=Summary;
run;
```

The data set Summary contains variables named Lot, WidthL, Width1, WidthM, WidthX, Width3, WidthH, WidthS, WidthN, DiameterL, Diameter1, DiameterM, DiameterX, Diameter3, DiameterH, DiameterS, and DiameterN.

Additionally, the following variables, if specified, are included:

- BY variables
- block variables
- symbol variable
- ID variables

Note that an OUTHISTORY= data set does not contain outlier values, and therefore cannot be used, in general, to save a schematic box plot. You can use an OUTBOX= data set to save a schematic box plot summary.

Input Data Sets

DATA= Data Set

You can read analysis variable measurements from a data set specified with the DATA= option in the PROC BOXPLOT statement. Each analysis variable specified in the PLOT statement must be a SAS variable in the data set. This variable provides measurements that are organized into groups indexed by the group variable. The group variable, specified in the PLOT statement, must also be a SAS variable in the DATA= data set. Each observation in a DATA= data set must contain a value for each analysis variable and a value for the group variable. If the i th group contains n_i measurements, there should be n_i consecutive observations for which the value of the group variable is the index of the i th group. For example, if each group contains 20 items and there are 30 groups, the DATA= data set should contain 600 observations. Other variables that can be read from a DATA= data set include the following:

- block variables
- symbol variable
- BY variables
- ID variables

BOX= Data Set

You can read group summary statistics and outlier information from a BOX= data set specified in the PROC BOXPLOT statement. This enables you to reuse **OUTBOX=** data sets that have been created in previous runs of the BOXPLOT procedure to reproduce schematic box plots.

A BOX= data set must contain the following variables:

- the group variable
- **_VAR_**, containing the analysis variable name
- **_TYPE_**, identifying features of box-and-whiskers plots
- **_VALUE_**, containing values of those features

Each observation in a BOX= data set records the value of a single feature of one group's box-and-whiskers plot, such as its mean. Consequently, a BOX= data set contains multiple observations per group. These must appear consecutively in the BOX= data set.

The **_TYPE_** variable identifies the feature whose value is recorded in a given observation. The following table lists valid **_TYPE_** variable values.

Table 26.9 Valid **_TYPE_** Values in a BOX= Data Set

TYPE	Description
N	group size
MIN	group minimum value
Q1	group first quartile
MEDIAN	group median
MEAN	group mean
Q3	group third quartile
MAX	group maximum value
STDDEV	group standard deviation
LOW	low outlier value
HIGH	high outlier value
LOWHISKR	low whisker value, if different from MIN
HIWHISKR	high whisker value, if different from MAX
FARLOW	low far outlier value
FARHIGH	high far outlier value

The features identified by **_TYPE_** values N, MIN, Q1, MEDIAN, MEAN, Q3, and MAX are required for each group.

Other variables that can be read from a BOX= data set include the following:

- the variable **_ID_**, containing labels for outliers
- the variable **_HTML_**, containing URLs to be associated with features on box plots

- block variables
- symbol variable
- BY variables
- ID variables

When you specify the keyword SCHEMATICID or SCHEMATICIDFAR with the **BOXSTYLE=** option, values of `_ID_` are used as outlier labels. If `_ID_` does not exist in the `BOX=` data set, the values of the first variable listed in the ID statement are used.

HISTORY= Data Set

You can read group summary statistics from a `HISTORY=` data set specified in the PROC BOXPLOT statement. This enables you to reuse **OUTHISTORY=** data sets that have been created in previous runs of the BOXPLOT procedure or to read output data sets created with SAS summarization procedures, such as PROC UNIVARIATE.

Note that a `HISTORY=` data set does *not* contain outlier information. Therefore, in general you cannot reproduce a schematic box plot from summary statistics saved in an `OUTHISTORY=` data set. To save and reproduce schematic box plots, use **OUTBOX=** and `BOX=` data sets.

A `HISTORY=` data set must contain the following:

- the group variable
- a group minimum variable for each analysis variable
- a group first-quartile variable for each analysis variable
- a group median variable for each analysis variable
- a group mean variable for each analysis variable
- a group third-quartile variable for each analysis variable
- a group maximum variable for each analysis variable
- a group standard deviation variable for each analysis variable
- a group size variable for each analysis variable

The names of the group summary statistics variables must be the analysis variable name concatenated with the following special suffix characters.

Group Summary Statistic	Suffix Character
group minimum	L
group first quartile	1
group median	M
group mean	X
group third quartile	3
group maximum	H
group standard deviation	S
group size	N

For example, consider the following statements:

```
proc boxplot history=Summary;
  plot (Weight Yieldstrength) * Batch;
run;
```

The data set `Summary` must include the variables `Batch`, `WeightL`, `Weight1`, `WeightM`, `WeightX`, `Weight3`, `WeightH`, `WeightS`, `WeightN`, `YieldstrengthL`, `Yieldstrength1`, `YieldstrengthM`, `YieldstrengthX`, `Yieldstrength3`, `YieldstrengthH`, `YieldstrengthS`, and `YieldstrengthN`.

Note that if you specify an analysis variable whose name contains the maximum of 32 characters, the summary variable names must be formed from the first 16 characters and the last 15 characters of the analysis variable name, suffixed with the appropriate character.

These other variables can be read from a `HISTORY=` data set:

- block variables
- symbol variable
- BY variables
- ID variables

Styles of Box Plots

A box-and-whiskers plot is displayed for the measurements in each group on the box plot. The *skeletal* style of the box-and-whiskers plot shown in [Figure 26.6](#) is the default. You can produce a *schematic* box plot by specifying the `BOXSTYLE=SCHEMATIC` option in the `PLOT` statement. [Figure 26.8](#) illustrates a typical schematic box plot and the locations of the fences (which are not displayed in actual output). See the description of the `BOXSTYLE=` option for complete details.

Figure 26.8 Schematic Box-and-Whiskers Plot

You can draw connecting lines between adjacent box-and-whiskers plots by using the **BOXCONNECT=keyword** option. For example, **BOXCONNECT=MEAN** connects the points representing the means of adjacent groups. Other available keywords are **MIN**, **Q1**, **MEDIAN**, **Q3**, and **MAX**. Specifying **BOXCONNECT** without a keyword is equivalent to specifying **BOXCONNECT=MEAN**. You can specify the color for the connecting lines with the **CCONNECT=** option.

Percentile Definitions

You can use the **PCTLDEF=** option to specify one of five definitions for computing quantile statistics (percentiles). Suppose that n is the number of nonmissing values for a variable and that x_1, x_2, \dots, x_n represent the ordered values of the analysis variable. For the t th percentile, set $p = t/100$.

For the following definitions numbered 1, 2, 3, and 5, express np as

$$np = j + g$$

where j is the integer part of np , and g is the fractional part of np . For definition 4, let

$$(n + 1)p = j + g$$

The t th percentile (call it y) can be defined as follows:

PCTLDEF=1	weighted average at x_{np} $y = (1 - g)x_j + gx_{j+1}$ where x_0 is taken to be x_1 .
PCTLDEF=2	observation numbered closest to np $y = x_i$ where i is the integer part of $np + 1/2$ if $g \neq 1/2$. If $g = 1/2$, then $y = x_j$ if j is even, or $y = x_{j+1}$ if j is odd.
PCTLDEF=3	empirical distribution function $y = x_j \text{ if } g = 0$ $y = x_{j+1} \text{ if } g > 0$
PCTLDEF=4	weighted average aimed at $x_{p(n+1)}$ $y = (1 - g)x_j + gx_{j+1}$ where x_{n+1} is taken to be x_n .
PCTLDEF=5	empirical distribution function with averaging $y = (x_j + x_{j+1})/2 \text{ if } g = 0$ $y = x_{j+1} \text{ if } g > 0$

Missing Values

An observation read from an input data set is not analyzed if the value of the group variable is missing. For a particular analysis variable, an observation read from a **DATA=** data set is not analyzed if the value of the analysis variable is missing.

Continuous Group Variables

By default, the PLOT statement treats numerical group variable values as *discrete* values and spaces the boxes evenly on the plot. The following statements produce the box plot in [Figure 26.9](#):

```
ods graphics off;
title 'Box Plot for Power Output';
proc boxplot data=Turbine;
    plot KWatts*Day;
run;
```

Figure 26.9 Box Plot with Discrete Group Variable

The labels on the horizontal axis in Figure 26.9 do not represent 10 consecutive days, but the box-and-whiskers plots are evenly spaced.

In order to treat the group variable as *continuous*, you can specify the **CONTINUOUS** or **HAXIS=** option when producing traditional graphics. Either option produces a box plot with a horizontal axis scaled for continuous group variable values. (ODS Graphics does not support a continuous group axis.)

The following statements produce the plot shown in Figure 26.10. The **TURNHLABELS** option orients the horizontal axis labels vertically so there is room to display them all.

```
title 'Box Plot for Power Output';
proc boxplot data=Turbine;
  plot KWatts*Day / turnhlabels
                    continuous;
run;
```

Figure 26.10 Box Plot with Continuous Group Variable

Note that the tick values on the horizontal axis represent consecutive days and that no box-and-whiskers plots are displayed for days when no turbine data were collected.

Positioning Insets

This section provides details on three different methods of positioning INSET boxes by using the **POSITION=** option. With the **POSITION=** option, you can specify the following:

- compass points
- keywords for margin positions
- coordinates in data units or percent axis units

Positioning the Inset Using Compass Points

You can specify the eight compass points (N, NE, E, SE, S, SW, W, and NW) as keywords for the POSITION= option. The default inset position is NW. The following statements create the display in Figure 26.11, which illustrates all eight compass positions:

```
title 'Box Plot for Power Output';
proc boxplot data=Turbine;
  plot KWatts*Day;
  inset nobs / height=2.5 cfill=blank header='NW' pos=nw;
  inset nobs / height=2.5 cfill=blank header='N ' pos=n ;
  inset nobs / height=2.5 cfill=blank header='NE' pos=ne;
  inset nobs / height=2.5 cfill=blank header='E ' pos=e ;
  inset nobs / height=2.5 cfill=blank header='SE' pos=se;
  inset nobs / height=2.5 cfill=blank header='S ' pos=s ;
  inset nobs / height=2.5 cfill=blank header='SW' pos=sw;
  inset nobs / height=2.5 cfill=blank header='W ' pos=w ;
run;
```

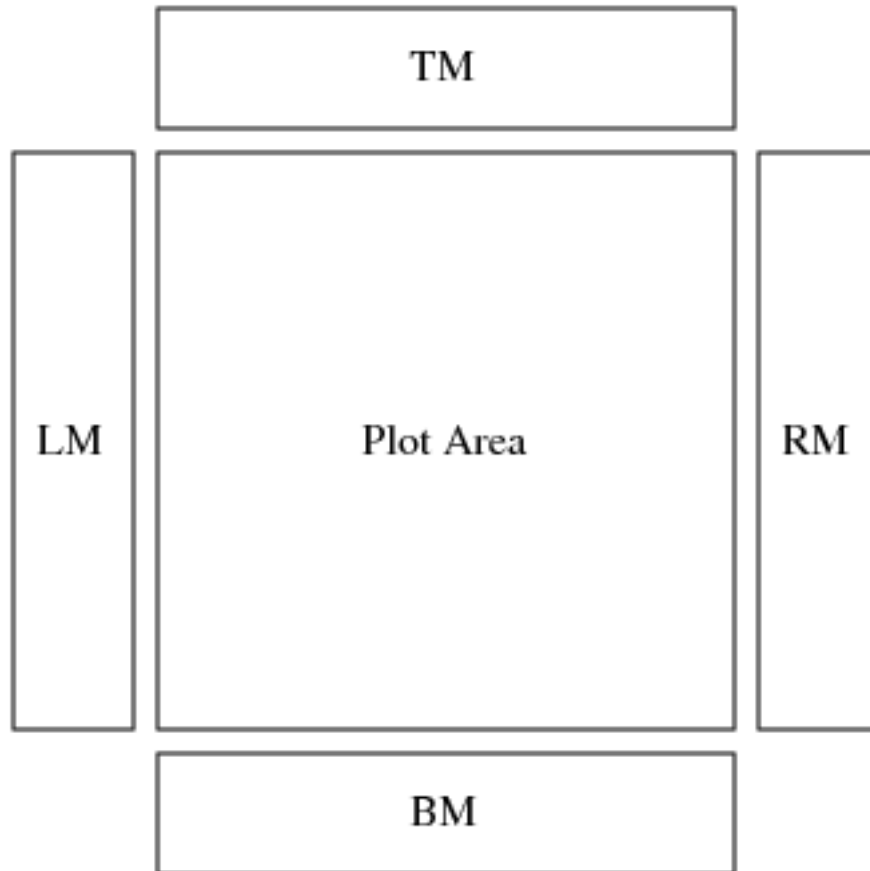

Figure 26.11 Insets Positioned Using Compass Points

Positioning the Inset in the Margins

You can also use the INSET statement to position an inset in one of the four margins surrounding the plot area by using the margin keyword LM, RM, TM, or BM, as illustrated in [Figure 26.12](#).

Figure 26.12 Positioning Insets in the Margins

For an example of an inset placed in the top margin, see [Output 26.1.1](#). Margin positions are recommended for insets containing a large number of statistics. If you attempt to display a lengthy inset in the interior of the plot, it is likely that the inset will collide with the data display.

Positioning the Inset Using Coordinates

You can also specify the position of an inset with coordinates by using the POSITION= (*x*, *y*) option. You can specify coordinates in axis percent units (the default) or in axis data units.

Data Unit Coordinates

If you specify the DATA option immediately following the coordinates, the inset is positioned using axis data units. For example, the following statements place the bottom-left corner of the inset at 07JUL on the horizontal axis and 3950 on the vertical axis:

```

title 'Box Plot for Power Output';
proc boxplot data=Turbine;
  plot KWatts*Day;
  inset nobs /
    header   = 'Position=(07JUL,3950)'
    position = ('07JUL94'd, 3950) data;
run;

```

The box plot is displayed in Figure 26.13. By default, the specified coordinates determine the position of the bottom-left corner of the inset. You can change this reference point with the `REFPOINT=` option, as in the next example.

Figure 26.13 Inset Positioned Using Data Unit Coordinates

Axis Percent Unit Coordinates

If you do not use the `DATA` option, the inset is positioned using axis percent units. The coordinates of the bottom-left corner of the display are (0, 0), while the coordinates of the top-right corner are (100, 100). For example, the following statements create a box plot with two insets, both positioned using coordinates in axis percent units:

```

title 'Box Plot for Power Output';
proc boxplot data=Turbine;
  plot KWatts*Day;
  inset nmin / position = (5,25)
           header   = 'Position=(5,25) '
           height    = 3
           cfill     = ywh
           refpoint  = tl;
  inset nmax / position = (95,95)
           header   = 'Position=(95,95) '
           height    = 3
           cfill     = ywh
           refpoint  = tr;
run;

```

The display is shown in Figure 26.14. Notice that the REFPOINT= option is used to determine which corner of the inset is placed at the coordinates specified with the POSITION= option. The first inset has REFPOINT=TL, so the top-left corner of the inset is positioned 5% of the way across the horizontal axis and 25% of the way up the vertical axis. The second inset has REFPOINT=TR, so the top-right corner of the inset is positioned 95% of the way across the horizontal axis and 95% of the way up the vertical axis. Note also that coordinates in axis percent units must be *between* 0 and 100.

Figure 26.14 Inset Positioned Using Axis Percent Unit Coordinates

Displaying Blocks of Data

To display data organized in blocks of consecutive observations, specify one or more *block variables* in parentheses after the group variable in the PLOT statement. The block variables must be variables in the input data set. The BOXPLOT procedure displays a legend identifying blocks of consecutive observations with identical values of the block variables. The legend displays one track of values for each block variable containing formatted values of the block variable.

The values of a block variable must be the same for all observations with the same value of the group variable. In other words, groups must be nested within blocks determined by block variables.

The following statements create a SAS data set containing diameter measurements for a part produced on three different machines:

```
data Parts;
  length Machine $ 4;
  input Sample Machine $ @;
  do i= 1 to 4;
    input Diam @;
    output;
  end;
  drop i;
  datalines;
1  A386  4.32 4.55 4.16 4.44
2  A386  4.49 4.30 4.52 4.61
3  A386  4.44 4.32 4.25 4.50
4  A386  4.55 4.15 4.42 4.49
5  A386  4.21 4.30 4.29 4.63
6  A386  4.56 4.61 4.29 4.56
7  A386  4.63 4.30 4.41 4.58
8  A386  4.38 4.65 4.43 4.44
9  A386  4.12 4.49 4.30 4.36
10 A455  4.45 4.56 4.38 4.51
11 A455  4.62 4.67 4.70 4.58
12 A455  4.33 4.23 4.34 4.58
13 A455  4.29 4.38 4.28 4.41
14 A455  4.15 4.35 4.28 4.23
15 A455  4.21 4.30 4.32 4.38
16 C334  4.16 4.28 4.31 4.59
17 C334  4.14 4.18 4.08 4.21
18 C334  4.51 4.20 4.28 4.19
19 C334  4.10 4.33 4.37 4.47
20 C334  3.99 4.09 4.47 4.25
21 C334  4.24 4.54 4.43 4.38
22 C334  4.23 4.48 4.31 4.57
23 C334  4.27 4.40 4.32 4.56
24 C334  4.70 4.65 4.49 4.38
;
```

The following statements create a box plot for the measurements in the Parts data set grouped into blocks by the block variable Machine:

```
ods graphics off;
title 'Box Plot for Diameter Grouped By Machine';
proc boxplot data=Parts;
  plot Diam*Sample (Machine);
  label Sample = 'Sample Number'
        Machine = 'Machine'
        Diam   = 'Diameter';
run;
```

Note the LABEL statement used to provide labels for the axes and for the block legend. The plot is shown in Figure 26.15.

Figure 26.15 Box Plot Using a Block Variable

The unique consecutive values of Machine (A386, A455, and C334) are displayed in a legend above the plot. That is the default location of the block legend. You can control the position of the block legend with the BLOCKPOS= option. See the BLOCKPOS= option for details.

By default, block variable values that are too long to fit into the available space in a block legend are not displayed. You can specify the BLOCKLABTYPE= option to display lengthy labels. Specify BLOCKLABTYPE=SCALED to scale down the text size of the values so they all fit. Use BLOCKLAB-

TYPE=TRUNCATED to truncate lengthy values. You can also use BLOCKLABTYPE=*height* to specify a text height in vertical percent screen units for the values.

You can control the position of legend labels with the BLOCKLABELPOS= option. Valid BLOCKLABELPOS= values are ABOVE (the default, as shown in Figure 26.15) and LEFT.

Clipping Extreme Values

By default a box plot's vertical axis is scaled to accommodate all the values in all groups. If the variation between groups is large with respect to the variation within groups, or if some groups contain extreme outlier values, the vertical axis scale can become so large that the box-and-whiskers plots are compressed. In such cases, you can clip the extreme values to produce a more readable plot, as illustrated in the following example.

A company produces copper tubing. The diameter measurements (in millimeters) for 15 batches of five tubes each are provided in the data set Newtubes:

```
data Newtubes;
  label Diameter='Diameter in mm';
  do Batch = 1 to 15;
    do i = 1 to 5;
      input Diameter @@;
      output;
    end;
  end;
  datalines;
69.13 69.83 70.76 69.13 70.81
85.06 82.82 84.79 84.89 86.53
67.67 70.37 68.80 70.65 68.20
71.71 70.46 71.43 69.53 69.28
71.04 71.04 70.29 70.51 71.29
69.01 68.87 69.87 70.05 69.85
50.72 50.49 49.78 50.49 49.69
69.28 71.80 69.80 70.99 70.50
70.76 69.19 70.51 70.59 70.40
70.16 70.07 71.52 70.72 70.31
68.67 70.54 69.50 69.79 70.76
68.78 68.55 69.72 69.62 71.53
70.61 70.75 70.90 71.01 71.53
74.62 56.95 72.29 82.41 57.64
70.54 69.82 70.71 71.05 69.24
;
```

The following statements create a box plot of the tube diameters:

```
ods graphics off;
title 'Box Plot for New Copper Tubes' ;
proc boxplot data=Newtubes;
  plot Diameter*Batch;
run;
```

The box plot is shown in Figure 26.16.

Figure 26.16 Compressed Box Plots

Note that the diameters in batch 2 are significantly larger, and those in batch 7 significantly smaller, than those in most of the other batches. The default vertical axis scaling causes the box-and-whiskers plots to be compressed.

You can produce a more useful box plot by specifying the `CLIPFACTOR=factor` option, where *factor* is a value greater than one. Clipping is applied as follows:

1. The mean of the first quartile values ($\overline{Q1}$) and the mean of the third quartile values ($\overline{Q3}$) are computed across all groups.
2. The following values define the clipping range:

$$y_{\max} = \overline{Q1} + (\overline{Q3} - \overline{Q1}) \times factor$$

and

$$y_{\min} = \overline{Q3} - (\overline{Q3} - \overline{Q1}) \times factor$$

Any statistic greater than y_{\max} or less than y_{\min} is ignored during vertical axis scaling.

NOTE:

- Clipping is applied only to the plotted statistics and not to the statistics saved in an output data set.
- A special symbol is used for clipped points (the default symbol is a square), and a legend is added to the chart indicating the number of boxes that were clipped.

The following statements use a clipping factor of 1.5 to create a box plot of the same data plotted in Figure 26.16:

```
title 'Box Plot for New Copper Tubes' ;
proc boxplot data=Newtubes;
  plot Diameter*Batch /
    clipfactor = 1.5;
run;
```

The clipped box plot is shown in Figure 26.17.

Figure 26.17 Box Plot with Clip Factor of 1.5

In Figure 26.17 the extreme values are clipped, making the box plot more readable. The box-and-whiskers plots for batches 2 and 7 are clipped completely, while the plot for batch 14 is clipped at both the top and bottom. Clipped points are marked with a square, and a clipping legend is added at the lower right of the display.

Other clipping options are available, as illustrated by the following statements:

```
title 'Box Plot for New Copper Tubes' ;
proc boxplot data=Newtubes;
  plot Diameter*Batch /
    clipfactor = 1.5
    clipsymbol = dot
    cliplegpos  = top
    cliplegend  = '# Clipped Boxes'
    clipsubchar = '#';
run;
```

Specifying **CLIPSYMBOL=DOT** marks the clipped points with a dot instead of the default square. Specifying **CLIPLEGPOS=TOP** positions the clipping legend at the top of the chart. The options **CLIPLEGEND='# Clipped Boxes'** and **CLIPSUBCHAR='#'** request the clipping legend “3 Clipped Boxes”.

Figure 26.18 shows the modified box plot.

Figure 26.18 Box Plot Using Clipping Options

For more information about clipping options, see the appropriate entries in the section “[PLOT Statement Options](#)” on page 979.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The appearance of a box plot produced using ODS Graphics is determined by the style associated with the ODS destination where the graph is produced. PLOT statement options used to control the appearance of traditional high-resolution graphs are ignored for ODS Graphics output.

When producing ODS graphical displays, the PLOT statement assigns a name to each graph it creates. You can use this name to reference the graph when using ODS. The name is listed in [Table 26.10](#).

Table 26.10 Graphs Produced by PROC BOXPLOT

ODS Graph Name	Plot Description
Boxplot	box-and-whiskers plots for groups

Examples: BOXPLOT Procedure

This section provides advanced examples of the PLOT statement.

Example 26.1: Displaying Summary Statistics in a Box Plot

This example demonstrates how you can use the INSET and INSETGROUP statements to include tables of summary statistics in your box plots. The following statements produce a box plot of the Turbine data set from the section “[Getting Started: BOXPLOT Procedure](#)” on page 963, augmented with insets containing summary statistics:

```
ods graphics off;
title 'Box Plot for Power Output';
proc boxplot data=Turbine;
  plot KWatts*Day;
  inset min mean max stddev /
    header = 'Overall Statistics'
    pos    = tm;
  insetgroup min max /
    header = 'Extremes by Day';
run;
```

The INSET statement produces an inset of overall summary statistics. The keywords listed before the slash (/) request the minimum, mean, maximum, and standard deviation computed over all days. The POS=TM option places the inset in the top margin of the plot.

The INSETGROUP statement produces an inset containing statistics calculated for each group separately. The MIN and MAX keywords request the minimum and maximum observations from each day, respectively.

The resulting plot is shown in [Output 26.1.1](#).

Output 26.1.1 Box Plot with Insets

Example 26.2: Using Box Plots to Compare Groups

In this example a box plot is used to compare the delay times of airline flights during the Christmas holidays with the delay times prior to the holiday period. The following statements create a data set named `Times` with the delay times in minutes for 25 flights each day. When a flight is canceled, the delay is recorded as a missing value.

```
data Times;
  informat Day date7. ;
  format Day date7. ;
  input Day @ ;
  do Flight=1 to 25;
    input Delay @ ;
    output;
  end;
  datalines;
16DEC88  4 12  2  2 18  5  6 21  0  0
          0 14  3  .  2  3  5  0  6 19
          7  4  9  5 10
17DEC88  1 10  3  3  0  1  5  0  .  .
          1  5  7  1  7  2  2 16  2  1
          3  1 31  5  0
18DEC88  7  8  4  2  3  2  7  6 11  3
          2  7  0  1 10  2  3 12  8  6
          2  7  2  4  5
19DEC88 15  6  9  0 15  7  1  1  0  2
          5  6  5 14  7 20  8  1 14  3
         10  0  1 11  7
20DEC88  2  1  0  4  4  6  2  2  1  4
          1 11  .  1  0  6  5  5  4  2
          2  6  6  4  0
21DEC88  2  6  6  2  7  7  5  2  5  0
          9  2  4  2  5  1  4  7  5  6
          5  0  4 36 28
22DEC88  3  7 22  1 11 11 39 46  7 33
         19 21  1  3 43 23  9  0 17 35
         50  0  2  1  0
23DEC88  6 11  8 35 36 19 21  .  .  4
          6 63 35  3 12 34  9  0 46  0
          0 36  3  0 14
24DEC88 13  2 10  4  5 22 21 44 66 13
          8  3  4 27  2 12 17 22 19 36
          9 72  2  4  4
25DEC88  4 33 35  0 11 11 10 28 34  3
         24  6 17  0  8  5  7 19  9  7
         21 17 17  2  6
26DEC88  3  8  8  2  7  7  8  2  5  9
          2  8  2 10 16  9  5 14 15  1
         12  2  2 14 18
;
```

In the following statements, the MEANS procedure is used to count the number of canceled flights for each day. This information is then added to the data set Times.

```
proc means data=Times noprint;
    var Delay;
    by Day;
    output out=Cancel nmiss=ncancel;
run;

data Times;
    merge Times Cancel;
    by Day;
run;
```

The following statements create a data set named Weather containing information about possible causes for delays, and then merge this data set with the data set Times:

```
data Weather;
    informat Day date7. ;
    format    Day date7. ;
    length Reason $ 16 ;
    input Day Flight Reason & ;
    datalines;
16DEC88  8    Fog
17DEC88  18   Snow Storm
17DEC88  23   Sleet
21DEC88  24   Rain
21DEC88  25   Rain
22DEC88  7    Mechanical
22DEC88  15   Late Arrival
24DEC88  9    Late Arrival
24DEC88  22   Late Arrival
;

data Times;
    merge Times Weather;
    by Day Flight;
run;
```

The following statements create a box plot for the complete set of data:

```
ods graphics off;
symbol1 v=plus;
symbol2 v=square;
symbol3 v=triangle;
title 'Box Plot for Airline Delays';
proc boxplot data=Times;
    plot Delay*Day = ncancel /
        nohlabel
        symbollegend = legend1;
    legend1 label = ('Cancellations:');
    label Delay = 'Delay in Minutes';
run;
goptions reset=symbol;
```

The level of the *symbol variable* `ncancel` determines the symbol marker for each group mean, and the `SYMBOLLEGEND=` option controls the appearance of the legend for the symbols. The `NOHLABEL` option suppresses the horizontal axis label. The resulting box plot is shown in [Output 26.2.1](#).

Output 26.2.1 Box Plot for Airline Data

The delay distributions from December 22 through December 25 are drastically different from the delay distributions during the preholiday period. Both the mean delay and the variability of the delays are much greater during the holiday period.

Example 26.3: Creating Various Styles of Box-and-Whiskers Plots

This example uses the flight delay data of the preceding example to illustrate how you can create box plots with various styles of box-and-whiskers plots. The following statements create a plot that displays skeletal box-and-whiskers plots:

```

title 'Analysis of Airline Departure Delays';
title2 'BOXSTYLE=SKELETAL';
proc boxplot data=Times;
  plot Delay*Day /
    boxstyle = skeletal
    nohlabel;
  label Delay = 'Delay in Minutes';
run;

```

In a skeletal box-and-whiskers plot, the whiskers are drawn from the quartiles to the extreme values of the group. The skeletal box plot is the default style, so you can also produce a skeletal box plot by omitting the **BOXSTYLE=** option. [Output 26.3.1](#) shows the skeletal box plot.

Output 26.3.1 BOXSTYLE=SKELETAL

The following statements request a schematic box:

```

title 'Analysis of Airline Departure Delays';
title2 'BOXSTYLE=SCHEMATIC';
proc boxplot data=Times;
  plot Delay*Day /
    boxstyle = schematic
    nohlabel;
  label Delay = 'Delay in Minutes';
run;

```

When you specify `BOXSTYLE=SCHEMATIC`, the whiskers are drawn to the most extreme points in the group that lie within the *fences*. The *upper fence* is defined as the third quartile (represented by the upper edge of the box) plus 1.5 times the interquartile range (IQR). The *lower fence* is defined as the first quartile (represented by the lower edge of the box) minus 1.5 times the interquartile range. Observations outside the fences are identified with a special symbol. The default symbol is a square, and you can specify the shape and color for this symbol with the `IDSYMBOL=` and `IDCOLOR=` options. Serifs are added to the whiskers by default. For further details, see the entry for the `BOXSTYLE=` option. The plot is shown in [Output 26.3.2](#).

Output 26.3.2 BOXSTYLE=SCHEMATIC

The following statements create a schematic box plot in which the observations outside the fences are labeled:

```

title 'Analysis of Airline Departure Delays';
title2 'BOXSTYLE=SCHEMATICID';
proc boxplot data=Times;
  plot Delay*Day /
    boxstyle = schematicid
    nohlabel;
  id Reason;
  label Delay = 'Delay in Minutes';
run;

```

If you specify BOXSTYLE=SCHEMATICID, schematic box-and-whiskers plots are created and the value of the first ID variable (in this case, Reason) is used to label each observation outside the fences. The box plot is shown in [Output 26.3.3](#).

Output 26.3.3 BOXSTYLE=SCHEMATICID

The following statements create a box plot with schematic box-and-whiskers plots in which only the extreme observations outside the fences are labeled:

```

title 'Analysis of Airline Departure Delays';
title2 'BOXSTYLE=SCHEMATICIDFAR';
proc boxplot data=Times;
  plot Delay*Day /
    boxstyle = schematicidf
    nohlabel;
  id Reason;
  label Delay = 'Delay in Minutes';
run;

```

If you specify `BOXSTYLE=SCHEMATICIDFAR`, the value of the first ID variable is used to label each observation outside the lower and upper *far fences*. The lower and upper far fences are located $3 \times \text{IQR}$ below the 25th percentile and $3 \times \text{IQR}$ above the 75th percentile, respectively. Observations between the fences and the far fences are identified with a symbol but are not labeled. The box plot is shown in [Output 26.3.4](#).

Output 26.3.4 BOXSTYLE=SCHEMATICIDFAR

Other options for controlling the display of high-resolution graphics box plots include the `BOXWIDTH=`, `BOXWIDTHSCALE=`, `CBOXES=`, `CBOXFILL=`, and `LBOXES=` options.

Example 26.4: Creating Notched Box-and-Whiskers Plots

The following statements use the flight delay data of [Example 26.1](#) to create box-and-whiskers plots with notches:

```
title 'Analysis of Airline Departure Delays';
title2 'Using the NOTCHES Option';
proc boxplot data=Times;
  plot Delay*Day /
    boxstyle = schematicid
    nohlabel
    notches;
  id Reason;
  label Delay = 'Delay in Minutes';
run;
```

The notches, requested with the [NOTCHES](#) option, measure the significance of the difference between two medians. The medians of two box plots are significantly different at approximately the 0.95 confidence level if the corresponding notches do not overlap. For example, in [Output 26.4.1](#), the median for December 20 is significantly different from the median for December 24.

Output 26.4.1 Notched Side-by-Side Box-and-Whiskers Plots

Example 26.5: Creating Box-and-Whiskers Plots with Varying Widths

This example shows how to create a box plot with box-and-whiskers plots whose widths vary proportionately with the group size. The following statements create a SAS data set named Times2 that contains flight departure delays (in minutes) recorded daily for eight consecutive days:

```
data Times2;
  label Delay = 'Delay in Minutes';
  informat Day date7. ;
  format Day date7. ;
  input Day @ ;
  do Flight=1 to 25;
    input Delay @ ;
    output;
  end;
  datalines;
01MAR90 12 4 2 2 15 8 0 11 0 0
          0 12 3 . 2 3 5 0 6 25
          7 4 9 5 10
02MAR90 1 . 3 . 0 1 5 0 . .
          1 5 7 . 7 2 2 16 2 1
          3 1 31 . 0
03MAR90 6 8 4 2 3 2 7 6 11 3
          2 7 0 1 10 2 5 12 8 6
          2 7 2 4 5
04MAR90 12 6 9 0 15 7 1 1 0 2
          5 6 5 14 7 21 8 1 14 3
          11 0 1 11 7
05MAR90 2 1 0 4 . 6 2 2 1 4
          1 11 . 1 0 . 5 5 . 2
          3 6 6 4 0
06MAR90 8 6 5 2 9 7 4 2 5 1
          2 2 4 2 5 1 3 9 7 8
          1 0 4 26 27
07MAR90 9 6 6 2 7 8 . . 10 8
          0 2 4 3 . . . 7 . 6
          4 0 . . .
08MAR90 1 6 6 2 8 8 5 3 5 0
          8 2 4 2 5 1 6 4 5 10
          2 0 4 1 1
;
```

The following statements create a box plot with varying box widths:

```
title 'Analysis of Airline Departure Delays';
title2 'Using the BOXWIDTHSCALE= Option';
proc boxplot data=Times2;
  plot Delay*Day /
    nohlabel
    boxstyle      = schematic
    boxwidthscale = 1
    bwslegend;
run;
```

The **BOXWIDTHSCALE=***value* option specifies that the widths of the box-and-whiskers plots vary in proportion to a particular function of the group size *n*. The function is determined by *value* and is identified on the box plot with a legend if the **BWSLEGEND** option is specified. The **BOXWIDTHSCALE=** option is useful in situations where the group sizes vary widely.

Output 26.5.1 shows the resulting box plot.

Output 26.5.1 Box Plot with Box-and-Whiskers Plots of Varying Widths

Example 26.6: Creating Box-and-Whiskers Plots Using ODS Graphics

The following statements use ODS Graphics to produce a box plot of the flight delay data from [Example 26.2](#).

```
ods graphics on;
proc boxplot data=Times;
  plot Delay*Day /
    boxstyle = schematic
    nohlabel;
  label Delay = 'Delay in Minutes';
run;
```

The resulting box plot is shown in [Output 26.6.1](#).

Output 26.6.1 Box Plot Produced Using ODS Graphics

ODS graphical displays, like traditional high-resolution graphs in SAS 9.2, are controlled by the ODS style currently in effect for the output destination where the box plots are produced. However, unlike high-resolution graphs, ODS graphs are unaffected by GOPTIONS and SYMBOL statements, and by PLOT statement options used to specify colors, fonts, and other features affecting box plot appearance. Options such as **BOXSTYLE=** and **NOHLABEL** are honored by the PLOT statement when producing ODS graphical output.

The following statements use the **HORIZONTAL** option, which is supported only by ODS Graphics, to produce a horizontal box plot:

```
proc boxplot data=Times;
  plot Delay*Day /
    boxstyle = schematic
    horizontal;
  label Delay = 'Delay in Minutes';
run;
```

The horizontal box plot is shown in [Output 26.6.2](#).

Output 26.6.2 Horizontal Box Plot

Overview: CALIS Procedure

Structural equation modeling is an important statistical tool in social and behavioral sciences. Structural equations express relationships among a system of variables that can be either observed variables (manifest variables) or unobserved hypothetical variables (latent variables). For an introduction to latent variable models, see Loehlin (2004); Bollen (1989b); Everitt (1984), or Long (1983); and for manifest variables with measurement errors, see Fuller (1987).

In structural models, as opposed to functional models, all variables are taken to be random rather than having fixed levels. For maximum likelihood (default) and generalized least squares estimation in PROC CALIS, the random variables are assumed to have an approximately multivariate normal distribution. Nonnormality, especially high kurtosis, can produce poor estimates and grossly incorrect standard errors and hypothesis tests, even in large samples. Consequently, the assumption of normality is much more important than in models with nonstochastic exogenous variables. You should remove outliers and consider transformations of nonnormal variables before using PROC CALIS with maximum likelihood (default) or generalized least squares estimation. Alternatively, model outliers can be downweighted during model estimation with robust methods. If the number of observations is sufficiently large, Browne's asymptotically distribution-free (ADF) estimation method can be used. If your data sets contain random missing data, the full information maximum likelihood (FIML) method can be used.

You can use the CALIS procedure to estimate parameters and test hypotheses for constrained and unconstrained problems in various situations, including but not limited to the following:

- exploratory and confirmatory factor analysis of any order
- linear measurement-error models or regression with errors in variables
- multiple and multivariate linear regression
- multiple-group structural equation modeling with mean and covariance structures
- path analysis and causal modeling
- simultaneous equation models with reciprocal causation
- structured covariance and mean matrices in various forms

To specify models in PROC CALIS, you can use a variety of modeling languages:

- **COSAN**—a generalized version of the COSAN program (McDonald 1978, 1980), uses general mean and covariance structures to define models
- **FACTOR**—supports the input of latent factor and observed variable relations
- **LINEQS**—like the EQS program (Bentler 1995), uses equations to describe variable relationships
- **LISMOD**—utilizes LISREL (Jöreskog and Sörbom 1985) model matrices to define models
- **MSTRUCT**—supports direct parameterizations in the mean and covariance matrices

- **PATH**—provides an intuitive causal path specification interface
- **RAM**—utilizes the formulation of the reticular action model (McArdle and McDonald 1984) to define models
- **REFMODEL**—provides a quick way for model referencing and respecification

Various modeling languages are provided to suit a wide range of researchers' background and modeling philosophy. However, statistical situations might arise where one modeling language is more convenient than the others. This will be discussed in the section “[Which Modeling Language?](#)” on page 1077.

In addition to basic model specification, you can set various parameter constraints in PROC CALIS. Equality constraints on parameters can be achieved by simply giving the same parameter names in different parts of the model. **Boundary**, **linear**, and **nonlinear** constraints are supported as well. If parameters in the model are dependent on additional parameters, you can define the dependence by using the **PARAMETERS** and the **SAS programming statements**.

Before the data are analyzed, researchers might be interested in studying some statistical properties of the data. PROC CALIS can provide the following statistical summary of the data:

- covariance and mean matrices and their properties
- descriptive statistics like means, standard deviations, univariate skewness, and kurtosis measures
- multivariate measures of kurtosis
- coverage of covariances and means, missing patterns summary, and means of the missing patterns when the FIML estimation is used
- weight matrix and its descriptive properties
- robust covariance and mean matrices with the robust methods

After a model is fitted and accepted by the researcher, PROC CALIS can provide the following supplementary statistical analysis:

- computing squared multiple correlations and determination coefficients
- direct and indirect effects partitioning with standard error estimates
- model modification tests such as Lagrange multiplier and Wald tests
- computing fit summary indices
- computing predicted moments of the model
- residual analysis on the covariances and means
- case-level residual diagnostics with graphical plots
- factor rotations
- standardized solutions with standard errors

- testing parametric functions, individually or simultaneously

When fitting a model, you need to choose an estimation method. The following estimation methods are supported in the CALIS procedure:

- diagonally weighted least squares (DWLS, with optional weight matrix input)
- full information maximum likelihood (FIML, which can treat observations with random missing values)
- generalized least squares (GLS, with optional weight matrix input)
- maximum likelihood (ML, for multivariate normal data); this is the default method
- robust estimation with maximum likelihood model evaluation (ROBUST option)
- unweighted least squares (ULS)
- weighted least squares or asymptotically distribution-free method (WLS or ADF, with optional weight matrix input)

Estimation methods implemented in PROC CALIS do not exhaust all alternatives in the field. For example, the partial least squares (PLS) method is not implemented. See the section “[Estimation Criteria](#)” on page 1309 for details about estimation criteria used in PROC CALIS. Note that there is a SAS/STAT procedure called PROC PLS, which employs the partial least squares technique but for a different class of models than those of PROC CALIS. For general path analysis with latent variables, consider using PROC CALIS.

All estimation methods need some starting values for the parameter estimates. You can provide starting values for any parameters. If there is any estimate without a starting value provided, PROC CALIS determines the starting value by using one or any combination of the following methods:

- approximate factor analysis
- default initial values
- instrumental variable method
- matching observed moments of exogenous variables
- McDonald’s method (McDonald and Hartmann 1992) method
- ordinary least squares estimation
- random number generation, if a seed is provided
- two-stage least squares estimation

Although no methods for initial estimates are completely foolproof, the initial estimation methods provided by PROC CALIS behave reasonably well in most common applications.

With initial estimates, PROC CALIS will iterate the solutions so as to achieve the optimum solution as defined by the estimation criterion. This is a process known as optimization. Because numerical problems

can occur in any optimization process, the CALIS procedure offers several optimization algorithms so that you can choose alternative algorithms when the one being used fails. The following optimization algorithms are supported in PROC CALIS:

- Levenberg-Marquardt algorithm (Moré 1978)
- trust-region algorithm (Gay 1983)
- Newton-Raphson algorithm with line search
- ridge-stabilized Newton-Raphson algorithm
- various quasi-Newton and dual quasi-Newton algorithms: Broyden-Fletcher-Goldfarb-Shanno and Davidon-Fletcher-Powell, including a sequential quadratic programming algorithm for processing nonlinear equality and inequality constraints
- various conjugate gradient algorithms: automatic restart algorithm of Powell (1977), Fletcher-Reeves, Polak-Ribiere, and conjugate descent algorithm of Fletcher (1980)
- iteratively reweighted least squares for robust estimation

In addition to the ability to save output tables as data sets by using the ODS OUTPUT statement, PROC CALIS supports the following types of output data sets so that you can save your analysis results for later use:

- **OUTEST=** data sets for storing parameter estimates and their covariance estimates
- **OUTFIT=** data sets for storing fit indices and some pertinent modeling information
- **OUTMODEL=** data sets for storing model specifications and final estimates
- **OUTSTAT=** data sets for storing descriptive statistics, robust covariances and means, residuals, predicted moments, and latent variable scores regression coefficients
- **OUTWGT=** data sets for storing the weight matrices used in the modeling

The **OUTEST=**, **OUTMODEL=**, and **OUTWGT=** data sets can be used as input data sets for subsequent analyses. That is, in addition to the input data provided by the **DATA=** option, PROC CALIS supports the following input data sets for various purposes in the analysis:

- **INEST=** data sets for providing initial parameter estimates. An **INEST=** data set could be an **OUTEST=** data set created from a previous analysis.
- **INMODEL=** data sets for providing model specifications and initial estimates. An **INMODEL=** data set could be an **OUTMODEL=** data set created from a previous analysis.
- **INWGT=** data sets for providing the weight matrices. An **INWGT=** data set could be an **OUTWGT=** data set created from a previous analysis.

The CALIS procedure uses ODS Graphics to create graphs as part of its output. High-quality residual histograms are available in PROC CALIS. See Chapter 21, “Statistical Graphics Using ODS,” for general information about ODS Graphics. See the section “ODS Graphics” on page 1384 and the **PLOTS=** option on page 1112 for specific information about the statistical graphics available with the CALIS procedure.

Structural Equation Modeling Application

The Structural Equation Modeling Application is a graphical user interface to structural equation modeling techniques. You can specify models in graphical form to represent the hypothesized relationships among the variables. It is accessed from JMP software and uses the CALIS procedure for its computations.

The application enables you to define model variables in a path diagram by dragging data set variables to the diagram and to define the relationship between the model variables by using an arrow tool. You can move the variables to arrange the path diagram exactly the way you want. You can easily make a copy of a model, modify it, and analyze the new model, and you can compare several models with appropriate fit statistics. Finally, you can save the model specifications and the results for later use.

The Structural Equation Modeling Application provides access to a subset of the capabilities in the CALIS procedure. It supports mainly the PATH model specification through the path diagram interface. It does not support many other advanced features in PROC CALIS. For details, see *SAS Structural Equation Modeling for JMP*.

Changes and Enhancements

The following sections describe the new features of this version of PROC CALIS.

Case-Level Residual Diagnostics

Residual analysis at the case level or observation level is available when you provide raw data input. The main features include graphical and nongraphical residual diagnostic tools for identifying outliers and leverage observations, for detecting departures from the theoretical residual distribution, and for studying the distribution of residuals over the range of predicted values of the dependent observed variables. Use the **RESIDUAL** option to request nongraphical output for residual diagnostics. Use the **PLOTS=** option to request graphical plots for residual diagnostics. See the section “[Case-Level Residuals, Outliers, Leverage Observations, and Residual Diagnostics](#)” on page 1339 for details about these new features. See [Example 27.14](#) for an example that illustrates the use of the residual diagnostic tools provided by PROC CALIS.

Robust Estimation

Robust estimation is available with the **ROBUST** option. Robust estimation methods downweight the model outliers during the estimation process so that estimates are not contaminated by outliers. Two robust methods are implemented in PROC CALIS. The direct robust method applies individual (casewise) weights to observations during the model estimation. This is the default robust method that you get when you specify the **ROBUST** option. The two-stage robust method estimates robust covariance and mean matrices in the first stage, and then it does an ML estimation of the model by inputting the robust covariance and mean matrices in the second stage. You can specify this method with the **ROBUST=SAT** option. See the **ROBUST** option for details about variants of the robust methods. See the section “[Robust Estimation](#)” on page 1315 for technical details of the robust estimation implemented in PROC CALIS.

Inputting Customized Baseline Model Fit

A class of fit indices, called incremental fit indices (see the section “[Incremental Indices](#)” on page 1335 for details), measures model fit by comparing the relative fit of the target model to that of a baseline model. Traditionally, this baseline model is the uncorrelatedness model, where the covariances of observed variables are all zero. PROC CALIS follows this tradition and uses the uncorrelatedness model as the baseline model when computing the incremental fit indices. However, if you have a situation where the uncorrelatedness model is not desirable, you can now define and fit your own baseline model in a separate analysis. PROC CALIS provides tools for you to input the fit information of your customized baseline model. If you use PROC CALIS to fit your customized baseline model, you can save the fit information in an **OUTFIT=** data set and then specify the data set as a **BASEFIT=** data set when fitting your target model. PROC CALIS can extract the fit information of the customized baseline model for the computations of incremental fit indices (and a few other indices that assume the degrees of freedom of a baseline model). Alternatively, you can directly input the fit function value and the degrees of freedom of your customized baseline model by using the **BASEFUNC=** option. See the **BASEFIT=** and the **BASEFUNC=** options for details.

Compatibility with the CALIS Procedure in SAS/STAT 9.2 or Earlier

In addition to the many important feature enhancements of the CALIS procedure since SAS/STAT 9.22, there have also been some rudimentary changes in the procedure. To help users make a smoother transition from earlier versions (SAS/STAT 9.2 or earlier), this section describes some of the major changes of the CALIS procedure since SAS/STAT 9.22.

Changes in Default Analysis Type and Parameterization

Table 27.1 lists some important changes in the default analysis type and parameterization since SAS/STAT 9.22. Some items that did not change are also included to make the scope of the changes clear. Notice that the part of this table about default parameterization applies only to models that have functional relations between variables. This class of functional models includes the following types of models: FACTOR, LINEQS, LISMOD, PATH, and RAM, although LISMOD and PATH models did not exist prior to SAS/STAT 9.22. This table does not apply to the default parameterization of the COSAN and MSTRUCT models. For these models, see the descriptions in the **COSAN** and **MSTRUCT** statements, or see the sections “[The MSTRUCT Model](#)” on page 1285 and “[The COSAN Model](#)” on page 1259.

Table 27.1 Default Analysis Type and Parameterization

Default Setting	SAS/STAT 9.22 or Later	Prior to SAS/STAT 9.22
Analysis type	Covariance analysis	Correlation analysis
Variances of independent factors and errors	Free parameters	Zero variances
Variances of independent observed variables	Free parameters	Free parameters
Covariances between independent factors	Free parameters ¹	Fixed zeros
Covariances between error variables	Fixed zeros	Fixed zeros
Covariances between independent observed variables	Free parameters	Free parameters

1. The exploratory FACTOR model is an exception. Covariances between unrotated factors are set to zeros by default.

- Covariance structure analysis is the default analysis type in SAS/STAT 9.22 or later.

Covariance structure analysis has been the default since SAS/STAT 9.22. The statistical theory for structural equation modeling has been developed largely for covariance structures rather than correlation structures. Also, most practical structural equation models nowadays are concerned with covariance structures. Therefore, the default analysis type with covariance structure analysis is more reasonable. You must now use the **CORR** option for correlation structure analysis.

- Variances of any types of variables are free parameters by default in SAS/STAT 9.22 or later.

Variances of any types of variables are assumed to be free parameters in almost all applications for functional models. Prior to SAS/STAT 9.22, default variances of independent factors and errors were set to fixed zeros. This default has changed since SAS/STAT 9.22. Variances of any types of variables in functional models are now free parameters by default. This eliminates the need to specify these commonly assumed variance parameters.

- Covariances between all exogenous variables (factors or observed variables), except for error variables, are free parameters by default in functional models in SAS/STAT 9.22 or later.

Since SAS/STAT 9.22, covariances between all exogenous variables, except for error variables, are free parameters by default in functional models such as LINEQS, LISMOD, PATH, RAM, and confirmatory FACTOR models. In exploratory FACTOR models, covariances between unrotated factors are set to zeros by default. This change of default setting reflects the structural equation modeling practice much better. The default covariances between error variables, or between errors and other exogenous variables, are fixed at zero in all versions. Also, the default covariances between independent observed variables are free parameters in all versions.

Certainly, you can override all default parameters by specifying various statements in SAS/STAT 9.22 or later. You can use the **PVAR**, **RAM**, **VARIANCE**, or specific **MATRIX** statement to override default fixed or free variance parameters. You can use the **COV**, **PCOV**, **RAM**, or specific **MATRIX** statement to override default fixed or free covariance parameters.

Changes in the Role of the VAR Statement in Model Specification

Like many other SAS procedures, PROC CALIS enables you to use the **VAR** statement to define the set of observed variables in the data set for analysis. Unlike many other SAS procedures, PROC CALIS has other statements for more flexible model specifications. Because you can specify observed variables in these model specification statements and in the VAR statement with PROC CALIS, a question might arise when the set of observed variables specified in the VAR statement is not exactly the same as the set of observed variables specified in the model specification statements. Which set of observed variables does PROC CALIS use for analysis? The answer might depend on which version of PROC CALIS you use.

For observed variables that are specified in both the VAR statement and at least one of the model specification statements (such as the LINEQS, PATH, RAM, COV, PCOV, PVAR, STD, and VARIANCE statements), PROC CALIS recognizes the observed variables without any difficulty (that is, if they actually exist in the data set) no matter which SAS version you are using.

For observed variables that are specified only in the model specification statements and not in the VAR statement specifications (if the VAR statement is used at all), PROC CALIS does not recognize the observed variables as they are because the VAR statement has been used to preselect the legitimate set of observed variables to analyze. In most models, these observed variables are instead treated as latent variables. Again, this behavior is the same for all versions of PROC CALIS. If mistreating observed variables as latent variables is a major concern, a simple solution is not to use the VAR statement at all. This ensures that PROC CALIS uses all the observed variable as they are if they are specified in the model specification statements.

Finally, for observed variables that are specified only in the VAR statement and not in any of the model specification statements, the behavior depends on which SAS version you are using. Prior to SAS/STAT 9.22, PROC CALIS simply ignored these observed variables. For SAS/STAT 9.22 or later, PROC CALIS still includes these observed variables for analysis. In this case, PROC CALIS treats these “extra” variables as exogenous variables in the model so that some default parameterization applies. See the section “[Default Analysis Type and Default Parameterization](#)” on page 1257 for explanations of why this could be useful.

Changes in the LINEQS Model Specifications

Prior to SAS/STAT 9.22, LINEQS was the most popular modeling language supported by PROC CALIS. Since then, PROC CALIS has implemented a new syntax system that does not require the use of parameter names. Together with the change in default parameterization and some basic modeling methods, the specification of LINEQS models becomes much simpler and intuitive in SAS/STAT 9.22 or later. [Table 27.2](#) lists the major syntax changes in LINEQS model specifications, followed by some notes.

Table 27.2 Changes in the LINEQS Model Syntax

Syntax	SAS/STAT 9.22 or Later	Prior to SAS/STAT 9.22
Free parameter specifications	Parameter names optional	Parameter names required
Error terms in equations	Required	Not required
Mean structure analysis	With the MEANSTR option	With the UCOV and AUG options
Intercept parameter specifications	With the Intercept or Intercep variable	With the INTERCEP variable
Mean parameter specifications	With the MEAN statement specifications	As covariances between variables and the INTERCEP variable
Treatment of short parameter lists	Free parameters after the last parameter specification	Replicating the last parameter specification
Parameter-prefix notation	With two trailing underscores (__) as suffix	With the suffix ‘:’

The explanations of these changes are as follows:

- The use of parameter names for free parameters is optional in SAS/STAT 9.22 or later.

Prior to SAS/STAT 9.22, you must use parameter names to specify free parameters. In SAS/STAT 9.22 or later, the use of parameter names is optional. For example, prior to SAS/STAT 9.22, you might use the following LINEQS model specifications:

```

lineqs
  A = x1 * B + x2(.5) * C + E1;
std
  B = var_b, C = var_c(1.2);
cov
  B C = cov_b_c;

```

In SAS/STAT 9.22 or later, you can simply use the following:

```

lineqs
  A = * B + (.5) * C + E1;
variance
  B, C = (1.2);
cov
  B C;

```

This example shows that the parameter names `x1`, `x2`, `var_b`, `var_c`, and `cov_b_c` for free parameters are not necessary in SAS/STAT 9.22 or later. PROC CALIS generates names for these unnamed free parameters automatically. Also, you can specify initial estimates in parentheses without using parameter names. Certainly, you can still use parameter names wherever you want to, especially when you need to constrain parameters by referring to their names. Notice that the STD statement prior to SAS/STAT 9.22 has a more meaningful alias, `VARIANCE`, in SAS/STAT 9.22 or later.

- An error term is required in each equation in the `LINEQS` statement in SAS/STAT 9.22 or later.

Prior to SAS/STAT 9.22, you can set an equation in the `LINEQS` statement without providing an error term such as the following:

```

lineqs
  A = x1 * F1;

```

This means that `A` is perfectly predicted from `F1` without an error. In SAS/STAT 9.22 or later, you need to provide an error term in each equation, and the preceding specification is not syntactically valid. If a perfect relationship is indeed desirable, you can equivalently set the corresponding error variance to zero. For example, the following specification in SAS/STAT 9.22 or later achieves the purpose of specifying a perfect relationship between `A` and `F1`:

```

lineqs
  A = x1 * F1 + E1;
variance
  E1 = 0.;

```

In the `VARIANCE` statement, the error variance of `E1` is fixed at zero, resulting in a perfect relationship between `A` and `F1`.

- Mean structure analysis is invoked by the `MEANSTR` option in SAS/STAT 9.22 or later.

Prior to SAS/STAT 9.22, you use the `AUG` and `UCOV` options together in the PROC CALIS statement to invoke the analysis of mean structures. These two options became obsolete in SAS/STAT 9.22.

This change actually reflects more than a name change. Prior to SAS/STAT 9.22, mean structures are analyzed as augmented covariance structures in the uncorrected covariance matrix (hence the AUG and UCOV options). There are many problems with this “augmented” matrix approach. In SAS/STAT 9.22 or later, the augmented matrix was abandoned in favor of the direct parameterization approach for the mean structures. Now you must use the [MEANSTR](#) option in the PROC CALIS statement to invoke the analysis of mean structures. Alternatively, you can specify the intercepts directly in the [LINEQS](#) statement or specify the means directly in the [MEAN](#) statement. See the next two items for more information.

- Intercept parameters are set as the coefficient effects of the Intercept variable in SAS/STAT 9.22 or later.

Prior to SAS/STAT 9.22, you specify the intercept variable in the equations of the [LINEQS](#) statement by using the special “variable” named ‘INTERCEP’. For example, in the following specification, *a1* is the intercept parameter for the equation with dependent variable *A*:

```
proc calis ucov aug;
lineqs
  A = a1 * INTERCEP + b1 * B + E1;
```

In SAS/STAT 9.22 or later, although ‘INTERCEP’ is still accepted by PROC CALIS, a more meaningful alias ‘Intercept’ is also supported, as shown in the following:

```
proc calis;
lineqs
  A = a1 * Intercept + b1 * B + E1;
```

Intercept or INTERCEP can be typed in uppercase, lowercase, or mixed case in all versions. In addition, with the use of the Intercept variable in the [LINEQS](#) statement specification, mean structure analysis is automatically invoked for all parts of the model without the need to use the [MEANSTR](#) option in the PROC CALIS statement in SAS/STAT 9.22 or later.

- Mean parameters are specified directly in the [MEAN](#) statement in SAS/STAT 9.22 or later.

Prior to SAS/STAT 9.22, you need to specify mean parameters as covariances between the corresponding variables and the INTERCEP variable. For example, the following statements specify the mean parameters, *mean_b* and *mean_c*, of variables *B* and *C*, respectively:

```
proc calis ucov aug;
lineqs
  A = a1 * INTERCEP + b1 * B + b2 * C + E1;
cov
  B INTERCEP = mean_b (3),
  C INTERCEP = mean_c;
```

In SAS/STAT 9.22 or later, you can specify these mean parameters directly in the [MEAN](#) statement, as in the following example:

```

proc calis;
lineqs
  A = a1 * Intercept + b1 * B + b2 * C + E1;
mean
  B = mean_b (3),
  C = mean_c;

```

This way, the types of parameters that are being specified are clearer.

- Short parameter lists do not generate constrained parameters in SAS/STAT 9.22 or later.

Prior to SAS/STAT 9.22, if you provide a shorter parameter list than expected, the last parameter specified is replicated automatically. For example, the following specification results in replicating varx as the variance parameters for variables x2–x10:

```

std
  x1-x10 = var0 varx;

```

This means that all variances for the last nine variables in the list are constrained to be the same. In SAS/STAT 9.22 or later, this is not the case. That is, var0 and varx are the variance parameters for x1 and x2, respectively, while the variances for x3–x10 are treated as unconstrained free parameters.

If you want to constrain the remaining parameters to be the same in the current version of PROC CALIS, you can use the following continuation syntax [...] at the end of the parameter list:

```

std
  x1-x10 = var0 varx [...];

```

The continuation syntax [...] repeats the specification of varx for all the remaining variance parameters for x3–x10.

- The parameter-prefix uses a new notation in SAS/STAT 9.22 or later.

Prior to SAS/STAT 9.22, you can use the parameter-prefix to generate parameter names as in the following example:

```

lineqs
  A = x: * B + x: * C + E1;
std
  B = var:, C = var: ;

```

In SAS/STAT 9.22 or later, you must replace the ‘:’ notation with two trailing underscores, ‘__’, as in the following:

```

lineqs
  A = x__ * B + x__ * C + E1;
variance
  B = var__, C = var__;

```

Both versions generate parameter names by appending unique integers to the prefix, as if the following has been specified:

```

lineqs
  A = x1 * B + x2 * C + E1;
variance
  B = var1, C = var2;

```

In SAS/STAT 9.22 or later, you can even omit the parameter-prefix altogether. For example, you can specify the following with a null parameter-prefix:

```

lineqs
  A = __ * B + __ * C + E1;
variance
  B = __, C = __;

```

In this case, PROC CALIS uses the internal prefix ‘_Parm’ to generate names, as if the following has been specified:

```

lineqs
  A = _Parm1 * B + _Parm2 * C + E1;
variance
  B = _Parm3, C = _Parm4;

```

Compatibility with the TCALIS Procedure in SAS/STAT 9.2

Prior to the extensive changes and feature enhancements of the CALIS procedure in SAS/STAT 9.22, an experimental version of the CALIS procedure, called PROC TCALIS, was made available in SAS/STAT 9.2. In fact, the CALIS procedure in SAS/STAT 9.22 or later builds on the foundations of the TCALIS procedure. Although the experimental TCALIS procedure and the current CALIS procedure have some similar features, they also have some major differences. This section describes these major differences so that users who have experience in using the TCALIS procedure can adapt better to the current version of the CALIS procedure. In this section, whenever the CALIS procedure is mentioned without version reference, it is assumed to be the PROC CALIS version in SAS/STAT 9.22 or later.

Naming Parameters Is Optional in PROC CALIS

In essence, the CALIS procedure does not require the use of parameter names in specifications, whereas the TCALIS procedure (like the PROC CALIS versions prior to SAS/STAT 9.22) does require the use of parameter names. For example, in the TCALIS procedure you might specify the following LINEQS model:

```

proc tcalis;
  lineqs
    X1 = 1.          * F1 + E1,
    X2 = 12          * F1 + E2,
    X3 = 13 (.2) * F1 + E3;
  cov
    E1 E2 = cv12;
run;

```

Two parameters for factor loadings are used in the specification: *l1* and *l2*. The initial value of *l2* is set to 0.2. The covariance between the error terms *E1* and *E2* is named *cv12*. These parameters are not constrained, and therefore names for these parameters are not required in PROC CALIS, as shown in the following specifications:

```
proc calis;
  lineqs
    X1 = 1.      * F1 + E1,
    X2 =         * F1 + E2,
    X3 = (0.2) * F1 + E3;
  cov
    E1 E2;
run;
```

Parameter names for the two loadings in the second and the third equations are automatically generated by PROC CALIS. So is the error covariance parameter between *E1* and *E2*. Except for the names of these parameters, the preceding PROC TCALIS and PROC CALIS specifications generate the same model.

Names for parameters are only optional in PROC CALIS, but they are not prohibited. PROC CALIS enables you to specify models efficiently without the burden of having to create parameter names unnecessarily. But you can still use parameter names and the corresponding syntax in PROC CALIS wherever you want to, much as you do in PROC TCALIS.

Another example is the following PATH model specification in PROC TCALIS:

```
proc tcalis;
  path
    X1 <--- F1    1. ,
    X2 <--- F1    l2 ,
    X3 <--- F1    l3 (0.2);
  pcov
    X1 X2 = cv12;
run;
```

Again, naming the unconstrained parameters *l1*, *l2*, and *cv12* is not required with the CALIS procedure, as shown in the following specification:

```
proc calis;
  path
    X1 <--- F1    = 1. ,      /* path entry 1 */
    X2 <--- F1    ,          /* path entry 2 */
    X3 <--- F1    = (0.2);    /* path entry 3 */
  pcov
    X1 X2;
run;
```

Without any parameter specification (that is, neither a name nor a value), the second path entry specifies a free parameter for the path effect (or coefficient) of *F1* on *X2*. The corresponding parameter name for the effect is generated by PROC CALIS internally. In the third path entry, only an initial value is specified. Again, a parameter name is not necessary there. Similarly, PROC CALIS treats this as a free path effect parameter with a generated parameter name. Lastly, the error covariance between *X1* and *X2* is also a free parameter with a generated parameter name.

Although in PROC CALIS naming unconstrained free parameters in the PATH model is optional, PROC CALIS requires the use of equal signs before the specifications of parameters, fixed values, or initial values. The TCALIS procedure does not enforce this rule. Essentially, this stricter syntax rule in PROC CALIS makes the parameter specifications distinguishable from path specifications in path entries and therefore is necessary for the development of the multiple-path syntax, which is explained in the next section.

Changes in the PATH Statement Syntax

The PATH statement syntax was first available in the TCALIS procedure and was also a major addition to the CALIS procedure in SAS/STAT 9.22. This statement is essential to the PATH modeling language for specifying general structural equation models. Table 27.3 summarizes the major differences between the two versions.

Table 27.3 Changes in the PATH Statement Syntax

Syntax	PROC CALIS	PROC TCALIS
Naming unconstrained free parameters	Optional	Required
Equal signs before parameter specifications	Required	Not used
Treatment of unspecified path parameters	Free parameters	Fixed constants at 1
Multiple-path syntax	Supported	Not supported
Extended path syntax	Supported	Not supported

The following example shows how to specify a PATH model in PROC TCALIS:

```
proc tcalis;
  path
    F1 ---> X1      ,
    F1 ---> X2      a2 (.3) ,
    F1 ---> X3      a3      ,
    F2 ---> X4      1.      ,
    F2 ---> X5      a5      ,
    F2 ---> X6      a6      ;
  pvar
    F1 F2 = fvar1 fvar2,
    X1-X6 = evar1-evar6;
  pcov
    F1 F2 = covF1F2;

run;
```

The following statements show to specify the preceding PATH model in PROC CALIS equivalently:

```
proc calis;
  path
    F1 ---> X1      = 1.      ,      /* path entry 1 */
    F1 ---> X2      = (.3)    ,      /* path entry 2 */
    F1 ---> X3      ,          /* path entry 3 */
    F2 ---> X4-X6 = 1. a5 a6 ,      /* path entry 4 */
    F1 <--> F1      ,          /* path entry 5 */
    F2 <--> F2      ,          /* path entry 6 */
    F1 <--> F2      = covF1F2 ,      /* path entry 7 */
    <--> X1-X6      = evar1-evar6; /* path entry 8 */

run;
```

The differences in specifications between the two versions are as follows:

- In PROC CALIS, naming unconstrained free parameters in the PATH statement is optional.

For example, in the PROC TCALIS specification, the parameter names `a2` and `a3` have been used for path entries 2 and 3, respectively. They can be omitted with the PROC CALIS specification.

- In PROC CALIS, you must use equal signs before parameter specifications in all path entries.

For example, equal signs are necessary in path entries 1, 2, 4, 7, and 8 to separate the parameter specifications from the path specifications. However, because equal signs are not part of the syntax in PROC TCALIS, the TCALIS procedure cannot distinguish parameter specifications from path specifications in path entries. Consequently, PROC TCALIS is incapable of handling multiple-path syntax such as path entry 4 and extended path syntax such as path entry 8.

- In PROC CALIS, unspecified parameters are treated as free parameters.

For example, path entries 3, 5, and 6 are free parameters for the path effect of `F1` on `X3`, the variance of `F1`, and the variance of `F2`, respectively. In contrast, these unspecified parameters are treated as fixed constants 1 in PROC TCALIS. That is also why path entry 1 must specify a fixed value of 1 explicitly with the PROC CALIS specification. Otherwise, PROC CALIS treats it as a free parameter for the path effect.

- In PROC CALIS, you can use the multiple-path syntax.

For example, path entry 4 specifies three different paths from `F2` in a single entry. The parameter specifications after the equal sign are distributed to the multiple paths specified in order (that is, to `X4`, `X5`, and `X6`, respectively). However, in PROC TCALIS you must specify these paths separately in three path entries.

- In PROC CALIS, you can use the extended path syntax to specify all kinds of parameters in the PATH statement.

For example, path entries 5 and 6 specify the variance parameters for `F1` and `F2`, respectively. Because these variances are unconstrained free parameters, you do not need to use parameter names (but you can use them if you want). In PROC TCALIS, however, you must specify these variance parameters in the PVAR statement. Path entries 7 and 8 in the PROC CALIS specification provide other examples of the extended path syntax available only in PROC CALIS. Path entry 7 specifies the covariance parameter between `F1` and `F2` as `CovF1F2` (although the name for this free parameter could have been omitted). You must specify this covariance parameter in the PCOV statement if you use PROC TCALIS. Path entry 8 specifies the error variances for `X1`–`X6` as `evar1`–`evar6`, respectively. You must specify these error variance parameters in the PVAR statement if you use PROC TCALIS. Essentially, in PROC CALIS you can specify all types of parameters in the PATH model as path entries in the PATH statement. See the [PATH](#) statement for details about the extended path syntax.

Changes in the Automatic Free Parameters in Functional Models

The CALIS and the TCALIS procedures differ in their treatment of automatic free parameters in functional models. Functional models refer to those models that can (but do not necessarily have to) analyze predictor-outcome or exogenous-endogenous relationships. In general, models that use the following statements are functional models: FACTOR, LINEQS, LISMOD, PATH, and RAM. Automatic free parameters in these functional models are those parameters that are free to estimate by default even if you do not specify them explicitly in the syntax. Table 27.4 indicates which types of parameters are automatic free parameters in PROC CALIS and PROC TCALIS.

Table 27.4 Automatic Free Parameters in PROC CALIS and PROC TCALIS

Automatic Free Parameters	PROC CALIS	PROC TCALIS
Variances		
Exogenous observed variables	Yes	Yes
Exogenous latent factors	Yes	Yes
Error variables	Yes	Yes
Covariances		
Between exogenous observed variables	Yes	Yes
Between exogenous latent factors	Yes ¹	No
Between exogenous observed variables and exogenous latent factors	Yes	No
Between error variables	No	No
Means		
Exogenous observed variables	Yes	Yes
Exogenous latent factors	No	No
Intercepts		
Endogenous observed variables	Yes	No
Endogenous latent factors	No	No

1. This does not apply to exploratory FACTOR models, where covariances between latent factors in the unrotated factor solution are fixed zeros.

Regarding the treatment of automatic free parameters, this table shows that unlike the CALIS procedure, PROC TCALIS does not set default free parameters in (1) the covariances between exogenous latent factors themselves and between any pairs of exogenous latent factors and observed variables, and (2) the intercepts for the endogenous observed variables.

You can compare these two schemes of setting automatic free parameters in the following three scenarios.

First, when no functional relationships are specified in the model (and hence no latent factors and no intercept parameters), the treatment of automatic free parameters by either PROC CALIS or PROC TCALIS leads to just-identified or saturated covariance and mean structures, which is certainly a reasonable “baseline” parameterization that saturates the relationships among observed variables.

Second, when there are functional relationships between observed variables in the model and no latent factors are involved, the treatment by PROC CALIS is more reasonable because it leads to a parameterization similar to that of linear regression models. That is, PROC CALIS sets the intercepts to free parameters. However, the treatment by PROC TCALIS would lead to restrictive linear regression models with zero intercepts.

Finally, when latent factors are involved, the treatment by PROC CALIS is more “natural” in the sense that the covariances among all exogenous variables are saturated in the model, rather than being restricted to zeros for the parts pertaining to latent factors, as in PROC TCALIS. Saturating the covariances between latent factors is seen to be more natural because all variables in empirical research are usually believed to be correlated, no matter how small the correlation.

Therefore, in general the PROC CALIS treatment of automatic free parameters is recommended. The treatment by PROC TCALIS might be more compatible to models that assume independent or uncorrelated latent factors such as the unrotated exploratory factor model. In this situation, to use PROC CALIS you must use the [PATH](#), [PVAR](#), [RAM](#), [VARIANCE](#), or specific [MATRIX](#) statements to set the covariances between factors to fixed zeros.

A Guide to the PROC CALIS Documentation

The CALIS procedure uses a variety of modeling languages to fit structural equation models. This chapter provides documentation for all of them. Additionally, some sections provide introductions to the model specification, the theory behind the software, and other technical details. While some introductory material and examples are provided, this chapter is not a textbook for structural equation modeling and related topics. For didactic treatment of structural equation models with latent variables, see Bollen (1989b) and Loehlin (2004).

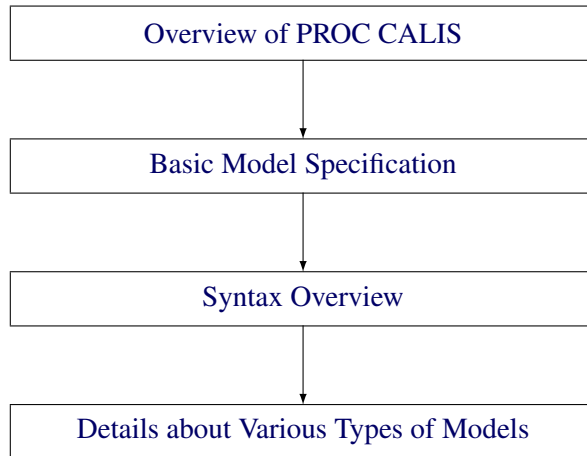

Reading this chapter sequentially is not a good strategy for learning about PROC CALIS. This section provides a guide or “road map” to the rest of the PROC CALIS chapter, starting with the basics and continuing through more advanced topics. Many sections assume that you already have a basic understanding of structural equation modeling.

The following table shows three different skill levels of using the CALIS procedure ([basic](#), [intermediate](#), and [advanced](#)) and their milestones.

Level	Milestone	Starting Section
Basic	You are able to specify simple models, but might make mistakes.	“Guide to the Basic Skill Level” on page 1057
Intermediate	You are able to specify more sophisticated models with few syntactic and semantic mistakes.	“Guide to the Intermediate Skill Level” on page 1062
Advanced	You are able to use the advanced options provided by PROC CALIS.	“Guide to the Advanced Skill Level” on page 1063

In the next three sections, each skill level is discussed, followed by an introductory section of the reference topics that are not covered in any of the skill levels.

Guide to the Basic Skill Level

Overview of PROC CALIS

The section “[Overview: CALIS Procedure](#)” on page 1040 gives you an overall picture of the CALIS procedure but without the details.

Basic Model Specification

The [structural equation example](#) in the section “[Getting Started: CALIS Procedure](#)” on page 1067 provides the starting point to learn the basic model specification. You learn how to represent your theory by using a path diagram and then translate the diagram into the [PATH model](#) for PROC CALIS to analyze. Because the PATH modeling language is new, this example is useful whether or not you have previous experience with PROC CALIS. The PATH model is specified in the section “[PATH Model](#)” on page 1068. The corresponding results are shown and discussed in [Example 27.17](#).

After you learn about the PATH modeling language and an example of its application, you can do either of the following:

- You can continue to learn more modeling languages in the section “[Getting Started: CALIS Procedure](#)” on page 1067.
- You can skip to the section “[Syntax Overview](#)” on page 1061 for an overview of the PROC CALIS syntax and learn other modeling languages at a later time.

You do not need to learn all of the modeling languages in PROC CALIS. Any one of the modeling languages (LINEQS, LISMOD, PATH, or RAM) is sufficient for specifying a very wide class of structural equation models. PROC CALIS provides different kinds of modeling languages because different researchers might have previously learned different modeling languages or approaches. To get a general idea about different kinds of modeling languages, the following subsections in the “[Getting Started: CALIS Procedure](#)” section are useful:

- LINEQS: Section “[LINEQS Model](#)” on page 1071
- RAM: Section “[RAM Model](#)” on page 1070

- LISMOD: Section “[LISMOD Model](#)” on page 1072
- FACTOR: Section “[A Factor Model Example](#)” on page 1073
- MSTRUCT: Section “[Direct Covariance Structures Analysis](#)” on page 1075

After studying the examples in the “[Getting Started: CALIS Procedure](#)” section, you can strengthen your understanding of the various modeling languages by studying more examples such as those in section “[Examples: CALIS Procedure](#)” on page 1385. Unlike the examples in the “[Getting Started: CALIS Procedure](#)” section, the examples in the “[Examples: CALIS Procedure](#)” section include the analysis results in addition to the explanations of the model specifications.

You can start with the following two sets of basic examples:

- MSTRUCT model examples
The basic MSTRUCT model examples demonstrate the testing of covariance structures directly on the covariance matrices. Although the MSTRUCT model is not the most common structural equation models in applications, these MSTRUCT examples can help you understand the basic form of covariance structures and the corresponding specifications in PROC CALIS.
- PATH model examples
The basic PATH model examples demonstrate how you can represent your model by path diagrams and by the PATH modeling language. These examples show the most common applications of structural equation modeling.

The following is a summary of the basic MSTRUCT model examples:

- “[Example 27.1: Estimating Covariances and Correlations](#)” on page 1385 shows how you can estimate the covariances and correlations with standard error estimates for the variables in your model. The model you fit is a saturated covariance structure model.
- “[Example 27.2: Estimating Covariances and Means Simultaneously](#)” on page 1390 extends [Example 27.1](#) to include the mean structures in the model. The model you fit is a saturated mean and covariance structure model.
- “[Example 27.3: Testing Uncorrelatedness of Variables](#)” on page 1392 shows a very basic covariance structure model, in which the covariance structures can be specified directly. The variables in this model are uncorrelated. You learn how to specify the covariance pattern directly.
- “[Example 27.4: Testing Covariance Patterns](#)” on page 1395 extends [Example 27.3](#) to include other covariance structures that you can specify directly.
- “[Example 27.5: Testing Some Standard Covariance Pattern Hypotheses](#)” on page 1397 illustrates the use of built-in covariance patterns supported by PROC CALIS.

The following is a summary of the basic PATH model examples:

- “[Example 27.6: Linear Regression Model](#)” on page 1401 shows how you can fit a linear regression model with the PATH modeling language of PROC CALIS. This example also introduces the path diagram representation of “causal” models. You compare results obtained from PROC CALIS and from the REG procedure, which is designed specifically for regression analysis.

- “[Example 27.7: Multivariate Regression Models](#)” on page 1406 extends [Example 27.6](#) in several different ways. You fit covariance structure models with more than one predictor, with direct and indirect effects. This example also discusses how you can choose the “best” model for your data.
- “[Example 27.8: Measurement Error Models](#)” on page 1424 explores the case where the predictor in simple linear regression is measured with error. The concept of latent true score variable is introduced. You use PROC CALIS to fit a simple measurement error model.
- “[Example 27.9: Testing Specific Measurement Error Models](#)” on page 1430 extends [Example 27.8](#) to test special measurement error models with constraints. By using PROC CALIS, you can constrain your measurement error models in many different ways. For example, you can constrain the error variances or the intercepts to test specific hypotheses.
- “[Example 27.10: Measurement Error Models with Multiple Predictors](#)” on page 1437 extends [Example 27.8](#) to include more predictors in the measurement error models. The measurement errors in the predictors can be correlated in the model.

More elaborate examples about the MSTRUCT and PATH models are listed as follows:

- “[Example 27.17: Path Analysis: Stability of Alienation](#)” on page 1499 shows you how to specify a simple PATH model and interpret the basic estimation results. The results are shown in considerable detail. The output and analyses include: a model summary, an initial model specification, an initial estimation method, an optimization history and results, residual analyses, residual graphics, estimation results, squared multiple correlations, and standardized results.
- “[Example 27.19: Fitting Direct Covariance Structures](#)” on page 1521 shows you how to fit your covariance structures directly on the covariance matrix by using the MSTRUCT modeling language. You also learn how to use the [FITINDEX](#) statement to create a customized model fit summary and how to save the fit summary statistics into an external file.
- “[Example 27.21: Testing Equality of Two Covariance Matrices Using a Multiple-Group Analysis](#)” on page 1537 uses the MSTRUCT modeling language to illustrate a simple multiple-group analysis. You also learn how to use the ODS SELECT statement to customize your printed output.
- “[Example 27.22: Testing Equality of Covariance and Mean Matrices between Independent Groups](#)” on page 1542 uses the [COVPATTERN=](#) and [MEANPATTERN=](#) options to show some tests of equality of covariance and mean matrices between independent groups. It also illustrates how you can improve your model fit by the exploratory use of the Lagrange multiplier statistics for releasing equality constraints.
- “[Example 27.24: Testing Competing Path Models for the Career Aspiration Data](#)” on page 1576 illustrates how you can fit competing models by using the [OUTMODEL=](#) and [INMODEL=](#) data sets for transferring and modifying model information from one analysis to another. This example also demonstrates how you can choose the best model among several competing models for the same data.

After studying the PATH and MSTRUCT modeling languages, you are able to specify most commonly used structural equation models by using PROC CALIS. To broaden your scope of structural equation modeling, you can study some basic examples that use the FACTOR and LINEQS modeling languages. These basic examples are listed as follows:

- “[Example 27.11: Measurement Error Models Specified As Linear Equations](#)” on page 1442 explores another way to specify measurement error models in PROC CALIS. The LINEQS modeling language is introduced. You learn how to specify linear equations of the measurement error model by using the LINEQS statement. Unlike the PATH modeling language, in the LINEQS modeling language, you need to specify the error terms explicitly in the model specification.
- “[Example 27.12: Confirmatory Factor Models](#)” on page 1448 introduces a basic confirmatory factor model for test items. You use the FACTOR modeling language to specify the factor-variable relationships.
- “[Example 27.13: Confirmatory Factor Models: Some Variations](#)” on page 1459 extends [Example 27.12](#) to include some variants of the confirmatory factor model. With the flexibility of the FACTOR modeling language, this example shows how you fit models with parallel items, tau-equivalent items, or partially parallel items.

More advanced examples that use the PATH, LINEQS, and FACTOR modeling languages are listed as follows:

- “[Example 27.14: Residual Diagnostics and Robust Estimation](#)” on page 1469 illustrates the use of several graphical residual plots to detect model outliers and leverage observations, to study the departures from the theoretical case-level residual distribution, and to examine the linearity and homoscedasticity of variance. In addition, this example illustrates the use of robust estimation technique to downweight the outliers and to estimate the model parameters.
- “[Example 27.15: The Full Information Maximum Likelihood Method](#)” on page 1483 shows how you can use the full information maximum likelihood (FIML) method to estimate your model when your data contain missing values. It illustrates the analysis of the data coverage of the sample variances, covariances, and means and the analysis of missing patterns and the mean profile. It also shows that the full information maximum likelihood method makes the maximum use of the available information from the data, as compared with the default ML (maximum likelihood) methods.
- “[Example 27.16: Comparing the ML and FIML Estimation](#)” on page 1493 discusses the similarities and differences between the ML and FIML estimation methods as implemented in PROC CALIS. It uses an empirical example to show how ML and FIML obtain the same estimation results when the data do not contain missing values.
- “[Example 27.18: Simultaneous Equations with Mean Structures and Reciprocal Paths](#)” on page 1514 is an econometric example that shows you how to specify models using the LINEQS modeling language. This example also illustrates the specification of reciprocal effects, the simultaneous analysis of the mean and covariance structures, the setting of bounds for parameters, and the definitions of metaparameters by using the [PARAMETERS](#) statement and [SAS programming statements](#). You also learn how to shorten your output results by using some [global display options](#) such as the [PSHORT](#) and [NOSTAND](#) options in the PROC CALIS statement.
- “[Example 27.20: Confirmatory Factor Analysis: Cognitive Abilities](#)” on page 1524 uses the FACTOR modeling language to illustrate confirmatory factor analysis. In addition, you use the [MODIFICATION](#) option in the PROC CALIS statement to compute LM test indices for model modifications.
- “[Example 27.25: Fitting a Latent Growth Curve Model](#)” on page 1591 is an advanced example that illustrates the use of structural equation modeling techniques for fitting latent growth curve models.

You learn how to specify random intercepts and random slopes by using the LINEQS modeling language. In addition to the modeling of the covariance structures, you also learn how to specify the mean structure parameters.

If you are familiar with the traditional Keesling-Wiley-Jöreskog measurement and structural models (Keesling 1972; Wiley 1973; Jöreskog 1973) or the RAM model (McArdle 1980), you can use the LISMOD or RAM modeling languages to specify structural equation models. The following example shows how to specify these types of models:

- “[Example 27.23: Illustrating Various General Modeling Languages](#)” on page 1567 extends [Example 27.17](#), which uses the PATH modeling language, and shows how to use the other general modeling languages: RAM, LINEQS, and LISMOD. These modeling languages enable you to specify the same path model as in [Example 27.17](#) and get equivalent results. This example shows the connections between the general modeling languages supported in PROC CALIS. A good understanding of [Example 27.17](#) is a prerequisite for this example.

Once you are familiar with various modeling languages, you might wonder which modeling language should be used in a given situation. The section “[Which Modeling Language?](#)” on page 1077 provides some guidelines and suggestions.

Syntax Overview

The section “[Syntax: CALIS Procedure](#)” on page 1078 shows the syntactic structure of PROC CALIS. However, reading the “[Syntax: CALIS Procedure](#)” section sequentially might not be a good strategy. The statements used in PROC CALIS are classified in the section “[Classes of Statements in PROC CALIS](#)” on page 1079. Understanding this section is a prerequisite for understanding single-group and multiple-group analyses in PROC CALIS. Syntax for single-group analyses is described in the section “[Single-Group Analysis Syntax](#)” on page 1082, and syntax for multiple-group analyses is described in the section “[Multiple-Group Multiple-Model Analysis Syntax](#)” on page 1082.

You might also want to get an overview of the options in the **PROC CALIS** statement. However, you can skip the [detailed listing](#) of the available options in the PROC CALIS statement. Most of these details serve as references, so you can consult them only when you need to. You can just read the summary tables for the available options in the PROC CALIS statement in the following subsections:

- “[Data Set Options](#)” on page 1083
- “[Model and Estimation Options](#)” on page 1084
- “[Options for Fit Statistics](#)” on page 1084
- “[Options for Statistical Analysis](#)” on page 1085
- “[Global Display Options](#)” on page 1085
- “[Optimization Options](#)” on page 1087

Details about Various Types of Models

Several subsections in the section “[Details: CALIS Procedure](#)” on page 1236 can help you gain a deeper understanding of the various types of modeling languages, as shown in the following table:

Language	Section
COSAN	“ The COSAN Model ” on page 1259
FACTOR	“ The FACTOR Model ” on page 1263
LINEQS	“ The LINEQS Model ” on page 1270
LISMOD	“ The LISMOD Model and Submodels ” on page 1277
MSTRUCT	“ The MSTRUCT Model ” on page 1285
PATH	“ The PATH Model ” on page 1288
RAM	“ The RAM Model ” on page 1294

The specification techniques you learn from the examples cover only parts of the modeling language. A more complete treatment of the modeling languages is covered in these subsections. In addition, you can also learn the mathematical models, model restrictions, and default parameterization of all supported modeling languages in these subsections. To get an overall idea about the default parameterization rules used in PROC CALIS, the section “[Default Analysis Type and Default Parameterization](#)” on page 1257 would be very useful. Understanding how PROC CALIS set default parameters would help you specify your models more efficiently and accurately.

Guide to the Intermediate Skill Level

At the intermediate level, you learn to minimize your mistakes in model specification and to establish more sophisticated modeling techniques. The following topics in the “[Details: CALIS Procedure](#)” section or elsewhere can help:

- The section “[Naming Variables and Parameters](#)” on page 1302 summarizes the naming rules and conventions for variable and parameter names in specifying models.
- The section “[Setting Constraints on Parameters](#)” on page 1303 covers various techniques of constraining parameters in model specifications.
- The section “[Automatic Variable Selection](#)” on page 1308 discusses how PROC CALIS treats variables in the models and variables in the data sets. It also discusses situations where the `VAR` statement specification is deemed necessary.
- The section “[Computational Problems](#)” on page 1360 discusses computational problems that occur quite commonly in structural equation modeling. It also discusses some possible remedies of the computational problem.
- The section “[Missing Values and the Analysis of Missing Patterns](#)” on page 1348 describes the default treatment of missing values.
- The statements `REFMODEL` on page 1223 and `RENAMEPARM` on page 1225 are useful when you need to make references to well-defined models when specifying a “new” model. See [Example 27.28](#) for an application.

Revisit topics and examples covered at the [basic](#) level, as needed, to help you better understand the topics at the intermediate level.

You can also study the following more advanced examples:

- “[Example 27.26: Higher-Order and Hierarchical Factor Models](#)” on page 1597 is an advanced example for confirmatory factor analysis. It involves the specifications of higher-order and hierarchical factor models. Because higher-order factor models cannot be specified by the FACTOR modeling language, you need to use the LINEQS model specification instead. A second-order factor model and a bifactor model are fit. Linear constraints on parameters are illustrated by using the [PARAMETERS](#) statement and [SAS programming statements](#). Relationships between the second-order factor model and the bifactor model are numerically illustrated.
- “[Example 27.27: Linear Relations among Factor Loadings](#)” on page 1613 is an advanced example of a first-order confirmatory factor analysis that uses the FACTOR modeling language. In this example, you learn how to use the [PARAMETERS](#) statement and [SAS programming statements](#) to set up dependent parameters in your model. You also learn how to specify the correlation structures for a specific confirmatory factor model.
- “[Example 27.28: Multiple-Group Model for Purchasing Behavior](#)” on page 1622 is a sophisticated example of analyzing a path model. The PATH modeling language is used. In this example, a two-group analysis of mean and covariance structures is conducted. You learn how to use the [REFMODEL](#) statement to reference properly defined models and the [SIMTESTS](#) statement to test a priori simultaneous hypotheses.
- “[Example 27.29: Fitting the RAM and EQS Models by the COSAN Modeling Language](#)” on page 1648 introduces the COSAN modeling language by connecting it with general RAM and EQS models. The model matrices of the RAM or EQS model are described. You specify these model matrices and the associated parameters in the COSAN modeling language.
- “[Example 27.30: Second-Order Confirmatory Factor Analysis](#)” on page 1681 constructs the covariance structure model of the second-order confirmatory factor model. You define the model matrices by using the COSAN modeling language.
- “[Example 27.31: Linear Relations among Factor Loadings: COSAN Model Specification](#)” on page 1689 shows how you can set linear constraints among model parameters under the COSAN model.
- “[Example 27.32: Ordinal Relations among Factor Loadings](#)” on page 1695 shows how you can set ordinal constraints among model parameters under the COSAN model.
- “[Example 27.33: Longitudinal Factor Analysis](#)” on page 1699 defines the covariance structures of a longitudinal factor model and shows how you can specify the covariance structure model with the COSAN modeling language.

Guide to the Advanced Skill Level

At the advanced level, you learn to use the advanced data analysis and output control tools supported by PROC CALIS.

Advanced Data Analysis Tools

The following advanced data analysis topics are discussed:

- Assessment of fit

The section “[Assessment of Fit](#)” on page 1326 presents the fit indices used in PROC CALIS. However, the more important topics covered in this section are about how model fit indices are organized and used, how residuals can be used to gauge the fitting of individual parts of the model, and how the coefficients of determination are defined for equations.

To customize your fit summary table, you can use the options on the [FITINDEX](#) statement.

- Case-level residual diagnostics

The section “[Case-Level Residuals, Outliers, Leverage Observations, and Residual Diagnostics](#)” on page 1339 describes details about how the residual diagnostics at the individual data level are accomplished in general structural equation modeling, and how they lead to the graphical techniques for detecting outliers and leverage observations, studying residual distributions, and examining linear relationships and heteroscedasticity of error variances.

- Effect partitioning

The section “[Total, Direct, and Indirect Effects](#)” on page 1343 discusses the total, direct, and indirect effects and their computations. The stability coefficient of reciprocal causation is also defined.

To customize the effect analysis, you can use the [EFFPART](#) statement.

- Counting and adjusting degrees of freedom

The section “[Counting the Degrees of Freedom](#)” on page 1323 describes how PROC CALIS computes model fit degrees of freedom and how you can use some options on the PROC CALIS statement to make degrees-of-freedom adjustments.

To adjust the model fit degrees of freedom, you can use the [DFREDUCE=](#) and [NOADJDF](#) options in the PROC CALIS statement.

- Standardized solutions

Standardization schemes used in PROC CALIS are described and discussed in the section “[Standardized Solutions](#)” on page 1345.

Standardized solutions are displayed by default. You can turn them off by using the [NOSTAND](#) option of the PROC CALIS statement.

- Model modifications

In the section “[Modification Indices](#)” on page 1346, modification indices such as Lagrange multiplier test indices and Wald statistics are defined and discussed. These indices can be used either to enhance your model fit or to make your model more precise.

To limit the modification process only to those parameters of interest, you can use the [LMTESTS](#) statement to customize the sets of LM tests conducted on potential parameters.

- A Priori Parametric Function Testing

You can use the [TESTFUNC](#) statement to test a priori hypotheses individually. You can use the [SIMTESTS](#) statement to test a priori hypotheses simultaneously.

Advanced Output Control Tools

To be more effective in presenting your analysis results, you need to be more sophisticated in controlling your output. Some customization tools have been discussed in the previous section “[Advanced Data Analysis Tools](#)” on page 1064 and might have been mentioned in the examples included in the [basic](#) and the [intermediate](#) levels. In the following topics, these output control tools are presented in a more organized way so that you can have a systematic study scheme of these tools.

- Global output control tools in PROC CALIS

You can control output displays in PROC CALIS either by the [global display options](#) or by the individual output printing options. Each global display option typically controls more than one output display, while each individual output display controls only one output display. The global display options can both enable and suppress output displays, and they can also alter the format of the output.

See the [ALL](#), [PRINT](#), [PSHORT](#), [PSUMMARY](#), and [NOPRINT](#) options for ways to control the appearances of the output. See the section “[Global Display Options](#)” on page 1085 for details about the global display options and their relationships with the individual output display options. Also see the [ORDERALL](#), [ORDERGROUPS](#), [ORDERMODELS](#), [ORDERSPEC](#), [PARMNAME](#), [PRIMAT](#), [NOORDERSPEC](#), [NOPARMNAME](#), [NOSTAND](#), and [NOSE](#) options which control the output formats.

- Customized analysis tools in PROC CALIS

Many individual output displays in PROC CALIS can be customized via specific options or statements. If you do not use these customization tools, the default output will usually contain a large number of displays or displays with very large dimensions. These customized analysis tools are as follows:

- The [ON=](#), [OFF=](#), [ON\(ONLY\)=](#) options in the [FITINDEX](#) statement enable you to select individual or groups of model fit indices or modeling information to display. You can still save the information of *all* fit indices in an external file by using the [OUTFIT=](#) option.
- The [EFFPART](#) statement enables you to customize the effect analysis. You display only those effects of substantive interest.
- The [LMTTESTS](#) statement enables you to customize the sets of LM tests of interest. You test only those potential parameters that are theoretically and substantively possible.

- Output selection and destinations by the ODS system

This kind of output control is used not only for PROC CALIS, but is used for all procedures that support the ODS system. The most common uses include output selection and output destinations assignment. You use the ODS SELECT statement together with the ODS table names or graph names to select particular output displays. See the section “[ODS Table Names](#)” on page 1368 for these names in PROC CALIS.

The default output destination of PROC CALIS is the listing destination. You can add or change the destinations by using statements such as `ods html` (for html output), `ods rtf` (for rich text output), and so on. For details, see Chapter 20, “[Using the Output Delivery System](#).”

Reference Topics

Some topics in the “[Details: CALIS Procedure](#)” section are intended primarily for references—you consult them only when you encounter specific problems in the PROC CALIS modeling or when you need to know the very fine technical details in certain special situations. Many of these reference topics in the “[Details: CALIS Procedure](#)” section are not required for practical applications of structural equation modeling. The following technical topics are discussed:

- Measures of multivariate kurtosis and skewness

This is covered in the section “[Measures of Multivariate Kurtosis](#)” on page 1349.

- Estimation criteria and the mathematical functions for estimation

The section “[Estimation Criteria](#)” on page 1309 presents formulas for various estimation criteria. The relationships among these criteria are shown in the section “[Relationships among Estimation Criteria](#)” on page 1318. To optimize an estimation criterion, you usually need its gradient and Hessian functions. These functions are detailed in the section “[Gradient, Hessian, Information Matrix, and Approximate Standard Errors](#)” on page 1321, where you can also find information about the computation of the standard error estimates in PROC CALIS. Unlike other estimation methods, the robust estimation methods do not optimize a discrepancy function themselves. The robust estimation methods that are implemented in PROC CALIS use the iteratively reweighted least squares (IRLS) method to obtain parameter convergence. The robust estimation technique is detailed in the section “[Robust Estimation](#)” on page 1315.

- Initial estimation

Initial estimates are necessary for all kinds of iterative optimization techniques. They are described in section “[Initial Estimates](#)” on page 1351.

- Use of optimization techniques

Optimization techniques are covered in section “[Use of Optimization Techniques](#)” on page 1352. See this section if you need to fine-tune the optimization.

- Output displays and control

The output displays in PROC CALIS are listed in the section “[Displayed Output](#)” on page 1363. General requirements for the displays are also shown.

With the ODS system, each table and graph has a name, which can be used on the ODS OUTPUT or ODS SELECT statement. See the section “[ODS Table Names](#)” on page 1368 for the ODS table and graph names.

- Input and output files

PROC CALIS supports several input and output data files for data, model information, weight matrices, estimates, fit indices, and estimation and descriptive statistics. The uses and the structures of these input and output data files are described in the sections “[Input Data Sets](#)” on page 1236 and “[Output Data Sets](#)” on page 1240.

Getting Started: CALIS Procedure

A Structural Equation Example

This example from Wheaton et al. (1977) illustrates the basic uses of the CALIS procedure and the relationships among the LINEQS, LISMOD, PATH, and RAM modeling languages. Different structural models for these data are analyzed in Jöreskog and Sörbom (1985) and in (Bentler 1995, p. 28). The data contain the following six (manifest) variables collected from 932 people in rural regions of Illinois:

Anomie67:	Anomie 1967
Powerless67:	Powerlessness 1967
Anomie71:	Anomie 1971
Powerless71:	Powerlessness 1971
Education:	Education level (years of schooling)
SEI:	Duncan’s socioeconomic index (SEI)

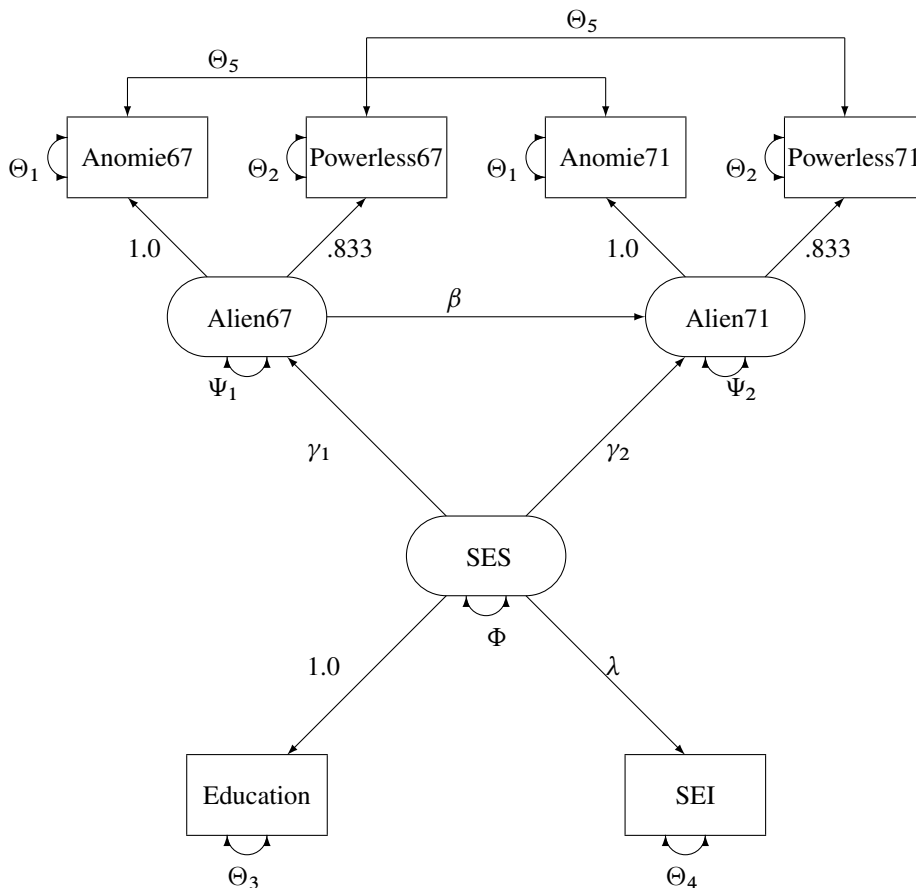

The covariance matrix of these six variables is stored in the data set named *Wheaton*.

It is assumed that anomie and powerlessness are indicators of an alienation factor and that education and SEI are indicators for a socioeconomic status (SES) factor. Hence, the analysis contains three latent variables (factors):

Alien67:	Alienation 1967
Alien71:	Alienation 1971
SES:	Socioeconomic status (SES)

The following path diagram shows the structural model used in Bentler (1985, p. 29) and slightly modified in Jöreskog and Sörbom (1985, p. 56):

Figure 27.1 Path Diagram of Stability and Alienation Example

In the path diagram shown in Figure 27.1, regressions of variables are represented by one-headed arrows. Regression coefficients are indicated along these one-headed arrows. Variances and covariances among the variables are represented by two-headed arrows. Error variances and covariances are also represented by two-headed arrows. This scheme of representing paths, variances and covariances, and error variances and covariances (McArdle 1988; McDonald 1985) is helpful in translating the path diagram to the PATH or RAM model input in the CALIS procedure.

PATH Model

Specification by using the PATH modeling language is direct and intuitive in PROC CALIS once a path diagram is drawn. The following statements specify the path diagram almost intuitively:

```
proc calis nobs=932 data=Wheaton;
  path
    Anomie67    <=== Alien67    = 1.0,
    Powerless67 <=== Alien67    = 0.833,
```

```

    Anomie71      <=== Alien71      = 1.0,
    Powerless71   <=== Alien71      = 0.833,
    Education     <=== SES           = 1.0,
    SEI           <=== SES           = lambda,
    Alien67       <=== SES           = gamma1,
    Alien71       <=== SES           = gamma2,
    Alien71       <=== Alien67      = beta;
pvar
    Anomie67      = theta1,
    Powerless67   = theta2,
    Anomie71      = theta1,
    Powerless71   = theta2,
    Education     = theta3,
    SEI           = theta4,
    Alien67       = psi1,
    Alien71       = psi2,
    SES           = phi;
pcov
    Anomie67      Anomie71      = theta5,
    Powerless67   Powerless71   = theta5;
run;

```

In the PROC CALIS statement, you specify *Wheaton* as the input data set, which contains the covariance matrix of the variables.

In the PATH model specification, all the one-headed arrows in the path diagram are represented as path entries in the **PATH** statement, with entries separated by commas. In each path entry, you specify a pair of variables and the direction of the path (either **<===** or **===>**), followed by a path coefficient, which is either a fixed constant or a parameter with a name in the specification.

All the two-headed arrows each with the same source and destination are represented as entries in the **PVAR** statement, with entries separated by commas. In the **PVAR** statement, you specify the variance or error (or partial) variance parameters. In each entry, you specify a variable and then a parameter name or a fixed parameter value. If the variable involved is exogenous in the model (serves only as a predictor; never being pointed at by one-headed arrows), you are specifying a variance parameter for an exogenous variable in the **PVAR** statement. Otherwise, you are specifying an error variance (or a partial variance) parameter for an endogenous variable.

All other two-headed arrows are represented as entries in the **PCOV** statement, with entries separated by commas. In the **PCOV** statement, you specify the covariance or error (or partial) covariance parameters. In each entry, you specify a pair of variables and then a parameter name or a fixed parameter value. If both variables involved in an entry are exogenous, you are specifying a covariance parameter. If both variables involved in an entry are endogenous, you are specifying an error (or partial) covariance parameter. When one variable is exogenous and the other is endogenous in an entry, you are specifying a partial covariance parameter that can be interpreted as the covariance between the exogenous variable and the error of the endogenous variable.

See [Example 27.17](#) for the results of the current PATH model analysis. For more information about the PATH modeling language, see the section “[The PATH Model](#)” on page 1288 and the [PATH statement](#) on page 1202.

RAM Model

The PATH modeling language is not the only specification method that you can use to represent the path diagram. You can also use the RAM, LINEQS or LISMOD modeling language to represent the diagram equivalently.

The RAM model specification in PROC CALIS resembles that of the PATH model, as shown in the following statements:

```
proc calis nobs=932 data=Wheaton;
  ram
    var = Anomie67      /* 1 */
          Powerless67   /* 2 */
          Anomie71      /* 3 */
          Powerless71   /* 4 */
          Education     /* 5 */
          SEI           /* 6 */
          Alien67       /* 7 */
          Alien71       /* 8 */
          SES,          /* 9 */
    _A_ 1 7 1.0,
    _A_ 2 7 0.833,
    _A_ 3 8 1.0,
    _A_ 4 8 0.833,
    _A_ 5 9 1.0,
    _A_ 6 9 lambda,
    _A_ 7 9 gamma1,
    _A_ 8 9 gamma2,
    _A_ 8 7 beta,
    _P_ 1 1 theta1,
    _P_ 2 2 theta2,
    _P_ 3 3 theta1,
    _P_ 4 4 theta2,
    _P_ 5 5 theta3,
    _P_ 6 6 theta4,
    _P_ 7 7 psi1,
    _P_ 8 8 psi2,
    _P_ 9 9 phi,
    _P_ 1 3 theta5,
    _P_ 2 4 theta5;
run;
```

In the **RAM** statement, you specify a list of entries for parameters, with entries separated by commas. In each entry, you specify the type of parameter (PATH, PVAR, or PCOV in the code), the associated variable or pair of variables and the path direction if applicable, and then a parameter name or a fixed parameter value. The types of parameters you specify in this RAM model are for path coefficients, variances or partial variances, and covariances or partial covariances. They bear the same meanings as those in the PATH model specified previously. The RAM model specification is therefore quite similar to the PATH model specification—except that in the RAM model you put all parameter specification in the same list under the RAM statement, whereas you specify different types of parameters separately under different statements in the PATH model.

See [Example 27.23](#) for partial results of the current RAM model analysis. For more information about the RAM modeling language, see the section “[The RAM Model](#)” on page 1294 and the [RAM statement](#) on page 1216.

LINEQS Model

The LINEQS modeling language uses equations to specify functional relationships among variables, as shown in the following statements:

```
proc calis nob=932 data=Wheaton;
  lineqs
    Anomie67      = 1.0      * f_Alien67 + E1,
    Powerless67   = 0.833    * f_Alien67 + E2,
    Anomie71      = 1.0      * f_Alien71 + E3,
    Powerless71   = 0.833    * f_Alien71 + E4,
    Education     = 1.0      * f_SES      + E5,
    SEI           = lambda   * f_SES      + E6,
    f_Alien67     = gamma1   * f_SES      + D1,
    f_Alien71     = gamma2   * f_SES      + beta * Alien67 + D2;
  std
    E1            = theta1,
    E2            = theta2,
    E3            = theta1,
    E4            = theta2,
    E5            = theta3,
    E6            = theta4,
    D1            = psi1,
    D2            = psi2,
    f_SES         = phi;
  cov
    E1 E3         = theta5,
    E2 E4         = theta5;
run;
```

In the **LINEQS** statement, equations are separated by commas. In each equation, you specify an endogenous variable on the left-hand side, and then predictors and path coefficients on the right-hand side of the equal side. The set of equations specified in this LINEQS model is equivalent to the system of paths specified in the preceding PATH (or RAM) model. However, there are some notable differences between the LINEQS and the PATH specifications.

First, in the LINEQS modeling language you must specify the error terms explicitly as exogenous variables. For example, E1, E2, and D1 are error terms in the specification. In the PATH (or RAM) modeling language, you do not need to specify error terms explicitly.

Second, equations specified in the LINEQS modeling language are oriented by the endogenous variables. Each endogenous variable can appear on the left-hand side of an equation only *once* in the **LINEQS** statement. All the corresponding predictor variables must then be specified on the right-hand side of the equation. For example, f_Alien71 is predicted from f_Alien67 and f_SES in the last equation of the **LINEQS** statement. In the PATH or RAM modeling language, however, you would specify the same functional relationships in two separate paths.

Third, you must follow some naming conventions for latent variables when using the LINEQS modeling language. The names of latent variables that are not errors or disturbances must start with an ‘f’ or ‘F’. Also, the names of the error variables must start with ‘e’ or ‘E’ and the names of the disturbance variables must start with ‘d’ or ‘D’. For example, variables Alien67, Alien71, and SES serve as latent factors in the previous PATH or RAM model specification. To comply with the naming conventions, these variables are named with an extra prefix ‘f_’ in the LINEQS model specification—that is, f_Alien67, f_Alien71, and

f_SES, respectively. In addition, because of the naming conventions of the LINEQS modeling language, E1–E6 serve as error terms and D1–D1 serve as disturbances in the specification.

A consequence of explicit specification of error terms in the **LINEQS** statement is that the partial variance and partial covariance concepts used in the **PATH** and **RAM** modeling languages are no longer needed. They are replaced by the variances or covariances of the error terms or disturbances. Errors and disturbances are exogenous variables by nature. Hence, in terms of variance and covariance specification, they are treated exactly the same way as other non-error exogenous variables in the LINEQS modeling language. That is, variance parameters for all exogenous variables, including errors and disturbances, are specified in the **VARIANCE** statement, and covariance parameters among exogenous variables, including errors and disturbances, are specified in **COV** statement.

See [Example 27.23](#) for partial results of the current LINEQS model analysis. For more information about the LINEQS modeling language, see the section “[The LINEQS Model](#)” on page 1270 and the [LINEQS statement](#) on page 1156.

LISMOD Model

The LISMOD language is quite different from the LINEQS, **PATH**, and **RAM** modeling languages. In the LISMOD specification, you define parameters as entries in model matrices, as shown in the following statements:

```
proc calis nobs=932 data=Wheaton;
  lismod
    yvar = Anomie67 Powerless67 Anomie71 Powerless71,
    xvar = Education SEI,
    etav = Alien67 Alien71,
    xiv  = SES;
  matrix _LAMBDAY_ [1,1] = 1.0,
                [2,1] = 0.833,
                [3,2] = 1.0,
                [4,2] = 0.833;
  matrix _LAMBDAX_ [1,1] = 1.0,
                [2,1] = lambda;
  matrix _GAMMA_   [1,1] = gamma1,
                [2,1] = gamma2;
  matrix _BETA_    [2,1] = beta;
  matrix _THETAY_  [1,1] = theta1,
                [2,2] = theta2,
                [3,3] = theta1,
                [4,4] = theta2,
                [3,1] = theta5,
                [4,2] = theta5;
  matrix _THETAX_  [1,1] = theta3,
                [2,2] = theta4;
  matrix _PSI_     [1,1] = psi1,
                [2,2] = psi2;
  matrix _PHI_     [1,1] = phi;
run;
```

In the **LISMOD** statement, you specify the lists of variables in the model. In the **MATRIX** statements, you specify the parameters in the LISMOD model matrices. Each **MATRIX** statement contains the matrix name of interest and then locations of the parameters, followed by the parameter names or fixed parameter

values. It would be difficult to explain the LISMOD specification here without better knowledge about the formulation of the mathematical model. For this purpose, see the section “[The LISMOD Model and Submodels](#)” on page 1277 and the [LISMOD statement](#) on page 1162. See also [Example 27.23](#) for partial results of the current LISMOD model analysis.

COSAN Model

The COSAN model specification is even more abstract than all of the modeling languages considered. Like the LISMOD model specification, to specify a COSAN model you need to define parameters as entries in model matrices. In addition, you must also provide the definitions of the model matrices and the matrix formula for the covariance structures in the COSAN model specification. Therefore, the COSAN model specification requires sophisticated knowledge about the formulation of the mathematical model. For this reason, the COSAN model specification of the preceding path model is not discussed here (but see [Example 27.29](#)). For more details about the COSAN model specification, see the section “[The COSAN Model](#)” on page 1259 and the [COSAN statement](#) on page 1122.

A Factor Model Example

In addition to the general modeling languages such as PATH, RAM, LINEQS, and LISMOD, the CALIS procedure provides a specialized language for factor analysis. In the FACTOR modeling language, you can specify either exploratory or confirmatory factor models. For exploratory factor models, you can specify the number of factors, factor extraction method, and rotation algorithm, among many other options. For confirmatory factor models, you can specify the variable-factor relationships, factor variances and covariances, and the error variances.

For example, the following is an exploratory factor model fitted to the Wheaton et al. (1977) data by using PROC CALIS:

```
proc calis nobs=932 data=Wheaton;
    factor n=2 rotate=varimax;
run;
```

In this model, you want to get the varimax-rotated solution with two factors. By default, the factor extraction method is maximum likelihood ([METHOD=ML](#)). Maximum likelihood exploratory factor analysis by PROC CALIS can also be done equivalently by the FACTOR procedure, as shown in the following statements for the Wheaton et al. (1977) data:

```
proc factor nobs=932 data=Wheaton n=2 rotate=varimax method=ml;
run;
```

Note that [METHOD=ML](#) is necessary because maximum likelihood is not the default method in PROC FACTOR.

Whereas you can use either the CALIS or FACTOR procedure to fit certain exploratory factor models, you can only use the CALIS procedure to fit confirmatory factor models. In a confirmatory factor model, you are assumed to have some prior knowledge about the variable-factor relations. For example, in your substantive theory, some observed variables are not related to certain factors in the model. The following statements illustrate the specification of a confirmatory factor model for Wheaton et al. (1977) data:

```

proc calis nob=932 data=Wheaton;
  factor
    Alien67 ==> Anomie67 Powerless67    = 1.0 load1,
    Alien71 ==> Anomie71 Powerless71    = 1.0 load2,
    SES      ==> Education SEI          = 1.0 load3;
  pvar
    Alien67      = phi11,
    Alien71      = phi22,
    SES          = phi33,
    Anomie67     = theta1,
    Powerless67  = theta2,
    Anomie71     = theta3,
    Powerless71  = theta4,
    Education    = theta5,
    SEI          = theta6;
  cov
    Alien71 Alien67 = phi21,
    SES      Alien67 = phi31,
    SES      Alien71 = phi32;
run;

```

Unlike the model fitted by the PATH, RAM, LINEQS, or LISMOD modeling language in previous sections, the confirmatory factor model considered here is purely a measurement model—that is, there are no functional relationships among factors in the model (beyond the covariances among factors) and hence it is a different model. In the **FACTOR** statement, you specify factors on the left-hand side of the entries, followed by arrows and the manifest variables that are related to the factors. On the right-hand side of the entries, you specify either parameter names or fixed parameter values for the corresponding factor loadings. In this example, there are three factors with three loadings to estimate. In the **PVAR** statement, you specify the parameters for factor variances and error variances of manifest variables. In the **COV** statement, you specify the factor covariances. As compared with the PATH, RAM, LINEQS, or LISMOD, the factor modeling language has more restrictions on parameters. These restrictions are listed as follows:

- factor-factor paths and variable-to-factor paths are not allowed
- error covariances and factor-error covariances are not allowed

For more information about exploratory and confirmatory factor models and the **FACTOR** modeling language, see the section “[The FACTOR Model](#)” on page 1263 or the [FACTOR statement](#) on page 1138.

Direct Covariance Structures Analysis

Previous examples are concerned with the implied covariance structures from the functional relationships among manifest and latent variables. In some cases, direct modeling of the covariance structures is not only possible, but indeed more convenient. The MSTRUCT modeling language in PROC CALIS is designed for this purpose. Consider the following four variables from the Wheaton et al. (1977) data:

Anomie67: Anomie 1967
 Powerless67: Powerlessness 1967
 Anomie71: Anomie 1971
 Powerless71: Powerlessness 1971

The covariance structures are hypothesized as follows:

$$\Sigma = \begin{pmatrix} \phi_1 & \theta_1 & \theta_2 & \theta_1 \\ \theta_1 & \phi_2 & \theta_1 & \theta_3 \\ \theta_2 & \theta_1 & \phi_1 & \theta_1 \\ \theta_1 & \theta_3 & \theta_1 & \phi_2 \end{pmatrix}$$

where:

ϕ_1 : Variance of Anomie
 ϕ_2 : Variance of Powerlessness
 θ_1 : Covariance between Anomie and Powerlessness
 θ_2 : Covariance between Anomie measures
 θ_3 : Covariance between Powerlessness measures

In the hypothesized covariance structures, the variances of Anomie and Powerlessness measures are assumed to stay constant over the two time points. Their covariances are also independent of the time of measurements. To test the tenability of this covariance structure model, you can use the following statements of the MSTRUCT modeling language:

```

proc calis nob=932 data=Wheaton;
mstruct
  var = Anomie67 Powerless67 Anomie71 Powerless71;
matrix _COV_ [1,1] = phi1,
              [2,2] = phi2,
              [3,3] = phi1,
              [4,4] = phi2,
              [2,1] = theta1,
              [3,1] = theta2,
              [3,2] = theta1,
              [4,1] = theta1,
              [4,2] = theta3,
              [4,3] = theta1;
run;

```

In the **MSTRUCT** statement, you specify the list of variables of interest with the **VAR=** option. The order of the variables in the list will be the order in the hypothesized covariance matrix. Next, you use the **MATRIX _COV_** statement to specify the parameters in the covariance matrix. The specification is a direct translation from the hypothesized covariance matrix. For example, the **[1,1]** element of the covariance matrix is fitted by the free parameter **phi1**. Depending on the hypothesized model, you can also specify fixed constants for the elements in the covariance matrix. If an element in the covariance matrix is not specified by either a parameter name or a constant, it is assumed to be a fixed zero.

The analysis of this model is carried out in [Example 27.19](#).

The **MSTRUCT** modeling language appears to be more restrictive than any of the other modeling languages discussed, in regard to the following limitations:

- It does not explicitly support latent variables in modeling.
- It does not explicitly support modeling of linear functional relations among variables (for example, paths).

However, these limitations are more apparent than real. In **PROC CALIS**, the parameters defined in models can be dependent. These dependent parameters can be defined further as functions of other parameters in the **PARAMETERS** and the **SAS programming statements**. With these capabilities, it is possible to fit structural models with latent variables and with linear functional relations by using the **MSTRUCT** modeling language. However, this requires a certain level of sophistication in statistical knowledge and in programming. Therefore, it is recommended that the **MSTRUCT** modeling language be used only when the covariance and mean structures are modeled directly.

For more information about the MSTRUCT modeling language, see the section “[The MSTRUCT Model](#)” on page 1285 and the [MSTRUCT statement](#) on page 1194.

Which Modeling Language?

Various modeling languages are supported in PROC CALIS because researchers are trained in or adhere to different schools of modeling. Different modeling languages reflect different modeling terminology and philosophies. The statistical and mathematical consequences by using these various modeling languages, however, might indeed be the same. In other words, you can use more than one modeling languages for certain types of models without affecting the statistical analysis. Given the choices, which modeling language is preferred? There are two guidelines for this:

- Use the modeling language that you are most familiar with.
- Use the most specialized modeling language whenever it is possible.

The first guideline calls for researchers’ knowledge about a particular modeling language. Use the language you know the best. For example, some researchers might find equation input language like LINEQS the most suitable, while others might feel more comfortable using matrix input language like LISMOD.

The second guideline depends on the nature of the model at hand. For example, to specify a factor analysis model in the CALIS procedure, the specialized FACTOR language, instead of the LISMOD language, is recommended. Using a more specialized the modeling language is less error-prone. In addition, using a specialized language like FACTOR in this case amounts to giving the CALIS procedure additional information about the specific mathematical properties of the model. This additional information is used to enhance computational efficiency and to provide more specialized results. Another example is fitting an equi-covariance model. You can simply use the MSTRUCT model specification, in which you specify the same parameter for all off-diagonal elements of the covariance elements. This is direct and intuitive. Alternatively, you could tweak a LINEQS model that would predict the same covariance for all variables. However, this is indirect and error-prone, especially for novice modelers.

In PROC CALIS, the FACTOR and MSTRUCT modeling languages are considered more specialized, while other languages are more general in applications. Whenever possible, you should use the more specialized languages. However, if your model involves some novel covariance or mean structures that are not covered by the more specialized modeling languages, you can consider the more generalized modeling languages. See [Example 27.33](#) for an application of the generalized COSAN model.

Syntax: CALIS Procedure

The following statements are available in the CALIS procedure:

```

PROC CALIS < options > ;
  BOUNDS boundary-constraints ;
  BY variables ;
  COSAN model-specifications ;
  COV covariance-parameters ;
  DETERM variables ;
  EFFPART effects ;
  FACTOR model-specifications ;
  FITINDEX fit-options ;
  FREQ variable ;
  GROUP group-number < / options > ;
  LINCON linear-constraints ;
  LINEQS equations ;
  LISMOD variable-lists ;
  LMTESTS test-options ;
  MATRIX parameter-specifications ;
  MEAN mean-parameters ;
  MODEL model-number < / options > ;
  MSTRUCT variable-list ;
  NLINCON nonlinear-constraints ;
  NLOPTIONS optimization-options ;
  OUTFILES file-options ;
  PARAMETERS parameter-specifications ;
  PARTIAL variables ;
  PATH paths ;
  PCOV covariance-parameters ;
  PVAR variance-parameters ;
  RAM model-specifications ;
  REFMODEL model-number < / options > ;
  RENAMEPARM parameter-assignments ;
  SIMTESTS simultaneous-tests ;
  STD variance-parameters ;
  STRUCTEQ variables < label > ;
  TESTFUNC parametric-functions ;
  VAR variables ;
  VARIANCE variance-parameters ;
  VARNAMES name-assignments ;
  WEIGHT variable ;
  Programming statements ;

```

Classes of Statements in PROC CALIS

To better understand the syntax of PROC CALIS, it is useful to classify the statements into classes. These classes of statements are described in the following sections.

PROC CALIS Statement

is the main statement that invokes the CALIS procedure. You can specify options for input and output data sets, printing, statistical analysis, and computations in this statement. The options specified in the PROC CALIS statement will propagate to all groups and models, but are superseded by the options specified in the individual **GROUP** or **MODEL** statements.

GROUP Statement

signifies the beginning of a group specification. A group in the CALIS procedure is an independent sample of observations. You can specify options for input and output data sets, printing, and statistical computations in this statement. Some of these group options in the **GROUP** statement can also be specified in the **MODEL** or PROC CALIS statement, but the options specified in the **GROUP** statement supersede those specified in the **MODEL** or PROC CALIS statement for the group designated in the **GROUP** statement. For group options that are available in both of the **GROUP** and PROC CALIS statements, see the section “Options Available in the GROUP and PROC CALIS Statements” on page 1153. For group options that are available in the **GROUP**, **MODEL**, and PROC CALIS statements, see the section “Options Available in GROUP, MODEL, and PROC CALIS Statements” on page 1154. If no GROUP statement is used, a single-group analysis is assumed. The group options for a single-group analysis are specified in the PROC CALIS statement.

The **GROUP** statement can be followed by *subsidiary group specification statements*, which specify further data processing procedures for the group designated in the **GROUP** statement.

Subsidiary Group Specification Statements

are for specifying additional data processing attributes for the input data. These statements are summarized in the following table:

Statement	Description
FREQ on page 1152	Specifies the frequency variable for the input observations
PARTIAL on page 1202	Specifies the partial variables
VAR on page 1228	Specifies the set of variables in analysis
WEIGHT on page 1235	Specifies the weight variable for the input observations

These statements can be used after the PROC CALIS statement or each **GROUP** statement. Again, the specifications within the scope of the **GROUP** statement supersede those specified after the PROC CALIS statement for the group designated in the **GROUP** statement.

MODEL Statement

signifies the beginning of a model specification. In the **MODEL** statement, you can specify the fitted groups, input and output data sets for model specification or estimates, printing options, statistical analysis, and computational options. Some of the options in the **MODEL** statement can also be specified in the PROC CALIS

statement. These options are called model options. Model options specified in the **MODEL** statement supersede those specified in the **PROC CALIS** statement. For model options that are available in both of the **MODEL** and **PROC CALIS** statements, see the section “Options Available in the **MODEL** and **PROC CALIS** Statements” on page 1193. If no **MODEL** statement is used, a single model is assumed and the model options are specified in the **PROC CALIS** statement.

Some of the options in the **MODEL** statement can also be specified in the **GROUP** statement. These options are called group options. The group options in the **MODEL** statement are transferred to the groups being fitted, but they are superseded by the group options specified in the associated **GROUP** statement. For group options that are available in the **GROUP** and the **MODEL** statements, see the section “Options Available in **GROUP**, **MODEL**, and **PROC CALIS** Statements” on page 1154.

The **MODEL** statement itself does not define the model being fitted to the data; the main and subsidiary model specification statements that follow immediately after the **MODEL** statement do. These statements are described in the next two sections.

Main Model Specification Statements

are for specifying the type of the modeling language and the main features of the model. These statements are summarized in the following table:

Statement	Description
COSAN on page 1122	Specifies general mean and covariance structures in matrix terms
FACTOR on page 1138	Specifies confirmatory or exploratory factor models
LINEQS on page 1156	Specifies models by using linear equations
LISMOD on page 1162	Specifies models in terms of LISREL-like model matrices
MSTRUCT on page 1194	Specifies parameters directly in the mean and covariance matrices
PATH on page 1202	Specifies models by using the causal paths of variables
RAM on page 1216	Specifies models by using RAM-like lists of parameters
REFMODEL on page 1223	Specifies a base model from which the target model is modified

You can use one of these statements for specifying one model. Each statement in the list represents a particular type of modeling language. After the main model specification statement, you might need to add subsidiary model specification statements, as described in the following section, to complete the model specification.

Subsidiary Model Specification Statements

are used to supplement the model specification. They are specific to the types of the modeling languages invoked by the main model specification statements, as shown in the following table:

Statement	Specification	Modeling Languages
COV on page 1132	Covariance parameters	FACTOR , LINEQS
MATRIX on page 1175	Parameters in matrices	COSAN , LISMOD , MSTRUCT
MEAN on page 1189	Mean or intercept parameters	FACTOR , LINEQS , PATH
PCOV on page 1212	(Partial) covariance parameters	PATH
PVAR on page 1214	(Partial) variance parameters	FACTOR , PATH
RENAMEPARAM on page 1225	New parameters by renaming	REFMODEL
VARIANCE on page 1231	Variance parameters	LINEQS

Notice that the RAM modeling language does not have any subsidiary model specification statements, because all model specification can be done in the [RAM](#) statement.

Model Analysis Statements

are used to request specific statistical analysis, as shown in the following table:

Statement	Analysis
DETERM on page 1136	Sets variable groups for computing the determination coefficients; same as the STRUCTEQ statement
EFFPART on page 1097	Displays and partitions the effects in the model
FITINDEX on page 1148	Controls the fit summary output
LMTESTS on page 1166	Defines the Lagrange multiplier test regions
SIMTESTS on page 1226	Defines simultaneous parametric function tests
STRUCTEQ on page 1136	Sets variable groups for computing the determination coefficients; same as the DETERM statement
TESTFUNC on page 1227	Tests individual parametric functions

Notice that the [DETERM](#) and the [STRUCTEQ](#) statements function exactly the same way.

Optimization Statements

are used to define additional parameters and parameter constraints, to fine-tune the optimization techniques, or to set the printing options in optimization, as shown in the following table:

Statement	Description
BOUNDS on page 1120	Defines the bounds of parameters
LINCON on page 1155	Defines the linear constraints of parameters
NLINCON on page 1196	Defines the nonlinear constraints of parameters
NLOPTIONS on page 1197	Sets the optimization techniques and printing options

Other Statements

that are not listed in preceding sections are summarized in the following table:

Statement	Description
BY on page 1121	Fits a model to different groups separately
OUTFILES on page 1197	Controls multiple output data sets
PARAMETERS on page 1199	Defines additional parameters or superparameters
SAS programming statements on page 1226	Define parameters or functions

Note that [SAS programming statements](#) include the [ARRAY](#) statement and the mathematical statements for defining parameter interdependence.

Single-Group Analysis Syntax

```
PROC CALIS < options > ;
    subsidiary group specification statements ;
    main model specification statement ;
    subsidiary model specification statements ;
    model analysis statements ;
    optimization statements ;
    other statements ;
```

In a single-group analysis, there is only one group and one model. Because all model or group specifications are unambiguous, the **MODEL** and **GROUP** statements are not necessary. The order of the statements is not important for parsing purposes, although you might still like to order them in a particular way to aid understanding. Notice that the **OUTFILES** statement is not necessary in single-group analyses, as it is designed for multiple-group situations. Output file options in a single-group analysis can be specified in the **PROC CALIS** statement.

Multiple-Group Multiple-Model Analysis Syntax

```
PROC CALIS < options > ;
    subsidiary group specification statements ;
    model analysis statements ;
    GROUP 1 < / group options > ;
        subsidiary group specification statements ;
    GROUP 2 < / group options > ;
        subsidiary group specification statements ;
    MODEL 1 < / model options > ;
        main model specification statement ;
        subsidiary model specification statements ;
        model analysis statements ;
    MODEL 2 < / model options > ;
        main model specification statement ;
        subsidiary model specification statements ;
        model analysis statements ;
    optimization statements ;
    other statements ;
```

The multiple uses of the **GROUP** and the **MODEL** statements characterize the multiple-group multiple-model analysis. Unlike the single-group analysis, the order of some statements in a multiple-group multiple-model syntax is important for parsing purposes.

A **GROUP** statement signifies the beginning of a group specification block and designates a group number for the group. The scope of a **GROUP** statement extends to the subsequent subsidiary group specification statements until another **MODEL** or **GROUP** statement is encountered. In the preceding syntax, **GROUP 1** and **GROUP 2** have separate blocks of subsidiary group specification statements. By using additional **GROUP** statements, you can add as many groups as your situation calls for. Subsidiary group specification statements declared before the first **GROUP** statement are in the scope of the **PROC CALIS** statement. This

means that these subsidiary group specification statements are applied globally to all groups unless they are respecified locally within the scopes of individual **GROUP** statements.

A **MODEL** statement signifies the beginning of a model specification block and designates a model number for the model. The scope of a **MODEL** statement extends to the subsequent main and subsidiary model specification statements until another **MODEL** or **GROUP** statement is encountered. In the preceding syntax, MODEL 1 and MODEL 2 have separate blocks of main and subsidiary model specification statements. By using additional **MODEL** statements, you can add as many models as your situation calls for. If you use at least one **MODEL** statement, any main and subsidiary model specification statements declared before the first **MODEL** statement are ignored.

Some model analysis statements are also bounded by the scope of the **MODEL** statements. These statements are: **DETERM**, **EFFPART**, **LMTESTS**, and **STRUCTEQ**. These statements are applied only locally to the model in which they belong. To apply these statements globally to all models, put these statements before the first **MODEL** statement.

Other model analysis statements are not bounded by the scope of the **MODEL** statements. These statements are: **FITINDEX**, **SIMTESTS**, and **TESTFUNC**. Because these statements are not model-specific, you can put these statements anywhere in a PROC CALIS run.

Optimization and other statements are not bounded by the scope of either the **GROUP** or **MODEL** statements. You can specify them anywhere between the PROC CALIS and the run statements without affecting the parsing of the models and the groups. For clarity of presentation, they are shown as last statement block in the syntax. Notice that the **BY** statement is not supported in a multiple-group setting.

PROC CALIS Statement

PROC CALIS < options > ;

The PROC CALIS statement invokes the CALIS procedure. There are many options in the PROC CALIS statement. These options, together with brief descriptions, are classified into different categories in the next few sections. An alphabetical listing of these options with more details then follows.

Data Set Options

You can use the following options to specify input and output data sets:

Option	Description
BASEFIT=	Inputs the fit information of the customized baseline model
DATA=	Inputs the data
INEST=	Inputs the initial values and constraints
INMODEL=	Inputs the model specifications
INWGT=	Inputs the weight matrix
OUTEST=	Outputs the estimates and their covariance matrix
OUTFIT=	Outputs the fit indices
OUTMODEL=	Outputs the model specifications
OUTSTAT=	Outputs the statistical results
OUTWGT=	Outputs the weight matrix
READADDPARM	Inputs the generated default parameters in the INMODEL= data set

Model and Estimation Options

You can use these options to specify details about estimation, models, and computations:

Option	Description
CORRELATION	Analyzes correlation matrix
COVARIANCE	Analyzes covariance matrix
COVPATTERN=	Specifies one of the built-in covariance structures
DEMPHAS=	Emphasizes the diagonal entries
EDF=	Defines number of observations by the number of error degrees of freedom
INWGTINV	Specifies that the INWGT= data set contains the inverse of the weight matrix
MEANPATTERN=	Specifies one of the built-in mean patterns
MEANSTR	Analyzes the mean structures
METHOD=	Specifies the estimation method
NOBS=	Defines the number of observations
NOMEANSTR	Deactivates the inherited MEANSTR option
RANDOM=	Specifies the seed for randomly generated initial values
RDF=	Defines nobis by the number of regression <i>df</i>
RIDGE=	Specifies the ridge factor for the covariance matrix
ROBPHI=	Specifies the tuning parameter for robust methods
ROBUST=	Specifies the type of robust method
START=	Specifies a constant for initial values
VARDEF=	Specifies the variance divisor
WPENALTY=	Specifies the penalty weight to fit correlations
WRIDGE=	Specifies the ridge factor for the weight matrix

Options for Fit Statistics

You can use these options to modify the default behavior of fit index computations, to control the display of fit indices, and specify output file for fit indices:

Option	Description
ALPHAECV=	Specifies the α level for computing the confidence interval of ECV (Browne and Cudeck 1993)
ALPHARMS=	Specifies the α level for computing the confidence interval of RMSEA (Steiger and Lind 1980)
BASEFUNC=	Specifies the function value and the degrees of freedom of the customized baseline model
CHICORRECT=	Specifies the chi-square correction factor
CLOSEFIT=	Defines the close fit value
DFREDUCE=	Reduces the degrees of freedom for model fit chi-square test
NOADJDF	Requests no degrees-of-freedom adjustment be made for active constraints
NOINDEXTYPE	Suppresses the printing of fit index types
OUTFIT=	Specifies the output data set for storing fit indices

These options can also be specified in the **FITINDEX** statement. However, to control the display of individual fit indices, you must use the **ON=** and **OFF=** options of the **FITINDEX** statement.

Options for Statistical Analysis

You can use these options to request specific statistical analysis and display and to set the parameters for statistical analysis:

Option	Description
ALPHALEV=	Specifies the α -level criterion for detecting leverage points
ALPHAOUT=	Specifies the α -level criterion for detecting outliers
ASYCOV=	Specifies the formula for computing asymptotic covariances
BIASKUR	Computes the skewness and kurtosis without bias corrections
EFFPART TOTEFF	Displays total, direct, and indirect effects
EXTENDPATH	Displays the extended path estimates
G4=	Specifies the algorithm for computing standard errors
KURTOSIS	Computes and displays kurtosis
MAXMISSPAT=	Specifies the maximum number of missing patterns to display
MODIFICATION	Computes modification indices
NOMISSPAT	Suppresses the display of missing pattern analysis
NOMOD	Suppresses modification indices
NOSTAND	Suppresses the standardized output
NSTDERR	Suppresses standard error computations
PCORR	Displays analyzed and estimated moment matrix
PCOVES	Displays the covariance matrix of estimates
PDETERM	Computes the determination coefficients
PESTIM	Prints parameter estimates
PINITIAL	Prints initial pattern and values
PLATCOV	Computes the latent variable covariances and score coefficients
PLOTS=	Specifies ODS Graphics selection
PWEIGHT	Displays the weight matrix
RESIDUAL=	Specifies the type of residuals being computed
SIMPLE	Prints univariate statistics
SLMW=	Specifies the probability limit for Wald tests
STDERR	Computes the standard errors
TMISSPAT=	Specifies the data proportion threshold for displaying the missing patterns

Global Display Options

There are two different kinds of global display options: one is for selecting output; the other is for controlling the format or order of output.

You can use the following options to select printed output:

Option	Description
NOPRINT	Suppresses the displayed output
PALL	Displays all displayed output (ALL)
PRINT	Adds default displayed output
PSHORT	Reduces default output (SHORT)
PSUMMARY	Displays fit summary only (SUMMARY)

In contrast to individual output printing options described in the section “Options for Statistical Analysis” on page 1085, the global display options typically control more than one output or analysis. The relations between these two types of options are summarized in the following table:

Options	PALL	PRINT	default	PSHORT	PSUMMARY
fit indices	*	*	*	*	*
linear dependencies	*	*	*	*	*
PESTIM	*	*	*	*	
iteration history	*	*	*	*	
PINITIAL	*	*	*		
SIMPLE	*	*	*		
STDERR	*	*	*		
RESIDUAL	*	*			
KURTOSIS	*	*			
PLATCOV	*	*			
TOTEFF	*	*			
PCORR	*				
MODIFICATION	*				
PWEIGHT	*				
PCOVES					
PDETERM					
PRIMAT					

Each column in the table represents a global display option. An “*” in the column means that the individual output or analysis option listed in the corresponding row turns on when the global display option in the corresponding column is specified.

Note that the column labeled with “default” is for default printing. If the **NOPRINT** option is not specified, a default set of output is displayed. The **PRINT** and **PALL** options add to the default output, while the **PSHORT** and **PSUMMARY** options reduce from the default output.

Note also that the **PCOVES**, **PDETERM**, and **PRIMAT** options cannot be turned on by any global display options. They must be specified individually.

The following global display options are for controlling formats and order of the output:

Option	Description
NOORDERSPEC	Displays model specifications and results according to the input order
NOPARMNAME	Suppresses the printing of parameter names in results
ORDERALL	Orders all output displays according to the model numbers, group numbers, and parameter types
ORDERGROUPS	Orders the group output displays according to the group numbers
ORDERMODELS	Orders the model output displays according to the model numbers
ORDERSPEC	Orders the model output displays according to the parameter types within each model
PARMNAME	Displays parameter names in model specifications and results
PRIMAT	Displays estimation results in matrix form

Optimization Options

You can use the following options to control the behavior of the optimization. Most of these options are also available in the [NLOPTIONS](#) statement.

Option	Description
ASINGULAR=	Specifies the absolute singularity criterion for inverting the information matrix
COVSING=	Specifies the singularity tolerance of the information matrix
FCONV=	Specifies the relative function convergence criterion
GCONV=	Specifies the gradient convergence criterion
INSTEP=	Specifies the initial step length (RADIUS=, SALPHA=)
LINESEARCH=	Specifies the line-search method
LSPRECISION=	Specifies the line-search precision (SPRECISION=)
MAXFUNC=	Specifies the maximum number of function calls
MAXITER=	Specifies the maximum number of iterations
MSINGULAR=	Specifies the relative M singularity of the information matrix
OMETHOD TECHNIQUE=	Specifies the minimization method
ROBITER=	Specifies the maximum number of iterations for estimating robust covariance and mean matrices
SINGULAR=	Specifies the singularity criterion for matrix inversion
UPDATE=	Specifies the update method for some optimization techniques
VSINGULAR=	Specifies the relative V singularity of information matrix
XCONV=	Specifies the relative parameter convergence criterion

PROC CALIS Statement Options

ALPHAECV= α

specifies a $(1 - \alpha)100\%$ confidence interval ($0 \leq \alpha \leq 1$) for the Browne and Cudeck (1993) expected cross-validation index (ECVI). The default value is $\alpha = 0.1$, which corresponds to a 90% confidence interval for the ECVI.

ALPHALEV | ALPHALEVERAGE= α

specifies the α -level criterion for detecting leverage observations (or leverage points) in case-level (observation-level) residual diagnostics. The default ALPHALEV= value is 0.01. An observation is a leverage observation if the p -value of its squared Mahalanobis distance (M-distance) for its predictor variables (including observed and latent variables) is smaller than the specified α -level, where the p -value is computed according to an appropriate theoretical chi-square distribution. The larger the ALPHALEV= value, the more liberal the criterion for detecting leverage observations.

In addition to displaying the leverage observations as defined by the ALPHALEV= criterion, PROC CALIS also displays the next 5 observations with the largest leverage M-distances for reference. However, the total number of observations in the displayed output cannot exceed 30 or the number of original observations, whichever is smaller.

This option is relevant only when residual analysis is requested with the [RESIDUAL](#) option and with raw data input.

ALPHAOUT | ALPHAOUTLIER= α

specifies the α -level criterion for detecting outliers in case-level (observation-level) residual diagnostics. The default ALPHAOUT= value is 0.01. An observation is an outlier if the p -value of its squared residual M-distance is smaller than the specified α -level, where the p -value is computed according to an appropriate theoretical chi-square distribution. The larger the ALPHAOUT= value, the more liberal the criterion for detecting outliers.

In addition to displaying the outliers as defined by the ALPHAOUT= criterion, PROC CALIS also displays the next 5 observations with the largest residual M-distances for reference. However, the total number of observations in the displayed output in the displayed output cannot exceed 30 or the number of original observations, whichever is smaller.

This option is relevant only when residual analysis is requested with the **RESIDUAL** option and with raw data input.

ALPHARMS | ALPHARMSEA= α

specifies a $(1 - \alpha)100\%$ confidence interval ($0 \leq \alpha \leq 1$) for the Steiger and Lind (1980) root mean square error of approximation (RMSEA) coefficient (see Browne and Du Toit 1992). The default value is $\alpha = 0.1$, which corresponds to a 90% confidence interval for the RMSEA.

ASINGULAR | ASING= r

specifies an absolute singularity criterion r ($r > 0$), for the inversion of the information matrix, which is needed to compute the covariance matrix. The default value for r or ASING= is the square root of the smallest positive double precision value.

When inverting the information matrix, the following singularity criterion is used for the diagonal pivot $d_{j,j}$ of the matrix:

$$|d_{j,j}| \leq \max(\text{ASING}, \text{VSING} * |H_{j,j}|, \text{MSING} * \max(|H_{1,1}|, \dots, |H_{n,n}|))$$

where *VSING* and *MSING* are the specified values in the **VSINGULAR=** and **MSINGULAR=** options, respectively, and $H_{j,j}$ is the j th diagonal element of the information matrix. Note that in many cases a normalized matrix $\mathbf{D}^{-1}\mathbf{H}\mathbf{D}^{-1}$ is decomposed (where $\mathbf{D}^2 = \text{diag}(\mathbf{H})$), and the singularity criteria are modified correspondingly.

ASYCOV | ASC=name

specifies the formula for asymptotic covariances used in the weight matrix **W** for WLS and DWLS estimation. The ASYCOV option is effective only if **METHOD=** WLS or **METHOD=** DWLS and no **INWGT=** input data set is specified. The following formulas are implemented:

- | | |
|------------------|--|
| BIASED: | Browne (1984) formula (3.4)
biased asymptotic covariance estimates; the resulting weight matrix is at least positive semidefinite. This is the default for analyzing a covariance matrix. |
| UNBIASED: | Browne (1984) formula (3.8)
asymptotic covariance estimates corrected for bias; the resulting weight matrix can be indefinite (that is, can have negative eigenvalues), especially for small N . |
| CORR: | Browne and Shapiro (1986) formula (3.2)
(identical to DeLeeuw (1983) formulas (2,3,4)) the asymptotic variances of the diagonal elements are set to the reciprocal of the value r specified by the WPENALTY= option (default: $r=100$). This formula is the default for analyzing a correlation matrix. |

By default, `AYSCOV=BIASED` is used for covariance analyses and `ASYCOV=CORR` is used for correlation analyses. Therefore, in almost all cases you do not need to set the `ASYCOV=` option once you specify the covariance or correlation analysis by the `COV` or `CORR` option.

BASEFIT | INBASEFIT=SAS-data-set

inputs the *SAS-data-set* that contains the fit information of the baseline model of your choice. This customized baseline model replaces the default uncorrelatedness model for computing several fit indices of your target model. Typically, you create the `BASEFIT=` data set by using the `OUTFIT=` option in a previous PROC CALIS fitting of your customized baseline model. Using the `BASEFIT=` option assumes that you fit your customized baseline model and your target model with the same data, number of groups (for multiple-group analysis), and estimation method. Typically, your baseline model should be more restrictive (or have fewer parameters) than your target model.

For example, the following statements use the compound symmetry model (`COVPATTERN=COMPSYM`) as the customized baseline model for the subsequent factor model with two factors:

```
proc calis data=abc outfit=outf method=glis covpattern=compsym;
    var=x1-x10;
run;

proc calis data=abc method=glis basefit=outf;
    factor n=2;
    var=x1-x10;
run;
```

The fit information of the customized baseline model is saved as an `OUTFIT=` data set called `outf`, which is then read as a `BASEFIT=` data set in the next PROC CALIS run for fitting the target factor model. Notice that in this example the baseline model and the target factor model use the same data set, `abc`, and the same GLS estimation method.

Alternatively, you can use the `BASEFUNC=` option to input the function value and the degrees of freedom of your customized baseline model. See the `BASEFUNC=` option for details. The `BASEFIT=` option is ignored if you also specify the `BASEFUNC=` option.

Notice that the fit information in the `BASEFIT=` data set does not affect the computation of all fit indices. Mainly, it affects the incremental fit indices, because these indices are defined as the incremental fit of a target model over a baseline model. Among all absolute and parsimonious fit indices, only the parsimonious goodness-of-fit (PGFI) index (Mulaik et al. 1989) is affected by the input fit information provided in the `BASEFIT=` data set.

If you specify `METHOD=LSDWLS`, `LSFIML`, `LSGLS`, or `LSML` for your target model, the fit information in the `BASEFIT=` data set is assumed to have been obtained from the DWLS, FIML, GLS, or ML estimation of your customized baseline model. Hence, the fit information in the `BASEFIT=` data set applies only to the second estimation of your target model. The unweighted least squares (ULS) estimation of the target model still uses the uncorrelatedness model as the baseline model for computing fit indices.

If you use a `BASEFIT=` data set to input the fit information of your customized baseline model in a multiple-group analysis, then the baseline model function values, chi-squares, and degrees of freedom for individual groups are not known and hence not displayed in the multiple-group fit summary table. The Bentler-Bonett normed fit index (NFI) is also not displayed in the multiple-group fit summary

table, because the baseline model function values for individual groups are not saved in the BASEFIT= data set.

BASEFUNC= $r(< DF=>i)$

BASEFUNC($< DF=>i$)= r

inputs the fit function value r and the degrees of freedom i of the baseline model of your choice. This customized baseline model replaces the default uncorrelatedness model for computing several fit indices of your target model. To use this option, you must first fit your customized baseline model and then use this option to input the baseline model fit information when you fit your target model.

Using the BASEFUNC= option assumes that you fit your customized baseline model and your target model with the same data, number of groups (for multiple-group analysis), and estimation method. Typically, your baseline model should be more restrictive (or have fewer parameters) than your target model.

For example, assume that after fitting a customized baseline model you find that the function value of the baseline model is 20.54 and the model degrees of freedom are 15. The following code inputs the function value and the degrees of freedom of the customized baseline model by using the BASEFUNC= option:

```
proc calis data=abc basefunc(df=15)=20.54;
  path
    f1 ==> x1-x5    = 1.,
    f2 ==> x6-x10   = 1.,
    f1 ==> f2;
run;
```

You can use the following equivalent syntax to provide the same baseline model fit information:

```
basefunc(df=15)=20.54
basefunc(15)=20.54
basefunc=20.54(df=15)
basefunc=20.54(15)
```

It is emphasized here that you should input the fit function value, but not the model fit chi-square value, of the baseline model in the BASEFUNC= option. For all estimation methods except the full information maximum likelihood (FIML) method in PROC CALIS, the model fit chi-square values are some multiples of the fit function values. See the section “[Estimation Criteria](#)” on page 1309 for the definitions of the various fit functions that are assumed by the BASEFUNC= option.

Alternatively, it might be easier to use the [BASEFIT=](#) option to specify the SAS data set that contains the baseline model fit information. Such a SAS data set is typically created by using the [OUTFIT=](#) option in the PROC CALIS fitting of your customized baseline model. See the [BASEFIT=](#) option for details. However, the BASEFIT= option is ignored if you also specify the BASEFUNC= option.

Notice that the specified values in the BASEFUNC= option do not affect the computation of all fit indices. Mainly, they affect the incremental fit indices, because these indices are defined as the incremental fit of a target model over a baseline model. Among all absolute and parsimonious fit indices, only the parsimonious goodness-of-fit (PGFI) index (Mulaik et al. 1989) is affected by the values provided in the BASEFUNC= option.

If you specify **METHOD=LSDWLS**, **LSFIML**, **LSGLS**, or **LSML** for your target model, the fit information provided by the **BASEFUNC=** option is assumed to have been obtained from the **DWLS**, **FIML**, **GLS**, or **ML** estimation of your customized baseline model. Hence, the fit information provided by the **BASEFUNC=** option applies only to the second estimation of your target model. The unweighted least squares (ULS) estimation of the target model still uses the uncorrelatedness model as the baseline model for computing fit indices.

If you use the **BASEFUNC=** option to input the fit information of your customized baseline model in a multiple-group analysis, then the baseline model function values, chi-squares, and degrees of freedom for individual groups are not known and hence not displayed in the multiple-group fit summary table. The Bentler-Bonett NFI is also not displayed in the multiple-group fit summary table, because the baseline model function values for individual groups are not provided with the **BASEFUNC=** option.

BIASKUR

computes univariate skewness and kurtosis by formulas uncorrected for bias.

See the section “[Measures of Multivariate Kurtosis](#)” on page 1349 for more information.

CHICORRECT | CHICORR= *name* | *c*

specifies a correction factor *c* for the chi-square statistics for model fit. You can specify a *name* for a built-in correction factor or a value between 0 and 1 as the **CHICORRECT=** value. The model fit chi-square statistic is computed as:

$$\chi^2 = (1 - c)(N - k)F$$

where *N* is the total number of observations, *k* is the number of independent groups, and *F* is the optimized function value. Application of these correction factors requires appropriate specification of the covariance structural model suitable for the chi-square correction. For example, using **CHICORRECT=UNCORR** assumes that you are fitting a covariance structure with free parameters on the diagonal elements and fixed zeros off-diagonal elements of the covariance matrix. Because all the built-in correction factors assume multivariate normality in their derivations, the appropriateness of applying these built-in chi-square corrections to estimation methods other than **METHOD=ML** is not known.

Valid *names* for the **CHICORRECT=** value are as follows:

COMPSYM | **EQVARCOV** specifies the correction factor due to Box (1949) for testing equal variances and equal covariances in a covariance matrix. The correction factor is:

$$c = \frac{p(p+1)^2(2p-3)}{6n(p-1)(p^2+p-4)}$$

where *p* (*p* > 1) represents the number of variables and *n* = (*N* - 1), with *N* denoting the number of observations in a single group analysis. This option is not applied when you also analyze the mean structures or when you fit multiple-group models.

EQCOVMAT specifies the correction factor due to Box (1949) for testing equality of covariance matrices. The correction factor is:

$$c = \frac{2p^2 + 3p - 1}{6(p+1)(k-1)} \left(\sum_{i=1}^k \frac{1}{n_i} - \frac{1}{\sum_{i=1}^k n_i} \right)$$

where p represents the number of variables, k ($k > 1$) represents the number of groups, and $n_i = (N_i - 1)$, with N_i denoting the number of observations in the i th group. This option is not applied when you also analyze the mean structures or when you fit single-group models.

FIXCOV

specifies the correction factor due to Bartlett (1954) for testing a covariance matrix against a hypothetical fixed covariance matrix. The correction factor is:

$$c = \frac{1}{6n} \left(2p + 1 - \frac{2}{p + 1} \right)$$

where p represents the number of variables and $n = (N - 1)$, with N denoting the number of observations in a single group analysis. This option is not applied when you also analyze the mean structures or when you fit multiple-group models.

SPHERICITY

specifies the correction factor due to Box (1949) for testing a spherical covariance matrix (Mauchly 1940). The correction factor is:

$$c = \frac{2p^2 + p + 2}{6np}$$

where p represents the number of variables and $n = (N - 1)$, with N denoting the number of observations in a single group analysis. This option is not applied when you also analyze the mean structures or when you fit multiple-group models.

TYPEH

specifies the correction factor for testing the H pattern (Huynh and Feldt 1970) directly. The correction factor is:

$$c = \frac{2p^2 - 3p + 3}{6n(p - 1)}$$

where p ($p > 1$) represents the number of variables and $n = (N - 1)$, with N denoting the number of observations in a single group analysis. This option is not applied when you also analyze the mean structures or when you fit multiple-group models.

This correction factor is derived by substituting p with $p - 1$ in the correction formula applied to Mauchly's sphericity test. The reason is that testing the H pattern of p variables is equivalent to testing the sphericity of the $(p - 1)$ orthogonal contrasts of the same set of variables (Huynh and Feldt 1970). See pp. 295–296 of Morrison (1990) for more details.

UNCORR

specifies the correction factor due to Bartlett (1950) and Box (1949) for testing a diagonal pattern of a covariance matrix, while the diagonal elements (variances) are unconstrained. This test is sometimes called Bartlett's test of sphericity—not to be confused with the sphericity test due to Mauchly (1940), which requires all variances in the covariance matrix to be equal. The correction factor is:

$$c = \frac{2p + 5}{6n}$$

where p represents the number of variables and $n = (N - 1)$, with N denoting the number of observations in a single group analysis. This option is not applied when you also analyze the mean structures or when you fit multiple-group models.

CLOSEFIT= p

defines the criterion value p for indicating a close fit. The smaller the better fit. The default value for close fit is .05.

CORRELATION | CORR

analyzes the correlation matrix, instead of the default covariance matrix. See the [COVARIANCE](#) option for more details.

COVARIANCE | COV

analyzes the covariance matrix. Because this is also the default analysis in PROC CALIS, you can simply omit this option when you analyze covariance rather than correlation matrices. If the [DATA=](#) input data set is a TYPE=CORR data set (containing a correlation matrix and standard deviations), the default COV option means that the covariance matrix is computed and analyzed.

Unlike many other SAS/STAT procedures (for example, the FACTOR procedure) that analyze correlation matrices by default, PROC CALIS uses a different default because statistical theories of structural equation modeling or covariance structure analysis are mostly developed for covariance matrices. You must use the [CORR](#) option if correlation matrices are analyzed.

COVPATTERN | COVPAT=*name*

specifies one of the built-in covariance structures for the data. The purpose of this option is to fit some commonly-used direct covariance structures efficiently without the explicit use of the MSTRUCT model specifications. With this option, the covariance structures are defined internally in PROC CALIS. The following *names* for the built-in covariance structures are supported:

COMPSYM | EQVARCOV specifies the compound symmetry pattern for the covariance matrix. That is, a covariance matrix with equal variances for all variables and equal covariance between any pairs of variables (EQVARCOV). PROC CALIS names the common variance parameter `_varparm` and the common covariance parameter `_covparm`. For example, if there are four variables in the analysis, the covariance pattern generated by PROC CALIS is:

$$\Sigma = \begin{pmatrix} \text{_varparm} & \text{_covparm} & \text{_covparm} & \text{_covparm} \\ \text{_covparm} & \text{_varparm} & \text{_covparm} & \text{_covparm} \\ \text{_covparm} & \text{_covparm} & \text{_varparm} & \text{_covparm} \\ \text{_covparm} & \text{_covparm} & \text{_covparm} & \text{_varparm} \end{pmatrix}$$

If you request a single-group maximum likelihood (METHOD=ML) covariance structure analysis by specifying the COVPATTERN=COMPSYM or COVPATTERN=EQVARCOV option and the mean structures are not modeled, the chi-square correction due to Box (1949) is applied automatically when the number of variables is greater than or equal to 2. See the [CHICORRECT=COMPSYM](#) option for the definition of the correction factor.

EQCOVMAT

specifies the equality of covariance matrices between multiple groups. That is, this option tests the null hypothesis that

$$H_0 : \Sigma_1 = \Sigma_2 = \dots = \Sigma_k = \Sigma$$

where Σ is a common covariance matrix for the k Σ_j 's ($j = 1, \dots, k; k > 1$). The elements of Σ are named `_cov_xx_yy` automatically by PROC CALIS, where

xx represents the row number and yy represents the column number. For example, if there are four variables in the analysis, the common Σ is defined as

$$\Sigma = \begin{pmatrix} _cov_1_1 & _cov_1_2 & _cov_1_3 & _cov_1_4 \\ _cov_2_1 & _cov_2_2 & _cov_2_3 & _cov_2_4 \\ _cov_3_1 & _cov_3_2 & _cov_3_3 & _cov_3_4 \\ _cov_4_1 & _cov_4_2 & _cov_4_3 & _cov_4_4 \end{pmatrix}$$

If you request a multiple-group maximum likelihood (METHOD=ML) covariance structure analysis by specifying the COVPATTERN=EQCOVMAT and the mean structures are not modeled, the chi-square correction due to Box (1949) is applied automatically. See the [CHICORRECT=EQCOVMAT](#) option for the definition of the correction factor.

SATURATED

specifies a saturated covariance structure model. This is the default option when you specify the [MEANPATTERN=](#) option without using the COVPATTERN= option. The elements of Σ are named $_cov_xx_yy$ automatically by PROC CALIS, where xx represents the row number and yy represents the column number. For example, if there are three variables in the analysis, Σ is defined as

$$\Sigma = \begin{pmatrix} _cov_1_1 & _cov_1_2 & _cov_1_3 \\ _cov_2_1 & _cov_2_2 & _cov_2_3 \\ _cov_3_1 & _cov_3_2 & _cov_3_3 \end{pmatrix}$$

SPHERICITY | SIGSQI specifies the spheric pattern of the covariance matrix (Mauchly 1940). That is, this option tests the null hypothesis that

$$H_0 : \Sigma = \sigma^2 \mathbf{I}$$

where σ^2 is a common variance parameter and \mathbf{I} is an identity matrix. PROC CALIS names the common variance parameter $_varparm$. For example, if there are three variables in the analysis, the covariance pattern generated by PROC CALIS is:

$$\Sigma = \begin{pmatrix} _varparm & 0 & 0 \\ 0 & _varparm & 0 \\ 0 & 0 & _varparm \end{pmatrix}$$

If you request a single-group maximum likelihood (METHOD=ML) covariance structure analysis by specifying the COVPATTERN=SPHERICITY or COVPATTERN=SIGSQI option and the mean structures are not modeled, the chi-square correction due to Box (1949) is applied automatically. See the [CHICORRECT=SPHERICITY](#) option for the definition of the correction factor.

UNCORR | DIAG

specifies the diagonal pattern of the covariance matrix. That is, this option tests the null hypothesis of uncorrelatedness—all correlations (or covariances) between variables are zero and the variances are unconstrained. PROC CALIS names the variance parameters $_varparm_xx$, where xx represents the row or column number. For example, if there are three variables in the analysis, the covariance pattern generated by PROC CALIS is:

$$\Sigma = \begin{pmatrix} _varparm_1 & 0 & 0 \\ 0 & _varparm_2 & 0 \\ 0 & 0 & _varparm_3 \end{pmatrix}$$

If you request a single-group maximum likelihood (METHOD=ML) covariance structure analysis by specifying the COVPATTERN=UNCORR or COVPATTERN=DIAG option and the mean structures are not modeled, the chi-square correction due to Bartlett (1950) is applied automatically. See the [CHICORRECT=UNCORR](#) option for the definition of the correction factor. Under the multivariate normal assumption, COVPATTERN=UNCORR is also a test of independence of the variables in the analysis.

When you specify the covariance structure model by means of the COVPATTERN= option, you can define the set of variables in the analysis by the [VAR](#) statement (either within the scope of the PROC CALIS statement or the [GROUP](#) statements). If the VAR statement is not used, PROC CALIS uses all numerical variables in the data sets.

Except for the EQCOVMAT pattern, all other built-in covariance patterns are primarily designed for single-group analysis. However, you can still use these covariance pattern options for multiple-group situations. For example, consider the following three-group analysis:

```
proc calis covpattern=compsym;
  group 1 / data=set1;
  group 2 / data=set2;
  group 3 / data=set3;
run;
```

In this specification, all three groups are fitted by the compound symmetry pattern. However, there would be no constraints across these groups. PROC CALIS generates two distinct parameters for each group: `_varparm_md1` and `_covparm_md1` for Group 1, `_varparm_md2` and `_covparm_md2` for Group 2, and `_varparm_md3` and `_covparm_md3` for Group 3. Similarly, the `_mdlxx` suffix, where `xx` represents the model number, is applied to the parameters defined by the SATURATED, SPHERICITY (or SIGSQI), and UNCORR (or DIAG) covariance patterns in multiple-group situations. However, chi-square correction, whenever it is applicable to single-group analysis, is not applied to such multiple-group analyses.

You can also apply the COVPATTERN= option partially to the groups in the analysis. For example, the following statements apply the spheric pattern to Group 1 and Group 2 only:

```
proc calis covpattern=sphericity;
  group 1 / data=set1;
  group 2 / data=set2;
  group 3 / data=set3;
  model 3 / group=3;
  path    x1 ==> y3;
run;
```

Group 3 is fitted by Model 3, which is specified explicitly by a PATH model with distinct covariance structures.

If the EQCOVMAT pattern is specified instead, as shown in the following statements, the equality of covariance matrices still holds for Groups 1 and 2:

```

proc calis covpattern=eqcovmat;
  group 1 / data=set1;
  group 2 / data=set2;
  group 3 / data=set3;
  model 3 / group=3;
    path    x1 ==> y3;
run;

```

However, Group 3 has its own covariance structures as specified in Model 3. In this case, the chi-square correction due to Box (1949) is not applied because the null hypothesis is no longer testing the equality of covariance matrices among the groups in the analysis.

Use the **MEANPATTERN=** option if you also want to analyze some built-in mean structures along with the covariance structures.

COVSING=*r*

specifies a nonnegative threshold *r*, which determines whether the eigenvalues of the information matrix are considered to be zero. If the inverse of the information matrix is found to be singular (depending on the **VSINGULAR=**, **MSINGULAR=**, **ASINGULAR=**, or **SINGULAR=** option), a generalized inverse is computed using the eigenvalue decomposition of the singular matrix. Those eigenvalues smaller than *r* are considered to be zero. If a generalized inverse is computed and you do not specify the **NOPRINT** option, the distribution of eigenvalues is displayed.

DATA=SAS-data-set

specifies an input data set that can be an ordinary SAS data set or a specially structured **TYPE=CORR**, **TYPE=COV**, **TYPE=UCORR**, **TYPE=UCOV**, **TYPE=SSCP**, or **TYPE=FACTOR** SAS data set, as described in the section “[Input Data Sets](#)” on page 1236. If the **DATA=** option is omitted, the most recently created SAS data set is used.

DEMPHAS | DE=*r*

changes the initial values of all variance parameters by the relationship:

$$s_{new} = r(|s_{old}| + 1)$$

where s_{new} is the new initial value and s_{old} is the original initial value. The initial values of all variance parameters should always be nonnegative to generate positive definite predicted model matrices in the first iteration. By using values of $r > 1$, for example, $r = 2$, $r = 10$, and so on, you can increase these initial values to produce predicted model matrices with high positive eigenvalues in the first iteration. The **DEMPHAS=** option is effective independent of the way the initial values are set; that is, it changes the initial values set in the model specification as well as those set by an **INMODEL=** data set and those automatically generated for the **FACTOR**, **LINEQS**, **LISMOD**, **PATH**, or **RAM** models. It also affects the initial values set by the **START=** option, which uses, by default, **DEMPHAS=100** if a covariance matrix is analyzed and **DEMPHAS=10** for a correlation matrix.

DFREDUCE | DFRED=*i*

reduces the degrees of freedom of the model fit χ^2 test by *i*. In general, the number of degrees of freedom is the total number of nonredundant elements in all moment matrices minus the number of parameters, *t*. Because negative values of *i* are allowed, you can also increase the number of degrees of freedom by using this option.

EDF | DFE=*n*

makes the effective number of observations $n + 1$. You can also use the **NOBS=** option to specify the number of observations.

EFFPART | PARTEFF | TOTEFF | TE

computes and displays total, direct, and indirect effects for the unstandardized and standardized estimation results. Standard errors for the effects are also computed. Note that this displayed output is not automatically included in the output generated by the **PALL** option.

Note also that in some situations computations of total effects and their partitioning are not appropriate. While total and indirect effects must converge in recursive models (models with no cyclic paths among variables), they do not always converge in nonrecursive models. When total or indirect effects do not converge, it is not appropriate to partition the effects. Therefore, before partitioning the total effects, the convergence criterion must be met. To check the convergence of the effects, PROC CALIS computes and displays the “stability coefficient of reciprocal causation”—that is, the largest modulus of the eigenvalues of the β matrix, which is the square matrix that contains the path coefficients of all endogenous variables in the model. Stability coefficients less than one provide a necessary and sufficient condition for the convergence of the total and the indirect effects. Otherwise, PROC CALIS does not show results for total effects and their partitioning. See the section “[Stability Coefficient of Reciprocal Causation](#)” on page 1345 for more information about the computation of the stability coefficient.

EXTENDPATH | GENPATH

displays the extended path estimates such as the variances, covariances, means, and intercepts in the table that contains the ordinary path effect (coefficient) estimates. This option applies to the PATH model only.

FCONV | FTOL=*r*

specifies the relative function convergence criterion. The optimization process is terminated when the relative difference of the function values of two consecutive iterations is smaller than the specified value of r ; that is,

$$\frac{|f(x^{(k)}) - f(x^{(k-1)})|}{\max(|f(x^{(k-1)})|, FSIZE)} \leq r$$

where $FSIZE$ can be defined by the **FSIZE=** option in the **NLOPTIONS** statement. The default value is $r = 10^{-FDIGITS}$, where $FDIGITS$ either can be specified in the **NLOPTIONS** statement or is set by default to $-\log_{10}(\epsilon)$, where ϵ is the machine precision.

G4=*i*

instructs that the algorithm to compute the approximate covariance matrix of parameter estimates used for computing the approximate standard errors and modification indices when the information matrix is singular. If the number of parameters t used in the model you analyze is smaller than the value of i , the time-expensive Moore-Penrose (G4) inverse of the singular information matrix is computed by eigenvalue decomposition. Otherwise, an inexpensive pseudo (G1) inverse is computed by sweeping. By default, $i = 60$.

See the section “[Estimation Criteria](#)” on page 1309 for more details.

GCONV | GTOL=*r*

specifies the relative gradient convergence criterion.

Termination of all techniques (except the CONGRA technique) requires the following normalized predicted function reduction to be smaller than *r*. That is,

$$\frac{[g(x^{(k)})]'[G^{(k)}]^{-1}g(x^{(k)})}{\max(|f(x^{(k)})|, FSIZE)} \leq r$$

where *FSIZE* can be defined by the *FSIZE*= option in the **NLOPTIONS** statement. For the CONGRA technique (where a reliable Hessian estimate **G** is not available),

$$\frac{\|g(x^{(k)})\|_2^2 \|s(x^{(k)})\|_2}{\|g(x^{(k)}) - g(x^{(k-1)})\|_2 \max(|f(x^{(k)})|, FSIZE)} \leq r$$

is used. The default value is $r = 10^{-8}$.

INEST | INVAR | ESTDATA=*SAS-data-set*

specifies an input data set that contains initial estimates for the parameters used in the optimization process and can also contain boundary and general linear constraints on the parameters. Typical applications of this option are to specify an **OUTEST**= data set from a previous PROC CALIS analysis. The initial estimates are taken from the values of the **PARMS** observation in the **INEST**= data set.

INMODEL | INRAM=*SAS-data-set*

specifies an input data set that contains information about the analysis model. A typical use of the **INMODEL**= option is when you run an analysis with its model specifications saved as an **OUTMODEL**= data set from a previous PROC CALIS run. Instead of specifying the **main** or **subsidiary** model specification statements in the new run, you use the **INMODEL**= option to input the model specification saved from the previous run.

Sometimes, you might create an **INMODEL**= data set from modifying an existing **OUTMODEL**= data set. However, editing and modifying **OUTMODEL**= data sets requires good understanding of the formats and contents of the **OUTMODEL**= data sets. This process could be error-prone for novice users. For details about the format of **INMODEL**= or **OUTMODEL**= data sets, see the section “**Input Data Sets**” on page 1236.

It is important to realize that **INMODEL**= or **OUTMODEL**= data sets contain only the information about the specification of the model. These data sets do not store any information about the bounds on parameters, linear and nonlinear parametric constraints, and programming statements for computing dependent parameters. If required, these types of information must be provided in the corresponding statement specifications (for example, **BOUNDS**, **LINCON**, and so on) in addition to the **INMODEL**= data set.

An **OUTMODEL**= data set might also contain default parameters added automatically by PROC CALIS from a previous run (for example, observations with **_TYPE**=**ADDP****COV**, **ADDP****MEAN**, or **ADDP****VAR**). When reading the **OUTMODEL**= model specification as an **INMODEL**= data set in a new run, PROC CALIS ignores these added parameters so that the model being read is exactly like the previous PROC CALIS specification (that is, before default parameters were added automatically). After interpreting the specification in the **INMODEL**= data set, PROC CALIS will then add default parameters appropriate to the new run. The purpose of doing this is to avoid inadvertent parameter constraints in the new run, where another set of automatic default parameters might have the same generated names as those of the generated parameter names in the **INMODEL**= data set.

If you want the default parameters in the INMODEL= data set to be read as a part of model specification, you must also specify the [READADDPARM](#) option. However, using the [READADDPARM](#) option should be rare.

INSTEP=*r*

For highly nonlinear objective functions, such as the EXP function, the default initial radius of the trust-region algorithms (TRUREG, DBLDOG, and LEVMAR) or the default step length of the line-search algorithms can produce arithmetic overflows. If an arithmetic overflow occurs, specify decreasing values of $0 < r < 1$ such as INSTEP=1E-1, INSTEP=1E-2, INSTEP=1E-4, and so on, until the iteration starts successfully.

- For trust-region algorithms (TRUREG, DBLDOG, and LEVMAR), the INSTEP option specifies a positive factor for the initial radius of the trust region. The default initial trust-region radius is the length of the scaled gradient, and it corresponds to the default radius factor of $r = 1$.
- For line-search algorithms (NEWRAP, CONGRA, and QUANEW), INSTEP specifies an upper bound for the initial step length for the line search during the first five iterations. The default initial step length is $r = 1$.

For more details, see the section “[Computational Problems](#)” on page 1360.

INWGT | INWEIGHT<(INV)>=SAS-data-set

specifies an input data set that contains the weight matrix **W** used in generalized least squares (GLS), weighted least squares (WLS, ADF), or diagonally weighted least squares (DWLS) estimation, if you do not specify the INV option at the same time. The weight matrix must be positive definite because its inverse must be defined in the computation of the objective function. If the weight matrix **W** defined by an INWGT= data set is not positive definite, it can be ridged using the [WRIDGE=](#) option. See the section “[Estimation Criteria](#)” on page 1309 for more information. If you specify the INWGT(INV)= option, the INWGT= data set contains the inverse of the weight matrix, rather than the weight matrix itself. Specifying the INWGT(INV)= option is equivalent to specifying the INWGT= and [INWGTINV](#) options simultaneously. With the INWGT(INV)= specification, the input matrix is not required to be positive definite. See the [INWGTINV](#) option for more details. If no INWGT= data set is specified, default settings for the weight matrices are used in the estimation process. The INWGT= data set is described in the section “[Input Data Sets](#)” on page 1236. Typically, this input data set is an [OUTWGT=](#) data set from a previous PROC CALIS analysis.

INWGTINV

specifies that the INWGT= data set contains the inverse of the weight matrix, rather than the weight matrix itself. This option is effective only with an input weight matrix specified in the [INWGT=](#) data set and with the generalized least squares (GLS), weighted least squares (WLS or ADF), or diagonally weighted least squares (DWLS) estimation. With this option, the input matrix provided in the INWGT= data set is not required to be positive definite. Also, the ridging requested by the [WRIDGE=](#) option is ignored when you specify the INWGTINV option.

KURTOSIS | KU

computes and displays univariate kurtosis and skewness, various coefficients of multivariate kurtosis, and the numbers of observations that contribute most to the normalized multivariate kurtosis. See the section “[Measures of Multivariate Kurtosis](#)” on page 1349 for more information. Using the KURTOSIS option implies the [SIMPLE](#) display option. This information is computed only if the [DATA=](#) data set is a raw data set, and it is displayed by default if the [PRINT](#) option is specified. The

multivariate least squares kappa and the multivariate mean kappa are displayed only if you specify **METHOD=WLS** and the weight matrix is computed from an input raw data set. All measures of skewness and kurtosis are corrected for the mean. Using the **BIASKUR** option displays the biased values of univariate skewness and kurtosis.

LINESEARCH | LIS | SMETHOD | SM=*i*

specifies the line-search method for the CONGRA, QUANEW, and NEWRAP optimization techniques. See Fletcher (1980) for an introduction to line-search techniques. The value of *i* can be any integer between 1 and 8, inclusively; the default is *i*=2.

- LIS=1** specifies a line-search method that needs the same number of function and gradient calls for cubic interpolation and cubic extrapolation; this method is similar to one used by the Harwell subroutine library.
- LIS=2** specifies a line-search method that needs more function calls than gradient calls for quadratic and cubic interpolation and cubic extrapolation; this method is implemented as shown in Fletcher (1987) and can be modified to an exact line search by using the **LSPRECISION=** option.
- LIS=3** specifies a line-search method that needs the same number of function and gradient calls for cubic interpolation and cubic extrapolation; this method is implemented as shown in Fletcher (1987) and can be modified to an exact line search by using the **LSPRECISION=** option.
- LIS=4** specifies a line-search method that needs the same number of function and gradient calls for stepwise extrapolation and cubic interpolation.
- LIS=5** specifies a line-search method that is a modified version of LIS=4.

LSPRECISION | LSP=*r*

SPPRECISION | SP=*r*

specifies the degree of accuracy that should be obtained by the line-search algorithms **LIS=2** and **LIS=3**. Usually an imprecise line search is inexpensive and successful. For more difficult optimization problems, a more precise and more expensive line search might be necessary (Fletcher 1980, p. 22). The second (default for NEWRAP, QUANEW, and CONGRA) and third line-search methods approach exact line search for small **LSPRECISION=** values. If you have numerical problems, you should decrease the **LSPRECISION=** value to obtain a more precise line search. The default **LSPRECISION=** values are displayed in the following table.

OMETHOD=	UPDATE=	LSP default
QUANEW	DBFGS, BFGS	<i>r</i> = 0.4
QUANEW	DDFP, DFP	<i>r</i> = 0.06
CONGRA	all	<i>r</i> = 0.1
NEWRAP	no update	<i>r</i> = 0.9

For more details, see Fletcher (1980, pp. 25–29).

MAXFUNC | MAXFU=*i*

specifies the maximum number *i* of function calls in the optimization process. The default values are displayed in the following table.

OMETHOD=	MAXFUNC default
LEVMar, NEWRAP, NRRIDG, TRUREG	$i = 125$
DBLDOG, QUANEW	$i = 500$
CONGRA	$i = 1000$

The default is used if you specify **MAXFUNC=0**. The optimization can be terminated only after completing a full iteration. Therefore, the number of function calls that is actually performed can exceed the number that is specified by the **MAXFUNC=** option.

MAXITER | MAXIT= $i < n$

specifies the maximum number i of iterations in the optimization process. Except for the iteratively reweighted least squares (IRLS) algorithm for the robust estimation of model parameters, the default values are displayed in the following table.

OMETHOD=	MAXITER default
LEVMar, NEWRAP, NRRIDG, TRUREG	$i = 50$
DBLDOG, QUANEW	$i = 200$
CONGRA	$i = 400$

The default maximum number of iterations for IRLS is 5000. The default value is used if you specify **MAXITER=0** or if you omit the **MAXITER** option.

The optional second value n is valid only for **OMETHOD=QUANEW** with nonlinear constraints. It specifies an upper bound n for the number of iterations of an algorithm and reduces the violation of nonlinear constraints at a starting point. The default is $n = 20$. For example, specifying

```
maxiter= . 0
```

means that you do not want to exceed the default number of iterations during the main optimization process and that you want to suppress the feasible point algorithm for nonlinear constraints.

MAXMISSPAT= n

specifies the maximum number of missing patterns to display in the output, where n is between 1 and 9,999. The default **MAXMISSPAT=** value is 10 or the number of missing patterns in the data, whichever is smaller. The number of missing patterns to display cannot exceed this **MAXMISSPAT=** value. This option is relevant only when there are incomplete observations (with some missing values in the analysis variables) in the input raw data set and when you use **METHOD=FIML** or **METHOD=LSFIML** for estimation.

Because the number of missing patterns could be quite large, PROC CALIS displays a limited number of the most frequent missing patterns in the output. The **MAXMISSPAT=** and the **TMISSPAT=** options are used in determining the number of missing patterns to display. The missing patterns are ordered according to the data proportions they account for, from the largest to the smallest. PROC CALIS displays a minimum number of the highest-frequency missing patterns. This minimum number is the smallest among five, the actual number of missing patterns, and the **MAXMISSPAT=** value. Then, PROC CALIS displays the subsequent high-frequency missing patterns if the data proportion accounted for by each of these patterns is at least as large as the proportion threshold set by the **TMISSPAT=** value (default at 0.05) until the total number of missing patterns displayed reaches the maximum set by the **MAXMISSPAT=** option.

MEANPATTERN | MEANPAT=name

specifies one of the built-in mean structures for the data. The purpose of this option is to fit some commonly-used direct mean structures efficiently without the explicit use of the MSTRUCT model specifications. With this option, the mean structures are defined internally in PROC CALIS. The following *names* for the built-in mean structures are supported:

EQMEANVEC specifies the equality of mean vectors between multiple groups. That is, this option tests the null hypothesis that

$$H_0 : \mu_1 = \mu_2 = \dots = \mu_k = \mu$$

where μ is a common mean vector for the k μ_j 's ($j = 1, \dots, k$). The elements of μ are named `_mean_xx` automatically by PROC CALIS, where `xx` represents the row number. For example, if there are four variables in the analysis, the common μ is defined as

$$\mu = \begin{pmatrix} \text{_mean_1} \\ \text{_mean_2} \\ \text{_mean_3} \\ \text{_mean_4} \end{pmatrix}$$

If you use the `COVPATTERN=EQCOVMAT` and `MEANPATTERN=EQMEANVEC` together in a maximum likelihood (METHOD=ML) analysis, you are testing a null hypothesis of the same multivariate normal distribution for the groups.

If you use the `MEANPATTERN=EQMEANVEC` option for a single-group analysis, the parameters for the single group are still created accordingly. However, the mean model for the single group contains only unconstrained parameters that would result in saturated mean structures for the model.

SATURATED

specifies a saturated mean structure model. This is the default mean structure pattern when the covariance structures are specified by the `COVPATTERN=` pattern and the mean structure analysis is invoked by `MEANSTR` option. The elements of μ are named `_mean_xx` automatically by PROC CALIS, where `xx` represents the row number. For example, if there are three variables in the analysis, μ is defined as

$$\mu = \begin{pmatrix} \text{_mean_1} \\ \text{_mean_2} \\ \text{_mean_3} \end{pmatrix}$$

UNIFORM

specifies a mean vector with a uniform mean parameter `_meanparm`. For example, if there are three variables in the analysis, the mean pattern generated by PROC CALIS is

$$\mu = \begin{pmatrix} \text{_meanparm} \\ \text{_meanparm} \\ \text{_meanparm} \end{pmatrix}$$

ZERO specifies a zero vector for the mean structures. For example, if there are four variables in the analysis, the mean pattern generated by PROC CALIS is:

$$\mu = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \end{pmatrix}$$

When you specify the mean structure model by means of the MEANPATTERN= option, you can define the set of variables in the analysis by the **VAR** statement (either within the scope of the PROC CALIS statement or the **GROUP** statements). If the VAR statement is not used, PROC CALIS uses all numerical variables in the data sets.

Except for the EQMEANVEC pattern, all other built-in mean patterns are primarily designed for single-group analysis. However, you can still use these mean pattern options for multiple-group situations. For example, consider the following three-group analysis:

```
proc calis meanpattern=uniform;
  group 1 / data=set1;
  group 2 / data=set2;
  group 3 / data=set3;
run;
```

In this specification, all three groups are fitted by the uniform mean pattern. However, there would be no constraints across these groups. PROC CALIS generates a distinct mean parameter for each group: `_meanparm_md11` for Group 1, `_meanparm_md12` for Group 2, and `_meanparm_md13` for Group 3. Similarly, the `_mdlxx` suffix, where `xx` represents the model number, is applied to the parameters defined by the SATURATED mean pattern in multiple-group situations.

You can also apply the MEANPATTERN= option partially to the groups in the analysis. For example, the following statements apply the ZERO mean pattern to Group 1 and Group 2 only:

```
proc calis meanpattern=zero;
  group 1 / data=set1;
  group 2 / data=set2;
  group 3 / data=set3;
  model 3 / group=3;
    path    x1 ==> y3;
    means x1 = mean_x1;
run;
```

Group 3 is fitted by Model 3, which is specified explicitly by a PATH model with a distinct mean parameter `mean_x1`.

If the EQMEANVEC pattern is specified instead, as shown in the following statements, the equality of mean vectors still holds for Groups 1 and 2:

```
proc calis meanpattern=eqmeanvec;
  group 1 / data=set1;
  group 2 / data=set2;
  group 3 / data=set3;
  model 3 / group=3;
    path    x1 ==> y3;
    means x1 = mean_x1;
run;
```

However, Group 3 has its own mean structures as specified in Model 3.

Use the **COVPATTERN=** option if you also want to analyze some built-in covariance structures along with the mean structures. If you use the **MEANPATTERN=** option but do not specify the **COVPATTERN=** option, a saturated covariance structure model (that is, **COVPATTERN=SATURATED**) is assumed by default.

MEANSTR

invokes the analysis of mean structures. By default, no mean structures are analyzed. You can specify the **MEANSTR** option in both the **PROC CALIS** and the **MODEL** statements. When this option is specified in the **PROC CALIS** statement, it propagates to all models. When this option is specified in the **MODEL** statement, it applies only to the local model. Except for the **COSAN** model, the **MEANSTR** option adds default mean parameters to the model. For the **COSAN** model, the **MEANSTR** option adds null mean vectors to the model. Instead of using the **MEANSTR** option to analyze the mean structures, you can specify the mean and the intercept parameters explicitly in the model by some model specification statements. That is, you can specify the intercepts in the **LINEQS** statement, the intercepts and means in the **PATH** or the **MEAN** statement, the **_MEAN_** matrix in the **MATRIX** statement, or the mean structure formula in the **COSAN** statement. The explicit mean structure parameter specifications are useful when you need to constrain the mean parameters or to create your own references of the parameters.

METHOD | MET | M=name

specifies the method of parameter estimation. The default is **METHOD=ML**. Valid values for *name* are as follows:

FIML

performs full information maximum-likelihood (FIML) or direct maximum likelihood parameter estimation for data with missing values. This method assumes raw input data sets. When there are no missing values in the analysis, the FIML method yields the same estimates as those by using the regular maximum likelihood (**METHOD=ML**) method with **VARDEF=N**.

Because the FIML method recomputes the mean estimates iteratively during estimation, it must intrinsically analyze the mean structures of models. If you do not specify the **MEANSTR** option or any mean parameters for your models (which is not required for using the FIML method), **PROC CALIS** assumes saturated mean structures for models. However, when computing fit statistics, these saturated mean structures would be ignored as if they were never modeled. If you do specify the **MEANSTR** option

	or any mean parameters for your models, these mean structures would be taken into account when computing fit statistics.
ML M MAX	performs normal-theory maximum-likelihood parameter estimation. The ML method requires a nonsingular covariance or correlation matrix.
GLS G	performs generalized least squares parameter estimation. If no INWGT= data set is specified, the GLS method uses the inverse sample covariance or correlation matrix as the weight matrix W . Therefore, METHOD=GLS requires a nonsingular covariance or correlation matrix.
WLS W ADF	performs weighted least squares parameter estimation. If no INWGT= data set is specified, the WLS method uses the inverse matrix of estimated asymptotic covariances of the sample covariance or correlation matrix as the weight matrix W . In this case, the WLS estimation method is equivalent to Browne's asymptotically distribution-free estimation (Browne 1982, 1984). The WLS method requires a nonsingular weight matrix.
DWLS D	performs diagonally weighted least squares parameter estimation. If no INWGT= data set is specified, the DWLS method uses the inverse diagonal matrix of asymptotic variances of the input sample covariance or correlation matrix as the weight matrix W . The DWLS method requires a nonsingular diagonal weight matrix.
ULS LS U	performs unweighted least squares parameter estimation.
LSFIML	performs unweighted least squares followed by full information maximum-likelihood parameter estimation.
LSML LSM LSMAX	performs unweighted least squares followed by normal-theory maximum-likelihood parameter estimation.
LSGLS LSG	performs unweighted least squares followed by generalized least squares parameter estimation.
LSWLS LSW LSADF	performs unweighted least squares followed by weighted least squares parameter estimation.
LSDWLS LSD	performs unweighted least squares followed by diagonally weighted least squares parameter estimation.
NONE NO	uses no estimation method. This option is suitable for checking the validity of the input information and for displaying the model matrices and initial values.

MODIFICATION | MOD

computes and displays Lagrange multiplier (LM) test indices for constant parameter constraints, equality parameter constraints, and active boundary constraints, as well as univariate and multivariate Wald test indices. The modification indices are not computed in the case of unweighted or diagonally weighted least squares estimation.

The Lagrange multiplier test (Bentler 1986; Lee 1985; Buse 1982) provides an estimate of the χ^2 reduction that results from dropping the constraint. For constant parameter constraints and active boundary constraints, the approximate change of the parameter value is displayed also. You can use this value to obtain an initial value if the parameter is allowed to vary in a modified model. See the section “[Modification Indices](#)” on page 1346 for more information.

Relying solely on the LM tests to modify your model can lead to unreliable models that capitalize purely on sampling errors. See MacCallum, Roznowski, and Necowitz (1992) for the use of LM tests.

MSINGULAR | MSING=*r*

specifies a relative singularity criterion r ($r > 0$) for the inversion of the information matrix, which is needed to compute the covariance matrix. If you do not specify the **SINGULAR=** option, the default value for r or **MSING=** is 1E-12; otherwise, the default value is $1E-4 \times SING$, where $SING$ is the specified **SINGULAR=** value.

When inverting the information matrix, the following singularity criterion is used for the diagonal pivot $d_{j,j}$ of the matrix:

$$|d_{j,j}| \leq \max(ASING, VSING * |H_{j,j}|, MSING * \max(|H_{1,1}|, \dots, |H_{n,n}|))$$

where $ASING$ and $VSING$ are the specified values of the **ASINGULAR=** and **VSINGULAR=** options, respectively, and $H_{j,j}$ is the j th diagonal element of the information matrix. Note that in many cases a normalized matrix $\mathbf{D}^{-1}\mathbf{H}\mathbf{D}^{-1}$ is decomposed (where $\mathbf{D}^2 = \text{diag}(\mathbf{H})$), and the singularity criteria are modified correspondingly.

NOADJDF

turns off the automatic adjustment of degrees of freedom when there are active constraints in the analysis. When the adjustment is in effect, most fit statistics and the associated probability levels will be affected. This option should be used when you believe that the active constraints observed in the current sample will have little chance to occur in repeated sampling. See the section “[Adjustment of Degrees of Freedom](#)” on page 1325 for more discussion on the issue.

NOBS=*nobs*

specifies the number of observations. If the **DATA=** input data set is a raw data set, *nobs* is defined by default to be the number of observations in the raw data set. The **NOBS=** and **EDF=** options override this default definition. You can use the **RDF=** option to modify the *nobs* specification. If the **DATA=** input data set contains a covariance, correlation, or scalar product matrix, you can specify the number of observations either by using the **NOBS=**, **EDF=**, and **RDF=** options in the PROC CALIS statement or by including a **_TYPE_='N'** observation in the **DATA=** input data set.

NOINDEXTYPE

disables the display of index types in the fit summary table.

NOMEANSTR

deactivates the inherited **MEANSTR** option for the analysis of mean structures. You can specify the **NOMEANSTR** option in both the PROC CALIS and the **MODEL** statements. When this option is specified in the PROC CALIS statement, it does not have any apparent effect because by default the mean structures are not analyzed. When this option is specified in the MODEL statement, it deactivates the inherited **MEANSTR** option from the PROC CALIS statement. In other words, this option is mainly used for resetting the default behavior in the local model that is specified within the scope of a particular MODEL statement. If you specify both the **MEANSTR** and **NOMEANSTR** options in the same statement, the **NOMEANSTR** option is ignored.

CAUTION: This option does not remove the mean structure specifications from the model. It only deactivates the **MEANSTR** option inherited from the PROC CALIS statement. The mean structures

of the model are analyzed as long as there are mean structure specifications in the model (for example, when you specify the means or intercepts in any of the [main](#) or [subsidiary](#) model specification statements).

NOMISSPAT

suppresses the display of the analytic results of the missing patterns. This option is relevant only when there are incomplete observations (with some missing values in the analysis variables) in the input raw data set and when you use [METHOD=FIML](#) or [METHOD=LSFIML](#) for estimation.

NOMOD

suppresses the computation of modification indices. The NOMOD option is useful in connection with the [PALL](#) option because it saves computing time.

NOORDERSPEC

prints the model results in the order they appear in the input specifications. This is the default printing behavior. In contrast, the [ORDERSPEC](#) option arranges the model results by the types of parameters. You can specify the NOORDERSPEC option in both the PROC CALIS and the [MODEL](#) statements. When this option is specified in the PROC CALIS statement, it does not have any apparent effect because by default the model results display in the same order as that in the input specifications. When this option is specified in the MODEL statement, it deactivates the inherited ORDERSPEC option from the PROC CALIS statement. In other words, this option is mainly used for resetting the default behavior in the local model that is specified within the scope of a particular MODEL statement. If you specify both the ORDERSPEC and NOORDERSPEC options in the same statement, the NOORDERSPEC option is ignored.

NOPARMNAME

suppresses the printing of parameter names in the model results. The default is to print the parameter names. You can specify the NOPARMNAME option in both the PROC CALIS and the [MODEL](#) statements. When this option is specified in the PROC CALIS statement, it propagates to all models. When this option is specified in the MODEL statement, it applies only to the local model.

NOPRINT | NOP

suppresses the displayed output. Note that this option temporarily disables the Output Delivery System (ODS). See Chapter 20, “[Using the Output Delivery System](#),” for more information.

NOSTAND

suppresses the printing of standardized results. The default is to print the standardized results.

NOSTDERR | NOSE

suppresses the printing of the standard error estimates. Standard errors are not computed for unweighted least squares (ULS) or diagonally weighted least squares (DWLS) estimation. In general, standard errors are computed even if the [STDERR](#) display option is not used (for file output). You can specify the NOSTDERR option in both the PROC CALIS and the [MODEL](#) statements. When this option is specified in the PROC CALIS statement, it propagates to all models. When this option is specified in the MODEL statement, it applies only to the local model.

OMETHOD | OM=name

TECHNIQUE | TECH=name

specifies the optimization method or technique. Because there is no single nonlinear optimization algorithm available that is clearly superior (in terms of stability, speed, and memory) for all applications,

different types of optimization methods or techniques are provided in the CALIS procedure. The optimization method or technique is specified by using one of the following *names* in the OMETHOD= option:

- CONGRA | CG** chooses one of four different conjugate-gradient optimization algorithms, which can be more precisely defined with the **UPDATE=** option and modified with the **LINESEARCH=** option. The conjugate-gradient techniques need only $O(t)$ memory compared to the $O(t^2)$ memory for the other three techniques, where t is the number of parameters. On the other hand, the conjugate-gradient techniques are significantly slower than other optimization techniques and should be used only when memory is insufficient for more efficient techniques. When you choose this option, **UPDATE=PB** by default. This is the default optimization technique if there are more than 999 parameters to estimate.
- DBLDOG | DD** performs a version of double dogleg optimization, which uses the gradient to update an approximation of the Cholesky factor of the Hessian. This technique is, in many aspects, very similar to the dual quasi-Newton method, but it does not use line search. The implementation is based on Dennis and Mei (1979) and (Gay 1983).
- LEVMAR | LM | MARQUARDT** performs a highly stable (but for large problems, memory- and time-consuming) Levenberg-Marquardt optimization technique, a slightly improved variant of the (Moré 1978) implementation. This is the default optimization technique for estimation methods other than the FIML if there are fewer than 500 parameters to estimate.
- NEWRAP | NRA** performs a usually stable (but for large problems, memory- and time-consuming) Newton-Raphson optimization technique. The algorithm combines a line-search algorithm with ridging, and it can be modified with the **LINESEARCH=** option.
- NRRIDG | NRR | NR | NEWTON** performs a usually stable (but for large problems, memory- and time-consuming) Newton-Raphson optimization technique. This algorithm does not perform a line search. Since OMETHOD=NRRIDG uses an orthogonal decomposition of the approximate Hessian, each iteration of OMETHOD=NRRIDG can be slower than that of OMETHOD=NEWRAP, which works with Cholesky decomposition. However, usually OMETHOD=NRRIDG needs fewer iterations than OMETHOD=NEWRAP. The NRRIDG technique is the default optimization for the FIML estimation if there are fewer than 500 parameters to estimate.
- QUANEW | QN** chooses one of four different quasi-Newton optimization algorithms that can be more precisely defined with the **UPDATE=** option and modified with the **LINESEARCH=** option. If boundary constraints are used, these techniques sometimes converge slowly. When you choose this option, **UPDATE=DBFGS** by default. If nonlinear constraints are specified in the **NLINCON** statement, a modification of Powell's VMCWD algorithm (Powell 1982a, b) is used, which is a sequential quadratic programming (SQP) method. This algorithm can be modified by specifying **VERSION=1**, which replaces the update of the Lagrange multiplier estimate vector μ to the original update of Powell (1978b, a)

that is used in the VF02AD algorithm. This can be helpful for applications with linearly dependent active constraints. The QUANEW technique is the default optimization technique if there are nonlinear constraints specified or if there are more than 499 and fewer than 1,000 parameters to estimate. The QUANEW algorithm uses only first-order derivatives of the objective function and, if available, of the nonlinear constraint functions.

TRUREG | TR

performs a usually very stable (but for large problems, memory- and time-consuming) trust-region optimization technique. The algorithm is implemented similar to Gay (1983) and Moré and Sorensen (1983).

NONE | NO

does not perform any optimization. This option is similar to **METHOD=NONE**, but **OMETHOD=NONE** also computes and displays residuals and goodness-of-fit statistics. If you specify **METHOD=ML**, **METHOD=LSML**, **METHOD=GLS**, **METHOD=LSGLS**, **METHOD=WLS**, or **METHOD=LSWLS**, this option enables computing and displaying (if the display options are specified) of the standard error estimates and modification indices corresponding to the input parameter estimates.

For fewer than 500 parameters ($t < 500$), **OMETHOD=NRRIDG** (Newton-Raphson Ridge) is the default optimization technique for the FIML estimation, and **OMETHOD=LEVVAR** (Levenberg-Marquardt) is the default optimization technique for the all other estimation methods. For $500 \leq t < 1,000$, **OMETHOD=QUANEW** (quasi-Newton) is the default method, and for $t \geq 1,000$, **OMETHOD=CONGRA** (conjugate gradient) is the default method. Each optimization method or technique can be modified in various ways. See the section “Use of Optimization Techniques” on page 1352 for more details.

ORDERALL

prints the model and group results in the order of the model or group numbers, starting from the smallest number. It also arrange some model results by the parameter types. In effect, this option turns on the **ORDERGROUPS**, **ORDERMODELS**, and **ORDERSPEC** options. The **ORDERALL** is not a default option. By default, the printing of the results follow the order of the input specifications.

ORDERGROUPS | ORDERG

prints the group results in the order of the group numbers, starting from the smallest number. The default behavior, however, is to print the group results in the order they appear in the input specifications.

ORDERMODELS | ORDERMO

prints the model results in the order of the model numbers, starting from the smallest number. The default behavior, however, is to print the model results in the order they appear in the input specifications.

ORDERSPEC

arranges some model results by the types of parameters. The default behavior, however, is to print the results in the order they appear in the input specifications. You can specify the **ORDERSPEC** option in both the PROC CALIS and the **MODEL** statements. When this option is specified in the PROC CALIS statement, it propagates to all models. When this option is specified in the MODEL statement, it applies only to the local model.

OUTEST=SAS-data-set

creates an output data set that contains the parameter estimates, their gradient, Hessian matrix, and boundary and linear constraints. For **METHOD=ML**, **METHOD=GLS**, and **METHOD=WLS**, the **OUTEST=** data set also contains the information matrix, the approximate covariance matrix of the parameter estimates ((generalized) inverse of information matrix), and approximate standard errors. If linear or nonlinear equality or active inequality constraints are present, the Lagrange multiplier estimates of the active constraints, the projected Hessian, and the Hessian of the Lagrange function are written to the data set.

See the section “**OUTEST= Data Set**” on page 1240 for a description of the **OUTEST=** data set. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

OUTFIT=SAS-data-set

creates an output data set that contains the values of the fit indices. See the section “**OUTFIT= Data Set**” on page 1254 for details.

OUTMODEL | OUTRAM=SAS-data-set

creates an output data set that contains the model information for the analysis, the parameter estimates, and their standard errors. An **OUTMODEL=** data set can be used as an input **INMODEL=** data set in a subsequent analysis by PROC CALIS. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

OUTSTAT=SAS-data-set

creates an output data set that contains the BY group variables, the analyzed covariance or correlation matrices, and the predicted and residual covariance or correlation matrices of the analysis. You can specify the correlation or covariance matrix in an **OUTSTAT=** data set as an input **DATA=** data set in a subsequent analysis by PROC CALIS. See the section “**OUTSTAT= Data Set**” on page 1250 for a description of the **OUTSTAT=** data set. If the model contains latent variables, this data set also contains the predicted covariances between latent and manifest variables and the latent variable score regression coefficients (see the **PLATCOV** option on page 1112). If the **FACTOR** statement is used, the **OUTSTAT=** data set also contains the rotated and unrotated factor loadings, the unique variances, the matrix of factor correlations, the transformation matrix of the rotation, and the matrix of standardized factor loadings.

You can use the latent variable score regression coefficients with PROC SCORE to compute factor scores.

If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

OUTWGT | OUTWEIGHT=SAS-data-set

creates an output data set that contains the elements of the weight matrix **W** or the its inverse **W⁻¹** used in the estimation process. The inverse of the weight matrix is output only when you specify an **INWGT=** data set with the **INWGT=** and **INWGTINV** options (or the **INWGT(INV)=** option alone) in the same analysis. As a result, the entries in the **INWGT=** and **OUTWGT=** data sets are consistent. In other situations where the weight matrix is computed by the procedure or obtained from the **OUTWGT=** data set without the **INWGTINV** option, the weight matrix is output in the **OUTWGT=** data set. Furthermore, if the weight matrix is computed by the procedure, the **OUTWGT=**

data set contains the elements of the weight matrix on which the **WRIDGE=** and the **WPENALTY=** options are applied.

You cannot create an **OUTWGT=** data set with an unweighted least squares or maximum likelihood estimation. The weight matrix is defined only in the GLS, WLS (ADF), or DWLS fit function. An **OUTWGT=** data set can be used as an input **INWGT=** data set in a subsequent analysis by PROC CALIS. See the section “**OUTWGT= Data Set**” on page 1254 for the description of the **OUTWGT=** data set. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

PALL | ALL

displays all optional output except the output generated by the **PCOVES** and **PDETERM** options.

CAUTION: The **PALL** option includes the very expensive computation of the modification indices. If you do not really need modification indices, you can save computing time by specifying the **NOMOD** option in addition to the **PALL** option.

PARMNAME

prints the parameter names in the model results. This is the default printing behavior. In contrast, the **NOPARMNAME** option suppresses the printing of the parameter names in the model results. You can specify the **PARMNAME** option in both the PROC CALIS and the **MODEL** statements. When this option is specified in the PROC CALIS statement, it does not have any apparent effect because by default model results show the parameter names. When this option is specified in the MODEL statement, it deactivates the inherited **NOPARMNAME** option from the PROC CALIS statement. In other words, this option is mainly used for resetting the default behavior in the local model that is specified within the scope of a particular MODEL statement. If you specify both the **PARMNAME** and **NOPARMNAME** options in the same statement, the **PARMNAME** option is ignored.

PCORR | CORR

displays the covariance or correlation matrix that is analyzed and the predicted model covariance or correlation matrix.

PCOVES | PCE

displays the following:

- the information matrix
- the approximate covariance matrix of the parameter estimates (generalized inverse of the information matrix)
- the approximate correlation matrix of the parameter estimates

The covariance matrix of the parameter estimates is not computed for estimation methods ULS and DWLS. This displayed output is not included in the output generated by the **PALL** option.

PDETERM | PDE

displays three coefficients of determination: the determination of all equations (DETAE), the determination of the structural equations (DETSE), and the determination of the manifest variable equations (DETMV). These determination coefficients are intended to be global means of the squared multiple correlations for different subsets of model equations and variables. The coefficients are displayed only when you specify a FACTOR, LINEQS, LISMOD, PATH, or RAM model, but they are displayed for all five estimation methods: ULS, GLS, ML, WLS, and DWLS.

You can use the [STRUCTEQ](#) statement to define which equations are structural equations. If you do not use the [STRUCTEQ](#) statement, PROC CALIS uses its own default definition to identify structural equations.

The term “structural equation” is not defined in a unique way. The LISREL program defines the structural equations by the user-defined BETA matrix. In PROC CALIS, the default definition of a structural equation is an equation that has a dependent left-side variable that appears at least once on the right side of another equation, or an equation that has at least one right-side variable that appears at the left side of another equation. Therefore, PROC CALIS sometimes identifies more equations as structural equations than the LISREL program does.

PESTIM | PES

displays the parameter estimates. In some cases, this includes displaying the standard errors and *t* values.

PINITIAL | PIN

displays the model specification with initial estimates and the vector of initial values.

PLATCOV | PLATMOM | PLC

displays the following:

- the estimates of the covariances among the latent variables
- the estimates of the covariances between latent and manifest variables
- the estimates of the latent variable means for mean structure analysis
- the latent variable score regression coefficients

The estimated covariances between latent and manifest variables and the latent variable score regression coefficients are written to the [OUTSTAT=](#) data set. You can use the score coefficients with PROC SCORE to compute factor scores.

PLOTS | PLOT < = *plot-request* >

PLOTS | PLOT < = (*plot-request* < ...*plot-request* >) >

specifies the ODS Graphics plots. When you specify only one *plot-request*, you can omit the parentheses around the *plot-request*. For example:

```
PLOTS=ALL
PLOTS=RESIDUALS
PLOTS=(PP RESBYPRED QQ)
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc calis plots;
  path y <=== x,
        y <=== z;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

You can specify the following *plot-requests*:

- ALL** displays all plots.
- CASERESID | CASERESIDUAL | CASERESIDUALS** displays all the case-level ODS Graphics plots enabled by the following *plot-requests*: CRESHIST, PP, QQ, RESBYLEV, and RESBYPRED. This option requires raw data input.
- CRESHIST | CRESIDUALHISTOGRAM** produces the ODS Graphics plot CaseResidualHistogram, which displays the distribution of the case-level (observation-level) residuals in the form of a histogram, where residuals are measured in terms of M-distances. This option requires raw data input.
- NONE** suppresses ODS Graphics plots.
- PP | PPLOT** produces the ODS Graphics plot ResPercentileByExpPercentile, which plots the observed percentiles of the residual M-distances against the theoretical percentiles. This plot is useful for showing departures from the theoretical distribution in terms of percentiles, and it is especially sensitive to departures in the middle region of the distribution. This option requires raw data input.
- QQ | QQPLOT** produces the ODS Graphics plot ResidualByQuantile, which plots the residual M-distances (observed quantiles) against the theoretical quantiles. This plot is useful for showing departures from the theoretical distribution in terms of quantiles, and it is especially sensitive to departures at the upper tail of the distribution. This option requires raw data input.
- RESBYLEV | RESIDUALBYLEVERAGE** produces the ODS Graphics plot ResidualByLeverage, which plots the residual M-distances against the leverage M-distances. This plot is useful for showing outliers and leverage observations graphically. See the [ALPHAOUT=](#) and [ALPHALEV=](#) options for detection criteria of outliers and leverage observations. This option requires raw data input.
- RESBYPRED | RESONFIT | RESIDUALBYPREDICTED | RESIDUALONFIT<(VAR= var-list)>** produces the ODS Graphics plot ResidualByPredicted, which plots the residuals against the predicted values of the dependent observed variables in the model. You can restrict the set of dependent variables to display by specifying *var-list* in the VAR= option. If *var-list* is not specified in the VAR= option, plots for all dependent observed variables are displayed. The residual on fit plots are useful for detecting nonlinear relationships in the model. If the relationships are linear and the residual variance is homoscedastic, the residuals should not show systematic pattern with the predicted values. This option requires raw data input.
- RESIDUAL | RESIDUALS** produces the ODS Graphics plot for the histogram of residuals in covariances and means rather than the case-level residuals. With this ODS Graphics plot, the nongraphical (legacy) output for the bar chart of residual tallies is redundant and therefore is suppressed. To display this bar chart together with the ODS Graphics for residual histogram, you must use the [RESIDUAL\(TALLY\)](#) option in the PROC CALIS statement. This option does not require raw data input.

PRIMAT | PMAT

displays parameter estimates, approximate standard errors, and *t* values in matrix form if you specify the analysis model using the [RAM](#) or [LINEQS](#) statement.

PRINT | PRI

adds the options **KURTOSIS**, **RESIDUAL**, **PLATCOV**, and **TOTEFF** to the default output.

PSHORT | SHORT | PSH

excludes the output produced by the **PINITIAL**, **SIMPLE**, and **STDERR** options from the default output.

PSUMMARY | SUMMARY | PSUM

displays the fit assessment table only.

PWEIGHT | PW

displays the weight matrix **W** used in the estimation. The weight matrix is displayed after the **WRIDGE=** and the **WPENALTY=** options are applied to it. However, if you specify an **INWGT=** data set by the **INWGT=** and **INWGTV** options (or the **INWGT(INV)=** option alone) in the same analysis, this option displays the elements of the inverse of the weight matrix.

RADIUS=*r*

is an alias for the **INSTEP=** option for Levenberg-Marquardt minimization.

RANDOM=*i*

specifies a positive integer as a seed value for the pseudo-random number generator to generate initial values for the parameter estimates for which no other initial value assignments in the model definitions are made. Except for the parameters in the diagonal locations of the central matrices in the model, the initial values are set to random numbers in the range $0 \leq r \leq 1$. The values for parameters in the diagonals of the central matrices are random numbers multiplied by 10 or 100. See the section “Initial Estimates” on page 1351 for more information.

RDF | DFR=*n*

makes the effective number of observations the actual number of observations minus the **RDF=** value. The degree of freedom for the intercept should not be included in the **RDF=** option. If you use PROC CALIS to compute a regression model, you can specify **RDF= *number-of-regressor-variables*** to get approximate standard errors equal to those computed by PROC REG.

READADDPARM | READADD

inputs the generated default parameters (for example, observations with **_TYPE_=ADDP**COV, **AD**DMEAN, or **ADDP**VAR) in the **INMODEL=** data set as if they were part of the original model specification. Typically, these default parameters in the **INMODEL=** data set were generated automatically by PROC CALIS in a previous analysis and stored in an **OUTMODEL=** data set, which is then used as the **INMODEL=** data set in a new run of PROC CALIS. By default, PROC CALIS does not input the observations for default parameters in the **INMODEL=** data set. In most applications, you do not need to specify this option because PROC CALIS is able to generate a new set of default parameters that are appropriate to the new situation after it reads in the **INMODEL=** data set. Undistinguished uses of the **READADDPARM** option might lead to unintended constraints on the default parameters.

RESIDUAL | RES <(TALLY | TALLIES)> < = NORM | VARSTAND | ASYSTAND >

displays the raw and normalized residual covariance matrix, the rank order of the largest residuals, and a bar chart of the residual tallies. If mean structures are modeled, mean residuals are also displayed and ranked.

For raw data input, this option also displays tables for case-level (observation-level) residual analysis, including outlier and leverage detections and departures of residuals from the theoretical residual

distributions. To set the criterion for detecting outliers, use the **ALPHAOUT=** option. To set the criterion for leverage observations, use the **ALPHALEV=** option. Case-level residual analysis is not available when you specify **METHOD=FIML**.

For the covariance and mean residuals, three types of normalized or standardized residual matrices can be chosen with the **RESIDUAL=** specification.

RESIDUAL= NORM	normalized residuals
RESIDUAL= VARSTAND	variance standardized residuals
RESIDUAL= ASYSTAND	asymptotically standardized residuals

When **ODS Graphics plots** of covariance and mean residuals are also requested, the bar charts of residual tallies are suppressed. They are replaced with high quality graphical histograms showing residual distributions. If you still want to display the bar charts in this situation, use the **RESIDUAL(TALLY)** or **RESIDUAL(TALLY)=** option.

The **RESIDUAL** option is also enabled by the **PRINT** option. See the section “**Assessment of Fit**” on page 1326 for more details about the definitions of residuals.

RIDGE< =r >

defines a ridge factor r for the diagonal of the covariance or correlation matrix **S** that is analyzed. The matrix **S** is transformed to:

$$\mathbf{S} \longrightarrow \tilde{\mathbf{S}} = \mathbf{S} + r(\text{diag}(\mathbf{S}))$$

If you do not specify r in the **RIDGE** option, PROC CALIS tries to ridge the covariance or correlation matrix **S** so that the smallest eigenvalue is about 10^{-3} . Because the weight matrix in the GLS method is the same as the observed covariance or correlation matrix, the **RIDGE=** option also applies to the weight matrix for the GLS estimation, unless you input the weight matrix by the **INWGT=** option.

CAUTION: The covariance or correlation matrix in the **OUTSTAT=** output data set does not contain the ridged diagonal.

ROBITER | ROBUSTITER =i

specifies the maximum number i of iterations for the iteratively reweighted least squares (IRLS) method to compute the robust mean and covariance matrices with the two-stage robust estimation. This option is relevant only with the use of the **ROBUST=** option and with raw data input. The default value is 5,000.

You can also specify this option in the **GROUP** statement so that different groups can use different **ROBITER=** values. Notice that the **ROBITER=** option does not specify the maximum number of iterations for the IRLS algorithm used in the direct robust estimation or in the second stage of the two-stage robust estimation. You can specify the **MAXITER=** option for this purpose.

ROBPHI | ROBUSTPHI =r

sets the tuning parameter r ($0 < r < 1$) for the robust estimation method that you specify using the **ROBUST=** option. The **ROBPHI=** value controls the criterion for downweighting observations. This value indicates approximately the proportion of observations that would receive weights less than 1 (that is, would be downweighted) according to certain theoretical distributions. The larger the **ROBPHI=** value, the more observations are downweighted (that is, with weights less than 1). The default value is 0.05.

You can also specify this option in the **GROUP** statement so that different groups can use different **ROBPHI=** values for the tuning parameters.

ROBUST | ROB < =name>

invokes the robust estimation method that downweights the outliers in estimation. You can use the **ROBUST** option only in conjunction with the ML method (**METHOD=ML**). More accurately, the robust estimation is done by using the iteratively reweighted least squares (IRLS) method under the normal distribution assumption. The model fit of robust estimation is evaluated with the ML discrepancy function.

You must provide raw data input for the robust estimation method to work. With the robust method, the Huber weights are applied to the observations so that outliers are downweighted during estimation. See the section “[Robust Estimation](#)” on page 1315 for details.

You can request the three different types of robust methods by using one of the following *names*:

RESIDUAL | DIRECT | RESID | RES <(E)> specifies a direct robust method that downweights observations with large residuals during the iterative estimation of the model. This method treats the disturbances (the error terms of endogenous latent factors) as errors or residuals (hence the keyword **E**) in the associated factor model when computing residual M-distances and factor scores during the robust estimation. The **(E)**specification is irrelevant if there are no endogenous latent factors in the model. This is the default robust method.

RESIDUAL | DIRECT | RESID | RES (F) specifies a direct robust method that downweights observations with large estimated residuals during the iterative estimation of the model. Unlike the **(E)**method, this method treats the disturbances (the error terms of endogenous latent factors) as factors (hence the keyword **F**) in the associated factor model when computing residual M-distances and factor scores during the robust estimation. The **(F)**specification is irrelevant if there are no endogenous latent factors in the model.

SAT | TWOSTAGE | UNSTRUCT | UNS specifies a two-stage robust method that downweights the observations with large M-distances in all observed variable dimensions when computing the covariance matrix and mean vector from the input raw data. As a results, this option produces a robust covariance matrix and a mean vector for a subsequent model estimation where no reweighting would be applied at the observational level. Hence, this is a two-stage method that applies weights only in the first stage for computing the robust covariance and mean matrices. This is in contrast with the **RES(E)** or **RES(F)** option, where weighting and reweighting of observations are applied directly during model estimation.

For details about these robust methods, see the section “[Robust Estimation](#)” on page 1315.

To control the proportion of the observations that are downweighted during the robust estimation, you can specify the value of the tuning parameter φ , which is between 0 and 1, by using the **ROBPHI=** option. Approximately, $\varphi \times 100\%$ of observations would receive weights less than 1 according to certain theoretical distributions. By default, the value of the tuning parameter φ is set to 0.05 for all robust methods in PROC CALIS.

By default, the robust method uses a maximum of 5,000 iterations to obtain parameter convergence through the IRLS algorithm. You can override this default maximum number of iterations by spec-

ifying the **ROBITER=** option. The default relative parameter convergence criterion for the robust method is $1E-8$. See the **XCONV=** option for the mathematical definition of this criterion and for information about overriding the default convergence criterion.

Because all robust methods reweight the observations iteratively, the observed variable means are always implicitly updated with the robust weights. Therefore, in a sense all robust methods intrinsically analyze the mean structures of models. If you do not specify the **MEANSTR** option or any mean parameters for your models, PROC CALIS assumes appropriate saturated mean structures for the models. However, when you are computing fit statistics, these saturated mean structures are ignored as if they were never modeled. If you do specify the **MEANSTR** option or any mean parameters for your models, these mean structures are taken into account in computing fit statistics.

In this release, robust estimation with the IRLS method is not supported when you specify the **BOUNDS**, **LINCON**, or **NLINCON** statement. However, you can still set parameter constraints by using the same parameter names or by specifying the **PARAMETERS** statement and the **SAS programming statements**. See the section “[Setting Constraints on Parameters](#)” on page 1303 for techniques to set up implicit parameter constraints by using the **PARAMETERS** statement and SAS programming statements.

SALPHA=*r*

is an alias for the **INSTEP=** option for line-search algorithms.

SIMPLE | S

displays means, standard deviations, skewness, and univariate kurtosis if available. This information is displayed when you specify the **PRINT** option. If the **KURTOSIS** option is specified, the **SIMPLE** option is set by default.

SINGULAR | SING =*r*

specifies the singularity criterion r ($0 < r < 1$) used, for example, for matrix inversion. The default value is the square root of the relative machine precision or, equivalently, the square root of the largest double precision value that, when added to 1, results in 1.

SLMW=*r*

specifies the probability limit used for computing the stepwise multivariate Wald test. The process stops when the univariate probability is smaller than r . The default value is $r=0.05$.

SPRECISION | SP=*r*

is an alias for the **LSPRECISION=** option.

START=*r*

specifies initial estimates for parameters as multiples of the r value. In all CALIS models, you can supply initial estimates individually as parenthesized values after each parameter name. Unspecified initial estimates are usually computed by various reasonable initial estimation methods in PROC CALIS. If none of the initialization methods is able to compute all the unspecified initial estimates, then the remaining unspecified initial estimates are set to r , $10|r|$, or $100|r|$. For variance parameters, $100|r|$ is used for covariance structure analyses and $10|r|$ is used for correlation structure analyses. For other types of parameters, r is used. The default value is $r = 0.5$. If the **DEMPHAS=** option is used, the initial values of the variance parameters are multiplied by the value specified in the **DEMPHAS=** option. See the section “[Initial Estimates](#)” on page 1351 for more information.

STDERR | SE

displays approximate standard errors if estimation methods other than unweighted least squares (ULS) or diagonally weighted least squares (DWLS) are used (and the **NOSTDERR** option is not specified). In contrast, the **NOSTDERR** option suppresses the printing of the standard error estimates. If you specify neither the **STDERR** nor the **NOSTDERR** option, the standard errors are computed for the **OUTMODEL=** data set. This information is displayed by default when you specify the **PRINT** option.

You can specify the **STDERR** option in both the **PROC CALIS** and the **MODEL** statements. When this option is specified in the **PROC CALIS** statement, it does not have any apparent effect because by default the model results display the standard error estimates (for estimation methods other than ULS and DWLS). When this option is specified in the **MODEL** statement, it deactivates the inherited **NOSTDERR** or **NOSE** option from the **PROC CALIS** statement. In other words, this option is mainly used for resetting the default behavior in the local model that is specified within the scope of a particular **MODEL** statement. If you specify both the **STDERR** and **NOSTDERR** options in the same statement, the **STDERR** option is ignored.

TMISSPAT | THRESHOLDMISSPAT | THRESMISSPAT=*n*

specifies the proportion threshold for the missing patterns to display in the output, where *n* is between 0 and 1. The default **TMISSPAT=** value is 0.05. This option is relevant only when there are incomplete observations (with some missing values in the analysis variables) in the input raw data set and when you use **METHOD=FIML** or **METHOD=LSFIML** for estimation.

Because the number of missing patterns could be quite large, **PROC CALIS** displays a limited number of the most frequent missing patterns in the output. Together with the **MAXMISSPAT=** option, this option controls the number of missing patterns to display in the output. See the **MAXMISSPAT=** option for a detailed description about how the number of missing patterns to display is determined.

UPDATE | UPD=*name*

specifies the update method for the quasi-Newton or conjugate-gradient optimization technique.

For **OMETHOD=CONGRA**, the following updates can be used:

PB	performs the automatic restart update method of Powell (1977) and Beale (1972). This is the default.
FR	performs the Fletcher-Reeves update (Fletcher 1980, p. 63).
PR	performs the Polak-Ribiere update (Fletcher 1980, p. 66).
CD	performs a conjugate-descent update of Fletcher (1987).

For **OMETHOD=DBLDOG**, the following updates (Fletcher 1987) can be used:

DBFGS	performs the dual Broyden, Fletcher, Goldfarb, and Shanno (BFGS) update of the Cholesky factor of the Hessian matrix. This is the default.
DDFP	performs the dual Davidon, Fletcher, and Powell (DFP) update of the Cholesky factor of the Hessian matrix.

For **OMETHOD=QUANEW**, the following updates (Fletcher 1987) can be used:

- BFGS** performs original BFGS update of the inverse Hessian matrix. This is the default for earlier releases.
- DFP** performs the original DFP update of the inverse Hessian matrix.
- DBFGS** performs the dual BFGS update of the Cholesky factor of the Hessian matrix. This is the default.
- DDFP** performs the dual DFP update of the Cholesky factor of the Hessian matrix.

VARDEF= DF | N | WDF | WEIGHT | WGT

specifies the divisor used in the calculation of covariances and standard deviations. The default value is VARDEF=N for the METHOD=FIML, and VARDEF=DF for other estimation methods. The values and associated divisors are displayed in the following table, where k is the number of partial variables specified in the **PARTIAL** statement. When a **WEIGHT** statement is used, w_j is the value of the WEIGHT variable in the j th observation, and the summation is performed only over observations with positive weight.

Value	Description	Divisor
DF	Degrees of freedom	$N - k - 1$
N	Number of observations	N
WDF	Sum of weights DF	$\sum_j^N w_j - k - 1$
WEIGHT WGT	Sum of weights	$\sum_j^N w_j$

VSINGULAR | VSING= r

specifies a relative singularity criterion r ($r > 0$) for the inversion of the information matrix, which is needed to compute the covariance matrix. If you do not specify the **SINGULAR=** option, the default value for r or VSING= is 1E-8; otherwise, the default value is *SING*, which is the specified **SINGULAR=** value.

When inverting the information matrix, the following singularity criterion is used for the diagonal pivot $d_{j,j}$ of the matrix:

$$|d_{j,j}| \leq \max(ASING, VSING * |H_{j,j}|, MSING * \max(|H_{1,1}|, \dots, |H_{n,n}|))$$

where *ASING* and *MSING* are the specified values of the **ASINGULAR=** and **MSINGULAR=** options, respectively, and $H_{j,j}$ is the j th diagonal element of the information matrix. Note that in many cases a normalized matrix $\mathbf{D}^{-1}\mathbf{H}\mathbf{D}^{-1}$ is decomposed (where $\mathbf{D}^2 = \text{diag}(\mathbf{H})$), and the singularity criteria are modified correspondingly.

WPENALTY | WPEN= r

specifies the penalty weight $r \geq 0$ for the WLS and DWLS fit of the diagonal elements of a correlation matrix (constant 1s). The criterion for weighted least squares estimation of a correlation structure is

$$\mathbf{F}_{WLS} = \sum_{i=2}^n \sum_{j=1}^{i-1} \sum_{k=2}^n \sum_{l=1}^{k-1} w^{ij,kl} (s_{ij} - c_{ij})(s_{kl} - c_{kl}) + r \sum_i^n (s_{ii} - c_{ii})^2$$

where r is the penalty weight specified by the WPENALTY= r option and the $w^{ij,kl}$ are the elements of the inverse of the reduced $(n(n-1)/2) \times (n(n-1)/2)$ weight matrix that contains only the nonzero rows and columns of the full weight matrix **W**. The second term is a penalty term to fit the

diagonal elements of the correlation matrix. The default value is 100. The reciprocal of this value replaces the asymptotic variance corresponding to the diagonal elements of a correlation matrix in the weight matrix **W**, and it is effective only with the **ASYCOV=**CORR option, which is the default for correlation analyses. The often used value $r = 1$ seems to be too small in many cases to fit the diagonal elements of a correlation matrix properly. The default **WPENALTY=** value emphasizes the importance of the fit of the diagonal elements in the correlation matrix. You can decrease or increase the value of r if you want to decrease or increase the importance of the diagonal elements fit. This option is effective only with the WLS or DWLS estimation method and the analysis of a correlation matrix.

See the section “[Estimation Criteria](#)” on page 1309 for more details.

CAUTION: If you input the weight matrix by the **INWGT=** option, the **WPENALTY=** option is ignored.

WRIDGE=*r*

defines a ridge factor r for the diagonal of the weight matrix **W** used in GLS, WLS, or DWLS estimation. The weight matrix **W** is transformed to

$$\mathbf{W} \longrightarrow \tilde{\mathbf{W}} = \mathbf{W} + r(\text{diag}(\mathbf{W}))$$

The **WRIDGE=** option is applied on the weight matrix before the following actions occur:

- the **WPENALTY=** option is applied on it
- the weight matrix is written to the **OUTWGT=** data set
- the weight matrix is displayed

CAUTION: If you input the weight matrix by the **INWGT=** option, the **OUTWGT=** data set will contain the same weight matrix without the ridging requested by the **WRIDGE=** option. This ensures that the entries in the **INWGT=** and **OUTWGT=** data sets are consistent. The **WRIDGE=** option is ignored if you input the inverse of the weight matrix by the **INWGT=** and **INWGTINV** options (or the **INWGT(INV)=** option alone).

XCONV | XTOL=*r*

specifies the relative parameter convergence criterion. Termination requires a small relative parameter (x) change in subsequent iterations, that is,

$$\frac{\max_j |x_j^{(k)} - x_j^{(k-1)}|}{\max(|x_j^{(k)}|, |x_j^{(k-1)}|, XSIZE)} \leq r$$

The default value for r is 1E–8 for robust estimation (see the **ROBUST** option) with the iteratively reweighted least squares method, and it is 0 for other estimation methods. The default value for **XSIZE** is 0. You can change this default value by specifying the **XSIZE=** option in the **NLOPTIONS** statement.

BOUNDS Statement

BOUNDS *constraint* <, *constraint* ... > ;

where *constraint* represents

< number operator > parameter-list < operator number >

You can use the BOUNDS statement to define boundary constraints for any independent parameter that has its name specified in the main or subsidiary model specification statements, the [PARAMETERS](#) statement, or the [INMODEL=](#) data set. You cannot define boundary constraints for dependent parameters created in [SAS programming statements](#) or elsewhere.

Valid operators are <=, <, >=, >, and = (or, equivalently, LE, LT, GE, GT, and EQ). The following is an example of the BOUNDS statement:

```
bounds      0.      <= a1-a9 x      <= 1. ,
            -1.      <= c2-c5
                        b1-b10 y      >= 0. ;
```

You must separate boundary constraints with a comma, and you can specify more than one BOUNDS statement. The feasible region for a parameter is the intersection of all boundary constraints specified for that parameter; if a parameter has a maximum lower boundary constraint greater than its minimum upper bound, the parameter is set equal to the minimum of the upper bounds.

The active set strategies made available in PROC CALIS treat strict inequality constraints < or > as if they were just inequality constraints <= or >=. For example, if you require x be strictly greater than zero so as to prevent an undefined value for $y = \log(x)$, specifying the following statement is insufficient:

```
BOUNDS x > 0;
```

Specify the following statement instead:

```
BOUNDS x > 1E-8;
```

If the CALIS procedure encounters negative variance estimates during the minimization process, serious convergence problems can occur. You can use the BOUNDS statement to constrain these parameters to nonnegative values. Although allowing negative values for variances might lead to a better model fit with smaller χ^2 value, it adds difficulties in interpretation.

BY Statement

BY variables ;

You can specify a BY statement with PROC CALIS to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the CALIS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.

- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

The BY statement is not supported if you define more than one group by using the [GROUP](#) statements.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

COSAN Statement

COSAN < **VAR**=*variable-list*, > *term* < + *term* ... > ;

where *variable-list* is a list of observed variables and *term* represents either one of the following forms:

matrix-definition < * *matrix-definition* ... > < *mean-definition* >

or

mean-definition

where *matrix-definition* is of the following form:

matrix-name < (*number-of-columns* < , *matrix-type* < , *transformation* >) >

and *mean-definition* is one of the following forms:

[/ *mean-vector*]

or

[**MEAN**=*mean-vector*]

where *mean-vector* is a vector name.

COSAN stands for covariance structure analysis (McDonald 1978, 1980). The COSAN model in PROC CALIS is a generalized version of the original COSAN model. See the section “[The COSAN Model](#)” on page 1259 for details of the generalized COSAN model. You can analyze a very wide class of mean and covariance structures with the COSAN modeling language, which consists of the COSAN statement as the [main model specification statement](#) and the [MATRIX](#) statement as the [subsidiary model specification statement](#). Use the following syntax to specify a COSAN model:

```
COSAN < VAR=variable-list, > term < + term ... > ;
MATRIX matrix-name parameters-in-matrix ;
/* Repeat the MATRIX statement as needed */ ;
VARNAMES name-assignments ;
```

The PROC CALIS statement invokes the COSAN modeling language. You can specify at most one COSAN statement in a model within the scope of either the PROC CALIS statement or a [MODEL](#) statement. To complete the COSAN model specification, you might need to add as many [MATRIX](#) statements as needed. Optionally, you can provide the variable names for the COSAN model matrices in the [VARNAMES](#) statement.

In the COSAN statement, you specify the list of observed variables for analysis in the **VAR=** option and the formulas for covariance and mean structures in the *terms*. If specified at all, the **VAR=** option must be

specified at the very beginning of the COSAN statement. The order of the variables in the VAR= option is important. It is the same order assumed for the row and column variables in the mean and covariance structures defined in the *terms*. If you do not specify the VAR= option, PROC CALIS selects all the numerical variables in the associated groups for analysis. To avoid confusion about the variables being analyzed in the model, it is recommended that you set the VAR= list explicitly in the COSAN statement.

To define the matrix formulas for the covariance and mean structures, you specify the *terms*, *matrix-definitions*, and *mean-vector* in the COSAN statement. The forms of the covariance and mean structures that are supported in PROC CALIS are mentioned in the section “[The COSAN Model](#)” on page 1259. In each *term*, you specify the covariance structures by listing the matrices in the *matrix-definitions*. These matrices must be in the proper order such that their matrix product produces the intended covariance structures. If you want to analyze the corresponding mean structures, specify the trailing *mean-vectors* in the *terms* whenever needed.

To illustrate the COSAN statement syntax, consider a factor-analytic model with six variables (var1–var6) and two factors. The covariance structures of the six variables are described by the matrix formula

$$\Sigma = \mathbf{F}\mathbf{P}\mathbf{F}' + \mathbf{U}$$

where Σ is a 6×6 symmetric matrix for the covariance matrix, \mathbf{F} is a 6×2 factor loading matrix, \mathbf{P} is a 2×2 (symmetric) factor covariance matrix, and \mathbf{U} is a 6×6 diagonal matrix of unique variances. You can use the following COSAN statement to specify the covariance structures of this factor model:

```
cosan var = var1-var6,
      F(2,GEN) * P(2,SYM) + U(6,DIA) ;
```

In the VAR= option of the COSAN statement, you define a list of six observed variables in the covariance structures. The order of the variables in the VAR= list determines the order of the row variables in the first matrix of each term in the model. That is, both matrices \mathbf{F} and \mathbf{U} have these six observed variables as their row variables, which are ordered the same way as in the VAR= list.

Next, you define the formula for the covariance structures by listing the matrices in the desired order *up to the central covariance matrix in each term*. In the first *term* of this example, you need to specify only $\mathbf{F}\mathbf{P}$ instead of the complete covariance structure formula $\mathbf{F}\mathbf{P}\mathbf{F}'$. The reason is that the latter part of the term (that is, after the central covariance matrix) contains only the transpose of the matrices that have already been defined. Hence, PROC CALIS can easily generate the complete term with the nonredundant information given.

In each of the *matrix-definitions*, you can provide the number of columns in the first argument (that is, the *number-of-columns* field) inside a pair of parentheses. You do not need to provide the number of rows because this information can be deduced from the given covariance structure formula. By using some keywords, you can optionally provide the matrix type in the second argument (that is, the *matrix-type* field) and the matrix transformation in the third argument (that is, the *transformation* field).

In the current example, $\mathbf{F}(2, \mathbf{GEN})$ represents a general rectangular (GEN) matrix \mathbf{F} with two columns. Implicitly, it has six rows because it is the first matrix of the first term in the covariance structure formula. $\mathbf{P}(2, \mathbf{SYM})$ represents a symmetric (SYM) matrix \mathbf{P} with two columns. Implicitly, it has two rows because it is premultiplied with \mathbf{F} , which has two columns. In the second term, $\mathbf{U}(6, \mathbf{DIA})$ represents a diagonal (DIA) matrix \mathbf{U} with six rows and six columns. Because you do not specify the third argument in these *matrix-definitions*, no transformation is applied to any of the matrices in the covariance structure formula.

PROC CALIS supports the following keywords for *matrix-type*:

IDE	specifies an identity matrix. If the matrix is not square, this specification describes an identity submatrix followed by a rectangular zero submatrix.
ZID	specifies an identity matrix. If the matrix is not square, this specification describes a rectangular zero submatrix followed by an identity submatrix.
DIA	specifies a diagonal matrix. If the matrix is not square, this specification describes a diagonal submatrix followed by a rectangular zero submatrix.
ZDI	specifies a diagonal matrix. If the matrix is not square, this specification describes a rectangular zero submatrix followed by a diagonal submatrix.
LOW	specifies a lower triangular matrix. The matrix can be rectangular.
UPP	specifies an upper triangular matrix. The matrix can be rectangular.
SYM	specifies a symmetric matrix. The matrix cannot be rectangular.
GEN	specifies a general rectangular matrix (default).

If you omit the *matrix-type* argument, PROC CALIS sets the type of matrix by default. For central covariance matrices, the default for *matrix-type* is SYM. For all other matrices, the default for *matrix-type* is GEN. For example, if **A** is not a central covariance matrix in the covariance structure formula, the following specifications are equivalent for a general matrix **A** with three columns:

```

A (3, GEN)
A (3)
A (3, )
A (3, , )

```

PROC CALIS supports the following two keywords for *transformation*:

INV	uses the inverse of the matrix.
IMI	uses the inverse of the difference between the identity and the matrix. For example, A (3, GEN, IMI) represents $(\mathbf{I} - \mathbf{A})^{-1}$.

Both INV or IMI require square (but not necessarily symmetric) matrices to transform. If you omit the *transformation* argument, no transformation is applied.

CAUTION: You can specify the same matrix by using the same *matrix-name* in different locations of the matrix formula in the COSAN statement. The *number-of-columns* and the *matrix-type* fields for matrices with identical *matrix-names* must be consistent. This consistency can be maintained easily by specifying each of these two fields only once in any of the locations of the same matrix. However, there is no restriction on the transformation for the same matrix in different locations. For example, while **R** must be the same 3×3 symmetric matrix throughout the formula in the following specification, the INV transformation of **R** applies only to the **R** matrix in the second term, but not to the same **R** matrix in the first term:

```

cosan var = var1-var6,
      B (3, GEN) * R (3, SYM) + H (3, DIA) * R (3, SYM, INV) ;

```

Mean and Covariance Structures

Suppose now you want to analyze the mean structures in addition to the covariance structures of the preceding factor model. The mean structure formula for μ of the observed variables is

$$\mu = Fv + a$$

where μ is a 6×1 vector for the observed variable means, v is a 2×1 vector for the factor means, and a is a 6×1 vector for the intercepts of the observed variables. To include the mean structures in the COSAN model, you need to specify the mean vector at the end of the *terms*, as shown in the following statement:

```
cosan var = var1-var6,
          F(2,GEN) * P(2,SYM) [/ v] + U(6,DIA) [/ a];
```

If you take the mean vectors within the brackets away from each of the *terms*, the formula for the covariance structures is generated as

$$\Sigma = FPF' + U$$

which is exactly the same covariance structure as described in a preceding example. Now, with the mean vectors specified at the end of each *term*, you analyze the corresponding mean structures simultaneously with the covariance structures.

To generate the mean structure formula, PROC CALIS replaces the central covariance matrices with the mean vectors in the *terms*. In the current example the mean structure formula is formed by replacing P and U with v and a , respectively. Hence, the first term of the mean structure formula is $F * v$, and the second term of the mean structure formula is simply a . Adding these two terms yields the desired mean structure formula for the model.

To make the mean vector specification more explicit, you can use the following equivalent syntax with the MEAN= option:

```
cosan var = var1-var6,
          F(2,GEN) * P(2,SYM) [mean=v] + U(6,DIA) [mean=a];
```

If a *term* in the specification does not have a mean vector (covariance matrix) specification, a zero mean vector (null covariance matrix) is assumed. For example, the following specification generates the same mean and covariance structures as the preceding example:

```
cosan var = var1-var6,
          F(2,GEN) * P(2,SYM) [/ v] + U(6,DIA) + [/ a];
```

The covariance structure formula for this specification is

$$\Sigma = FPF' + U + 0$$

where 0 in the last term represents a null matrix. The corresponding mean structure formula is

$$\mu = Fv + 0 + a$$

where 0 in the second term represents a zero vector.

Specifying Models with No Explicit Central Covariance Matrices

In some situations, the central covariance matrices in the covariance structure formula are not defined explicitly. For example, the covariance structure formula for an orthogonal factor model is:

$$\Sigma = \mathbf{F}\mathbf{F}' + \mathbf{U}$$

Again, assuming that \mathbf{F} is a 6×2 factor loading matrix and \mathbf{U} is a 6×6 diagonal matrix for unique variances, you can specify the covariance structure formula as in the following COSAN statement:

```
cosan var = var1-var6,
          F(2,GEN) + U(6,DIA);
```

In determining the proper formula for the covariance structures, PROC CALIS detects whether the last matrix specified in each *term* is symmetric. If you specify this last matrix explicitly with the SYM, IDE (with the same number of rows and columns), or DIA type, it is certainly a symmetric matrix. If you specify this last matrix without an explicit *matrix-type* and it has the same number of rows and columns, it is also treated as a symmetric matrix for the central covariance matrix of the *term*. Otherwise, this last matrix is not symmetric and PROC CALIS treats the *term* as if an identity matrix has been inserted for the central covariance matrix. For example, for the orthogonal factor model specified in the preceding statement, PROC CALIS correctly generates the first term as $\mathbf{F}\mathbf{F}' = \mathbf{F}\mathbf{I}\mathbf{F}'$ and the second term as \mathbf{U} .

Certainly, you might also specify your own central covariance matrix explicitly for the orthogonal factor model. That is, you add an identity matrix into the COSAN model specification as shown in the following statement:

```
cosan var = var1-var6,
          F(2,GEN) * I(2,IDE) + U(6,DIA);
```

Specifying Mean Structures for Models with No Central Covariance Matrices

When you specify covariance structures with central covariance matrices explicitly defined in the *terms*, the corresponding mean structure formula is formed by replacing the central covariance matrices with the *mean-vectors* that are specified in the brackets. However, when there is no central covariance matrix explicitly specified in a *term*, the last matrix of the *term* in the covariance structure formula is replaced with the *mean-vector* to generate the mean structure formula. Consider the following specification where there is no central covariance matrix defined explicitly in the first *term* of the COSAN model:

```
cosan var = var1-var6,
          A(6,GEN) [ / v];
```

The generated formulas for the covariance and mean structures are

$$\begin{aligned}\Sigma &= \mathbf{A}\mathbf{A}' \\ \mu &= \mathbf{v}\end{aligned}$$

If, instead, you intend to fit the following covariance and mean structures

$$\begin{aligned}\Sigma &= \mathbf{A}\mathbf{A}' \\ \mu &= \mathbf{A}\mathbf{v}\end{aligned}$$

you must put an explicit identity matrix for the central covariance matrix in the first *term*. That is, you can use the following specification:

```

cosan var = var1-var6,
      A(6,GEN) * I(6,IDE) [ / v];

```

Specifying Parameters in Matrices

By specifying the COSAN statement, you define the covariance and mean structures in matrix formulas for the observed variables. To specify the parameters in the model matrices, you need to use the [MATRIX](#) statements.

For example, for an orthogonal factor model with six variables (var1–var6) and two factors, the 6×2 factor loading matrix **F** might take the following form:

$$\mathbf{F} = \begin{pmatrix} x & 0 \\ x & 0 \\ x & 0 \\ 0 & x \\ 0 & x \\ 0 & x \end{pmatrix}$$

The 6×6 unique variance matrix **U** might take the following form:

$$\mathbf{U} = \begin{pmatrix} x & 0 & 0 & 0 & 0 & 0 \\ 0 & x & 0 & 0 & 0 & 0 \\ 0 & 0 & x & 0 & 0 & 0 \\ 0 & 0 & 0 & x & 0 & 0 \\ 0 & 0 & 0 & 0 & x & 0 \\ 0 & 0 & 0 & 0 & 0 & x \end{pmatrix}$$

where each *x* in the matrices represents a free parameter to estimate and 0 represents a fixed zero value. The covariance structures for the observed variables are described by the following formula:

$$\Sigma = \mathbf{F}\mathbf{F}' + \mathbf{U}$$

To specify the entire model, you use the following statements to define the covariance structure formula and the free parameters in the model matrices:

```

cosan var = var1-var6,
      F(2,GEN) + U(6,DIA);
matrix F [1 to 3,@1],[4 to 6,@2];
matrix U [1,1],[2,2],[3,3],[4,4],[5,5],[6,6];

```

In the [MATRIX](#) statements, you specify the free parameters in the matrices. For the factor loading matrix **F**, you specify that rows 1, 2, and 3 in column 1 and rows 4, 5, and 6 in column 2 are free parameters. For the unique variance matrix **U**, you specify that all diagonal elements are free parameters. All other unspecified entries in the matrices are fixed zeros by default. Certainly, you can also specify fixed zeros explicitly. For the current example, you can specify matrix **F** equivalently as:

```

matrix F [1 to 3,@1],[4 to 6,@2],
      [4 to 6,@1] = 0. 0. 0.,
      [1 to 3,@2] = 0. 0. 0.;

```

See the [MATRIX statement](#) on page 1175 for various ways to specify the parameters in matrices.

Matrix Names versus Parameter Names

Although parameter names and matrix names in PROC CALIS are both arbitrary SAS names for denoting mathematical entities in the model, their usages are very different in one aspect. That is, parameter names are globally defined in the procedure, while matrix names are only locally defined in models.

Consider the following two-group analysis example:

```
proc calis;
  group 1 / data=g1;
  group 2 / data=g2;
  model 1 / group=1;
    cosan var = var1-var6,
      F(2,GEN) * I(2,IDE) + U(6,DIA);
    matrix F [1 to 3,@1],[4 to 6,@2];
    matrix U [1,1] = u1-u6;
  model 2 / group=2;
    cosan var = var1-var6,
      F(1,GEN) * I(1,IDE) + D(6,DIA);
    matrix F [1 to 6,@1];
    matrix D [1,1] = u1-u6;
run;
```

In this example, you fit Model 1 to Group 1 and Model 2 to Group 2. You specify a matrix called **F** in each of the models. However, the two models are not constrained by this “same” matrix **F**. In fact, matrix **F** in Model 1 is a 6×2 matrix but matrix **F** in Model 2 is a 6×1 matrix. In addition, none of the parameters in the **F** matrices are constrained by the parameter names (simply because no parameter names are used). This illustrates that matrix names in PROC CALIS are defined only locally within models.

In contrast, in this example you use different matrix names for the second terms of the two models. In Model 1, you define a 6×6 diagonal matrix **U** for the second term; and in Model 2, you define a 6×6 diagonal matrix **D** for the second term. Are these two matrices necessarily different? The answer depends on how you define the parameters in these matrices. In the MATRIX statement for **U**, all diagonal elements of **U** are specified as free parameters u_1 – u_6 . Similarly, in the MATRIX statement for **D**, all diagonal elements of **D** are also specified free parameters u_1 – u_6 . Because you use the same sets of parameter names in both of these MATRIX statements, matrices **U** and **D** are essentially constrained to be the same even though their names are different. This illustrates that parameter names are defined globally in PROC CALIS.

The following points summarize how PROC CALIS treats matrix and parameter names differently:

- Matrices with the same name in the same model are treated as identical.
- Matrices with the same name in different models are not treated as identical.
- Parameters with the same name are identical throughout the entire PROC CALIS specification.
- Cross-model constraints on matrix elements are set by using the same parameter names, but not the same matrix names.

Row and Column Variable Names for Matrices

You can use the **VARNAMES** statement to define the column variable names for the model matrices of a COSAN model. However, you do not specify the row variable names for the model matrices directly because they are determined by the column variable names of the related matrices in the covariance and mean structure formulas. For example, the following specification names the column variables of matrices **F** and **I**:

```
cosan var = var1-var6,
          F(2,GEN) * I(2,IDE) + U(6,DIA) ;
varnames
  F = [Factor1 Factor2],
  I = F;
```

The column names for matrix **F** are Factor1 and Factor2. The row names of matrix **F** are var1–var6 because it is the first matrix in the first term. Matrix **I** has the same column variable names as those for matrix **F**, as specified in the last specification of the **VARNAMES** statement. Because matrix **I** is a central covariance matrix, its row variable names are the same as its column variable names: Factor1 and Factor2. You do not specify the column variables names for matrix **U** in the **VARNAMES** statement. However, because it is the first matrix in the second term, its row variable names are the same as that of the **VAR=** list in the COSAN statement. Because matrix **U** is also the central covariance matrix in the second term, its column variable names are the same its row variable names, which has been determined to be var1–var6. See the **VARNAMES** statement for more details.

Default Parameters

Unlike other modeling languages in PROC CALIS, the COSAN modeling language does not set any default free parameters for the model matrices. There is only one type of default parameters in the COSAN model: fixed values for matrix elements. These fixed values can be 0 or 1. For matrices with the IDE or ZID type, all elements are predetermined with either 0 or 1. They are fixed matrices in the sense that you cannot override these default fixed values. For all other matrix types, PROC CALIS sets their elements to fixed zeros by default. You can override these default zeros by specifying them explicitly in the **MATRIX** statements.

Modifying a COSAN Model from a Reference Model

In this section, it is assumed that you use a **REFMODEL** statement within the scope of a **MODEL** statement and the reference model (or base model) is also a COSAN model. The reference model is referred to as the old model, while the model that makes reference to this old model is referred to as the new model. If the new model is not intended to be an exact copy of the old model, you can use the following extended COSAN modeling language to make modifications within the scope of the **MODEL** statement for the new model. The syntax is similar to, but not exactly the same as, the ordinary COSAN modeling language. (See the section “COSAN Statement” on page 1122.) The respecification syntax for a COSAN model is as follows:

```
COSAN ;
MATRIX matrix-name parameters-in-matrix ;
/* Repeat the MATRIX statement as needed */ ;
VARNAMES name-assignments ;
```

In the respecification, the COSAN statement is optional. In fact, the purpose of using the COSAN statement at all is to remind yourself that a COSAN model is used in the model definition. If you use the COSAN statement, you cannot specify the **VAR=** option or the covariance and mean structure formula. This means

that the model form and the observed variable references of the new model must be the same as the old (reference) model. The reason for enforcing these model structures is to ensure that the **MATRIX** statement respecifications are consistently interpreted.

You can optionally use the **VARNAMES** statement in the respecification. If the variable names for a COSAN matrix are defined in the old model but not redefined the new model, all variable names for that matrix are duplicated in the new model. However, specification of variable names for a COSAN matrix in the new model overrides the corresponding specification in the old model.

You can respecify or modify the elements of the COSAN model matrices by using the **MATRIX** *matrix-name* statements. The syntax of the **MATRIX** statements for respecifications is the same as that in the ordinary COSAN modeling language, but with one more feature. In the respecification syntax, you can use the missing value ‘.’ to drop a parameter specification from the old model.

The new model is formed by integrating with the old model in the following ways:

Duplication:	If you do not specify in the new model a parameter location that exists in the old model, the old parameter specification is duplicated in the new model.
Addition:	If you specify in the new model a parameter location that does not exist in the old model, the new parameter specification is used in the new model.
Deletion:	If you specify in the new model a parameter location that also exists in the old model and the new parameter is denoted by the missing value ‘.’, the old parameter specification is not copied into the new model.
Replacement:	If you specify in the new model a parameter location that also exists in the old model and the new parameter is not denoted by the missing value ‘.’, the new parameter specification replaces the old one in the new model.

For example, the following two-group analysis specifies Model 2 by referring to Model 1 in the **REF-MODEL** statement:

```
proc calis;
  group 1 / data=d1;
  group 2 / data=d2;
  model 1 / group=1;
  cosan
    var = x1-x6,
    F(2,GEN) * PHI(2,SYM) + PSI(6,SYM);
  matrix F
    [1,1] = 1.,
    [2,1] = load2,
    [3,1] = load3,
    [4,2] = 1.,
    [5,2] = load5,
    [6,2] = load6;
  matrix PHI
    [1,1] = phi1,
    [2,2] = phi2,
    [2,1] = phi21;
  matrix PSI
    [1,1] = psi1,
    [2,2] = psi2,
    [3,3] = psi3,
    [4,4] = psi4,
    [5,5] = psi5,
```

```

                                [6,6] = psi6;
varnames F    = [Factor1 Factor2],
        PHI = F;
model 2 / group=2;
  refmodel 1;
  matrix F          [3,1] = load2;      /* replacement */
  matrix PHI        [2,1] = .;          /* deletion */
  matrix PSI        [3,1] = psi31;      /* addition */
  varnames F    = [FF1 FF2],
run;

```

In this example, Model 2 is the new model which refers to the old model, Model 1. It illustrates the four types of model integration by using the MATRIX statements:

- Duplication: Except for the **F**[3, 1] and **PHI**[2, 1] elements, all parameter specifications in the old model are duplicated in the new model.
- Addition: The **PSI**[3, 1] element is added with a new parameter **psi31** in the new model. This indicates the presence of a correlated error in Model 2, but not in Model 1.
- Deletion: The **PHI**[2, 1] element is no longer a free parameter in the new model. This means that the two latent factors are correlated in Model 1, but not in Model 2.
- Replacement: The **F**[3, 1] element defined in Model 2 replaces the definition in the old model. This element is now a free parameter named **load2**. Because the **F**[2, 1] element (via duplication from the old model) is also a free parameter with this same name, **F**[3, 1] and **F**[2, 1] are constrained to be the same in Model 2, but not in Model 1.

With the VARNAMES statement specification in Model 1, the two columns of matrix **F** are labeled with **Factor1** and **Factor2**, respectively. In addition, because **PHI=F** is specified in the VARNAMES statement of Model 1, the row and column of matrix **PHI** in Model 1 also contain **Factor1** and **Factor2** as the variable names. In Model 2, with the explicit VARNAMES specifications the two columns of matrix **F** are labeled with **FF1** and **FF2**, respectively. These names are not the same as those for matrix **F** in the old (reference) model. However, because **PHI=F** is *not* specified in the VARNAMES statement of Model 2, the row and column of matrix **PHI** in Model 2 contain **Factor1** and **Factor2** as the variable names, which are duplicated from the old (reference) model.

COSAN Models and Other Models

Because the COSAN model is a more general model than any other model considered in PROC CALIS, you can virtually fit any other type of model in PROC CALIS by using the COSAN modeling language. See the section “[Special Cases of the Generalized COSAN Model](#)” on page 1261, [Example 27.29](#), and [Example 27.30](#) for illustrations and discussions.

In general, it is recommended that you use the more specific modeling languages such as FACTOR, LINEQS, LISMOD, MSTRUCT, PATH, and RAM. Because the COSAN model is very general in its formulation, PROC CALIS cannot exploit the specific model structures to generate reasonable initial estimates the way it does with other specific models such as FACTOR and PATH. If you do not provide initial estimates for a COSAN model, PROC CALIS uses some default starting values such as 0.5. See the **START=** option for controlling the starting value. See the **RANDOM=** option for setting random starting values. There are

other reasons for preferring specific modeling languages whenever possible. The section “Which Modeling Language?” on page 1077 discusses these various reasons. However, when the covariance structures are complicated and are difficult to specify otherwise, the COSAN modeling language is a very useful tool. See [Example 27.31](#) and [Example 27.33](#) for illustrations.

COV Statement

COV *assignment* <, *assignment* ... > ;

where *assignment* represents

var-list < * *var-list2* > < = *parameter-spec* >

The COV statement is a subsidiary model specification statement for the confirmatory [FACTOR](#) and [LINEQS](#) models. In the LINEQS model, the COV statement defines the covariances among the exogenous variables, including errors and disturbances. In the confirmatory FACTOR model, the COV statement defines the factor covariances. In each *assignment* of the COV statement, you specify variables in the *var-list* and the *var-list2* lists, followed by the covariance parameter specification in the *parameter-spec* list. The latter two specifications are optional.

You can specify the following five types of the parameters for the covariances:

- an unnamed free parameter
- an initial value
- a fixed value
- a free parameter with a name provided
- a free parameter with a name and initial value provided

Consider a LINEQS model with exogenous variables V1, V2, V3, and V4. The following COV statement shows the five types of specifications in five *assignments*:

```
cov V2 V1 ,
    V3 V1 = (0.3) ,
    V3 V2 = 1.0 ,
    V4 V1 = phi1 ,
    V4 V2 = phi2(0.2) ;
```

In this statement, **cov(V2,V1)** is specified as an unnamed free parameter. For this covariance, PROC CALIS generates a parameter name with the `_Parm` prefix and appended with a unique integer (for example, `_Parm1`). **cov(V3,V1)** is an unnamed free parameter but with an initial value of 0.3. PROC CALIS also generates a parameter name for this covariance. **cov(V3,V2)** is a fixed value of 1.0. This value stays the same in the estimation. **cov(V4,V1)** is a free parameter named `phi1`. **cov(V4,V2)** is a free parameter named `phi2` with an initial value of 0.2.

Note that the *var-list* and *var-list2* lists on the left-hand side of the equal sign of the COV statement should contain only names of *exogenous* variables. Hence, the COV statement is different from the [PCOV](#) statement

in which you can list both exogenous and endogenous variables, although the COV and PCOV statements share the same syntax.

You can use the COV statement for specifying covariance parameters in the **FACTOR** and **LINEQS** models. In the **FACTOR** model, the COV statement specifies the covariances among latent factors. In the **LINEQS** model, the COV statement specifies the covariances among all observed or latent exogenous variables, including error and disturbance terms.

If you specify only the *var-list* list, then you are specifying the so-called within-list covariances. If you specify both of the *var-list* and *var-list2* lists, then you are specifying the so-called between-list covariances. An asterisk is used to separate the two variable lists. You can use one of these two alternatives to specify the covariance parameters. **Figure 27.2** illustrates the within-list and between-list covariance specifications.

Figure 27.2 Within-List and Between-List Covariances

Within-List Covariances

The left panel of the figure shows that the same set of four variables are used in both the rows and columns. This yields six nonredundant covariances to specify. In general, with a *var-list* list with k variables in the COV statement, there are $k(k - 1)/2$ distinct covariance parameters you can specify. The variable order of the *var-list* list is important. For example, the left panel of **Figure 27.2** corresponds to the following COV statement specification:

```
cov E1-E4 = phi1-phi6;
```

This specification is equivalent to the following specification:

```
cov E2 E1 = phi1,
    E3 E1 = phi2, E3 E2 = phi3,
    E4 E1 = phi4, E4 E2 = phi5, E4 E3 = phi6;
```

Another way to assign distinct parameter names with the same prefix is to use the so-called prefix-name. For example, the following COV statement specification is exactly the same as the preceding specification:

```
cov E1-E4 = 6*phi__ ; /* phi with two trailing underscores */
```

In the COV statement, `phi__` is a prefix-name with the root `phi`. The notation `6*` means this prefix-name is applied six times, resulting in a generation of the six parameter names `phi1`, `phi2`, ..., `phi6` for the six covariance parameters.

The root of the prefix-name should have few characters so that the generated parameter name is not longer than 32 characters. To avoid unintentional equality constraints, the prefix-names should not coincide with other parameter names.

You can also specify the within-list covariances as unnamed free parameters, as shown in the following statement:

```
cov E1-E4;
```

This specification is equivalent to the following specification:

```
cov E2 E1,
    E3 E1, E3 E2,
    E4 E1, E4 E2, E4 E3;
```

Between-List Covariances

The right panel of [Figure 27.2](#) illustrates the application of the between-list covariance specification. The set of row variables is different from the set of column variables. You intend to specify the cross covariances of the two sets of variables. There are four of these covariances in the figure. In general, with k_1 and k_2 variable names in the two variable lists (separated by an asterisk) in a COV statement, there are $k_1 \times k_2$ distinct covariances to specify. Again, variable order is very important. For example, the right panel of [Figure 27.2](#) corresponds to the following between-list covariance specification:

```
cov E1 E2 * E3 E4 = phi1-phi4;
```

This is equivalent to the following specification:

```
cov E1 E3 = phi1, E1 E4 = phi2,
    E2 E3 = phi3, E2 E4 = phi4;
```

You can also use the prefix-name specification for the same specification, as shown in the following statement:

```
cov E1 E2 * E3 E4 = 4*phi__ ; /* phi with two trailing underscores */
```

Mixed Parameter Lists

You can specify different types of parameters for the list of covariances. For example, you use a list of parameters with mixed types in the following statement:

```
cov E1-E4 = phi1(0.1) 0.2 phi3 phi4(0.4) (0.5) phi6;
```

This specification is equivalent to the following specification:

```

cov E2 E1 = phi1(0.1) ,
    E3 E1 = 0.2        , E3 E2 = phi3,
    E4 E1 = phi4(0.4) , E4 E2 = (0.5), E4 E3 = phi6;

```

Notice that an initial value that follows a parameter name is associated with the free parameter. Therefore, in the original mixed list specification, 0.1 is interpreted as the initial value for the parameter phi1, but not as the initial estimate for the covariance between E3 and E1. Similarly, 0.4 is the initial value for the parameter phi4, but not the initial estimate for the covariance between E4 and E2.

However, if you indeed want to specify that phi1 is a free parameter *without* an initial value and 0.1 is an initial estimate for the covariance between E3 and E1 (while keeping all other things the same), you can use a null initial value specification for the parameter phi1, as shown in the following statement:

```

cov E1-E4 = phi1() (0.1) phi3 phi4(0.4) (0.5) phi6;

```

This way 0.1 becomes the initial estimate for the covariance between E3 and E1. Because a parameter list with mixed types might be confusing, you can break down the specifications into separate *assignments* to remove ambiguities. For example, you can use the following equivalent specification:

```

cov E2 E1 = phi1 ,
    E3 E1 = (0.1)    , E3 E2 = phi3,
    E4 E1 = phi4(0.4) , E4 E2 = (0.5), E4 E3 = phi6;

```

Shorter and Longer Parameter Lists

If you provide fewer parameters than the number of covariances in the variable lists, all the remaining parameters are treated as unnamed free parameters. For example, the following specification assigns a fixed value to `cov(E1,E3)` while treating all the other three covariances as unnamed free parameters:

```

cov E1 E2 * E3 E4 = 1.0;

```

This specification is equivalent to the following specification:

```

cov E1 E3 = 1.0, E1 E4, E2 E3, E2 E4;

```

If you intend to fill up all values by the last parameter specification in the list, you can use the continuation syntax [...], [...], or [...], as shown in the following example:

```

cov E1 E2 * E3 E4 = 1.0 phi [...];

```

This means that `cov(E1,E3)` is a fixed value of 1 and all the remaining three covariances are free parameter named phi. The last three covariances are thus constrained to be equal by using the same parameter name.

However, you must be careful not to provide too many parameters. For example, the following specification results in an error:

```

cov E1 E2 * E3 E4 = 1.0 phi2(2.0) phi3 phi4 phi5 phi6;

```

The parameters after phi4 are excessive.

Default Covariance Parameters

In the confirmatory FACTOR model, by default all factor covariances are free parameters. In the LINEQS model, by default all covariances among exogenous manifest and latent variables (excluding error or disturbance variables) are also free parameters. For these default free parameters, PROC CALIS generate the parameter names with the `_Add` prefix and appended with unique integer suffixes. You can also use the COV statement specification to override these default covariance parameters in situations where you want to set parameter constraints, provide initial or fixed values, or make parameter references.

Another type of default covariances are fixed zeros. In the LINEQS model, covariances among errors or disturbances are all fixed zeros by default. Again, you can override the default fixed values by providing explicit specification of these covariances in the COV statement.

Modifying a Covariance Parameter Specification from a Reference Model

If you define a new model by using a reference (old) model in the `REFMODEL` statement, you might want to modify some parameter specifications from the COV statement of the reference model before transferring the specifications to the new model. To change a particular covariance specification from the reference model, you can simply respecify the same covariance with the desired parameter specification in the COV statement of the new model. To delete a particular covariance parameter from the reference model, you can specify the desired covariance with a missing value specification in the COV statement of the new model.

For example, suppose that the covariance between variables V1 and V2 is specified in the reference model but you do not want this covariance specification be transferred to the new model. You can use the following COV statement specification in the new model:

```
cov  V1 V2 = . ;
```

Note that the missing value syntax is valid only when you use it with the `REFMODEL` statement. See the section “[Modifying a LINEQS Model from a Reference Model](#)” on page 1160 for a more detailed example of the LINEQS model respecification with the `REFMODEL` statement. See the section “[Modifying a FACTOR Model from a Reference Model](#)” on page 1146 for a more detailed example of the FACTOR model respecification with the `REFMODEL` statement.

As discussed in a preceding section, PROC CALIS generates some default free covariance parameters for the LINEQS and FACTOR models if you do not specify them explicitly in the COV statement. When you use the `REFMODEL` statement for defining a reference model, these default free covariance parameters in the old (reference) model are not transferred to the new model. Instead, the new model generates its own set of default free covariance parameters *after* it is resolved from the reference model, the `REFMODEL` statement options, the `RENAMEPARM` statement, and the COV statement specifications in the new model. This also implies that if you want any of the covariance parameters to be constrained across the models by means of the `REFMODEL` specification, you must specify them explicitly in the COV statement of the reference model so that the same covariance specification is transferred to the new model.

DETERM Statement

```
DETERM | STRUCTEQ variables </ option> ;
```

where *option* represents:

LABEL | NAME= *name*

The DETERM statement is used to compute the determination coefficient of the listed dependent *variables* in the model. The precursor of the DETERM statement is the STRUCTEQ statement, which enables you to define the list of the dependent variables of the structural equations. Because the term *structural equation* is not defined in a unique way, a more generic concept of determination coefficients is revealed by the DETERM statement.

You can specify the DETERM statement as many times as you want for computing determination coefficients for the sets of dependent *variables* of interest. You can label each set of dependent variables by using the LABEL= option. Note that you cannot use the DETERM statement in an MSTRUCT model because there are no dependent variables in this type of model.

EFFPART Statement

EFFPART *effect* <, *effect*> ;

where *effect* represents:

var-list < *direction* *var-list2*>

and *direction* is the direction of the effect, as indicated by one of the following: ==>, --->, ==>, -->, =>, ->, >, <==, <---, <==, <--, <=, <-, or <.

In the EFFPART statement, you select those effects you want to analyze by partitioning the total effects into direct and indirect effects, with estimated standard errors. The EFFPART or TOTEFF option of the PROC CALIS statement also enables you to analyze effects. The difference is that the EFFPART or TOTEFF option displays effects on *all* endogenous variables, while the EFFPART statement shows only the effects of interest. In addition, the EFFPART statement enables you to arrange the effects in any way you like. Hence, the EFFPART statement offers a more precise and organized way to present various results of effects.

The EFFPART statement supports the following three types of effect specifications:

- >, =>, ->, ==>, -->, ===>, or ----> direction

Example:

```
effpart x1 x3-x5 ==> y1 y2;
```

This will display *four* separate tables, respectively for the effects of X1, X3, X4, and X5 on Y1 and Y2. Each table contains the total, direct, and indirect effects of an X-variable on the two Y-variables.

- <, <=, <-, <==, <---, <===, or <---- direction

Example:

```
effpart Y1 Y2 <=== X1 X3-X5;
```

This will display *two* separate tables, respectively for the effects on Y1 and Y2, by X1, X3, X4, and X5. Each table contains the total, direct, and indirect effects of the four X-variables on a Y-variable. Certainly, the results produced from this statement are essentially the same as the previous statement. The difference is about the organization of the effects in the tables.

- no direction

Example:

```
effpart Y1 Y2 X1-X3;
```

In this case, variables on the list are analyzed one by one to determine the nature of the effects. If a variable has nonzero effects on any other variables in the model, a table of the total, direct, and indirect effects of the variable on those variables is displayed. If a variable is endogenous, a table of total, direct, and indirect effects of those variables that have nonzero effects on the variable is displayed. Note that an endogenous variable in a model might also have effects on other endogenous variables. Therefore, the two cases mentioned are not mutually exclusive—a variable listed in the EFFPART statement might yield two tables for effect analysis.

FACTOR Statement

```
FACTOR < EFA-options | CFA-spec > ;
```

where *EFA-options* are options for the exploratory factor analysis that are described in the section “[Exploratory Factor Analysis](#)” on page 1138 and *CFA-spec* is a specification of confirmatory factor analysis that is described in the section “[Confirmatory Factor Analysis](#)” on page 1142.

In the FACTOR statement, you can specify either *EFA-options*, *CFA-spec*, or neither of these. However, you cannot specify both *EFA-options* and *CFA-spec* at the same time. If no option is specified or there is at least one *EFA-option* (exploratory factor analysis option) specified in the FACTOR statement, an [exploratory factor model](#) is analyzed. Otherwise, a [confirmatory factor model](#) is analyzed with the *CFA-spec*. These two types of models are discussed in the next two sections.

Exploratory Factor Analysis

```
FACTOR < EFA-options > ;
```

For the exploratory factor model with orthogonal factors, PROC CALIS assumes the following model structures for the population covariance or correlation matrix Σ :

$$\Sigma = \mathbf{F}\mathbf{F}' + \mathbf{U}$$

where \mathbf{F} is the factor loading matrix and \mathbf{U} is a diagonal matrix of error variances. In this section, p denotes the number of manifest variables corresponding to the rows and columns of matrix Σ , and n denotes the number of factors (or components, if the [COMPONENT](#) option is specified in the FACTOR statement)

corresponding to the columns of the factor loading matrix \mathbf{F} . While the number of manifest variables is set automatically by the number of variables in the **VAR** statement or in the input data set, the number of factors can be set by the **N=** option in the **FACTOR** statement.

The unrestricted exploratory factor model is not identified because any orthogonal rotated factor loading matrix $\tilde{\mathbf{F}} = \mathbf{F}\mathbf{\Theta}$ satisfies the same model structures as \mathbf{F} does, where $\mathbf{\Theta}$ is any orthogonal matrix so that $\mathbf{\Theta}'\mathbf{\Theta} = \mathbf{\Theta}\mathbf{\Theta}' = \mathbf{I}$. Mathematically, the covariance or correlation structures can be expressed as:

$$\mathbf{\Sigma} = \tilde{\mathbf{F}}\tilde{\mathbf{F}}' + \mathbf{U} = \mathbf{F}\mathbf{\Theta}\mathbf{\Theta}'\mathbf{F}' + \mathbf{U} = \mathbf{F}\mathbf{F}' + \mathbf{U}$$

To obtain an identified orthogonal factor solution as a starting point, the $n(n - 1)/2$ elements in the upper triangle of \mathbf{F} are constrained to zeros in **PROC CALIS**. Initial estimates for factor loadings and unique variances are computed by an algebraic method of approximate factor analysis. Given the initial estimates, final estimates are obtained through the iterative optimization of an objective function, which depends on the estimation method specified in the **METHOD=** option (default with **ML**—maximum likelihood) of the **PROC CALIS** statement.

To make the factor solution more interpretable, you can use the **ROTATE=** option in the **FACTOR** statement to obtain a rotated factor loading matrix with a “simple” pattern. Rotation can be orthogonal or oblique. The rotated factors remain uncorrelated after an orthogonal rotation but would be correlated after an oblique rotation. The model structures of an oblique solution are expressed in the following equation:

$$\mathbf{\Sigma} = \tilde{\mathbf{F}}\mathbf{P}\tilde{\mathbf{F}}' + \mathbf{U}$$

where $\tilde{\mathbf{F}}$ is the rotated factor loading matrix and \mathbf{P} is a symmetric matrix for factor correlations. See the sections “[The FACTOR Model](#)” on page 1263 and “[Exploratory Factor Analysis Models](#)” on page 1265 for more details about exploratory factor models.

You can also do exploratory factor analysis by the more dedicated **FACTOR** procedure. Even though extensive comparisons of the factor analysis capabilities between the **FACTOR** and **CALIS** procedures are not attempted here, some general points can be made here. In general, the **FACTOR** procedure provides more factor analysis options than the **CALIS** procedure does, although both procedures have some unique factor analysis features that are not shared by the other. **PROC CALIS** requires more computing time and memory than **PROC FACTOR** because it is designed for more general structural estimation problems and is not able to exploit all the special properties of the unconstrained factor analysis model. For maximum likelihood analysis, you can use either **PROC FACTOR** (with **METHOD=ML**, which is not the default method in **PROC FACTOR**) or **PROC CALIS**. Because the initial unrotated factor solution obtained by **PROC FACTOR** uses a different set of identification constraints than that of **PROC CALIS**, you would observe different initial **ML** factor solutions for the procedures. Nonetheless, the initial solutions by both procedures are statistically equivalent.

The following *EFA-options* are available in the **FACTOR** statement:

COMPONENT | COMP

computes a component analysis instead of a factor analysis (the diagonal matrix \mathbf{U} in the model is set to 0). Note that the rank of $\mathbf{F}\mathbf{F}'$ is equal to the number n of components in \mathbf{F} . If n is smaller than the number of variables in the moment matrix $\mathbf{\Sigma}$, the matrix of predicted model values is singular and maximum likelihood estimates for \mathbf{F} cannot be computed. You should compute **ULS** estimates in this case.

HEYWOOD | HEY

constrains the diagonal elements of **U** to be nonnegative. Equivalently, you can constrain these elements to positive values by the **BOUNDS** statement.

GAMMA=*p*

specifies the orthomax weight used with the option **ROTATE=ORTHOMAX**. Alternatively, you can use **ROTATE=ORTHOMAX(*p*)** with *p* representing the orthomax weight. There is no restriction on valid values for the orthomax weight, although the most common values are between 0 and the number of variables. The default **GAMMA=** value is one, resulting in the varimax rotation.

N=*n*

specifies the number of first-order factors or components. The number of factors (*n*) should not exceed the number of manifest variables (*p*) in the analysis. For the saturated model with $n = p$, the **COMP** option should generally be specified for **U** = 0; otherwise, $df < 0$. For $n = 0$ no factor loadings are estimated, and the model is $\Sigma = U$, with a diagonal **U** matrix. By default, $n = 1$.

NORM< = KAISER | NONE >

Kaiser-normalizes the rows of the factor pattern for rotation. **NORM=KAISER**, which is the default, has exactly the same effect as **NORM**. You can turn off the normalization by **NORM=NONE**.

RCONVERGE=*p***RCONV=*p***

specifies the convergence criterion for rotation cycles. Rotation stops when the scaled change of the simplicity function value is less than the **RCONVERGE=** value. The default convergence criterion is:

$$|f_{new} - f_{old}|/K < \epsilon$$

where f_{new} and f_{old} are simplicity function values of the current cycle and the previous cycle, respectively, $K = \max(1, |f_{old}|)$ is a scaling factor, and ϵ is 1E-9 by default and is modified by the **RCONVERGE=** value.

RITER=*i*

specifies the maximum number of cycles *i* for factor rotation. The default *i* is the greater of 10 times the number of variables and 100.

ROTATE | R=*name*

specifies an orthogonal or oblique rotation of the initial factor solution. Although **ROTATE=PRINCIPAL** is actually not a rotation method, it is put here for convenience. By default, **ROTATE=NONE**.

Valid *names* for orthogonal rotations are as follows:

BIQUARTIMAX | BIQMAX specifies orthogonal biquartimax rotation. This corresponds to the specification **ROTATE=ORTHOMAX(0.5)**.

EQUAMAX | E specifies orthogonal equamax rotation. This corresponds to the specification **ROTATE=ORTHOMAX** with **GAMMA=*n*/2**.

FACTORPARSIMAX | FPA specifies orthogonal factor parsimax rotation. This corresponds to the specification **ROTATE=ORTHOMAX** with **GAMMA=*n***.

NONE | N specifies that no rotation be performed, leaving the original orthogonal solution.

ORTHCF($p1, p2$) | **ORCF**($p1, p2$) specifies the orthogonal Crawford-Ferguson rotation (Crawford and Ferguson 1970) with the weights $p1$ and $p2$ for variable parsimony and factor parsimony, respectively. See the definitions of weights in Chapter 35, “[The FACTOR Procedure](#).”

ORTHGENCF($p1, p2, p3, p4$) | **ORGENCF**($p1, p2, p3, p4$) specifies the orthogonal generalized Crawford-Ferguson rotation (Jennrich 1973), with the four weights $p1$, $p2$, $p3$, and $p4$. For the definitions of these weights, see the section “[Simplicity Functions for Rotations](#)” on page 2244 in Chapter 35, “[The FACTOR Procedure](#).”

ORTHOMAX<($p1$)> | **ORMAX**<($p1$)> specifies the orthomax rotation (see Harman 1976) with orthomax weight $p1$. If **ROTATE**=**ORTHOMAX** is used, the default $p1$ value is 1 unless specified otherwise in the **GAMMA**= option. Alternatively, **ROTATE**=**ORTHOMAX**($p1$) specifies $p1$ as the orthomax weight or the **GAMMA**= value. For the definitions of the orthomax weight, see the section “[Simplicity Functions for Rotations](#)” on page 2244 in Chapter 35, “[The FACTOR Procedure](#).”

PARSIMAX | **PA** specifies orthogonal parsimax rotation. This corresponds to the specification **ROTATE**=**ORTHOMAX** with

$$\text{GAMMA} = \frac{p \times (n - 1)}{p + n - 2}$$

PRINCIPAL | **PC** specifies a principal axis rotation. If **ROTATE**=**PRINCIPAL** is used with a factor rather than a component model, the following rotation is performed:

$$\mathbf{F}_{new} = \mathbf{F}_{old} \mathbf{T}, \quad \text{with} \quad \mathbf{F}'_{old} \mathbf{F}_{old} = \mathbf{T} \mathbf{\Lambda} \mathbf{T}'$$

where the columns of matrix **T** contain the eigenvectors of $\mathbf{F}'_{old} \mathbf{F}_{old}$.

QUARTIMAX | **QMAX** | **Q** specifies orthogonal quartimax rotation. This corresponds to the specification **ROTATE**=**ORTHOMAX**(0).

VARIMAX | **V** specifies orthogonal varimax rotation. This corresponds to the specification **ROTATE**=**ORTHOMAX** with **GAMMA**=1.

Valid *names* for oblique rotations are as follows:

BIQUARTIMIN | **BIQMIN** specifies biquartimin rotation. It corresponds to the specification **ROTATE**=**OBLIMIN**(.5) or **ROTATE**=**OBLIMIN** with **TAU**=.5.

COVARIMIN | **CVMIN** specifies covarimin rotation. It corresponds to the specification **ROTATE**=**OBLIMIN**(1) or **ROTATE**=**OBLIMIN** with **TAU**=1.

OBBIQUARTIMAX | **OBIQMAX** specifies oblique biquartimax rotation.

OBEQUAMAX | **OE** specifies oblique equamax rotation.

OBFACORPARSIMAX | **OFPA** specifies oblique factor parsimax rotation.

OBLICF($p1, p2$) | **OBCF**($p1, p2$) specifies the oblique Crawford-Ferguson rotation (Crawford and Ferguson 1970) with the weights $p1$ and $p2$ for variable parsimony and factor parsimony, respectively. For the definitions of these weights, see the section “[Simplicity Functions for Rotations](#)” on page 2244 in Chapter 35, “[The FACTOR Procedure](#).”

OBLIGENCF($p1, p2, p3, p4$) | **OBGENCF**($p1, p2, p3, p4$) specifies the oblique generalized Crawford-Ferguson rotation (Jennrich 1973) with the four weights $p1$, $p2$, $p3$, and $p4$. For the definitions of these weights, see the section “Simplicity Functions for Rotations” on page 2244 in Chapter 35, “The FACTOR Procedure.”

OBLIMIN<($p1$)> | **OBLMIN**<($p1$)> specifies the oblimin rotation with oblimin weight $p1$. If **ROTATE=OBLIMIN** is used, the default $p1$ value is zero unless specified otherwise in the **TAU=** option. Alternatively, **ROTATE=OBLIMIN**($p1$) specifies $p1$ as the oblimin weight or the **TAU=** value. For the definitions of the oblimin weight, see the section “Simplicity Functions for Rotations” on page 2244 in Chapter 35, “The FACTOR Procedure.”

OBPARSIMAX | **OPA** specifies oblique parsimax rotation.

OBQUARTIMAX | **OQMAX** specifies oblique quartimax rotation. This is the same as the **QUARTIMIN** method.

OBVARIMAX | **OV** specifies oblique varimax rotation.

QUARTIMIN | **QMIN** specifies quartimin rotation. It is the same as the oblique quartimax method. It also corresponds to the specification **ROTATE=OBLIMIN**(0) or **ROTATE=OBLIMIN** with **TAU=0**.

TAU= p

specifies the oblimin weight used with the option **ROTATE=OBLIMIN**. Alternatively, you can use **ROTATE=OBLIMIN**(p) with p representing the oblimin weight. There is no restriction on valid values for the oblimin weight, although for practical purposes a negative or zero value is recommended. The default **TAU=** value is 0, resulting in the quartimin rotation.

Confirmatory Factor Analysis

FACTOR *factor-variables-relation* <, *factor-variables-relation* ... > ;

where each *factor-variables-relation* is defined as

factor right-arrow var-list < = *parameter-spec* >

where *right-arrow* is one of the following: **===>**, **---->**, **==>**, **-->**, **=>**, **->**, or **>**.

To complete the specification of a confirmatory factor model, you might need to use the **PVAR**, **COV**, and **MEAN** statements to specify the variance, partial variance, covariance, and mean parameters in the model, as shown in the following syntax:

```
FACTOR factor-variable-relation <, factor-variables-relation ... > ;
PVAR partial-variance-parameters ;
COV covariance-parameters ;
MEAN mean-parameters ;
```

The model structures for the covariance matrix Σ of the confirmatory factor model are described in the equation

$$\Sigma = \mathbf{F}\mathbf{P}\mathbf{F}' + \mathbf{U}$$

where **F** is the factor loading matrix, **P** is a symmetric matrix for factor correlations, and **U** is a diagonal matrix of error variances.

If the mean structures are also analyzed, the model structures for the mean vector μ of the confirmatory factor model are described in the equation

$$\mu = \alpha + F\nu$$

where α is the intercept vector for the observed variables and ν is the vector for factor means. See the sections “[The FACTOR Model](#)” on page 1263 and “[Confirmatory Factor Analysis Models](#)” on page 1266 for more details about confirmatory factor models.

The FACTOR statement is the main model specification statement for the confirmatory factor model. The specifications in the FACTOR statement concern the factor loading pattern in the **F** matrix. More details follow after a brief description of the subsidiary model specification statements: PVAR, COV, and MEAN.

By default, the factor variance parameters in the diagonal of matrix **P** and the error variances in the diagonal of matrix **U** are free parameters in the confirmatory factor model. However, you can override these default parameters by specifying them explicitly in the PVAR statement. For example, in some confirmatory factor models, you might want to set some of these variances to fixed constants, or you might want to set equality constraints by using the same parameter name at different parameter locations in your model.

By default, factor covariances, which are the off-diagonal elements of matrix **P**, are free parameters in the confirmatory factor model. However, you can override these default covariance parameters by specifying them explicitly in the COV statement. Note that you cannot use the [COV](#) statement to specify the error covariances—they are always fixed zeros in the confirmatory factor analysis model.

By default, all factor means are fixed zeros and all intercepts are free parameters if the mean structures are analyzed. You can override these defaults by explicitly specifying the means of the factors in vector ν and the intercepts of the manifest variables in vector α in the [MEAN](#) statement.

Because the default parameterization of the confirmatory FACTOR model already covers most commonly used parameters in matrices **P**, **U**, α , and ν , the specifications in the PVAR, COV, and MEAN statements are secondary to the specifications in the FACTOR statement, which specifies the factor pattern of the **F** matrix. The following example statement introduces the syntax of the confirmatory FACTOR statement. Suppose that there are nine manifest variables V1–V9 in your sample and you want to fit a model with four factors, as shown in the following FACTOR statement:

```
factor
  g_factor   ===>  V1-V9 ,
  factor_a   ===>  V1-V3 ,
  factor_b   ===>  V4-V6 ,
  factor_c   ===>  V7-V9 ;
```

In this factor model, you assume a general factor `g_factor` and three group-factors: `factor_a`, `factor_b`, and `factor_c`. The general factor `g_factor` is related to all manifest variables in the sample, while each group-factor is related only to three manifest variables. This example fits the following pattern of factor pattern of **F**:

	g_factor	factor_a	factor_b	factor_c
V1	x	x		
V2	x	x		
V3	x	x		
V4	x		x	
V5	x		x	
V6	x		x	
V7	x			x
V8	x			x
V9	x			x

where an x represents an unnamed free parameter and all other cells that are blank are fixed zeros. For each of these unnamed parameters, PROC CALIS generates a parameter name with the `_Parm` prefix and appended with a unique integer (for example, `_Parm1`, `_Parm2` and so on).

An unnamed free parameter is only one of the following five types of parameters (*parameter-spec*) you can specify at the end of each *factor-variables-relation*:

- an unnamed free parameter
- an initial value
- a fixed value
- a free parameter with a name provided
- a free parameter with a name and initial value provided

To illustrate these different types of parameter specifications, consider the following factor pattern for **F**:

	g_factor	factor_a	factor_b	factor_c
V1	g_load1	1.		
V2	g_load2	x		
V3	g_load3	x		
V4	g_load4		1.	
V5	g_load5		load_a	
V6	g_load6		load_b	
V7	g_load7			1.
V8	g_load8			load_c
V9	g_load9			load_c

where an x represents an unnamed free parameter, a constant 1 represents a fixed value, and each name in a cell represents a name for a free parameter. You can specify this factor pattern by using the following FACTOR statement:

```
factor
  g_factor    ==>  V1-V9    = g_load1-g_load9 (9*0.6) ,
  factor_a    ==>  V1-V3    = 1. (.7 .8) ,
  factor_b    ==>  V4-V6    = 1. load_a (.9) load_b ,
  factor_c    ==>  V7-V9    = 1. 2*load_c ;
```

In the first entry of the FACTOR statement, you specify that the loadings of V1–V9 on g_factor are free parameters g_load1–g_load9 with all given an initial estimate of 0.6. The syntax `9*0.6` means that `0.6` is repeated nine times. Because they are enclosed in a pair parentheses, all these values are treated as initial estimates, but not fixed values.

The second entry of the FACTOR statement can be split into the following specification:

```
factor_a    ===>   V1      = 1.    ,
factor_a    ===>   V2      = (.7) ,
factor_a    ===>   V3      = (.8) ,
```

This means that the first loading is a fixed value of 1, while the other loadings are unnamed free parameters with initial estimates 0.7 and 0.8, respectively. For each of these unnamed parameters with initial values, PROC CALIS also generates a parameter name with the `_Parm` prefix and appended with a unique integer.

The third entry of the FACTOR statement can be split into the following specification:

```
factor_b    ===>   V4      = 1.    ,
factor_b    ===>   V5      = load_a (.9) ,
factor_b    ===>   V6      = load_b ,
```

This means that the first loading is a fixed value of 1, the second loading is a free parameter named `load_a` with an initial estimate of 0.9, and the third loading is a free parameter named `load_b` without an initial estimate. PROC CALIS generates the initial value for this free parameter.

The fourth entry of the FACTOR statement states that the first loading is a fixed 1 and the remaining two loadings are free parameters named `load_c`. No initial estimate is given. But because the two loadings have the same parameter name, they are constrained to be equal in the estimation.

Notice that an initial value that follows after a parameter name is associated with the free parameter. For example, in the third entry of the FACTOR statement, the specification `(.9)` after `load_a` is interpreted as the initial value for the parameter `load_a`, but not as the initial estimate for the next loading for V6.

However, if you indeed want to specify that `load_a` is a free parameter *without* an initial value and `(0.9)` is an initial estimate for the loading for V6, you can use a null initial value specification for the parameter `load_a`, as shown in the following specification:

```
factor_b    ===>   V4-V6    = 1. load_a() (.9) ,
```

This way 0.9 becomes the initial estimate of the loading for V6. Because a parameter list with mixed parameter types might be confusing, you can split the specification into separate entries to remove ambiguities. For example, you can use the following equivalent specification:

```
factor_b    ===>   V4      = 1. ,
factor_b    ===>   V5      = load_a ,
factor_b    ===>   V6      = (.9) ,
```

Shorter and Longer Parameter Lists

If you provide fewer parameters than the number of loadings that are specified in the corresponding *factor-variable-relation*, all the remaining parameters are treated as unnamed free parameters. For example, the following specification assigns a fixed value of 1.0 to the first loading, while treating the remaining two loadings as unnamed free parameters:

```
factor
  factor_a    ==>    V1-V3    = 1.;
```

This specification is equivalent to the following specification:

```
factor
  factor_a    ==>    V1      = 1.,
  factor_a    ==>    V2 V3    ;
```

If you intend to fill up all values with the last parameter specification in the list, you can use the continuation syntax [...], [...], or [...], as shown in the following example:

```
factor
  g_factor    ==>    V1-V30    = 1. (.5) [...];
```

This means that the loading of V1 on g_factor is a fixed value of 1.0, while the remaining 29 loadings are unnamed free parameters with all given an initial estimate of 0.5.

However, you must be careful not to provide too many parameters. For example, the following specification results in an error:

```
factor
  g_factor    ==>    V1-V3    = load1-load6;
```

The parameter list has six parameters for three loadings. Parameters after load3 are excessive.

Default Parameters

It is important to understand the default parameters in the FACTOR model. First, if you know which parameters are default free parameters, you can make your specification more efficient by omitting the specifications of those parameters that can be set by default. For example, because all error variances in the confirmatory FACTOR model are free parameters by default, you do not need to specify them with the PVAR statement if these error variances are not constrained. Second, if you know which parameters are default free parameters, you can specify your model accurately. For example, because all factor variance and covariances in the confirmatory FACTOR model are free parameters by default, you must use the COV statement to restrict the covariances among the factors if you want to fit an orthogonal factor model. See the section “[Default Parameters in the FACTOR Model](#)” on page 1270 for details about the default parameters of the FACTOR model.

Modifying a FACTOR Model from a Reference Model

This section assumes that you use a [REFMODEL](#) statement within the scope of a [MODEL](#) statement and that the reference model (or base model) is a factor model, either exploratory or confirmatory. The reference model is called the old model, and the model that refers to the old model is called the new model. If the new model is not intended to be an exact copy of the old FACTOR model, you can use the extended FACTOR modeling language described in this section to make modifications from the old model before transferring the specifications to the new model.

Using the **REFMODEL** statement for defining new factor models is not recommended in the following cases:

- If your old model is an exploratory factor analysis model, then specification by using the **FACTOR** modeling language in the new model replaces the old model completely. In this case, the use of the **REFMODEL** statement is superfluous and should be avoided.
- If your old model is a confirmatory factor analysis model, then specification of an exploratory factor model by using the **FACTOR** statement in the new model also replaces the old model completely. Again, the use of the **REFMODEL** statement is superfluous and should be avoided.

The nontrivial case where you might find the **REFMODEL** statement useful is when you modify an old confirmatory factor model to form a new confirmatory factor model. This nontrivial case is the focus of discussion in the remaining of the section.

The extended **FACTOR** modeling language for modifying model specification bears the same syntax as that of the ordinary **FACTOR** modeling language (see the section “**Confirmatory Factor Analysis**” on page 1142). The syntax is:

```
FACTOR factor-variable-relation ;
PVAR partial-variance-parameters ;
COV covariance-parameters ;
MEAN mean-parameters ;
```

The new model is formed by integrating with the old model in the following ways:

Duplication:	If you do not specify in the new model a parameter location that exists in the old model, the old parameter specification is duplicated in the new model.
Addition:	If you specify in the new model a parameter location that does not exist in the old model, the new parameter specification is added in the new model.
Deletion:	If you specify in the new model a parameter location that also exists in the old model and the new parameter is denoted by the missing value ‘.’, the old parameter specification is not copied into the new model.
Replacement:	If you specify in the new model a parameter location that also exists in the old model and the new parameter is not denoted by the missing value ‘.’, the new parameter specification replaces the old one in the new model.

For example, consider the following two-group analysis:

```

proc calis;
  group 1 / data=d1;
  group 2 / data=d2;
  model 1 / group=1;
    factor
      F1 ==> V1-V3    = 1. load1 load2,
      F2 ==> V4-V6    = 1. load3 load4,
      F3 ==> V7-V9    = 1. load5 load6;
    cov
      F1 F2 = c12,
      F2 F3 = c23;
    pvar
      F1-F3 = c1-c3,
      V1-V9 = ev1-ev9;
  model 2 / group=2;
    refmodel 1;
    factor
      F1 ==> V1      = loada,
      F2 ==> V4      = loadb,
      F3 ==> V7      = loadc;
    cov
      F1 F2 = .,
      F1 F3 = c13;
run;

```

In this specification, you specify Model 2 by referring to Model 1 in the **REFMODEL** statement; Model 2 is the new model which refers to the old model, Model 1. Because the **PVAR** statement is not used in new model, all variance and partial variance parameter specifications in the **PVAR** statement of the old model are duplicated in the new model. The covariance parameter **c23** for covariance between F2 and F3 in the **COV** statement of the old model is also duplicated in the new model. Similarly, loading parameters **load1**–**load6** for some specific factor matrix locations are duplicated from the old model to the new model.

The new model has an additional parameter specification that the old model does not have. In the **COV** statement of the new model, covariance parameter **c13** for the covariance between F1 and F3 is added.

In the same statement, the covariance between F1 and F2 is denoted by the missing value ‘.’. The missing value indicates that this parameter location in the old model should not be included in the new model. The consequence of this deletion from the old model is that the covariance between F1 and F2 is a fixed zero in the new model.

Finally, the three new loading specifications in the **FACTOR** statement of the new model replace the fixed ones in the old model. They are now free parameters **loada**, **loadb**, and **loadc** in the new model.

FITINDEX Statement

FITINDEX *option* < *option* ... > ;

You can use the **FITINDEX** statement to set the options for computing and displaying the fit indices, or to output the fit indices. All but the **OFF=** and **ON=** options of the **FITINDEX** statement are also available in the **PROC CALIS** statement. The options set in the **FITINDEX** statement will overwrite those set in the **PROC CALIS** statement.

For the listing of fit indices and their definitions, see the section “Overall Model Fit Indices” on page 1329. Note that not all fit indices are available with all estimation methods, which is specified by the **METHOD=** option of the PROC CALIS statement. See the section “Fit Indices and Estimation Methods” on page 1336 for more details.

The options of the FITINDEX statement are as follows:

ALPHAECV= α

specifies a $(1 - \alpha)100\%$ confidence interval ($0 \leq \alpha \leq 1$) for the Browne and Cudeck (1993) expected cross validation index (ECVI). See the **ALPHAECV=** option of the PROC CALIS statement on page 1087.

ALPHARMS= α

specifies a $(1 - \alpha)100\%$ confidence interval ($0 \leq \alpha \leq 1$) for the Steiger and Lind (1980) root mean square error of approximation (RMSEA) coefficient. See the **ALPHARMS=** option of the PROC CALIS statement on page 1088.

BASEFIT | INBASEFIT=*SAS-data-set*

inputs the *SAS-data-set* that contains the fit information of the baseline model of your choice. See the **BASEFIT=** option of the PROC CALIS statement on page 1089.

BASEFUNC= $r(< DF=>i)$

BASEFUNC($< DF=>i$)= r

inputs the fit function value r and the degrees of freedom i of the baseline model of your choice. See the **BASEFUNC=** option of the PROC CALIS statement on page 1090.

CHICORRECT | CHICORR = *name* | *c*

specifies a correction factor c for the chi-square statistics for model fit. See the **CHICORRECT=** option of the PROC CALIS statement on page 1091.

CLOSEFIT= p

defines the criterion value p for indicating a close fit. See the **CLOSEFIT=** option of the PROC CALIS statement on page 1093.

DFREDUCE= i

reduces the degrees of freedom of the χ^2 test by i . See the **DFREDUCE=** option of the PROC CALIS statement on page 1096.

NOADJDF

turns off the automatic adjustment of degrees of freedom when there are active constraints in the analysis. See the **NOADJDF** option of the PROC CALIS statement on page 1106.

NOINDEXTYPE

disables the display of index types in the fit summary table. See the **NOINDEXTYPE** option of the PROC CALIS statement on page 1106.

OFF | OFFLIST= [*names*] | {*names*}

turns off the printing of one or more fit indices or modeling information as indicated by *names*, where a *name* represents a fit index, a group of fit indices, or modeling information. *Names* must be specified inside a pair of parentheses and separated by spaces. By default, all fit indices are printed. See the **ON=** option for the value of *names*.

ON | ONLIST < (ONLY) > = [names] | {names}

turns on the printing of one or more fit indices or modeling information as indicated by *names*, where a *name* represents a fit index, a group of fit indices, or modeling information. *Names* must be specified inside a pair of parentheses and separated by spaces. Because all fit indices and modeling information are printed by default, using an ON= list alone is redundant. When both ON= and OFF= lists are specified, the ON= list will override the OFF= list for those fit indices or modeling information that appear on both lists. If an ON(ONLY)= list is used, only those fit indices or modeling information specified in the list will be printed. Effectively, an ON(ONLY)= list is the same as the specification with an ON= list with the same selections and an OFF=ALL list in the FITINDEX statement.

Output Control of Fit Index Groups and Modeling Information Group

You can use the following *names* to refer to the groups of fit indices or modeling information available in PROC CALIS:

ABSOLUTE	Absolute or stand-alone fit indices that measures the model fit without using a baseline model.
ALL	All fit indices available in PROC CALIS.
INCREMENTAL	Incremental fit indices that measure model fit by comparing with a baseline model.
MODELINFO	General modeling information including sample size, number of variables, number of variables, and so on.
PARSIMONY	Fit indices that take model parsimony into account.

Output Control of Modeling Information

You can use the following *names* to refer to the individual modeling information available in PROC CALIS:

BASECHISQ	Chi-square statistic for the baseline model.
BASEDF	Degrees of freedom of the chi-square statistic for the baseline model.
BASEFUNC	Baseline model function value.
BASELOGLIKE	Baseline model -2 log-likelihood function value for METHOD=FIML.
BASEPROBCHI	p -value of the chi-square statistic for the baseline model fit.
BASESTATUS	Status of the baseline model fitting for METHOD=FIML.
NACTCON	Number of active constraints.
NIOBS	Number of incomplete observations for METHOD=FIML.
NMOMENTS	Number of elements in the moment matrices being modeled.
NOBS	Number of observations assumed in the analysis.
NPARM NPARMS	Number of independent parameters.
NVAR	Number of variables.
SATFUNC	Saturated model function value for METHOD=FIML.
SATLOGLIKE	Saturated model -2 log-likelihood function value for METHOD=FIML.
SATSTATUS	Status of the saturated model fitting for METHOD=FIML.

Output Control of Absolute Fit Indices

You can use the following *names* to refer to the individual absolute fit indices available in PROC CALIS:

CHISQ	Chi-square statistic for model fit.
CN CRITICAL_N	Hoelter's critical N.
CONTRLIKE	Percentage contribution to the Log-likelihood function value of each group in multiple-group analyses with METHOD=FIML.
CONTRIBUTION CONTCHI	Percentage contribution to the chi-square value for multiple-group analyses.
DF	Degrees of freedom for the chi-square test for model fit.
ELLIPTIC	Elliptical chi-square statistic for ML and GLS methods in single-group analyses without mean structures. This index is computed only when you input the raw data with the KURTOSIS option specified.
FUNCVAL	Optimized function value.
GFI	Goodness-of-fit index by Jöreskog and Sörbom.
LOGLIKE	Fitted model -2 log-likelihood function value for METHOD=FIML.
PROBCHI	<i>P</i> -value of the chi-square statistic for model fit.
PROBELLIPTIC	<i>P</i> -value of the elliptical chi-square statistic.
RMR	Root mean square residual.
SRMR	Standardized root mean square residual.
ZTEST	Z-test of Wilson and Hilferty.

Output Control of Parsimonious Fit Indices

You can use the following *names* to refer to the individual parsimonious fit indices available in PROC CALIS:

AGFI	Adjusted GFI.
AIC	Akaike information criterion.
CAIC	Bozdogan corrected AIC.
CENTRALITY	McDonald centrality measure.
ECVI	Expected cross-validation index.
ECVI_LL LL_ECVI	Lower confidence limit for ECVI.
ECVI_UL UL_ECVI	Upper confidence limit for ECVI.
PGFI	Parsimonious GFI.
PROBCLFIT	Probability of close fit.
RMSEA	Root mean squares of error approximation.
RMSEA_LL LL_RMSEA	Lower confidence limit for RMSEA.
RMSEA_UL UL_RMSEA	Upper confidence limit for RMSEA.

SBC Schwarz Bayesian criterion.

Output Control of Incremental Fit Indices

You can use the following *names* to refer to the individual incremental fit indices available in PROC CALIS:

BENTLERCFI | **CFI** Bentler comparative fit index.

BENTLERNFI Bentler-Bonett normed fit index.

BENTLERNNFI Bentler-Bonett nonnormed fit index.

BOLLENNFI Bollen normed fit index (Rho1).

BOLLENNNFI Bollen nonnormed fit index (Delta2).

PNFI James et al. parsimonious normed fit index.

OUTFIT=SAS-data-set

creates an output data set containing the values of the fit indices. This is the same as the **OUTFIT= option of the PROC CALIS statement** on page 1110. See the section “**OUTFIT= Data Set**” on page 1254 for details.

FREQ Statement

FREQ *variable* ;

If one variable in your data set represents the frequency of occurrence for the other values in the observation, specify the variable’s name in a FREQ statement. PROC CALIS then treats the data set as if each observation appears n_i times, where n_i is the value of the FREQ variable for observation i . Only the integer portion of the value is used. If the value of the FREQ variable is less than 1 or is missing, that observation is not included in the analysis. The total number of observations is considered to be the sum of the FREQ values. You can use only one FREQ statement within the scope of each **GROUP** or the PROC CALIS statement.

GROUP Statement

GROUP i *</options>* ;

where i is an assigned group number between 1 and 9999, inclusively.

The GROUP statement signifies the beginning of a group specification block and designates a group number for the group. All [subsidiary group specification statements](#) after a GROUP statement belong in that group until another **MODEL** or **GROUP** statement is used. The subsidiary group specification statements refer to one of the following four statements:

- [FREQ statement on page 1152](#)
- [PARTIAL statement on page 1202](#)
- [VAR statement on page 1228](#)
- [WEIGHT statement on page 1235](#)

For example, consider the following statements:

```
proc calis;
  var X1-X4;
  group 1 / label='Women' data=women_data;
    freq Z;
  group 2 / label='Men' data=men_data;
    partial P;
  model 1 / group = 1-2;
    factor N=1; /* One factor exploratory factor analysis */
run;
```

In the GROUP statements, two groups are defined. Group 1, labeled as ‘Women’, refers to the data set `women_data`. Group 2, labeled as ‘Men’, refers to the data set `men_data`. Both groups are fitted by an exploratory factor model defined in Model 1, as indicated in the GROUP= option of the [MODEL](#) statement. While the frequency variable Z defined in the [FREQ](#) statement is applicable only to Group 1, the partial variable P defined in the [PARTIAL](#) statement is applicable only to Group 2. However, the [VAR](#) statement, which appears before the definitions of both groups, applies globally to both Group 1 and Group 2. Therefore, variables X1–X4 are the analysis variables in the two groups.

You can set group-specific *options* in each GROUP statement. All but one (that is, the LABEL= option) of these *options* are also available in the [MODEL](#) and [PROC CALIS](#) statements. If you set these group-specific *options* in the PROC CALIS statement, they will apply to all groups unless you respecify them in the GROUP statement. If you set these group-specific *options* in the [MODEL](#) statement, they will apply to all groups that are fitted by the associated model. In general, the group-specific options are transferred from the PROC CALIS statement to the [MODEL](#) statements (if present) and then to the fitted groups. In the transferring process, options are overwritten by the newer ones. If you want to apply some group-specific options to a particular group only, you should set those options in the GROUP statement corresponding to that group.

Option Available in the GROUP Statement Only

LABEL | NAME=name

specifies a label for the current group. You can use any valid SAS names up to 256 characters for labels. You can also use quote strings for the labels. This option can be specified only in the GROUP statement, not the PROC CALIS statement.

Options Available in the GROUP and PROC CALIS Statements

These options are available in the GROUP and PROC CALIS statements:

Option	Description
DATA= on page 1096	Specifies the input data set
INWGT= on page 1099	Specifies the data set that contains the weight matrix
OUTSTAT= on page 1110	Specifies the data set for storing the statistical results
OUTWGT= on page 1110	Specifies the data set for storing the weight matrix
ROBITER= on page 1115	Specifies the maximum number of iterations for estimating robust covariance and mean matrices
ROBPHI= on page 1115	Specifies the tuning parameter for robust methods

See the section “PROC CALIS Statement Options” on page 1087 for more details about these options. If you specify these options in the PROC CALIS statement, they are transferred to *all* GROUP statements. They might be overwritten by the respecifications in the individual GROUP statements.

Options Available in GROUP, MODEL, and PROC CALIS Statements

These options are available in the GROUP, MODEL, and PROC CALIS statements:

Option	Description
ALPHALEV= on page 1087	Specifies the α -level criterion for detecting leverage points
ALPHAOUT= on page 1088	Specifies the α -level criterion for detecting outliers
BIASKUR on page 1091	Computes the skewness and kurtosis without bias corrections
EDF= on page 1097	Defines nob _s by the number of error <i>df</i>
INWGTINV on page 1099	Specifies that the INWGT= data set contains the inverse of the weight matrix
KURTOSIS on page 1099	Computes and displays kurtosis
MAXMISSPAT= on page 1101	Specifies the maximum number of missing patterns to display
NOBS= on page 1106	Defines the number of observations (nob _s)
NOMISSPAT on page 1107	Suppresses the display of missing pattern analysis
PCORR on page 1111	Displays analyzed and estimated moment matrix
PLOTS= on page 1112	Specifies ODS Graphics selection
PWEIGHT on page 1235	Displays the weight matrix
RDF DFR= on page 1114	Defines nob _s by the number of regression <i>df</i>
RESIDUAL RES on page 1114	Computes the default residuals
RESIDUAL RES= on page 1114	Specifies the type of residuals
RIDGE on page 1115	Specifies the ridge factor for covariance matrix
SIMPLE on page 1117	Prints univariate statistics
TMISSPAT= on page 1118	Specifies the data proportion threshold for displaying the missing patterns
VARDEF= on page 1119	Specifies variance divisor
WPENALTY= on page 1119	Specifies the penalty weight to fit correlations
WRIDGE= on page 1120	Specifies the ridge factor for the weight matrix

If you specify these options in the PROC CALIS statement, they are transferred to all MODEL statements. These options are overwritten by the respecifications in the individual MODEL statements. After these options are resolved in a given MODEL statement, they are transferred further to the GROUP statements

of which the associated groups are fitted by the model. Again, these options might be overwritten by the respecifications in the individual GROUP statements.

LINCON Statement

LINCON *constraint* <, *constraint* ... > ;

where *constraint* represents one of the following:

- *number operator linear-term*
- *linear-term operator number*

and *linear-term* is

< +|- > < *coefficient* * > *parameter* < +|- > < *coefficient* * > *parameter* ... >

The LINCON statement specifies a set of linear equality or inequality constraints of the following form:

$$\sum_{j=1}^n a_{ij} x_j \leq b_i, \quad i = 1, \dots, m$$

The constraints must be separated by commas. Each linear constraint i in the statement consists of a linear combination $\sum_j a_{ij} x_j$ of a subset of the n parameters x_j , $j = 1, \dots, n$, and a constant value b_i separated by a comparison operator. Valid operators are <=, <, >=, >, and = or, equivalently, LE, LT, GE, GT, and EQ. PROC CALIS cannot enforce the strict inequalities < or >. Note that the coefficients a_{ij} in the linear combination must be constant numbers and must be followed by an asterisk and the name of a parameter (that is, listed in the PARMS, [main](#), or [subsidiary](#) model specification statements). The following is an example of the LINCON statement that sets a linear constraint on parameters x1 and x2:

```
lincon      x1 + 3 * x2 <= 1;
```

Although you can express boundary constraints of individual parameters in LINCON statements, it is much more convenient to specify these boundary constraints with the [BOUNDS](#) statement. For example, the following LINCON statement essentially specifies boundary constraints on four parameters:

```
lincon      x1 <= 1,
            x2 <= 1,
            v1 > 0,
            v2 > 0;
```

Instead of using the LINCON statement, you can specify the following BOUNDS statement:

```
bounds      x1 x2 <= 1,
            v1 v2 > 0;
```

Another advantage of using the BOUNDS statement for setting bounds for individual parameters is that when a boundary constraint becomes active in the solution (that is, when the final estimate is on the boundary), a Lagrange multiplier test on releasing the boundary constraint would be conducted when you also specify the [MOD](#) option. However, no Lagrange multiplier test would be conducted if you specified the boundary constraint with the LINCON statement.

LINEQS Statement

LINEQS < *equation* < , *equation* ... > > ;

where *equation* represents:

dependent = *term* < + *term* ... >

and each *term* represents one of the following:

- *coefficient-name* < (*number*) > < * > *variable-name*
- *prefix-name* < (*number*) > < * > *variable-name*
- < *number* > < * > *variable-name*

The LINEQS statement is a [main model specification statement](#) that invokes the LINEQS modeling language. You can specify at most one LINEQS statement in a model, within the scope of either the PROC CALIS statement or a [MODEL](#) statement. To completely specify a LINEQS model, you might need to add some [subsidiary model specification statements](#) such as the VARIANCE, COV, and MEAN statements. The syntax for the LINEQS modeling language is as follows:

```
LINEQS < equation < , equation ... > > ;
VARIANCE partial-variance-parameters ;
COV covariance-parameters ;
MEAN mean-parameters ;
```

In the LINEQS statement, you use equations to specify the linear functional relations among manifest and latent variables. Equations in the LINEQS statement are separated by commas.

In the [VARIANCE](#) statement, you specify the variance parameters. In the [COV](#) statement, you specify the covariance parameters. In the [MEAN](#) statement, you specify the mean parameters. For details of these subsidiary model specification statements, see the syntax of these statements.

In the LINEQS statement, in addition to the functional relations among variables, you specify the coefficient parameters of interest in the equations. There are five types of parameters you can specify in equations, as shown in the following example:

```
linesqs
  V1 =          * F1 + E1,
  V2 = (.5)     * F1 + E2,
  V3 = 1.       * F1 + E3,
  V4 = b4       * F1 + E4;
  V5 = b5 (.4) * F1 + E5;
```

In this example, you have manifest variables V1–V5, which are related to a latent factor, denoted by F1, as specified in the equations. In each equation, you have one outcome variable (V-variable), one predictor variable (F1, which is assumed to be a latent factor, the so-called F-variable), and one error variable (E-variable). The following four types of parameters have been specified:

- an unnamed free parameter

The effect of F1 on V1 in the first equation is an unnamed free parameter. Although you specify nothing before the asterisk sign, the effect parameter is effectively specified. For an unnamed free

parameter, PROC CALIS generates a parameter name with the `_Parm` prefix and appended with a unique integer (for example, `_Parm1`, `_Parm2`, and so on).

- an initial value

The effect of F1 on V2 in the second equation is an unnamed free parameter with an initial estimate of 0.5. PROC CALIS also generates a parameter name for this specification. Notice that you must use a pair of parentheses for the initial value specification because it is interpreted as a fixed value otherwise, as described in the next case.

- a fixed value

The effect of F1 on V3 in the third equation is an unnamed free parameter with a fixed value of 0.5. A fixed value remains the same in the estimation. There is no parameter name for a fixed constant in the model.

- a free parameter with a name

The effect of F1 on V4 in the fourth equation is a free parameter named `b4`. You do not provide an initial estimate for this free parameter.

- a free parameter with a name and an initial estimate

The effect of F1 on V5 in the fifth equation is a free parameter named `b5` with an initial estimate of 0.4. Parameters with no starting values are initialized by various heuristic and effective methods in PROC CALIS. See the section “[Initial Estimates](#)” on page 1351 for details.

Notice that there must be an error term in each equation. The error terms in equation must start with the prefix ‘E’, ‘e’, ‘D’, or ‘d’. See the section “[Representing Latent Variables in the LINEQS Model](#)” on page 1158 for details about naming the factors and error terms. The effect or the path coefficient attached to an error term must be 1.0. This is implicitly specified as in the preceding example. For example, there is no parameter specification nor an asterisk sign before the error term `E1` in the first equation, as shown in the following:

```
V1 =          * F1 + E1,
```

This specification is the same as the following explicit specification with a fixed constant 1.0 for the effect of the error term `E1`:

```
V1 =          * F1 + 1. * E1,
```

The equivalence shown here implies that you can also specify the third equation in the following equivalent way:

```
V3 =  F1 + E3,
```

This implicitly specifies a constant 1.0 for the effect of F1 on V3. You must be very careful about the distinction between this specification and the following one with an asterisk before F1:

```
V3 =  * F1 + E3,
```

With an asterisk sign, the effect of F1 on V3 becomes an unnamed free parameter in the current specification. This interpretation is very different from the preceding one without an asterisk sign before F1, which assumes a fixed constant of 1.0.

Except for the unnamed free parameter specification, you can omit the asterisk signs in all other types of parameter specifications. That is, you can use the following equivalent statement for the preceding LINEQS specification:

```
lineqs
  V1 =          * F1 + E1,
  V2 = (.5)      F1 + E2,
  V3 = 1.        F1 + E3,
  V4 = b4        F1 + E4;
  V5 = b5 (.4)   F1 + E5;
```

Again, you cannot omit the asterisk in the first equation because it is intended to denote an unnamed free parameter.

If your model contains many unconstrained parameters and it is too cumbersome to find different parameter names, you can specify all those parameters by the same prefix-name. A prefix name is a short name called “root” followed by two underscores __. Whenever a prefix-name is encountered, the CALIS procedure generates a parameter name by appending a unique integer to the root. Hence, the prefix-name should have few characters so that the generated parameter name is not longer than thirty-two characters. To avoid unintentional equality constraints, the prefix names should not coincide with explicitly defined parameter names. The following statement illustrates the uses prefix-names:

```
lineqs
  V1 = 1.      * F1 + E1,
  V2 = b__    * F1 + E2,
  V3 = b__    * F1 + E3,
  V4 = b__    * F1 + E4;
  V5 = b__    * F1 + E5;
```

In the five equations, only the first equation has a fixed constant 1.0 for the effect of F1 on V1. For all the remaining equations, the effects of F1 on the variables are all free parameters with the prefix b. The generated parameter names for these effects have unique integers appended to this prefix. For example, b1, b2, b3, and b4 are the parameter names for these effects.

Representing Latent Variables in the LINEQS Model

Because latent variables are widely used in structural equation modeling, PROC CALIS needs a way to identify different types of latent variables that are specified in the LINEQS model. This is accomplished by following some naming conventions for the latent variables. See the section “[Naming Variables in the LINEQS Model](#)” on page 1272 for details about these naming rules. Essentially, latent factors (systematic sources) must start with the letter ‘F’ or ‘f’. Error terms must start with the letter ‘E’, ‘e’, ‘D’, or ‘d’. Prefix ‘E’ or ‘e’ represents the error term of an endogenous *manifest* variable. Prefix ‘D’ or ‘d’ represents the disturbance (or error) term of an endogenous *latent* variable. Although D- and E- variables are conceptually different, for modeling purposes ‘D’ and ‘E’ prefixes are interchangeable in the LINEQS modeling language. Essentially, only the distinction between latent factors (systematic sources) and errors or disturbances (unsystematic sources) is critical in specifying a proper LINEQS model. Manifest variables in the LINEQS model do not need to follow additional naming rules beyond those required by the general SAS System—they are recognized by PROC CALIS by referring to the variables in the input data sets.

Types of Variables and Semantic Rules of Equations

Depending on their roles in the system of equations, variables in a LINEQS model can be classified into endogenous or exogenous. An endogenous variable is a variable that serves as an outcome variable (left-hand side of an equation) in one of the equations. All other variables are exogenous variables, including those manifest variables that do not appear in any equations but are included in the model because they are specified in the **VAR** statement for the analysis.

Merely following the syntactic rules described so far is not sufficient to define a proper system of equations that PROC CALIS can analyze. You also need to observe the following semantic rules:

- Only manifest or latent variables can be endogenous. This means that you cannot specify any error or disturbances variables on the left-hand side of the equations. This also means that error and disturbance variables are always exogenous in the LINEQS model.
- An endogenous variable that appears on the left-hand side of an equation cannot appear on the left-hand side of another equation. In other words, you have to specify all the predictors for an endogenous variable in a single equation.
- An endogenous variable that appears on the left-hand side of an equation cannot appear on the right-hand side of the same equation. This prevents a variable to have a direct effect on itself (but indirect effect on itself is possible).
- Each equation must contain one and only one *unique* error term, be it an E-variable for a manifest outcome variable or a D-variable for a latent outcome variable. If, indeed, you want to specify an equation without an error term, you can equivalently set the variance of the error term to a fixed zero in the **VARIANCE** statement.

Mean Structures in Equations

To fit a LINEQS model with mean structures, you can specify the **MEANSTR** option in the PROC CALIS or the associated **MODEL** statement. This generates the default mean and intercept parameters for the model (see the section “**Default Parameters**” on page 1160). Alternatively, you can specify the intercept parameters with the Intercept variable in the equations or the mean parameters in the **MEAN** statement. The Intercept variable in the LINEQS model is a special “variable” that contains the value 1 for each observation. You do not need to have this variable in your input data set, nor do you need to generate it in the DATA step. It serves as a notational convenience in the LINEQS modeling language. The actual intercept parameter is expressed as a coefficient parameter with the intercept variable. For example, consider the following LINEQS model specification:

```
lineqs
  V1 = a1 (10) * Intercept + 1.0      * F1 + E1,
  V2 =          * Intercept +          * F1 + E2,
  V3 =          + b2                  * F1 + E3,
  V4 = a2        * Intercept + b2      * F1 + E4,
  V5 = a2        * Intercept + b4 (.4) * F1 + E5;
```

In the first equation, a1, with a starting value at 10, is the intercept parameter of V1. In the second equation, the intercept parameter of V2 is an unnamed free parameter. In the third equation, although you do not specify the Intercept variable, the intercept parameter of manifest variable V3 is assumed to be a free parameter

by default. See the section “[Default Parameters](#)” on page 1160 for more details about default parameters. In the fourth and the fifth equations, the intercept parameters are both named `a2`. This means that these intercepts are constrained to be the same in the estimation.

In some cases, you might need to set the intercepts to fixed constants such as zeros. You can use the following syntax:

```
lineqs
  V1 = 0 * Intercept + F_intercept + a2 * F_slope + E1;
```

This sets the intercept parameter of `V1` to a fixed zero. An example of this application is the analysis of latent growth curve model in which you define the intercept as a random variable represented by a latent factor (for example, `F_intercept` in the specification). See [Example 27.25](#) for a detailed example.

To complete the specification of the mean structures in the LINEQS model, you might want to use the `MEAN` statement to specify the mean parameters. For example, the following statements specify the means of `F_intercept` and `F_slope` as unnamed free parameters in the LINEQS model:

```
lineqs
  V1 = 0 * Intercept + F_intercept + 1 * F_slope + E1;
mean
  F_intercept F_slope;
```

See the [MEAN](#) statement for details.

Default Parameters

It is important to understand the default parameters in the LINEQS model. First, if you know which parameters are default free parameters, you can make your specification more efficient by omitting the specifications of those parameters that can be set by default. For example, because all variances and covariances among exogenous variables (excluding error terms) are free parameters by default, you do not need to specify them with the `COV` and `VARIANCE` statements if these variances and covariances are not constrained. Second, if you know which parameters are default fixed zero parameters, you can specify your model accurately. For example, because all error covariances in the LINEQS model are fixed zeros by default, you must use the `COV` statement to specify the covariances among the errors if you want to fit a model with correlated errors. See the section “[Default Parameters in the LINEQS Model](#)” on page 1276 for details about the default parameters of the LINEQS model.

Modifying a LINEQS Model from a Reference Model

This section assumes that you use a `REFMODEL` statement within the scope of a `MODEL` statement and that the reference model (or base model) is a LINEQS model. The reference model is called the old model, and the model being defined is called the new model. If the new model is not intended to be an exact copy of the old model, you can use the extended LINEQS modeling language described in this section to make modifications within the scope of the `MODEL` statement for the new model.

The syntax of the extended LINEQS modeling language is the same as that of the ordinary LINEQS modeling language (see the section “[LINEQS Statement](#)” on page 1156):

```
LINEQS < equation <, equation ... > >;
  VARIANCE partial-variance-parameters;
  COV covariance-parameters;
  MEAN mean-parameters;
```

The new model is formed by integrating with the old model in the following ways:

- Duplication:** If you do not specify in the new model an equation with an outcome variable (that is, a variable on the left side of the equal sign) that exists in the old model, the equation with that outcome variable in the old model is duplicated in the new model. For specifications other than the LINEQS statement, if you do not specify in the new model a parameter location that exists in the old model, the old parameter specification is duplicated in the new model.
- Addition:** If you specify in the new model an equation with an outcome variable that does not exist as an outcome variable in the equations of the old model, the equation is added in the new model. For specifications other than the LINEQS statement, if you specify in the new model a parameter location that does not exist in the old model, the new parameter specification is added in the new model.
- Deletion:** If you specify in the new model an equation with an outcome variable that also exists as an outcome variable in an equation of the old model and you specify the missing value '.' as the only term on the right-hand side of the equation in the new model, the equation with the same outcome variable in the old model is not copied into the new model. For specifications other than the LINEQS statement, if you specify in the new model a parameter location that also exists in the old model and the new parameter is denoted by the missing value '.', the old parameter specification is not copied into the new model.
- Replacement:** If you specify in the new model an equation with an outcome variable that also exists as an outcome variable in an equation of the model and the right-hand side of the equation in the new model is not denoted by the missing value '.', the new equation replaces the old equation with the same outcome variable in the new model. For specifications other than the LINEQS statement, if you specify in the new model a parameter location that also exists in the old model and the new parameter is not denoted by the missing value '.', the new parameter specification replaces the old one in the new model.

For example, the following two-group analysis specifies Model 2 by referring to Model 1 in the **REFMODEL** statement:

```
proc calis;
  group 1 / data=d1;
  group 2 / data=d2;
  model 1 / group=1;
    lineqs
      V1   =      1 * F1   + E1,
      V2   = load1 * F1   + E2,
      V3   = load2 * F1   + E3,
      F1   =      b1 * V4   + b2 * V5 + b3 * V6 + D1;
    variance
      E1-E3 = ve1-ve3,
      D1    = vd1,
      V4-V6 = phi4-phi6;
    cov
      E1 E2 = cve12;
  model 2 / group=2;
  refmodel 1;
```

```

lineqs
  V3   = load1 * F1 + E3;
cov
  E1 E2 = .,
  E2 E3 = cve23;
run;

```

Model 2 is the new model which refers to the old model, Model 1. This example illustrates the four types of model integration:

- Duplication: All equations, except the one with outcome variable V3, in the old model are duplicated in the new model. All specifications in the VARIANCE and COV statements, except the covariance between E1 and E2, in the old model are also duplicated in the new model.
- Addition: The parameter cve23 for the covariance between E2 and E3 is added in the new model.
- Deletion: The specification of covariance between E1 and E2 in the old model is not copied into the new model, as indicated by the missing value '.' specified in the new model.
- Replacement: The equation with V3 as the outcome variable in the old model is replaced with a new equation in the model. The new equation uses parameter load1 so that it is now constrained to be the same as the regression coefficient in the equation with V2 as the outcome variable.

LISMOD Statement

LISMOD < *var-lists* > ;

where *var-lists* represent one or more of the following:

- **YVAR** | **YV** | **Y** = *var-list*
- **XVAR** | **XV** | **X** = *var-list*
- **ETAVAR** | **ETAV** | **ETA** = *var-list*
- **XIVAR** | **XIV** | **XI** | **KSIVAR** | **KSIV** | **KSI** = *var-list*

LISMOD stands for LISREL modeling, where LISREL is the program developed by Jöreskog and Sörbom (1988). Like the original implementation of LISREL, LISMOD uses a matrix specification interface. To complete the LISMOD specification, you might need to add as many **MATRIX** statements as needed, as shown in the following statement structure for the LISMOD model:

```

LISMOD var-lists ;
MATRIX matrix-name parameters-in-matrix ;
Repeat the MATRIX statement as needed ;

```

The *matrix-name* in the **MATRIX** statement should be one of the twelve model matrices in LISMOD, as listed in the following:

- Matrices in the structural model: `_ALPHA_`, `_KAPPA_`, `_BETA_`, `_GAMMA_`, `_PHI_`, or `_PSI_`
- Matrices in the measurement model for y-variables: `_NUY_`, `_LAMBDAY_`, or `_THETAY_`
- Matrices in the measurement model for x-variables: `_NUX_`, `_LAMBDA_`, or `_THETA_`

See the section “[Model Matrices in the LISMOD Model](#)” on page 1279 for definitions of these matrices and their roles in the LISMOD modeling language. See the [MATRIX statement](#) on page 1175 for the details of parameter specification.

In the LISMOD statement, you can specify the following four lists of variables:

- `YVAR=` list is for manifest variables y that are directly related to the endogenous latent variables η (eta). Variables in the list are called y-variables.
- `XVAR=` list is for manifest variables x that are directly related to the exogenous latent variables ξ (xi or ksi). Variables in the list are called x-variables.
- `ETAVAR=` list is for endogenous latent variables η . Variables in the list are called η -variables.
- `XIVAR=` list is for exogenous latent variables ξ . Variables in the list are called ξ -variables.

The order of variables in the lists of the LISMOD statement is used to define the variable order in rows and columns of the LISMOD model matrices.

Depending on the model of interest, you might not need to specify all the lists of variables. When some variable lists are not specified, the full model reduces to specialized submodels. However, to be a proper submodel in the LISMOD modeling language, it is necessary (but not sufficient) that at least one of the `YVAR=` or `XVAR=` lists is defined. See the section “[LISMOD Submodels](#)” on page 1282 for the details about LISMOD submodels that PROC CALIS can handle.

An example of a LISMOD model specification is shown as follows:

```
proc calis;
  lismod xvar=x1-x3 yvar=y1-y6 xivar=xi etavar=eta1-eta2;
  matrix _LAMBDAY_   [,1] = 1. load3 load4,
                    [,2] = 0. 0. 0. 1. load5 load6;
  matrix _THETAY_    [1,1] = ey1-ey3,
                    [2,1] = cey;
  matrix _LAMBDA_     [,] = 1. load1 load2;
  matrix _THETA_      [1,1] = 3*ex;
  matrix _GAMMA_      [,1] = beta1 beta2;
  matrix _PHI_        [1,1] = phi;
  matrix _PSI_        [1,1] = psi1-psi2;
run;
```

In this example, you have three x-variables x_1 – x_3 , six y-variables y_1 – y_6 , one ξ -variable ξ , and two η -variables η_1 – η_2 . The numbers of variables in these lists define the dimensions of the LISMOD model matrices. For example, matrix `_LAMBDAY_` is 6×2 , with y_1 – y_6 as the row variables and η_1 – η_2 as the column variables. Matrix `_THETA_` is 3×3 , with x_1 – x_3 as the row and column variables. In the MATRIX statements, you specify parameters in the elements of the matrices. After the matrix name, you specify in square brackets ‘[’ and ‘]’ the starting row and column numbers of the first element to be parameterized. After the equal sign, you specify fixed or free parameters for the matrix elements.

Depending on how you specify the starting row and column numbers, the parameter specification might proceed differently. See the **MATRIX statement** on page 1175 for a detailed description. In this example, the first specification of the parameters in the `_LAMBDAY_` matrix starts from [1,1]—meaning that it starts from the first column and proceeds downwards. As a result, the [1,1] element is a fixed constant 1.0, the [2,1] element is a free parameter called `load3`, and the [3,1] element is a free parameter called `load4`. Similarly, in the second specification in the `_LAMBDAY_` matrix, the [1,2], [2,2], [3,2], and [4,2] elements take constant values 0, 0, 0, and 1, respectively, and the [5,2] and [6,2] elements are free parameters `load5` and `load6`, respectively.

You can also use similar notation to specify the parameters of a row. For example, with the notation [2,] for the starting row and column numbers, specification proceeds to the left with the same second row in the matrix.

If you have specified both starting row and column numbers, such as those in the first specification in matrix `_THETAY_`, the parameter specification starts from [1,1] and proceeds to the next row and column numbers—that is [2,2], [3,3], and so on. This results in specifying the diagonal elements of matrix `_THETAY_` as free parameters `ey1`, `ey2`, and `ey3`.

With the notation [,], no starting row and column numbers are specified. Specification starts from the first valid element in the matrix and proceeds row-wise for all valid elements in the matrix. For example, in the matrix `_LAMBDAX_` statement, the [1,1] element of matrix `_LAMBDAX_` is a fixed constant 1, and the [1,2] and [1,3] elements are free parameters `load1` and `load2`, respectively.

Default Parameters

It is important to understand the default parameters in the LISMOD model. First, if you know which parameters are default free parameters, you can make your specification more efficient by omitting some specifications. For example, because all variances and covariances among the exogenous ξ -variables (excluding error terms) are free parameters by default, you do not need to specify them with **MATRIX** statement if these variances and covariances are not constrained. Second, if you know which parameters are default fixed zero parameters, you can specify your model accurately. For example, because all measurement errors in the LISMOD model are fixed zeros by default, you must use the **MATRIX** statement to specify the covariances among the errors in the Θ_x (`_THETAX_`) or Θ_y (`_THETAY_`) matrices if you want to fit a model with some correlated measurement errors. See the section “**Default Parameters in the LISMOD Model**” on page 1285 for details about the default parameters of the LISMOD model.

Modifying a LISMOD Model from a Reference Model

This section assumes that you use a **REFMODEL** statement within the scope of a **MODEL** statement and that the reference model (or base model) is also a LISMOD model. The reference model is called the old model, and the model that refers to this old model is called the new model. If the new model is not intended to be an exact copy of the old model, you can use the extended LISMOD modeling language described in this section to make modifications within the scope of the **MODEL** statement for the new model. The syntax is similar to, but not exactly the same as, the ordinary LISMOD modeling language (see the section “**LISMOD Statement**” on page 1162). The respecification syntax for a LISMOD model is shown as follows:

```
LISMOD ;
MATRIX matrix-name parameters-in-matrix ;
Repeat the MATRIX statement as needed ;
```

First, in the respecification you should not put any variable lists in the LISMOD statement. The reason is that the parameter respecifications in the new model refer to the variable lists of the old model. Therefore, the variable lists in the new model are implicitly assumed to be exactly the same as those in the old model. Because of this, the LISMOD statement is entirely optional for the respecification in the new model.

Second, you can use **MATRIX** *matrix-name* statements to modify the old model by using the same syntax as in the LISMOD modeling language. The *matrix-name* can be one of the twelve possible LISMOD matrices. In addition, in the respecification syntax you can use the missing value '.' to drop a parameter specification from the old model.

The new model is formed by integrating with the old model in the following ways:

- Duplication: If you do not specify in the new model a parameter location that exists in the old model, the old parameter specification is duplicated in the new model.
- Addition: If you specify in the new model a parameter location that does not exist in the old model, the new parameter specification is used in the new model.
- Deletion: If you specify in the new model a parameter location that also exists in the old model and the new parameter is denoted by the missing value '.', the old parameter specification is not copied into the new model.
- Replacement: If you specify in the new model a parameter location that also exists in the old model and the new parameter is not denoted by the missing value '.', the new parameter specification replaces the old one in the new model.

For example, the following two-group analysis specifies Model 2 by referring to Model 1 in the **REFMODEL** statement:

```
proc calis;
  group 1 / data=d1;
  group 2 / data=d2;
  model 1 / group=1;
    lismod xvar=X1-X3 yvar=Y1-Y6 xivar=xi etavar=eta1-eta2;
    matrix _LAMBDAY_  [,1] = 1. load3 load4,
                      [,2] = 0. 0. 0. 1. load5 load6;
    matrix _THETAY_   [1,1] = ey1-ey3,
                      [2,1] = cey;
    matrix _LAMBDAX_   [, ] = 1. load1 load2;
    matrix _THETAX_    [1,1] = 3*ex;
    matrix _GAMMA_     [,1] = beta1 beta2;
    matrix _PHI_        [1,1] = phi;
    matrix _PSI_        [1,1] = psi1-psi2;
  model 2 / group=2;
    refmodel 1;
    matrix _THETAY_    [2,1] = .;
    matrix _THETAX_    [1,1] = ex1-ex3;
    matrix _BETA_       [2,1] = beta;
run;
```

In this example, Model 2 is the new model which refers to the old model, Model 1. It illustrates the four types of model integration:

- **Duplication:** All parameter locations and specifications in the old model are duplicated in the new model, except for the [2,1] element in matrix `_THETAY_` and the diagonal of matrix `_THETAX_`, which are modified in the new model.
- **Addition:** The `_BETA_[2,1]` parameter location is added with a new parameter `beta` in the new model. This indicates that *eta1* is a predictor variable of *eta2* in the new model, but not in the old model.
- **Deletion:** Because the missing value ‘.’ is used for the parameter value, the `_THETAY_[2,1]` parameter location is no longer defined as a free parameter in the new model. In the old model, the same location is defined by the free parameter `cey`.
- **Replacement:** The diagonal elements of the `_THETAX_` matrix in the new model are now defined by three distinct parameters `ex1–ex3`. This replaces the old specification where a single constrained parameter `ex` is applied to all the diagonal elements in the `_THETAX_` matrix.

LMTESTS Statement

LMTESTS | **LMTEST** *option* < *option* ... > ;

where *option* represents one of the following:

- *display-option*
- *test-set*

and *test-set* represents one of the following:

- *set-name* = [*regions*]
- *set-name* = { *regions* }

where *set-name* is the name of the set of Lagrange multiplier (LM) tests defined by the *regions* that follow after the equal sign and *regions* are keywords denoting specific sets of parameters in the model.

You can use the LMTESTS statement to set *display-options* or to customize the *test-sets* for the LM tests. The LMTESTS statement is one of the [model analysis statements](#). It can be used within the scope of the CALIS statement so that the options will apply to all models. It can also be used within the scope of each **MODEL** statement so that the options will apply only locally. Therefore, different models within a CALIS run can have very different LMTESTS *options*.

The LM Tests Display Options

The following are the *display-options* for the LM tests:

DEFAULT

conducts the default sets of LM tests for freeing fixed parameters in the model. This option is used when you need to reset the default sets of LM tests in the local model. For example, you might have turned off the default LM tests by using the NODEFAULT option in the LMTESTS statement within the scope of PROC CALIS statement. However, for the model under the scope of a particular **MODEL** statement, you can use this DEFAULT option in the local LMTESTS statement to turn on the default LM tests again.

MAXRANK

sets the maximum number of rankings within a set of LM tests. The actual number of test rankings might be smaller because the number of possible LM tests within a set might be smaller than the maximum number requested.

NODEFAULT

turns off the default sets of LM tests for freeing fixed parameters in the model. As a result, only the customized LM tests defined in the *test-sets* of the LMTESTS statement are conducted and displayed. Note that the LM tests for equality and active boundary constraints are not turned off by this option. If you specify this option in the LMTESTS statement within the scope of the PROC CALIS statement, it will propagate to all models.

NORANK

turns off the ranking of the LM tests. Ranking of the LM tests is done automatically when the model modification indices are requested. The NORANK option is ignored if you also set the MAXRANK option.

LMMAT

prints the sets of LM tests in matrix form, in addition to the normal LM test results.

The Customized Sets of LM Tests: Syntax of the Test-sets

In addition to the *display-options*, you can define customized sets of LM tests as *test-sets* in the LMTESTS statement. You can define as many *test-sets* as you like. Ranking of the LM tests will be done individually for each *test-set*. For example, the following LMTESTS statement requests that the default sets of LM tests not be conducted by the NODEFAULT option. Instead, two customized *test-sets* are defined.

```
lmtests nodefault MyFirstSet=[ALL] MySecondSet=[COVEXOG COVERR];
```

The first customized set MyFirstSet pulls all possible parameter locations together for the LM test ranking (ALL keyword). The second customized set MySecondSet pulls only the covariances among exogenous variables (COVEXOG keyword) and among errors (COVERR keyword) together for the LM test ranking.

Two different kinds of *regions* for LM tests are supported in PROC CALIS: matrix-based or non-matrix-based.

The matrix-based *regions* can be used if you are familiar with the matrix representations of various types of models. Note that defining *test-sets* by using matrix-based *regions* does not mean that LM tests are printed in matrix format. It means only that the parameter locations within the specified matrices are included into the specific *test-sets* for LM test ranking. For matrix output of LM tests, use the LMMAT option in the LMTESTS statement.

Non-matrix-based *regions* do not assume the knowledge of the model matrices. They are easier to use in most situations. In addition, non-matrix-based *regions* can cover special subsets of parameter locations that cannot be defined by model matrices and submatrices. For example, because of the compartmentalization according to independent and dependent variables in the LINEQS model matrices, the sets of LM tests defined by the LINEQS matrix-based *regions* are limited. For example, you cannot use any matrix-based *regions* to request LM tests for new paths to existing independent variables in the LINEQS model. Such a matrix does not exist in the original specification. However, you can use the non-matrix based *region* NEWENDO to refer to these new paths.

The *regions* for parameter locations are specified by keywords in the LMTESTS statement. Because the *regions* are specific to the types of models, they are described separately for each model type in the following.

The LM Test Regions for COSAN Models

ALLMAT

specifies all parameter locations in all matrices.

CENTRAL

specifies all parameter locations in the central covariance matrices in all terms.

MATRIX | MAT | MATSET = [set-of-matrices] | {set-of-matrices}

specifies the parameter locations in the matrices specified in *set-of-matrices*.

MEANVEC

specifies all parameter locations in the central mean vectors in all terms.

OUTER

specifies all parameter locations in all matrices except for the central covariance matrices and central mean vectors in all terms.

The LM Test Regions for FACTOR Models

The keywords for the matrix-based regions are associated with the FACTOR model matrices. See the section “[Summary of Matrices in the FACTOR Model](#)” on page 1268 for the definitions and properties of these matrices.

Keywords for Matrix-Based Regions

FACTERRV | FACTERRV

specifies the error variances.

FACTFCOV | FACTFCOV

specifies the covariances among factors.

FACTINTE | FACTINTE

specifies the intercepts.

FACTLOAD | FACTLOAD

specifies the factor loadings.

FACTMEAN | FACTMEAN

specifies the factor means.

Keywords for Non-Matrix-Based Regions

ALL

specifies all parameter locations.

COV

specifies the covariances among factors.

COVERR

specifies the covariances among errors.

COVFACT | COVLV

specifies the covariances among factors.

FIRSTMOMENTS

specifies the means of factors and the intercepts.

INTERCEPTS

specifies the intercepts.

LOADINGS

specifies the factor loadings.

MEANS | MEAN

specifies the means of factors.

The LM Test Regions for LINEQS Models

Keywords for Matrix-Based Regions

The keywords for the matrix-based regions are associated with the LINEQS model matrices. See the section “[Matrix Representation of the LINEQS Model](#)” on page 1272 for definitions of these model matrices and see the section “[Summary of Matrices and Submatrices in the LINEQS Model](#)” on page 1274 for the names and properties and the model matrices and submatrices.

EQSALPHA | EQSALPHA

specifies the intercepts of dependent variables.

EQSBETA | EQSBETA

specifies effects of dependent variables on dependent variables.

EQSGAMMA | _EQSGAMMA_SUB_ | EQSGAMMA | EQSGAMMASUB

specifies the effects of independent variables (excluding errors) on dependent variables. Because effects of errors on dependent variables are restricted to ones in the LINEQS model, LM tests on **_EQSGAMMA_** and **_EQSGAMMA_SUB_** (submatrix of **_EQSGAMMA_**) are the same.

EQSNU | _EQSNU_SUB_ | EQSNU | EQSNUSUB

specifies the means of independent variables (excluding errors). Because means of errors are restricted to zero in the LINEQS model, LM tests on **_EQSNU_** and **_EQSNU_SUB_** (submatrix of **_EQSNU_**) are the same.

EQSPHI | EQSPHI

specifies variances and covariances among all independent variables, including errors.

EQSPHI11 | EQSPHI11

specifies variances and covariances among independent variables, excluding errors.

EQSPHI21 | EQSPHI21

specifies covariances between errors and disturbances with other independent variables.

EQSPHI22 | EQSPHI22

specifies variances and covariances among errors and disturbances.

Keywords for Non-Matrix-Based Regions**ALL**

specifies all possible parameter locations.

COV

specifies all covariances among independent variables, including errors and disturbances.

COVERR

specifies covariances among errors or disturbances.

COVEXOG

specifies covariances among independent variables, excluding errors and disturbances.

COVEXOGERR

specifies covariances of errors and disturbances with other independent variables.

COVLV | COVFACT

specifies covariances among latent variables (excluding errors and disturbances).

COVMV | COVOV

specifies covariance among independent manifest variables.

EQUATION | EQUATIONS

specifies all possible linear relationships among variables.

FIRSTMOMENTS

specifies means and intercepts.

INTERCEPTS | INTERCEPT

specifies intercepts of dependent variables.

LV==>LV | LV->LV

specifies all possible effects of latent factors on latent factors.

LV==>MV | LV->MV | MV<==LV | MV<-LV

specifies all possible effects of latent factors on manifest variables.

LV<==MV | LV<-MV | MV==>LV | MV->LV

specifies all possible effects of manifest variables on latent factors.

MEANS | MEAN

specifies the means of independent factors.

MV==>MV | MV->MV

specifies all possible effects of manifest variables on manifest variables.

NEWDEP | NEWENDO

specifies effects of other variables on the independent variables in the original model.

PATHS | PATH

specifies all possible linear relationships among variables.

The LM Test Regions for LISMOD Models

The keywords for the matrix-based regions are associated with the LISMOD model matrices. See the section “[Model Matrices in the LISMOD Model](#)” on page 1279 for the definitions and properties of these matrices.

Keywords for Matrix-Based Regions**_ALPHA_ | ALPHA**

specifies the _ALPHA_ matrix.

BETA | BETA

specifies the _BETA_ matrix.

GAMMA | GAMMA

specifies the _GAMMA_ matrix.

KAPPA | KAPPA

specifies the _KAPPA_ matrix.

LAMBDA | LAMBDA

specifies the _LAMBDA_X_ and _LAMBDA_Y_ matrices.

_LAMBDA_X_ | LAMBDA_X

specifies the _LAMBDA_X_ matrix.

_LAMBDA_Y_ | LAMBDA_Y

specifies the _LAMBDA_Y_ matrix.

NU | NU

specifies the _NU_X_ and _NU_Y_ matrices.

_NU_X_ | NU_X

specifies the _NU_X_ matrix.

_NU_Y_ | NU_Y

specifies the _NU_Y_ matrix.

PHI | PHI

specifies the _PHI_ matrix.

PSI | PSI

specifies the _PSI_ matrix.

THETA | THETA

specifies the _THETA_X_ and _THETA_Y_ matrices.

THETAX | THETAX

specifies the _THETAX_ matrix.

THETAY | THETAY

specifies the _THETAY_ matrix.

Keywords for Non-Matrix-Based Regions**ALL**

specifies all model matrices.

COV

specifies all covariance parameters in _THETAY_, _THETAX_, _PHI_, and _PSI_.

COVERR

specifies all covariances for errors or disturbances in _THETAY_, _THETAX_, and _PSI_.

COVFACT | COVLV

specifies all covariances among latent factors in _PHI_ when the ξ -variables exist, and in _PSI_ when the η -variables exist without the presence of the ξ -variables.

FIRSTMOMENTS

specifies all intercepts and means in _NUY_, _NUX_, _ALPHA_, and _KAPPA_.

INTERCEPTS | INTERCEPT

specifies all intercepts in _NUY_, _NUX_, and _ALPHA_.

LOADING | LOADINGS

specifies the coefficients in _LAMBDAY_ and _LAMBDAX_.

LV==>LV | LV->LV

specifies the effects of latent variables on latent variables. Depending on the type of LISMOD model, the _BETA_ and _GAMMA_ might be involved.

LV==>MV | LV->MV | MV<==LV | MV<-LV

specifies the effects of latent variables on manifest variables. Depending on the type of LISMOD model, the _LAMBDAY_, _LAMBDAX_, and _GAMMA_ matrices might be involved.

MEANS | MEAN

specifies the mean parameters. Depending on the type of LISMOD model, the _ALPHA_ and _KAPPA_ matrices might be involved.

MV==>MV | MV->MV

specifies effects of manifest variables on manifest variables. Depending on the type of LISMOD model, the _BETA_ and _GAMMA_ matrices might be involved.

PATHS | PATH

specifies all path coefficients. Depending on the type of LISMOD model, the _LAMBDAY_, _LAMBDAX_, _BETA_, and _GAMMA_ matrices might be involved.

The LM Test Regions for MSTRUCT Models

The keywords for the matrix-based regions are associated with the MSTRUCT model matrices. See the section “[Model Matrices in the MSTRUCT Model](#)” on page 1286 for the definitions and properties of these matrices.

Keywords for Matrix-Based Regions

MSTRUCTCOV | _COV_ | MSTRUCTCOV
specifies the _MSTRUCTCOV_ or _COV_ matrix.

MSTRUCTMEAN | _MEAN_ | MSTRUCTMEAN
specifies the _MSTRUCTMEAN_ or _MEAN_ vector.

Keywords for Non-Matrix-Based Regions

ALL
specifies the _MSTRUCTCOV_ (or _COV_) and _MSTRUCTMEAN_ (or _MEAN_) matrices.

COV
specifies the _MSTRUCTCOV_ or _COV_ matrix.

MEANS | MEAN
specifies the _MSTRUCTMEAN_ or _MEAN_ matrix.

The LM Test Regions for PATH and RAM Models

The keywords for the matrix-based regions are associated with the submatrices of the RAM model matrices. See the section “[Partitions of the RAM Model Matrices and Some Restrictions](#)” on page 1296 for the definitions of these submatrices and the section “[Summary of Matrices and Submatrices in the RAM Model](#)” on page 1298 for the summary of the names and properties of these submatrices.

Keywords for Matrix-Based Regions

RAMA | _A_ | RAMA
specifies the _RAMA_ matrix.

_RAMA_LEFT_ | _A_LEFT_ | RAMALEFT
specifies the left portion of the _RAMA_ matrix.

_RAMA_LL_ | _A_LL_ | RAMALL
specifies the lower left portion of the _RAMA_ matrix.

_RAMA_LR_ | _A_LR_ | RAMALR
specifies the lower right portion of the _RAMA_ matrix.

_RAMA_LOWER_ | _A_LOWER_ | RAMALOWER
specifies the lower portion of the _RAMA_ matrix. This is equivalent to the region specified by the NEWENDO keyword.

_RAMA_RIGHT_ | _A_RIGHT_ | RAMARIGHT
specifies the right portion of the _RAMA_ matrix.

_RAMA_UPPER_ | _A_UPPER_ | RAMAUPPER
specifies the upper portion of the _RAMA_ matrix.

RAMALPHA | RAMALPHA
specifies the _RAMALPHA_ matrix.

RAMBETA | RAMBETA
specifies the _RAMBETA_ matrix.

RAMGAMMA | RAMGAMMA
specifies the _RAMGAMMA_ matrix.

RAMNU | RAMNU
specifies the _RAMNU_ matrix.

RAMP | _P_ | RAMP
specifies the _RAMP_ matrix.

RAMP11 | RAMP11
specifies the _RAMP11_ matrix.

RAMP21 | RAMP21
specifies the _RAMP21_ matrix.

RAMP22 | RAMP22
specifies the _RAMP22_ matrix.

RAMW | _W_ | RAMW
specifies the _RAMW_ vector.

Keywords for Non-Matrix-Based Regions

ALL
specifies all possible parameter locations.

ARROWS | ARROW
specifies all possible paths (that is, the entries in the _RAMA_ matrix).

COV
specifies all covariances and partial covariances (that is, the entries in the _RAMP_ matrix).

COVERR
specifies partial covariances among endogenous variables (that is, the entries in the _RAMP11_ matrix).

COVEXOG
specifies covariances among exogenous variables (that is, the entries in the _RAMP22_ matrix).

COVEXOGERR
specifies partial covariances of endogenous variables with exogenous variables (that is, the entries in the _RAM21_ matrix).

COVLV | COVFACT

specifies covariance among latent factors (that is, entries in `_RAMP11_` pertaining to latent variables).

COVMV | COVOV

specifies covariance among manifest variables (that is, entries in `_RAMP11_` pertaining to manifest variables).

FIRSTMOMENTS

specifies means or intercepts (that is, entries in `_RAMW_` vector).

INTERCEPTS | INTERCEPT

specifies intercepts for endogenous variables (that is, entries in `_RAMALPHA_` vector).

LV==>LV | LV->LV

specifies effects of latent variables on latent variables.

LV==>MV | LV->MV | MV<==LV | MV<-LV

specifies effects of latent variables on manifest variables.

LV<==MV | LV<-MV | MV==>LV | MV->LV

specifies effects of manifest variables on latent variables.

MEANS | MEAN

specifies the means of exogenous variables (that is, entries in the `_RAMNU_` vector).

MV==>MV | MV->MV

specifies effects of manifest variables on manifest variables.

NEWENDO

specifies new paths to the exogenous variables in the original model.

PATHS | PATH

specifies all possible paths (that is, the entries in the `_RAMA_` matrix).

MATRIX Statement

MATRIX *matrix-name* < *location* <= *parameter-spec* > < , *location* <= *parameter-spec* ... > > > ;

MATRIX statement specifies the matrix elements (locations) and their parameters. Parameters can be fixed or free, with or without initial estimates. The *matrix-name* indicates the matrix to specify in the MATRIX statement. The *location* indicates the starting row and column numbers of the matrix being specified and the *parameter-spec* is a list of free or fixed parameters for the elements that are indicated by the *location*.

The MATRIX statement is a [subsidiary model specification statement](#) of the COSAN, LISMOD, and MSTRUCT modeling languages. You might need to use the MATRIX statements as many times as needed for specifying your model. However, you can use the MATRIX statement at most once for each distinct model matrix.

Valid Matrix Names for the COSAN Model

The valid *matrix-names* depend on the your specification in the COSAN statement in which you define the COSAN model matrices and their properties. Except for those fixed matrices with the IDE or ZID type, you can use the MATRIX statement to specify any COSAN model matrices you define in the COSAN statement.

Valid Matrix Names for the LISMOD Model

There are 12 model matrices in the LISMOD model, and they correspond to the following valid *matrix-names* :

- matrices and their types in the measurement model for the y -variables

LAMBDAY the matrix of regression coefficients of the y -variables on the η -variables (general, GEN)

NUY the vector of intercept terms of the y -variables (general, GEN)

THETAY the error covariance matrix for the y -variables (symmetric, SYM)

- matrices and their types in the measurement model for the x -variables

LAMBDAX the matrix of regression coefficients of the x -variables on the ξ -variables (general, GEN)

NUX the vector of intercept terms of the x -variables (general, GEN)

THETAX the error covariance matrix for the x -variables (symmetric, SYM)

- matrices and their types in the structural model

ALPHA the vector of intercept terms of the η -variables (general, GEN)

BETA the matrix of regression coefficients of the η -variables on the η -variables (general, GEN)

GAMMA the matrix of regression coefficients of the η -variables on the ξ -variables (general, GEN)

KAPPA the mean vector for the ξ -variables (general, GEN)

PHI the covariance matrix for the ξ -variables (symmetric, SYM)

PSI the error covariance matrix for the η -variables (symmetric, SYM)

Valid Matrix Names for the MSTRUCT Modeling Language

The following *matrix-names* are valid for the MSTRUCT modeling language:

COV the covariance matrix (symmetric, SYM)

MEAN the mean vector (general, GEN)

Specifying Locations in Model Matrices

The five main types of matrix *locations* (elements) specification in the MATRIX statement are briefly described in the following:

- **Unspecified *location*:** Blank or [,]
Use this notation to specify the [1,1] element of the matrix, and to specify the remaining *valid* elements of the matrix in a prescribed order until all the parameters in the *parameter-spec* list are assigned.
- **Row-and-column *location*:** [i, j], [@i, j], [i, @j], or [@i, @j]
Use this notation to specify the [i, j] element of a matrix, and to specify the remaining elements of the matrix in the order indicated by the *location* notation until all the parameters in the *parameter-spec* list are assigned.
- **Row *location* only:** [i,], [@i,], or [iset,]
Use this notation to specify the first *valid* matrix element in the [i]-th row (for the first two notations) or the [i1]-th row (for the [iset,] notation, where *iset*=(i1, i2, ...) is a set of row numbers), and to specify the remaining elements of the matrix in the order indicated by the *location* notation until all the parameters in the *parameter-spec* list are assigned.
- **Column *location* only:** [, j], [, @j], or [, jset]
Use this notation to specify the first *valid* matrix element in the [j]-th column (for the first two notations) or the [j1]-th column (for the [, jset] notation, where *jset*=(j1, j2, ...) is a set of columns), and to specify the remaining elements of the matrix in the order indicated by the *location* notation until all the parameters in the *parameter-spec* list are assigned.
- **Row-and-column-sets *location*:** [iset, jset], [iset, j], or [i, jset]
Use this notation to specify the [i1, j1] element of the matrix, where i1 is either the same as i or the first row number specified in *iset*, and j1 is either the same as j or the first column number specified in *jset*, and to specify the remaining elements of the matrix in the order indicated by the *location* notation until all the parameters in the *parameter-spec* list are assigned.

Consider the following points about the *location* specifications:

- In the description of the various *location* specifications, the starting matrix element for parameter assignment is relatively well-defined. However, if the *parameter-spec* list has more than one parameter, there are more matrix elements to assign with the parameters in the *parameter-spec* list. If there is no *parameter-spec* list, a set of matrix elements are specified as unnamed free parameters. Hence, the actual number of elements specified by these *location* specifications depends on the length of the *parameter-spec* list.
- Because more than one matrix element could be specified in any of these *location* specifications, it is important to understand the order that PROC CALIS uses to assign the matrix elements.
- In some of the *location* specifications, either the row or column is unspecified and the assignment of the matrix element starts with the first *valid* element given the column or the row number. This first *valid* element depends on the type of the matrix in question.

The next few sections describe the parameter assignments in more detail for each of these *location* specifications in the MATRIX statement.

Unspecified Location: Blank or [,]

This notation means that all valid elements started with the [1,1] element of the matrix specified in the model. If no *parameter-spec* list is specified, all valid elements in the matrix are unnamed free parameters. For these elements, PROC CALIS generates parameter names with the `_Parm` prefix followed by a unique integer (for example, `_Parm1`, `_Parm2`, and so on). If a *parameter-spec* list is specified, the assignment of parameters starts with the [1,1] element and proceeds to the next *valid* elements in the same row. If the entire row of valid elements is assigned with parameters, it proceeds to the next row and so on, until all the parameters in the *parameter-spec* list are assigned. The valid element given the row or column number depends on the type of matrix in question. The following examples illustrate the usage of the unspecified *location* notation.

Suppose that `_GAMMA_` is a general 3×3 matrix. The following statement specifies four elements of this matrix:

```
matrix _GAMMA_ [,] = gg1-gg4;
```

Equivalently, you can use the following blank *location* specification:

```
matrix _GAMMA_ = gg1-gg4;
```

Both specifications are equivalent to the following elementwise specification:

```
matrix _GAMMA_ [1,1] = gg1,
               [1,2] = gg2,
               [1,3] = gg3,
               [2,1] = gg4;
```

With the unspecified *location* for the matrix `_GAMMA_`, the first row is filled up with the parameters first. Then it proceeds to the next row and so on until all parameters in the *parameter-spec* list are assigned. Because there are four parameters and `_GAMMA_` has three columns, the parameter `gg4` is assigned to the `_GAMMA_[2, 1]` element.

However, if the preceding specification is for a 3×3 matrix symmetric matrix `_PHI_`, the parameters are assigned differently. That is, the following specification has different matrix elements assigned with the parameters:

```
matrix _PHI_ = gg1-gg4;
```

Because symmetric matrices contain redundant elements, parameters are assigned only to the lower triangular elements (including the diagonal elements). As a result, the following elementwise specification reflects the preceding specification of matrix `_PHI_`:

```
matrix _PHI_ [1,1] = gg1,
             [2,1] = gg2,
             [2,2] = gg3,
             [3,1] = gg4;
```

The case for lower triangular matrices is the same as the case for symmetric matrices. That is, only the lower triangular elements are valid elements for the parameter assignments.

For upper triangular matrices, only the upper triangular elements (including the diagonal elements) are valid for the parameter assignments. For example, consider the following specification of a 3×3 upper triangular matrix `UPP`:

```
matrix UPP = gg1-gg4;
```

The matrix elements assigned with the parameters are the same as the following elementwise specification:

```
matrix UPP [1,1] = gg1,
           [1,2] = gg2,
           [1,3] = gg3,
           [2,2] = gg4;
```

If a 4×4 diagonal matrix is specified by the preceding MATRIX statement, the parameters are assigned to the following elements: [1,1], [2,2], [3,3], and [4,4].

Lastly, if there is no *parameter-spec* list for the unspecified *location* notation, all valid parameters in the matrix being specified are unnamed free parameters. For example, if **A** is a 4×4 general rectangular matrix, the following specification assigns 16 unnamed free parameters to all of the elements in **A**:

```
matrix A [,];
```

PROC CALIS generates parameters _Parm1, _Parm2, ..., _Parm16 to the elements [1,1], [1,2], [1,3], ..., [4,3], [4,4], respectively.

However, if **S** is a 4×4 *symmetric* matrix, the following specification assigns only 10 unnamed free parameters to the lower triangular elements of **S**:

```
matrix S;
```

PROC CALIS generates parameters _Parm1, _Parm2, ..., _Parm10 to the elements [1,1], [2,1], [2,2], ..., [4,3], [4,4], respectively.

Row-and-Column Location: [*i*, *j*], [*@i*, *j*], [*i*, *@j*], or [*@i*, *@j*]

All these notations provide the starting row (*i*) and column (*j*) numbers for the assignment of the parameters in the *parameter-spec* list. The notations are different in the way they proceed to the next element in the matrix. If no *parameter-spec* list is specified, only the single element [*i*, *j*] is an unnamed free parameter. For this [*i*, *j*] element, PROC CALIS generates a parameter name with the _Parm prefix followed by a unique integer (for example, _Parm1). If a *parameter-spec* list is specified, the assignment of parameters starts with the [*i*, *j*] element and proceeds to next element until all the parameters in the *parameter-spec* list are assigned. The following summarizes how the assignment of parameter proceeds, depending on the uses of the @ sign before the starting row or column number:

- [*i*, *j*] specifies the [*i*, *j*] element, and proceeds to [*i*+1, *j*+1], [*i*+2, *j*+2], and so on.
- [*@i*, *j*] specifies the [*i*, *j*] element, and proceeds to [*i*, *j*+1], [*i*, *j*+2], [*i*, *j*+3], and so on.
- [*i*, *@j*] specifies the [*i*, *j*] element, and proceeds to [*i*+1, *j*], [*i*+2, *j*], [*i*+3, *j*], and so on.
- [*@i*, *@j*] specifies the [*i*, *j*] element only.

The following examples illustrates the usage of the row-and-column *location* notation.

The simplest case is the specification of a single element as an unnamed free parameter. For example, the following statement specifies that [1,4] in matrix **A** is an unnamed free parameter:

```
matrix A [1,4];
```

PROC CALIS generates a parameter name with the `_Parm` prefix for this element. In this case, using the `@` sign before the row or column number is optional. That is, the following statements are all the same specification:

```
matrix A [1,4];
matrix A [@1,4];
matrix A [1,@4];
matrix A [@1,@4];
```

You can specify more than one unnamed free parameter by using multiple *location* specifications, as shown in the following example:

```
matrix A [1,4], [3,5];
```

Elements `[1,4]` and `[3,5]` of matrix **A** are both unnamed free parameters. However, when a *parameter-spec* list is specified after the *location*, more than one parameters might be specified. The use of the `@` determines how the elements in the matrix are assigned with the parameters in the *parameter-spec* list. The following examples illustrate this under various situations.

For example, consider the following specification of a 4×4 matrix general matrix **A**:

```
matrix A
  [1,1] = a b c;
```

The three parameters `a`, `b`, and `c`, are assigned to the matrix elements `[1,1]`, `[2,2]`, and `[3,3]`, respectively. That is, this specification is equivalent to the following elementwise specification:

```
matrix A
  [1,1] = a ,
  [2,2] = b ,
  [3,3] = c ;
```

However, with the `@` sign, the assignment is different. For example, consider the `@` sign attached to the row number in the following specification:

```
matrix A
  [@1,1] = a b c;
```

The `@` sign fixes the row number to 1. As a result, this specification is equivalent to the following elementwise specification:

```
matrix A
  [1,1] = a ,
  [1,2] = b ,
  [1,3] = c ;
```

Using the `@` sign before the column number fixes the column number. For example, consider the following specification of matrix **A**:

```
matrix A
  [2,@2] = a b c;
```

The @ sign fixes the column number to 2. As a result, this specification is equivalent to the following elementwise specification:

```
matrix A
  [2,2] = a ,
  [3,2] = b ,
  [4,2] = c ;
```

If you put the @ sign in both of the row and column numbers, only one element is intended to be assigned. For example, the following specification means that only $A[2, 3]$ is assigned with the parameter a:

```
matrix A
  [@2,@3] = a;
```

But you could specify this simply as the statement without the @ sign:

```
matrix A
  [2,3] = a;
```

Notice that the matrix type does not play a role in determining the elements for the parameter assignments in the row-and-column *location* specification. You have to make sure that the parameters are assigned in the valid elements of the matrix. For example, suppose that S is a 4×4 symmetric matrix and you specify the following statement for its elements:

```
matrix A
  [@3,2] = a b c;
```

The elements to be assigned with the parameters a, b, and c, are $[3, 2]$, $[3, 3]$, and $[3, 4]$, respectively. However, because S is symmetric, you can specify only the nonredundant elements in the lower triangular of S . Hence, the specification of the $[3, 4]$ element is not valid and it generates an error.

Row Location Only: $[i,]$, $[@i,]$, or $[iset,]$

All these notations provide the starting row $[i1,]$ for the assignment of the parameters in *parameter-spec*, where $i1$ is i for the first two *location* notations or $i1$ is the first row specified in *iset*, where $iset = (i1, i2, \dots)$ is a set of row numbers. Because no column location is specified, the starting element is the first valid element in the $i1$ -th row of the matrix.

If no *parameter-spec* list is specified, all the valid elements in the entire $i1$ -th row of the matrix are unnamed free parameters. If a set of row numbers is specified in *iset*, all the valid elements in the all the rows specified in *iset* are unnamed free parameters.

If a *parameter-spec* list is specified, the assignment of parameters starts with the first valid elements of the $i1$ -th row. The assignment proceeds to next valid elements in the same row. The $[i,]$ specification proceeds row by row for parameter assignment while the $[@i,]$ specification stays at the same i -th row. The $[iset,]$ specification indicates and limits the sequence of rows to be assigned with the parameter in the *parameter-spec* list. The assignment stops when all the parameters in the *parameter-spec* list are assigned. The following summarizes how the assignment of parameters proceeds in more precise terms:

- $[i,]$ specifies the first valid element in row i and proceeds to the valid elements in rows $i, i+1, i+2, \dots$, until all parameters in the *parameter-spec* list are assigned.

- `[@i,]` specifies the first valid elements in row `i` and proceeds to the valid elements in the *same* row until all parameters in the *parameter-spec* list are assigned.
- `[iset,]` specifies the first valid elements in row `i1`, where `i1, i2, ...` are the rows specified in *iset*. It proceeds to the valid elements in rows `i1, i2, ...`, until all parameters in the *parameter-spec* list are assigned.

The following examples illustrates the usage of the row *locations*.

The simplest case is the specification of all valid elements of a single row as unnamed free parameters. For example, the following specification of a 3×3 rectangular matrix **A** assigns unnamed free parameters to all the elements in the second row of matrix **A**:

```
matrix A [2,];
```

PROC CALIS generates parameter names with the `_Parm` prefix for these elements. For example, the `[2,1]`, `[2,2]`, and `[2,3]` elements are named with `_Parm1`, `_Parm2`, and `_Parm3`, respectively.

Using the `@` sign before the row number in this case is optional. That is, the following statement is the same specification:

```
matrix A [@2,];
```

If you specify a set of row numbers without the *parameter-spec* list, all valid elements of the specified rows are unnamed free parameters. For example, consider the following specification of a 6×6 symmetric matrix **S**:

```
matrix S [1 3 5,];
```

This specification specifies unnamed free parameters for the lower triangular elements in the first, third, and fifth rows of matrix **S**. It is equivalent to the following specification:

```
matrix S [1,],
          [3,],
          [5,];
```

As a result, this means that the following elements in matrix **S** are free parameters: `[1,1]`, `[3,1]`, `[3,2]`, `[3,3]`, `[5,1]`, `[5,2]`, `[5,3]`, `[5,4]`, and `[5,5]`. Notice that only the elements in the lower triangular of those specified rows in **S** are free parameters. This shows that parameter assignment with the row *location* notation depends on the matrix type.

With the use of the *parameter-spec* list, the parameter assignment with the row *location* notation stops when all the parameters are assigned. For example, consider the following specification of a 4×4 *general* (rectangular) matrix **A**:

```
matrix A
  [2,] = a b c;
```

The three parameters `a`, `b`, and `c`, are assigned to the matrix elements `[2,1]`, `[2,2]`, and `[2,3]`, respectively. However, a different assignment of the parameters applies if you use the same specification for a 4×4 *symmetric* matrix **S**, as shown in the following statement:

```
matrix S
  [2,] = a b c;
```

Because there are redundant elements in a symmetric matrix, you can specify only the lower triangular elements. Therefore, the row *location* specification is equivalent to the following elementwise specification:

```
matrix S
  [2,1] = a ,
  [2,2] = b ,
  [3,1] = c ;
```

When all the valid row elements are assigned with the parameters, the assignment proceeds to the next row. This is why the last parameter assignment is for `S[3, 1]`. The same assignment sequence applies to matrices with the lower triangular type (LOW).

For matrices with the upper triangular matrix type (UPP), only the elements in the upper triangular are assigned. For example, consider a 4×4 upper triangular matrix `U` with the following row *location* specification:

```
matrix U
  [2,] = a b c d;
```

The assignment of parameters is the same as the following elementwise specification:

```
matrix U
  [2,2] = a ,
  [2,3] = b ,
  [2,4] = c ,
  [3,3] = d;
```

The first valid element in the second row of the `U` matrix is `U[2, 2]`. Because all the valid elements in the second row are assigned with parameters, the last element has to go to the valid element in the next row. Hence, the parameter `d` is assigned to `U[3, 3]`.

For matrices with the diagonal matrix type (DIA), only the diagonal elements are assigned. For example, consider a 4×4 upper diagonal matrix `D` with the following row *location* specification:

```
matrix D
  [2,] = a b c;
```

The assignment of parameters is the same as the following elementwise specification:

```
matrix D
  [2,2] = a ,
  [3,3] = b ,
  [4,4] = c ;
```

If you use an `@` sign before the row number in the row *location* specification, the row number cannot move—it cannot proceed to the next row even if the valid elements in that row are already filled with the parameters in *parameter-spec*. All other behavior of the `[@i,]` specification is the same as that of the `[i,]` specification. For example, consider the following specification of a 4×4 *general* (rectangular) matrix `A`:

```
matrix A
  [@2,] = a b c d;
```

The four parameters a, b, c, and d, are assigned to the matrix elements [2,1], [2,2], [2,3], and [2,4], respectively. This is exactly the same result as the following specification without the @ sign:

```
matrix A
  [2,] = a b c d;
```

Here, all the elements of the second row of matrix A are assigned with elements. However, if one more parameter is specified in the *parameter-spec* list, the behavior for the two types of row *location* specifications are different. The following specification without the @ sign proceeds to the next row for the last parameter:

```
matrix A
  [2,] = a b c d e;
```

That is, the parameter e is assigned to the A[3,1] element. However, the following specification *with* the @ sign results in an out-of-bound error:

```
matrix A
  [@2,] = a b c d e;
```

The out-of-bound error is due to the fact that the row number must be fixed so that the parameter e is forced to be assigned to A[2,5], which does not exist.

However, the distinction between the row *location* specifications with and without the @ sign is not very important in common practice because in most cases you do not want the parameter assignment to proceed row after row automatically with a long list of parameters. For example, consider the following specification of a 4×4 *symmetric* matrix S:

```
matrix S
  [2,] = s21 s22 s31 s32 s33 s41 s42 s43;
```

This specification is equivalent to the following specification:

```
matrix S
  [2,] = s21 s22,
  [3,] = s31 s32 s33,
  [4,] = s41 s42 s43;
```

Although this specification is not as concise as the preceding one, it specifies more clearly about how parameters are assigned to each of the three rows of the S matrix. In this specification, you make sure that each of the three row *location* specifications has just enough parameters for the given row without proceeding to the next row for additional parameter assignments. With this kind of “careful” row *location* specifications, you do not need to use the @ sign before the row numbers at all.

The last type of row *location* specification is the [*iset*,] notation, where *iset* means a set of row numbers. This specification type provides the set of row numbers for the assignment of the parameters in the *parameter-spec* list. For example, consider the following specification of a 4×4 *general* matrix A:

```
matrix A
  [2 4,] = a21 a22 a23 a24 a41 a42 a43 a44;
```

This specification is equivalent to the following statement with two row *location* specifications:

```
matrix A
  [2,] = a21 a22 a23 a24,
  [4,] = a41 a42 a43 a44;
```

In other words, the assignment of parameters follows the order of rows provided in the *iset*. Notice that the *iset* notation merely provides the order of rows to be assigned with the parameters in the *parameter-spec* list; it is not an error if you provide a shorter parameter list than that of the total number of elements in the rows. For example, the following specification of a 4×4 *general* matrix **A** is valid:

```
matrix A
  [2 4,] = a21 a22 a23 a24;
```

This specification has the same results as the following statement with one row *location*:

```
matrix A
  [2,] = a21 a22 a23 a24;
```

However, a valid specification does not mean it is a good representation of the problem. Providing more rows in the *iset* specification than intended is simply not a good practice.

Although a shorter *parameter-spec* list is acceptable, a longer list results in an error. For example, the following specification of a 4×4 *symmetric* matrix **S** results in an error:

```
matrix S
  [2 to 3,] = s21 s22 s31 s32 s33 extra1 extra2;
```

The `[2 to 3,]` not only gives the sequence of the rows for the parameter assignment, it also limits the set of rows to assign. Because matrix **S** is symmetric and because only the second and the third rows are supposed to be assigned with the *iset* specification, the parameters `extra1` and `extra2` are excessive.

Column Location Only: `[, j]`, `[, @j]`, or `[, jset]`

These notations mirror that of the row *location* notations. Instead of the rows being specified, the columns are specified by these notations. Therefore, you can understand the column *location* notations the same way as the row *location* notations.

All these column *location* notations provide the starting column `[, j1]` for the assignment of the parameters in *parameter-spec*, where `j1` is `j` for the first two *location* notations or `j1` is the first column specified in *jset*, where *jset* = (`j1`, `j2`, ...) is a set of column numbers. Because no row location is specified, the starting element is the first valid element in the `j1`-th column of the matrix.

If no *parameter-spec* list is specified, all the valid elements in the entire `j1`-th column of the matrix are unnamed free parameters. If a set of column numbers is specified in *jset*, all the valid elements in the all the columns specified in *jset* are unnamed free parameters.

If a *parameter-spec* list is specified, the assignment of parameters starts with the first valid elements of the `j1`-th column. The assignment proceeds to next valid elements in the same column. The `[, j]` specification proceeds column by column for parameter assignment while the `[, @j]` specification stays at the same `j`-th column. The `[, jset]` specification indicates and limits the sequence of columns to be assigned with the parameter in the *parameter-spec* list. The assignment stops when all the parameters in the *parameter-spec* list are assigned. The following list summarizes how the assignment of parameters proceeds:

- `[, j]` specifies the first valid element in column `j` and proceeds to the valid elements in columns `j`, `j+1`, `j+2`, ..., until all parameters in the *parameter-spec* list are assigned.

- `[, @j]` specifies the first valid elements in column `j` and proceeds to the valid elements in the *same* column until all parameters in the *parameter-spec* list are assigned.
- `[, jset]` specifies the first valid elements in column `j1`, where `j1, j2, ...` are the columns specified in *jset*. It proceeds to the valid elements in columns `j1, j2, ...`, until all parameters in the *parameter-spec* list are assigned.

See the section “Row Location Only: `[i,]`, `[@i,]`, or `[iset,]`” on page 1181 for examples, which are applicable to the usage of the column *locations*.

Row-and-Column-Sets Location: `[iset, jset]`, `[iset, j]`, or `[i, jset]`

These notations specify the sets of row and column elements for the assignment of the parameters in the *parameter-spec* list. In the first notation, you specify the set of row numbers in *iset* = (`i1, i2, ...`), and the set of column numbers in *jset* = (`j1, j2, ...`). The last two notations are special cases of the first notation. The `[iset, j]` notation specifies only one column with *jset* = `j1 = j`. The `[i, jset]` notation specifies only one row with *iset* = `i1 = i`. For the last two notations, adding the `@` sign before `j` or `i` is optional. In general, the row-and-column-sets *locations* specify the matrix elements in the following order:

```
[i1, j1], [i1, j2], ...,
[i2, j1], [i2, j2], ...,
[i3, j1], [i3, j2], ...,
..., ..., ...,
[ir, j1], [ir, j2], ..., [ir, js]
```

where `r` represents the number of rows in the *iset* and `s` represents the number of columns in the *jset*. Note that this ordering of elements does not necessarily mean that all these elements are specified. The number of elements specified depends on the length of the *parameter-spec* list.

If no *parameter-spec* list is specified after the *location* notation, all the `r × s` elements specified in the *iset* and *jset* are unnamed free parameters. PROC CALIS generates parameter names with the `_Parm` prefix for these elements.

If a *parameter-spec* list is specified after the *location* notation, the total number of matrix elements that are assigned with the parameters is the same as the number of parameter specifications in the *parameter-spec* list.

The following examples illustrates the usage of the row-and-column-sets *locations*.

The simplest case is the specification of all elements in the *iset* and *jset* as free parameters, as shown in the following statement:

```
matrix _Gamma_ [2 3,4 1];
```

This means that `_Gamma_[2, 4]`, `_Gamma_[2, 1]`, `_Gamma_[3, 4]`, and `_Gamma_[3, 1]` are all free parameters in the matrix. For these elements, PROC CALIS generates parameter names with the `_Parm` prefix followed by a unique integer (for example, `_Parm1`, `_Parm2`, ...). This row-and-column-sets *location* specification is the same as the following specification:

```
matrix _Gamma_ [2,4 1], [3,4 1];
```

It is also equivalent to the following elementwise specification:

```
matrix _Gamma_ [2,4], [2,1], [3,4], [3,1];
```

If you provide a *parameter-spec* list after the row-and-column-sets *location*, the parameters in the list are assigned to the matrix elements. For example, consider the following specification:

```
matrix _Gamma_ [2 3,4 1] = gamma1-gamma4;
```

This specification is equivalent to the following elementwise specification:

```
matrix _Gamma_ [2,4] = gamma1,
                  [2,1] = gamma2,
                  [3,4] = gamma3,
                  [3,1] = gamma4;
```

It is not necessary for all the elements specified in the row-and-column-sets *location* to be assigned with the parameters in the *parameter-spec* list. For example, the following *iset* and *jset* specify a maximum of six elements, but only five parameters are assigned as a result of a shorter *parameter-spec* list:

```
matrix _Gamma_ [2 to 4,1 5] = gamma1-gamma4;
```

This specification is equivalent to the following elementwise specification:

```
matrix _Gamma_ [2,1] = gamma1,
                  [2,5] = gamma2,
                  [3,1] = gamma3,
                  [3,5] = gamma4,
                  [4,1] = gamma5;
```

In this case, `_Gamma_[4,5]` is not specified and is fixed at zero by default.

With the row-and-column-sets *location* specifications, you need to be aware of the matrix type being specified. For example, the following specification of the symmetric matrix *S* results in an out-of-bounds error:

```
matrix S [1 2,1 2] = s1-s4;
```

This specification is equivalent to the following elementwise specification:

```
matrix S [1,1] = s1,
          [1,2] = s2,
          [2,1] = s3,
          [2,2] = s4;
```

The specification of the *S*[1,2] element is not valid because you can specify only the lower triangular elements of a symmetric matrix in PROC CALIS. The upper triangular elements are redundant and are taken into account by PROC CALIS during computations.

Specifying Fixed and Free Parameters in Model Matrices

For clarity in describing various *location* notations, the *parameter-spec* list contains only free parameters in the examples. In general, you can specify fixed values, free parameters, and initial values in the *parameter-spec* list. The syntax for the *parameter-spec* list is the same as the *parameter-spec* list for the [VARIANCE](#) statement. You can specify the following five types of the parameters in the MATRIX statement:

- an unnamed free parameter
- an initial value
- a fixed value
- a free parameter with a name provided
- a free parameter with a name and initial value provided

The following example demonstrates these five types of specifications:

```
matrix A  [1,2],
          [1,3] = (.2),
          [1,4] = .3,
          [2,3] = a1,
          [2,4] = a2(.5);
```

In this statement, $A[1, 2]$ is an unnamed free parameter. For this element, PROC CALIS generates a parameter name with the `_Parm` prefix and appended with a unique integer (for example, `_Parm1`). $A[1, 3]$ is an unnamed free parameter with an initial value of 0.2. PROC CALIS also generates a parameter name for this element. $A[1, 4]$ is fixed at 0.3. This value does not change in estimation. $A[2, 3]$ is a free parameter named `a1`. No initial value is given for this element. $A[2, 4]$ is a free parameter named `a2` with an initial value of 0.5.

You can also specify different types of parameters in the *parameter-spec* list. The preceding specification is equivalent to the following specification:

```
matrix A  [1,2],
          [1 2,3 4] = (.2) .3 a1-a2 (.5);
```

Notice that 0.5 is the initial value for `a2` but not for `a1` because this specification is the same as:

```
matrix A  [1,2],
          [1 2,3 4] = (.2) .3 a1 a2(.5);
```

When you use *parameter-spec* lists with mixed parameters, you must be careful about how the initial value syntax is interpreted with and without a parameter name before it. With a parameter before the initial value, the initial value is for the parameter, as shown in the following statement:

```
matrix S  [1,1] = s1 s2 (.2);
```

This specification is the same as the following elementwise specification:

```
matrix S  [1,1] = s1,
          [2,2] = s2(.2);
```

This means that 0.2 is the initial value of parameter `s2`, but not interpreted as an unnamed free parameter for $S[3, 3]$. If you do intend to set the free parameter `s2` for $S[2, 2]$ without an initial value and set the initial value 0.2 for $S[3, 3]$, you can use a null initial value for the `s2` parameter, as shown in the following:

```
matrix S [1,1] = s1 s2() (.2);
```

This specification is the same as the following elementwise specification:

```
matrix S [1,1] = s1,
          [2,2] = s2,
          [3,3] = (.2);
```

Modifying a Parameter Specification from a Reference Model

If you define a new COSAN, LISMOD, or MSTRUCT model by using a reference (old) model in the [REFMODEL](#) statement, you might want to modify some parameter specifications from the [MATRIX](#) statement of the reference model before transferring the specifications to the new model. To change a particular matrix element specification from the reference model, you can simply respecify the same matrix element with the desired parameter specification in the [MATRIX](#) statement of the new model. To delete a particular matrix parameter from the reference model, you can specify the desired matrix element with a missing value specification in the [MATRIX](#) statement of the new model.

For example, suppose that `_PHI_[1,2]` is a free parameter in the reference model but you do not want this matrix element be a free parameter in the new model, you can use the following specification in the new model:

```
matrix _PHI_ [1,2] = .;
```

Notice that the missing value syntax is valid only when you use the [REFMODEL](#) statement. See the section “[Modifying a COSAN Model from a Reference Model](#)” on page 1129 for a more detailed example of COSAN model respecification. See the section “[Modifying a LISMOD Model from a Reference Model](#)” on page 1164 for a more detailed example of LISMOD model respecification. See the section “[Modifying an MSTRUCT Model from a Reference Model](#)” on page 1195 for a more detailed example of MSTRUCT model respecification.

MEAN Statement

```
MEAN assignment <, assignment ... >;
```

where *assignment* represents:

```
var-list < = parameter-spec >
```

The [MEAN](#) statement specifies the mean or intercept parameters in connection with the [FACTOR](#), [LINEQS](#), and [PATH](#) modeling languages. With the [MEAN](#) statement specification, [PROC CALIS](#) analyzes the mean structures in addition to the covariance structures.

In each *assignment* of the [MEAN](#) statement, you list the *var-list* that you want to specify for their means or intercepts. Optionally, you can provide a list of parameter specifications in a *parameter-spec* after an equal sign for each *var-list*. The syntax of the [MEAN](#) statement is exactly the same as that of the [VARIANCE](#) statement. See the [VARIANCE statement](#) on page 1231 for details about the syntax.

For the confirmatory [FACTOR](#) or [PATH](#) model, the variables in a *var-list* can be exogenous or endogenous. You specify the mean of a variable if the variable is exogenous. You specify the intercept of a variable if

the variable is endogenous. However, for the LINEQS model, you can specify only the means of exogenous variables whose type is not error (that is, not the E- or D- variables) in the MEAN statement. You cannot specify the intercept parameters in the MEAN statement for the LINEQS model. Instead, you must specify the intercepts in the equations of the **LINEQS** statement. For the exploratory FACTOR model, the MEAN statement is used merely to include the mean structures into analysis. In this case, the parameter specification by the *assignment* syntax is not interpreted. Instead, the intercept parameters for the exploratory factor model are automatically generated by PROC CALIS.

You can specify the following five types of the parameters for the means or intercepts in the MEAN statement:

- an unnamed free parameter
- an initial value
- a fixed value
- a free parameter with a name provided
- a free parameter with a name and initial value provided

For example, consider a PATH model with exogenous variables x1, x2, and x3 and endogenous variables y4 and y5. The following MEAN statement illustrates the five types of specifications in five *assignments*:

```
mean x1 ,
      x2 = (3.0) ,
      x3 = 1.5,
      y4 = intercept1,
      y5 = intercept2(0.6) ;
```

In this statement, the mean of x1 is specified as an unnamed free parameter. For this mean, PROC CALIS generates a parameter name with the `_Parm` prefix and appended with a unique integer (for example, `_Parm1`). The mean of x2 is an unnamed free parameter with an initial value of 3.0. PROC CALIS also generates a parameter name for this mean. The mean of x3 is a fixed value of 1.5. This value stays the same during the estimation. The intercept of endogenous variable y4 is a free parameter named `intercept1`. The intercept of endogenous variable y5 is a free parameter named `intercept2` with an initial value of 0.6.

The syntax of the MEAN statement is the same as the syntax of the VARIANCE statement. See the **VARIANCE** statement for more illustrations about the usage.

Default Mean and Intercept Parameters

If the mean structures are analyzed, either the means or intercepts of the *manifest* variables in the FACTOR, LINEQS, or PATH model are free parameters by default. If a manifest variable is exogenous, then its mean is a free parameter by default. If a manifest variable is endogenous, then its intercept is a free parameter by default. Except for the exploratory FACTOR model, PROC CALIS generates parameter names for these default free mean or intercept parameters that include the `_Add` prefix and are appended with unique integer suffixes. The default intercepts of the exploratory FACTOR model use the `_a` prefix instead. For the confirmatory FACTOR model and the PATH model, you can use the MEAN statement to override these default mean or intercept parameters in situations where you want to set parameter constraints, provide initial or fixed values, or make parameter references. However, you cannot override any default intercept

parameters for the exploratory FACTOR model. For the LINEQS model, you can use the MEAN statement specification to override only the default mean parameters. The intercept parameters of the LINEQS model must be specified in the equations of the [LINEQS](#) statement.

Fixed zero is another type of default mean or intercept parameters for the FACTOR, LINEQS, or PATH model. All the intercepts and means of the *latent* variables in these models are fixed zeros by default. For the confirmatory FACTOR and PATH models, you can override these default fixed zeros by using the MEAN statement specifications. However, you cannot override the fixed zero factor means for the exploratory FACTOR model. For the LINEQS model, you can override only the default fixed zeros of latent variables whose type is not error. That is, you can use the MEAN statement to override the default zero mean for the exogenous latent factors (excluding the error or disturbance variables) or use the LINEQS statement to override the default zero intercept for the endogenous latent factors. The fixed zero means for the error or disturbance variables in the LINEQS model reflects model restrictions—there is no way you can override these default zero means.

Modifying a Mean or Intercept Parameter Specification from a Reference Model

If you define a new FACTOR (confirmatory factor model only), LINEQS, or PATH model by using a reference (old) model in the [REFMODEL](#) statement, you might want to modify some parameter specifications from the MEAN statement of the reference model before transferring the specifications to the new model. To change a particular mean or intercept specification from the reference model, you can simply respecify the same mean or intercept with the desired parameter specification in the MEAN statement of the new model. To delete a particular mean or intercept parameter from the reference model, you can specify the desired mean or intercept with a missing value specification in the MEAN statement of the new model.

For example, suppose that the mean of F1 is specified in the reference model, but you do not want this mean specification be transferred to the new model. You can use the following MEAN statement specification in the new model:

```
mean F1 = .;
```

Note that the missing value syntax is valid only when you use with the [REFMODEL](#) statement. See the section “[Modifying a FACTOR Model from a Reference Model](#)” on page 1146 for a more detailed example of FACTOR model respecification. See the section “[Modifying a LINEQS Model from a Reference Model](#)” on page 1160 for a more detailed example of LINEQS model respecification. See the section “[Modifying a PATH Model from a Reference Model](#)” on page 1211 for a more detailed example of PATH model respecification.

As discussed in a preceding section, PROC CALIS generates default free mean or intercept parameters for manifest variables in the FACTOR, LINEQS, or PATH model if you do not specify them explicitly in the MEAN statement (and the LINEQS statement for the LINEQS model). When you use the [REFMODEL](#) statement for defining a reference model, these default free mean or intercept parameters in the old (reference) model are not transferred to the new model. Instead, the new model generates its own set of default free mean or intercept parameters *after* the new model is resolved from the reference model, the [REFMODEL](#) statement options, the [RENAMEPARM](#) statement, and the MEAN statement (and the LINEQS statement for the LINEQS model) specifications in the new model. This also implies that if you want any of the mean or intercept parameters to be constrained across the models by means of the [REFMODEL](#) specification, you must specify them explicitly in the MEAN statement (or the LINEQS statement for the LINEQS model) of the reference model so that the same mean or intercept specification is transferred to the new model.

MODEL Statement

MODEL *i* < / options > ;

where *i* is an assigned model number between 1 and 9999, inclusively.

A MODEL statement signifies the beginning of a model specification block and designates a model number for the model. All [main](#) and [subsidiary](#) model specification statements after a MODEL statement belong in that model until another MODEL or [GROUP](#) statement is encountered.

The MODEL statement itself does not serve the purpose of model specification, which is actually done by the [main](#) and [subsidiary](#) model specification statements that follow it. The MODEL statement serves as a “place-holder” of specification of a single model. It also makes the reference to a model easier with an assigned model number. For example, consider the following statements:

```
proc calis;
  group 1 / data=women_data;
  group 2 / data=men_data;
  model 1 / group=1 label='Women Model';
    {model 1 specification here}
  model 2 / group=2 label='Men Model';
    {model 2 specification here}
run;
```

This example illustrates a two-group analysis with two models. One is **model 1** labeled as ‘Women Model’ in a MODEL statement. Another is **model 2** labeled as ‘Men Model’ in another MODEL statement. The two groups, **group 1** and **group 2**, as defined in two separate [GROUP](#) statements, are fitted by **model 1** and **model 2**, respectively, as indicated by the GROUP= option of the MODEL statements. Within the scope of **model 1**, you provide model specification statements by using the [main](#) and [subsidiary](#) model specification statements. Usually, one of the following main model specification statements is used: [FACTOR](#), [LINEQS](#), [LISMOD](#), [MSTRUCT](#), [PATH](#), [RAM](#), or [REFMODEL](#). Similarly, you provide another set of model specification statements within the scope of **model 2**.

Hence, for an analysis with a single group, the use of the MODEL statement is not necessary because the model that fits the group is unambiguous.

You can set model-specific *options* in each MODEL statement. All but two of these *options* are also available in the [PROC CALIS](#) statement. If you set these *options* in the PROC CALIS statement, they apply to all models, unless you respecify them in the local MODEL statements. If you want to apply some *options* only to a particular model, specify these *options* in the MODEL statement that corresponds to that model.

You can also set group-specific *options* in the MODEL statement. These group *options* apply to the groups that are specified in GROUP= option of the MODEL statement. See the section “[Options Available in the GROUP and PROC CALIS Statements](#)” on page 1153 for a detailed descriptions of these group *options*.

Options Available Only in the MODEL Statement

LABEL | **NAME**=*name*

specifies a label for the model. You can use any valid SAS names up to 256 characters for labels. You can also use quoted strings for labels.

GROUP | GROUPS=*int-list*

specifies a list of integers which represent the groups to be fitted by the model.

Options Available in the MODEL and PROC CALIS Statements

The following options are available in the MODEL and PROC CALIS statements. If you specify these options in the PROC CALIS statement, they are transferred to all MODEL statements. These options might be overwritten by the respecifications in the local MODEL statements.

Option	Description
DEMPHAS= on page 1096	Emphasizes the diagonal entries
EFFPART TOTEFF on page 1097	Displays total, direct, and indirect effects
EXTENDPATH GENPATH on page 1097	Displays the extended path estimates that include variances and covariances
INEST= on page 1098	Specifies the data set that contains the initial values and constraints
INMODEL INRAM= on page 1098	Specifies the data set that contains the model specifications
MEANSTR on page 1104	Analyzes the mean structures
MODIFICATION on page 1105	Computes modification indices
NOMEANSTR on page 1106	Deactivates the inherited MEANSTR option
NOMOD on page 1107	Suppresses modification indices
NOORDERSPEC on page 1107	Displays model specifications and results according to the input order
NOPARMNAME on page 1107	Suppresses the printing of parameter names in results
NOSTAND on page 1107	Suppresses the standardized output
NOSTDERR on page 1107	Suppresses standard error computations
ORDERSPEC on page 1109	Orders the model output displays according to the parameter types within each model
OUTEST= on page 1110	Specifies the data set that outputs the estimates and their covariance matrix
OUTMODEL OUTRAM= on page 1110	Specifies the output data set for storing the model specification and results
PARMNAME on page 1111	Displays parameter names in model specifications and results
PDETERM on page 1111	Computes the determination coefficients
PESTIM on page 1112	Prints parameter estimates
PINITIAL on page 1112	Prints initial pattern and values
PLATCOV on page 1112	Computes the latent variable covariances and scoring coefficients
PRIMAT on page 1113	Displays results in matrix forms
READADDPARM on page 1114	Instructs generated default parameters be read in the INMODEL= data set
STDERR on page 1118	Computes the standard errors

Options Available in MODEL, GROUP, and PROC CALIS Statements

Some options in the **GROUP** statement can also be specified in the **MODEL** statements. Group options that are specified the **MODEL** statements are transferred to the **GROUP** statements that define the groups that are fitted by the associated models in the **MODEL** statements. This is a little more convenient than setting the common group options individually in the **GROUP** statements for all fitted groups by a model. See the section “Options Available in **GROUP**, **MODEL**, and **PROC CALIS** Statements” on page 1154 for a reference of these options.

MSTRUCT Statement

MSTRUCT < **VAR**=*var-list* > ;

MSTRUCT stands for matrix structures. As opposed to other modeling languages, in which the mean and covariance structures are implied from paths, equations, or complicated model matrix computations, the **MSTRUCT** language is for direct structured mean and covariance models.

In the **MSTRUCT** statement, you define the list of variables. You can use **MATRIX** statements to specify the parameters in the mean and covariance structures:

```
MSTRUCT < VAR=var-list > ;
MATRIX _COV_ parameters-in-matrix ;
MATRIX _MEAN_ parameters-in-matrix ;
```

You use the **MATRIX _COV_** statement to specify the covariance and variance parameters in the structured covariance matrix. When applicable, you use the **MATRIX _MEAN_** statement to specify the parameters in the structured mean vector. Each of these matrices can be specified no more than once within a model. See the **MATRIX statement** on page 1175 for details. If you do not use any **MATRIX** statement for specifying parameters, a saturated model is assumed. This means that all elements in the covariance and mean (if modeled) matrices are free parameters in the model.

The order of variables in the *var-list* of the **MSTRUCT** statement is important; it is used to refer to the row and column variables of the **_COV_** and the **_MEAN_** matrices. The variables specified in the list should be present in the input data set that is intended for the **MSTRUCT** model. With direct mean and covariance structures on the observed variables, no latent variables are explicitly involved in the **MSTRUCT** modeling language. However, this does not mean that the **MSTRUCT** modeling language cannot handle latent variable models. With additional specifications in the **PARAMETERS** and the **SAS programming statements**, it is possible to fit certain latent variable models by using the **MSTRUCT** modeling language. Despite this, the code might get too complicated and error-prone. Hence, using the **MSTRUCT** modeling language for latent variable modeling is not recommended for novice users. The **LINEQS**, **LISMOD**, **PATH**, or **RAM** modeling language should be considered first for latent variable modeling.

Default Parameters

It is important to understand the default parameters in the **MSTRUCT** model. If you know which parameters are default free parameters, you can make your specification more efficient by omitting the specifications of those parameters that can be set by default. For example, you do not need to specify any elements of the **_COV_** matrix if all elements are supposed to free parameters. See the section “Default Parameters in the **MSTRUCT Model**” on page 1287 for details about the default parameters of the **FACTOR** model.

Modifying an MSTRUCT Model from a Reference Model

This section assumes that you use a **REFMODEL** statement within the scope of a **MODEL** statement and that the reference model (or base model) is also an MSTRUCT model. The reference model is called the old model, and the model that refers to the old model is called the new model. If the new model is not intended to be an exact copy of the old model, you can use the following extended MSTRUCT modeling language to make modifications within the scope of the **MODEL** statement for the new model. The syntax is similar to, but not exactly the same as, the ordinary MSTRUCT modeling language, as described in the section “**MSTRUCT Statement**” on page 1194. The syntax for respecifying or modifying an MSTRUCT model takes the following form:

```
MSTRUCT ;
    MATRIX _COV_ parameters-in-matrix ;
    MATRIX _MEAN_ parameters-in-matrix ;
```

In the respecification, you should not put any **VAR=** list in the MSTRUCT statement, as you would do for specifying the original base model. The reason is that parameter respecifications in the new model refer to the variables in the **VAR=** list of the old model. Therefore, the **VAR=** list in the new model is implicitly assumed to be exactly the same as that in the old model. This renders the specification of a **VAR=** list of the MSTRUCT statement of the new model unnecessary. Because the **VAR=** option is the only possible option in the MSTRUCT statement, it also implies that the entire MSTRUCT statement is optional for the new model.

You can use the **MATRIX _COV_** and **MATRIX _MEAN_** statements to modify from the old model by using the same syntax as in ordinary MSTRUCT modeling language. In addition, in the respecification syntax, you can use the missing value ‘.’ to drop a parameter location from the old model.

The new model is formed by integrating with the old model in the following ways:

- Duplication:** If you do not specify in the new model a parameter location that exists in the old model, the old parameter specification is duplicated in the new model.
- Addition:** If you specify in the new model a parameter location that does not exist in the old model, the new parameter specification is used in the new model.
- Deletion:** If you specify in the new model a parameter location that also exists in the old model and the new parameter is denoted by the missing value ‘.’, the old parameter specification is not copied into the new model.
- Replacement:** If you specify in the new model a parameter location that also exists in the old model and the new parameter is not denoted by the missing value ‘.’, the new parameter specification replaces the old one in the new model.

For example, consider the following statements for a two-group analysis:

```
proc calis;
    group 1 / data=d1;
    group 2 / data=d2;
    model 1 / group=1;
        mstruct var=V1-V6;
        matrix _COV_ [1,1] = 6*vparm (8.),
                        [2,] = cv21,
                        [3,] = cv31,
                        [4,] = cv41 cv42 cv43,
```

```

[5,] = cv51 cv52 cv53 cv54,
[6,] = cv61 cv62 cv63 cv64 cv65;
model 2 / group=2;
  refmodel 1;
  matrix _COV_ [2,] = 3.,
               [3,2] = cv32,
               [4,] = . . . ,
               [5,] = . . . ,
               [6,] = . . . ;
run;

```

In these statements, you specify Model 2 by referring to Model 1 in the **REFMODEL** statement. Hence, Model 2 is called the new model that refers to the old model, Model 1. Because they are not respecified in the new model, all parameters on the diagonal of the covariance matrix are duplicated from the old model for the new model. Similarly, parameter locations associated with the cv54, cv64, and cv65 parameters are also duplicated in the new model.

An added parameter in the new model is cv32 for the covariance between V3 and V2. This parameter location is not specified in the old model.

In the new model, parameters for the covariances between the variable sets {V1 V2 V3} and {V4 V5 V6} are all deleted from the old model. The corresponding parameter locations for these covariances are given missing values ‘.’ in the new model, indicating that they are no longer free parameters as in the old model. Deleting these parameters amounts to setting the corresponding covariances to fixed zeros in the new model.

Finally, covariance between V2 and V1 is changed from a free parameter cv21 in the old model to a fixed constant 3 in the new model. This illustrates the replacement rule of the respecification syntax.

NLINCON Statement

NLINCON | **NLC** *constraint* <, *constraint* ... >;

where *constraint* represents one of the following:

- *number operator variable-list number operator*
- *variable-list number operator*
- *number operator variable-list*

You can specify nonlinear equality and inequality constraints with the **NLINCON** or **NLC** statement. The QUANEW optimization subroutine is used when you specify nonlinear constraints by using the **NLINCON** statement.

The syntax of the **NLINCON** statement is similar to that of the **BOUNDS** statement, except that the **NLINCON** statement must contain the names of variables that are defined in the program statements and are defined as continuous functions of parameters in the model. They must not be confused with the variables in the data set.

As with the **BOUNDS** statement, one- or two-sided constraints are allowed in the **NLINCON** statement; equality constraints must be one sided. Valid operators are <=, <, >=, >, and = (or, equivalently, LE, LT, GE, GT, and EQ).

PROC CALIS cannot enforce the strict inequalities < or > but instead treats them as <= and >=, respectively. The listed nonlinear constraints must be separated by commas. The following is an example of the **NLINCON** statement that constrains the nonlinear parametric function $x_1 * x_1 + u_1$ to a fixed value of 1:

```
nlincon    xx = 1;
xx = x1 * x1 + u1;
```

Note that x_1 and u_1 are parameters defined in the model. The following three NLINCON statements, which require xx_1 , xx_2 , and xx_3 to be between zero and ten, are equivalent:

```
nlincon 0. <= xx1-xx3,
          xx1-xx3 <= 10;
nlincon 0. <= xx1-xx3 <= 10.;
nlincon 10. >= xx1-xx3 >= 0.;
```

NLOPTIONS Statement

NLOPTIONS *options* ;

Many options that are available in SAS/OR PROC NLP can be specified for the optimization subroutines in PROC CALIS by using the NLOPTIONS statement. The NLOPTIONS statement provides more displayed and file output control on the results of the optimization process, and it permits the same set of termination criteria as in PROC NLP. These are more technical options that you might not need to specify in most cases.

Several statistical procedures support the use of NLOPTIONS statement. The syntax of NLOPTIONS statement is common to all these procedures and can be found in the section “[NLOPTIONS Statement](#)” on page 482 in Chapter 19, “[Shared Concepts and Topics](#).”

See the section “[Use of Optimization Techniques](#)” on page 1352 for more information about the use of optimization techniques in PROC CALIS.

OUTFILES Statement

OUTFILES | **OUTFILE** *file-option* < *file-option* ... > ;

where *file-option* represents one of the following:

- OUTMODEL | OUTRAM= *file-name* [MODEL= *int-list* < , *int-list* >]
- OUTSTAT= *file-name* [GROUP= *int-list* < , *int-list* >]
- OUTWGT= *file-name* [GROUP= *int-list* < , *int-list* >]

with *file-name* representing an output file name and *int-list* representing list of model or group numbers

Use the OUTFILES statement when you need to output multiple-group or multiple-model information to output files in a complex way. In each OUTFILES statement, each possible *file-option* should appear no more than once. However, as needed, you can use the OUTFILES statement more than once. For example, suppose you want to create two OUTWGT= files for different sets of groups. You can specify the OUTFILES statement twice, as shown in the following specification:

```
outfiles outwgt=file1 [group=1,2];
outfiles outwgt=file2 [group=3,4];
```

In the first OUTFILES statement, the weights for groups 1 and 2 are output to the file file1. In the second OUTFILES statement, the weights for groups 3 and 4 are output to the file file2.

When the **OUTMODEL=**, **OUTSTAT=**, or **OUTWGT=** option is intended for *all* groups or models, you can simply specify the option in the PROC CALIS statement. Only when you need to output the group (model) information from *more than one* group (model), *but not all* groups (models), to a single output file does the use the OUTFILES statement become necessary. For example, consider the following specification:

```
proc calis method=glis;
  outfiles outmodel=outmodel [model=1,3]
           outwgt=outwgt [group=1,2]
           outstat=outstat [group=2,3];
  group 1 / data=g1;
  group 2 / data=g2;
  group 3 / data=g3 outwgt=outwgt3;
  model 1 / group=1;
           factor N=3;
  model 2 / group=2;
           factor N=2;
  model 3 / group=3;
           factor N=3;
run;
```

You fit three different factor models to three groups: Model 1 for Group 1, Model 2 for Group 2, and Model 3 for group 3. In the OUTFILES statement, you output model information from models 1 and 3 to an output file named outmodel, weight matrices from groups 1 and 2 to outwgt, and statistics from groups 2 and 3 to outstat. In each of these output files, you have information from more than one (but not all) groups or models. In the **GROUP** statement for group 3, you have another **OUTWGT=** file named outwgt3 for group 3 alone.

Note that you cannot specify the preceding output file organization by using the following statements:

```
proc calis method=glis;
  group 1 / data=g1 outwgt=outwgt;
  group 2 / data=g2 outwgt=outwgt outstat=outstat;
  group 3 / data=g3 outwgt=outwgt3 outstat=outstat;
  model 1 / group=1 outmodel=outmodel;
           factor N=3;
  model 2 / group=2;
           factor N=2;
  model 3 / group=3 outmodel=outmodel;
           factor N=3;
run;
```

This specification will not work because SAS forbids the repeated specification of the same output file in the same PROC CALIS run. That is, you cannot specify **OUTWGT=outwgt**, **OUTSTAT=outstat**, or **OUTMODEL=outmodel** more than once in the PROC CALIS run without causing file invocation problems (however, multiple specification of the same input file is not a problem).

If you specify any of the output files for a group (or a model) in both of the OUTFILES and the **GROUP** (or **MODEL**) statements, the destination specified in the more specific **GROUP** (or **MODEL**) statement will be used. For example, for the following specification PROC CALIS will save the Model 2 information in the **OUTMODEL=outmodel2** data set, but not in the **OUTMODEL=outfile1** data set:

```

proc calis method=glis;
  outfiles outmodel=outfile1 [model=1,2];
  group 1 / data=g1;
  group 2 / data=g2;
  model 1 / group=1;
    factor N=3;
  model 2 / group=2 outmodel=outmodel2;
    factor N=2;
run;

```

The OUTFILES statement is intended for arranging output files in a complex way. The use of the OUTFILES statement is unnecessary in the following situations:

- If you have a single-sample analysis, you do not need to use the **GROUP** statement. As a result, you can simply use the **OUTSTAT=** or **OUTWGT=** options in the **PROC CALIS** statement for specifying the output destinations. Therefore, the OUTFILES statement is not needed.
- If you have a single model in your analysis, you do not need to use the **MODEL** statement. As a result, you can simply use the **OUTMODEL=** options in the **PROC CALIS** statement for specifying the output destination. Therefore, the OUTFILES statement is not needed.
- If you have multiple groups or multiple models in your analysis and information for all groups or models is output to the same file, you do not need to use the OUTFILES statement. You can simply use the **OUTSTAT=**, **OUTWGT=**, or **OUTMODEL=** options in the **PROC CALIS** statement because the output file information is automatically propagated from the PROC CALIS statement to the groups or models.
- If you have multiple groups or multiple models in your analysis and each group or model has a unique output data file destination (including cases where some groups or models might not have any output files), you do not need to use the OUTFILES statement. You can simply specify the **OUTSTAT=**, **OUTWGT=**, or **OUTMODEL=** options in the **GROUP** or **MODEL** statements.

PARAMETERS Statement

PARAMETERS | **PARMS** *parameters* <=> *numbers* | (*numbers*)>
 <<,> *parameters* <=> *numbers* | (*numbers*)> ... >;

The PARAMETERS statement defines parameters that are useful in the modeling. You can specify more than one PARAMETERS statement.

The three main uses of the PARAMETERS statement are as follows:

- Define independent parameters that are not specified in your model. In some modeling situations, it is more convenient (practically or conceptually) to define the model parameters as functions of these independent parameters. PROC CALIS computes the estimates and their standard errors for these independent parameters.

- Define dependent parameters of interest. These dependent parameters are then defined as functions of the model parameters in the SAS programming statements. PROC CALIS computes the estimates and their standard errors for these dependent parameters.
- Provide initial values for the free parameters in the model if they have not been specified in the model specification statements.

For example, the following statements illustrate the three main uses of the PARAMETERS statement:

```
proc calis;
  path
    v1 <=== v2 = b1,
    v1 <=== v3 = b2,
    v2 <=== v4 = b3 (0.9) ,
    v3 <=== v5 = b4;
  parameters a1 (0.1) a2 (0.2) b3 (0.3) b4 (0.4) b5;
  b1 = -a1 / a2;
  b2 = 1 / a2;
  b5 = b3 - b4;
run;
```

In the PARAMETERS statement, you specify five parameters that take different roles in the modeling. Parameters *a1* and *a2* are independent parameters that are not specified in the PATH statement, which specifies four paths with four parameters for the path coefficients *b1*, *b2*, *b3*, and *b4*. The two SAS programming statements immediately after the PARAMETERS statement define parameters *b1* and *b2* as functions of parameters *a1* and *a2*. Because *a1* and *a2* appear only on the right side of the programming statements, they are independent parameters of the model. In addition, *b1* and *b2* are dependent parameters because they appear on the left side of the first two programming statements. Independent parameters *a1* and *a2* are provided with initial values 0.1 and 0.2, respectively, in the PARAMETERS statement. Because the initial values these two independent parameters are used, dependent parameters *b1* and *b2* are also initialized with values -0.5 and 5 , respectively.

Parameters *b3* and *b4* appear in both the PATH and PARAMETERS statements. Because these two parameters are already specified in the PATH statement, their initial values might have been defined in the model. For example, parameter *b3* in the PATH statement has an initial value of 0.9. This initial value is *not* replaced by the initial value of 0.3 specified in the PARAMETERS statement. However, because you do not specify an initial value for parameter *b4* in the PATH statement, the initial value of 0.4 specified in the PARAMETERS statement is used. In general, the initial values that are specified in the PARAMETERS statement do not replace the initial values that have already been specified for the same parameters in the model.

Parameter *b5* in the PARAMETERS statement is a dependent parameter, which is defined as the difference between the model parameters *b3* and *b4* in the last SAS programming statement. No initial value for this dependent parameter is provided (nor is it needed). By definition, dependent parameters are functions of other parameters, so their initial values are computed. In this example, parameter *b5* takes an initial value of 0.5, the difference between the initial values of *b3* and *b4*.

It is not necessary to provide initial values for the parameters in the PARAMETERS statement. For the independent parameters without initial values specified, PROC CALIS generates the initial values from the **START=** value in the PROC CALIS statement. The default **START=** value is 0.5. If you specify the **RANDOM=** option in the PROC CALIS statement, random numbers are generated for the initial values of

the independent parameters. For the dependent parameters, PROC CALIS computes the initial values by using the SAS programming statements.

In general, the number of parameters and the number of initial values do not have to match. When you specify fewer initial values than parameter names, PROC CALIS either generates or computes the initial values. When you specify more values than parameter names, the extra values are ignored.

For example, consider the following statements:

```
parameters c1 c2 c3 c4 (0.2 0.3 0.4);
parameters d1 d2 d3 d4 (0.1 0.2 0.3 0.4 0.5);
run;
```

The first PARAMETERS statement has a shorter initial value list than the parameter list. The initial values 0.2, 0.3, and 0.4 are assigned to c2, c3, and c4, respectively. PROC CALIS generates the initial value for c1. The second PARAMETERS statement has a longer initial value list than the parameter list. The initial values 0.1, 0.2, 0.3, and 0.4 are assigned to d1, d2, d3, and d4, respectively. The extra initial value 0.5 is ignored.

When the lengths of the parameter list and the initial value list match, you can use an equal sign between the lists freely without affecting the assignments of the initial values. For example, each of the following PARAMETERS statements assigns the initial values alpha=0.5 and beta=-0.5:

```
parameters alfa 0.5 beta -0.5;
parameters alfa = 0.5 beta = -0.5;
parameters alfa (0.5) beta (-0.5);
parameters alfa = (0.5) beta = (-0.5);
parameters alfa beta 0.5 -0.5;
parameters alfa beta = 0.5 -0.5;
parameters alfa beta (0.5 -0.5);
parameters alfa beta = (0.5 -0.5);
```

However, when the parameter list is longer than the initial value list, the equal sign affects the assignments of the initial values. For example, the following statement assigns the initial values to the last three parameters, c2, c3, and c4:

```
parameters c1 c2 c3 c4 (0.2 0.3 0.4);
```

But with an equal sign between the lists, the following statement assigns the initial values to the first three parameters, c1, c2, and c3:

```
parameters c1 c2 c3 c4 = (0.2 0.3 0.4);
```

To make initial value assignments less ambiguous, you can use commas to separate parameter lists. For example, the following statement clearly assigns the initial values to c2, c3, and c4:

```
parameters c1, c2 c3 c4 (0.2 0.3 0.4);
```

This specification is equivalent to the same specification without the comma. But the specification is certainly less ambiguous with the comma.

Proper grouping of the parameter and initial value lists with the use of commas helps make the specification in the PARAMETERS statement clear. For example, consider the following specification:

```
parameters c1 c2 c3 c4 = (0.1 0.2 0.3) c5 c6 (0.6);
```

Initial values 0.1, 0.2, 0.3, and 0.6 are assigned to parameters c1, c2, c3, and c6, respectively. Initial values for other parameters are either generated or computed by PROC CALIS. A much better practice is to use the following equivalent specification:

```
parameters c1 c2 c3 (0.1 0.2 0.3), c4 c5, c6 (0.6);
```

Matching the number of parameters and the number of initial values (if provided) in entries separated by commas in the PARAMETERS statement is highly recommended. It reduces ambiguities and makes your code more interpretable.

It is important to notice that PROC CALIS does not have better alternatives to generate initial values (such as those for setting the initial values of the model parameters) for the independent parameters specified in the PARAMETERS statement other than using either the **START=** value or random values generated by using the **RANDOM=** option. These ad hoc initial values are arbitrary and might not always lead to converged solutions. Therefore, you should try to provide good initial values for those independent parameters that are defined only in the PARAMETERS statement.

Do not confuse the PARAMETERS statement with the **VAR** statement. While you specify the parameters of the model in the PARAMETERS statement, you specify analysis variables in the **VAR** statement. See the [VAR statement](#) on page 1228 for more details.

CAUTION: The **OUTMODEL=** and **OUTRAM=** data sets do not contain any information about the PARAMETERS statement or the SAS programming statements.

PARTIAL Statement

PARTIAL *variables* ;

If you want the analysis to be based on a partial correlation or covariance matrix, use the PARTIAL statement to list the variables used to partial out the variables in the analysis. You can specify only one PARTIAL statement within the scope of each **GROUP** or PROC CALIS statement.

PATH Statement

PATH *path* <, *path* ... > ;

where *path* represents any of the following specifications:

- single-headed path for defining functional relationship
- double-headed path for specifying variances or covariances
- 1-path for specifying means or intercepts

For example, the following PATH statement contains only the single-headed paths:

```

path
v1    <==== v2,
v2    <==== v4 v5,      /* same as: v2 <==== v4 and v2 <==== v5 */
v3    <==== v5,        /* same as: v5 <==== v3 */
v4 v5 <==== v6 v7;     /* same as: v4 <==== v6, v4 <==== v7,
                        v5 <==== v6, and v5 <==== v7 */

```

Although the most common definition of paths refer to these single-headed paths, PROC CALIS extends the definition of paths to include the so-called “variance-paths,” “covariance-paths,” and “1-paths” that refer to the variance, covariance, and the mean or intercept parameters, respectively. Corresponding to these extended path definitions, PROC CALIS provides the double-headed path and 1-path syntax. For example, the following PATH statement contains single-headed paths for specifying functional relationships and double-headed paths for specifying variances and covariances:

```

path
v1    <==== v3-v5,      /* same as: v1 <==== v3, v1 <==== v4, and v1 <==== v5 */
v2    <==== v4 v5,
v3    <==== v5,
v1    <==> v1,          /* error variance of v1 */
<==> v2 v3,            /* error variances of v2 and v3 */
v2    <==> v3,          /* error covariance between v2 and v3 */
<==> [v4 v5];          /* variances and covariance for v4 and v5 */

```

The following PATH statement contains single-headed paths for specifying functional relationships and 1-paths for specifying means and intercepts:

```

path
v1    <==== v3-v5,
v2    <==== v4 v5,
v3    <==== v5,
1     <==> v1,          /* intercepts for v1 */
1     <==> v2-v3,       /* intercepts for v2 and v3 */
1     <==> v4 v5;       /* means of v4 and v5 */

```

Details about the syntax of these three different types of *paths* are described later. Instead of using double-headed paths and 1-paths, you can also specify these parameters by the [subsidiary model specification statements](#) such as the PVAR, PCOV, and the MEAN statements, as shown in the following syntactic structure of the PATH modeling language:

```

PATH path <, path ... > ;
PVAR partial-variance-parameters ;
PCOV partial-covariance-parameters ;
MEAN mean-parameters ;

```

Typically, in this syntactic structure the *paths* contains only single-headed paths for representing the functional relationships among variables, which could be observed or latent. The *paths* are separated by commas. You can specify at most one PATH statement in a model within the scope of either the PROC CALIS statement or a [MODEL](#) statement.

Next, the [PVAR](#) statement specifies the parameters for the variances or error (partial) variances. The [PCOV](#) statement specifies the parameters for the covariances or error (partial) covariances. The [MEAN](#) statement specifies the parameters for the means or intercepts. For details about these subsidiary model specification statements, see the syntax of the individual statements.

A natural question now arises. For the specification of variances, covariances, intercepts, and means, should you use the extended path syntax that includes double-headed paths and 1-paths or the subsidiary model specification statements such as the PVAR, PCOV, and MEAN statements? If you want to specify all parameters in a single statement and hence output and view all the parameter estimates in a single output table, then the extended path syntax would be your choice. If you want to use more common language for specifying and viewing the parameters or the estimates of variances, covariances, means, and intercepts, then the subsidiary model specification statements serve the purpose better.

You are not restricted to using extended path syntax or the subsidiary model statements exclusively in a PATH model specification. For example, you might specify the variance of *v1* by using the double-headed path syntax and the variance of *v2* by using the PVAR statement. The only restriction is that you cannot specify the same parameter twice. In addition, even if you specify your PATH model without using double-headed paths or 1-paths, you can include the estimation results associated with these extended paths in the same output table for the single-headed paths by using the [EXTENDPATH](#) or [GENPATH](#) option. This way all the estimates of the PATH model can be shown in a single output table.

The Single-Headed Path Syntax for Specifying Functional Relationships

var-list arrow var-list2 < = parameter-spec >

where *var-list* and *var-list2* are lists of variables, *parameter-spec* is an optional specification of parameters, and *arrow* represents either a *left-arrow* is one of the following forms:

<===, <---, <==, <--, <=, <-, or <

or a *right-arrow* is one of the following forms:

===>, --->, ==>, -->, =>, ->, or >

In each single-headed path, you specify two lists of variables: *var-list* and *var-list2*. Depending on the direction of the *arrow* specification, one group of variables contains the outcome variables and the other group contains the predictor variables. Optionally, you can specify the *parameter-spec* at the end of each path entry. You can specify the following five types of the parameters for the path entries:

- unnamed free parameters
- initial values
- fixed values
- free parameters with names provided
- free parameters with names and initial values provided

For example, in the following statement you specify a model with five paths:

```
path
  v1 <=== f1 ,
  v2 <=== f1 = (0.5) ,
  v3 <=== f1 = 1. ,
  v4 <=== f1 = b1 ,
  v5 <=== f1 = b2 (.4) ;
```

The first path entry specifies a path from *f1* to *v1*. The effect of *f1* (or the path coefficient) on *v1* is an unnamed free parameter. For this path effect parameter, PROC CALIS generates a parameter name with the *_Parm* prefix and appended with a unique integer (for example, *_Parm1*). The second path entry specifies a path from *f1* to *v2*. The effect of *f1* is also an unnamed free parameter with an initial estimate of 0.5. PROC CALIS also generates a parameter name for effect parameter. The third path entry specifies a path from *f1* to *v3*. The effect of *f1* is also a fixed value of 1.0. This value stays the same in the model estimation. The fourth path entry specifies a path from *f1* to *v4*. The effect of *f1* is a free parameter named *b1*. The fifth path entry specifies a path from *f1* to *v5*. The effect of *f1* is a free parameter named *b2*, with an initial value of 0.4.

You can specify multiple variables in the *var-list* and *var-list2* lists. For example, the following statement specifies five paths from *f1* to *v1–v5*:

```
path
  f1 ==> v1-v5;
```

All the five effects of *f1* on the five variables are unnamed free parameters. If both *var-list* and *var-list2* lists contain multiple variables, you must be careful about the order of the variables when you also specify parameters at the end of the path entry. For example, the following statement specifies the paths from the predictor variables *x1–x2* to the outcome variables *y1–y3*:

```
path
  y1-y3 <=== x1-x2 = a1-a6;
```

The PATH statement specifies six paths in the path entry. These six paths have effect parameters *a1–a6*. This specification is equivalent to the following specification:

```
path
  y1 <=== x1 = a1;
  y1 <=== x2 = a2;
  y2 <=== x1 = a3;
  y2 <=== x2 = a4;
  y3 <=== x1 = a5;
  y3 <=== x2 = a6;
```

The following statement shows another example of multiple-path specification:

```
path
  x1-x2 ==> y1-y3 = b1-b6;
```

This specification is equivalent to the following specification with separate path specifications:

```
path
  x1 ==> y1 = b1;
  x1 ==> y2 = b2;
  x2 ==> y3 = b3;
  x2 ==> y1 = b4;
  x2 ==> y2 = b5;
  x2 ==> y3 = b6;
```

You can also specify parameter with mixed types in any path entry, as shown in the following specification:

```

path
  f1 ==> y1-y3    = 1.  b1(.5) (.3) ,
  f2 ==> y4-y6    = 1.  b2  b3(.7) ;

```

This specification is equivalent to the following expanded version:

```

path
  f1 ==> y1      = 1. ,
  f1 ==> y2      = b1(.5) ,
  f1 ==> y3      = (.3) ,
  f2 ==> y4      = 1. ,
  f2 ==> y5      = b2 ,
  f2 ==> y6      = b3(.7) ;

```

Notice that in the original specification with multiple-path entries, 0.5 is interpreted as the initial value for the parameter *b1*, but not as the initial estimate for the path from *f1* to *y3*. In general, an initial value that follows a parameter name is associated with the free parameter.

If you indeed want to specify that *b1* is a free parameter *without* an initial estimate and 0.5 is the initial estimate for the path from *f1* to *y3* (while keeping all other specification the same), you can use a null initial value specification, as shown in the following statement:

```

path
  f1 ==> y1-y3    = 1.  b1() (.5) ,
  f2 ==> y4-y6    = 1.  b2  b3(.7) ;

```

This way 0.5 becomes the initial value for the path from *f1* to *y3*. Because a parameter list with mixed types might be confusing, you can break down the specifications into separate path entries to remove ambiguities. For example, you can use the following specification equivalently:

```

path
  f1 ==> y1      = 1. ,
  f1 ==> y2      = b1 ,
  f1 ==> y3      = (.5) ,
  f2 ==> y4-y6   = 1.  b2  b3(.7) ;

```

The equal signs in the path entries are optional when the parameter lists do not start with a parameter name. For example, the preceding specification is the same as the following specification:

```

path
  f1 ==> y1      1. ,
  f1 ==> y2      = b1 ,
  f1 ==> y3      (.5) ,
  f2 ==> y4-y6   1.  b2  b3(.7) ;

```

Notice that in the second path entry, you must retain the equal sign because *b1* is a parameter name. Omitting the equal sign makes the specification erroneous because *b1* is treated as a variable. This might cause serious estimation problems. Omitting the equal signs might be cosmetically appealing in specifying fixed values or initial values (for example, the first and the third path entries). However, the gain of doing that is not much as compared to the clarity of specification that results from using the equal signs consistently.

NOTE: You do not need to specify single-headed paths from the errors or disturbances (that is, error terms) in the PATH model specification, even though the functional relationships between variables are not assumed to be perfect. Essentially, the roles of error terms in the PATH model are in effect represented by the

associated default error variances of the endogenous variables, making it unnecessary to specify any single-headed paths from error or disturbance variables.

The Double-Headed Path Syntax That Uses Two Variable Lists for Specifying Variances and Covariances

var-list two-headed-arrow var-list2 < = parameter-spec >

where a *two-headed-arrow* is one of the following forms:

<==>, *<-->*, *<=>*, *<->*, or *<>*

This syntax enables you to specify covariances between the variables in *var-list* and the variables in *var-list2*. Consider the following example:

```
path
  v1      <==>  v2,
  v3 v4   <==>  v5 v6 v7 = cv1-cv6;
```

The first double-headed path specifies the covariance between v1 and v2 as an unnamed free parameter. PROC CALIS generates a name for this unnamed free parameter. The second double-headed path specifies six covariances with parameters named cv1–cv6. This multiple-covariance specification is equivalent to the following elementwise covariance specification:

```
path
  v3 <==> v5   = cv1,
  v3 <==> v6   = cv2,
  v3 <==> v7   = cv3,
  v4 <==> v5   = cv4,
  v4 <==> v6   = cv5,
  v4 <==> v7   = cv6;
```

Note that the order of variables in the list is important for determining the assignment of the parameters in the *parameter-spec* list.

If the same variable appears in both of the *var-list* and *var-list2* lists, the “covariance” specification becomes a variance specification for that variable. For example, the following statement specifies two variances:

```
path
  v1      <==>  v1      = 1.0,
  v2      <==>  v2 v3 = sigma2 cv23;
```

The first double-headed path entry specifies the variance of v1 as a fixed value of 1.0. The second double-headed path entry specifies the variance of v2 as a free parameter named sigma2, and then the covariance between v2 and v3 as a free parameter named cv23.

It results in an error if you attempt to use this syntax to specify the variance and covariances among a set of variables. For example, suppose you intend to specify the variances and covariances among v1–v3 as unnamed free parameters by the following statement:

```
path
  v1-v3   <==>  v1-v3 ;
```

This specification expands to the following elementwise specification:

```

path
  v1 <==> v1 ,
  v1 <==> v2 ,
  v1 <==> v3 ,
  v2 <==> v1 ,
  v2 <==> v2 ,
  v2 <==> v3 ,
  v3 <==> v1 ,
  v3 <==> v2 ,
  v3 <==> v3 ;

```

There are nine variance or covariance specifications, but all of the covariances are specified twice. This is treated as a duplication error. The correct way is to specify only the nonredundant covariances, as shown in the following elementwise specification:

```

path
  v1 <==> v1 ,
  v2 <==> v1 ,
  v2 <==> v2 ,
  v3 <==> v1 ,
  v3 <==> v2 ,
  v3 <==> v3 ;

```

However, the elementwise specification is quite tedious when the number of variables is large. Fortunately, there is another syntax for double-headed paths to deal with this situation. This syntax is discussed next.

The Double-Headed Path Syntax That Uses a Single Variable List for Specifying Variances

two-headed-arrow var-list < = parameter-spec >

This syntax enables you to specify variances among the variables in *var-list*. Consider the following example:

```

path
  <==> v1      = (0.8) ,
  <==> v2-v4 ;

```

The first double-headed path entry specifies the variance of v1 as an unnamed free parameter with an initial estimate of 0.8. The second double-headed path entry specifies the variances of v2–v4 as unnamed free parameters. No initial values are given for these three variances. PROC CALIS generates names for all these variance parameters. You can specify these variances equivalently by the elementwise covariance specification syntax, as shown in the following, but former syntax is much more efficient.

```

path
  v1 <==> v1      = (0.8) ,
  v2 <==> v2 ,
  v3 <==> v3 ,
  v4 <==> v4 ;

```

The Double-Headed Path Syntax That Uses a Single Variable List for Specifying Variances and Covariances

two-headed-arrow [*var-list*] < = *parameter-spec* >

This syntax enables you to specify all the variances and covariances among the variables in *var-list*. For example, the following statement specifies all the variances and covariances among v2–v4:

```
path
  <==> [v2-v4]   = 1.0   cv32   cv33(0.5)   cv42   .7   cv44;
```

This specification is more efficient as compared with the following equivalent specification with element-wise variance or covariance definitions:

```
path
  v2 <==> v2      = 1.0 ,
  v3 <==> v2      = cv32 ,
  v3 <==> v3      = cv33(0.5) ,
  v4 <==> v2      = cv42 ,
  v4 <==> v3      = .7 ,
  v4 <==> v4      = cv44;
```

The double-headed path Syntax for Specifying Nonredundant Covariances

two-headed-arrow (*var-list*)< = *parameter-spec* >

This syntax enables you to specify all the nonredundant covariances among the variables in *var-list*. For example, the following statement specifies all the nonredundant covariances between v2–v4:

```
path
  <==> (v2-v5)   = cv1-cv6;
```

This specification is equivalent to the following elementwise specification:

```
path
  v3 <==> v2      = cv1 ,
  v4 <==> v2      = cv2 ,
  v4 <==> v3      = cv3 ,
  v5 <==> v2      = cv4 ,
  v5 <==> v3      = cv5 ,
  v5 <==> v4      = cv6 ;
```

The 1-path Syntax for Specifying Means and Intercepts

1 *right-arrow* *var-list* < = *parameter-spec* >

where a *right-arrow* is one of the following forms:

==>, --->, ==>, -->, =>, ->, or >

This syntax enables you to specify the means or intercepts of the variables in *var-list* as paths from the constant **1**. Consider the following example:

```

path
  v1 <=== v2-v4,
  1 ==> v1 = alpha,
  1 ==> v2-v4 = 3*kappa;

```

The first single-headed path specifies that v_1 is predicted by variables v_2 , v_3 , and v_4 . Next, the first 1-path entry specifies either the intercept of v_1 as a free parameter named α . It is the intercept, rather than the mean, of v_1 because endogenous in the PATH model. The second 1-path entry specifies the means of v_2 – v_4 as constrained parameters. All these means or intercepts are named κ so that they have the same estimate.

Therefore, whether the parameter is a mean or an intercept specified with the 1-path syntax depends on whether the associated variable is endogenous or exogenous in the model. The intercept is specified if the variable is endogenous. Otherwise, the mean of the variable is specified. Fortunately, any variable in the model can have either a mean or intercept (but not both) to specify. Therefore, the 1-path syntax is applicable to either the mean or intercept specification without causing conflicts.

Shorter and Longer Parameter Lists

If you provide fewer parameters in *parameter-spec* than the number of paths in a *path* entry, all the remaining parameters are treated as unnamed free parameters. For example, the following specification specifies the free parameter β to the first path and assigns unnamed free parameters to the remaining four paths:

```

path
  f1 ==> y1 z1 z2 z3 z4 = beta;

```

This specification is equivalent to the following specification:

```

path
  f1 ==> y1 = beta,
  f1 ==> z1 z2 z3 z4;

```

If you intend to fill up all values with the last parameter specification in the list, you can use the continuation syntax [...], [...], or [...], as shown in the following example:

```

path
  f1 ==> y1 z1 z2 z3 z4 = beta gamma [...];

```

This specification is equivalent to the following specification:

```

path
  f1 ==> y1 z1 z2 z3 z4 = beta 4*gamma;

```

The repetition factor $4*$ means that γ repeats 4 times.

However, you must be careful not to provide too many parameters. For example, the following specification results in an error:

```

path
  SES_Factor ==> y1 z1 z2 z3 z4 = beta gamma1-gamma6;

```

Because there are only five paths in the specification, parameters γ_5 and γ_6 are excessive.

Default Parameters

It is important to understand the default parameters in the PATH model. First, knowing which parameters are default free parameters makes your specification more efficient by omitting the specifications of those parameters that can be set by default. For example, because all variances and covariances among exogenous variables (excluding error terms) are free parameters by default, you do not need to specify them in the PATH model if these variances and covariances are not constrained. Second, knowing which parameters are default fixed zero parameters enables you to specify your model accurately. For example, because all error covariances in the PATH model are fixed zeros by default, you must use the PCOV statement or the double-headed path syntax to specify the partial (error) covariances among the endogenous variables if you want to fit a model with correlated errors. See the section “[Default Parameters in the PATH Model](#)” on page 1293 for details about the default parameters of the PATH model.

Modifying a PATH Model from a Reference Model

If you define a new model by using a reference (old) model in the **REFMODEL** statement, you might want to modify some path specifications from the PATH statement of the reference model before transferring the specifications to the new model. To change a particular path specification from the reference model, you can simply respecify the same path with the desired parameter specification in the PATH statement of the new model. To delete a particular path and its associated parameter from the reference model, you can specify the desired path with a missing value specification in the PATH statement of the new model.

```
PATH path <, path ... > ;
PVAR partial-variance-parameters ;
PCOV partial-covariance-parameters ;
MEAN mean-parameters ;
```

The new model is formed by integrating with the old model in the following ways:

- Duplication: If you do not specify in the new model a parameter location that exists in the old model, the old parameter specification is duplicated in the new model.
- Addition: If you specify in the new model a parameter location that does not exist in the old model, the new parameter specification is used in the new model.
- Deletion: If you specify in the new model a parameter location that also exists in the old model and the new parameter is denoted by the missing value ‘.’, the old parameter specification is not copied into the new model.
- Replacement: If you specify in the new model a parameter location that also exists in the old model and the new parameter is not denoted by the missing value ‘.’, the new parameter specification replaces the old one in the new model.

For example, consider the following specification of a two-group analysis:

```
proc calis;
  group 1 / data=d1;
  group 2 / data=d2;
  model 1 / group=1;
  path
    v1 <=== f1   = 1.,
    v2 <=== f1   = load1,
    v3 <=== f1   = load2,
```

```

        f1 <=== v4    = b1,
        f1 <=== v5    = b2,
        f1 <=== v6    = b3;
    pvar
        E1-E3        = ve1-ve3,
        f1            = vd1,
        v5-v6        = phi4-phi6;
    pcov
        v1 v2        = cve12;
model 2 / group=2;
    refmodel 1;
    path
        v3 <=== f1    = load1,
    pcov
        v1 v2        = .,
        v2 v3        = cve23;
run;

```

You specify Model 2 by referring to Model 1 in the **REFMODEL** statement. Model 2 is the new model that refers to the old model, Model 1. This example illustrates the four types of model integration rules for the new model:

- **Duplication:** All parameter specifications, except for the partial covariance between **v1** and **v2** and the **v3 <=== f1** path in the old model, are duplicated in the new model.
- **Addition:** The parameter **cve23** for the partial covariance between **v2** and **v3** is added in the new model because there is no corresponding specification in the old model.
- **Deletion:** The specification of partial covariance between **v1** and **v2** in the old model is not copied into the new model, as indicated by the missing value '.' specified in the new model.
- **Replacement:** The new path **v3 <=== f1** replaces the same path in the old model with parameter **load1** for the path coefficient. Thus, in the new model paths **v3 <=== f1** and **v2 <=== f1** are now constrained to have the same path coefficient parameter **load1**.

PCOV Statement

PCOV *assignment* <, *assignment* ... > ;

where *assignment* represents:

var-list < * *var-list2* > < = *parameter-spec* >

The PCOV statement is a subsidiary model specification statement for the **PATH** model. You can use the PCOV statement only with the PATH modeling language. The PCOV statement specifies the covariances of exogenous variables, or the error covariances of endogenous variables in the PATH model. It can also specify the covariance between an exogenous variable and the error term of an endogenous variables, although this usage is rare in practice.

In each *assignment* of the COV statement, you specify variables in the *var-list* and the *var-list2* lists, followed by the covariance parameter specification in the *parameter-spec* list. The latter two specifications

are optional. The syntax of the PCOV statement is the same as that of the [COV statement](#) on page 1132 for details about specifying within- and between-list (partial) covariances.

The concept behind the PCOV statement is broader than that of the [COV statement](#). The PCOV statement supports the partial covariance parameter specification in addition to the covariance parameter specification, which is the only type of parameter that the [COV statement](#) supports. This difference is also reflected from the sets of *var-list* and *var-list2* that you can use in the PCOV statement. In the [COV statement](#), variables on the left-hand side of an *assignment* must be exogenous. However, in the PCOV statement, you can specify both exogenous and endogenous variables. If a pair of variables are both exogenous in a specification, you are defining a covariance parameter between the variables. If a pair of variables are both endogenous in a specification, you are defining a partial covariance parameter between the variables. This partial covariance is usually interpreted as the error covariance between the two endogenous variables. If one variable is exogenous while the other is endogenous, you are defining a covariance parameter between the exogenous variable and the error term for the endogenous variable.

You can specify the following five types of the parameters for the partial covariances in the PCOV statement:

- an unnamed free parameter
- an initial value
- a fixed value
- a free parameter with a name provided
- a free parameter with a name and initial value provided

For example, consider a PATH model with exogenous variables x1, x2, and x3 and endogenous variables y4, y5 and y6. The following PCOV statement shows the five types of specifications in five *assignments*:

```
pcov x1 x2 ,
      x1 x3 = (0.5) ,
      x2 x3 = 2.0,
      y4 y5 = psi1,
      y5 y6 = psi2(0.4) ;
```

In this statement, the covariance between x1 and x2 is specified as an unnamed free parameter. For this covariance, PROC CALIS generates a parameter name with the `_Parm` prefix and appended with a unique integer (for example, `_Parm1`). The covariance between x1 and x3 is an unnamed free parameter with an initial value of 0.5. PROC CALIS also generates a parameter name for this covariance. The covariance between x2 and x3 is a fixed value of 2.0. This value stays the same during the estimation. The error covariance between endogenous variables y4 and y5 is a free parameter named `psi1`. The error covariance between endogenous variables y5 and y6 is a free parameter named `psi2` with an initial value of 0.4.

The syntax of the PCOV statement is the same as the syntax of the [COV statement](#). See the [COV statement](#) for more illustrations about the usage.

Default Covariance Parameters

Although the PCOV statement specification is conceptually broader than the [COV statement](#) specification, their related default set of covariance parameters is the same—that is, all covariances among *exogenous* manifest and latent variables (excluding error or disturbance variables) are free parameters. Because the

PCOV statement applies only to the PATH model, it is easy to understand why the covariances do not apply to the error or disturbance terms. The PATH model, as implemented in PROC CALIS, simply does not use any explicit error or disturbance terms. For the default free covariance parameters, PROC CALIS generate the parameter names with the `_Add` prefix and appended with unique integer suffixes. You can also use the PCOV statement specification to override these default covariance parameters in situations where you want to set parameter constraints, provide initial or fixed values, or make parameter references.

Another type of default partial covariances are fixed zeros. This default applies to the partial (error) covariances among all *endogenous* variables, and to the partial covariances between all *exogenous* variables and all *endogenous* variables in the path model. Again, you can override the default fixed values by providing explicit specification of these partial or error covariances in the PCOV statement.

Modifying a Covariance or Partial Covariance Parameter Specification from a Reference Model

If you define a new PATH model by using a reference (old) model in the `REFMODEL` statement, you might want to modify some parameter specifications from the PCOV statement of the reference model before transferring the specifications to the new model. To change a particular partial covariance specification from the reference model, you can simply respecify the same covariance with the desired parameter specification in the PCOV statement of the new model. To delete a particular partial covariance parameter from the reference model, you can specify the desired partial covariance with a missing value specification in the PCOV statement of the new model.

For example, suppose that you are defining a new PATH model by using the `REFMODEL` statement and that the covariance between variables `f1` and `v2` is defined as a fixed or free parameter in the reference model. If you do not want this fixed parameter specification to be copied into your new model, you can use the following specification in the new model:

```
pcov f1 v2 = . ;
```

Note that the missing value syntax is valid only when you use it with the `REFMODEL` statement. See the section “[Modifying a PATH Model from a Reference Model](#)” on page 1211 for a more detailed example of the PATH model respecification.

As discussed in the section “[Default Covariance Parameters](#)” on page 1213, PROC CALIS generates some default free covariance parameters for the PATH model if you do not specify them explicitly in the PCOV statement. When you use the `REFMODEL` statement for defining a reference model, these default free covariance parameters in the old (reference) model are not transferred to the new model. Instead, the new model generates its own set of default free covariance parameters *after* the new model is resolved from the reference model, the `REFMODEL` statement options, the `RENAMEPARM` statement, and the PCOV statement specifications in the new model. This also implies that if you want any of the (partial) covariance parameters to be constrained across the models by means of the `REFMODEL` specification, you must specify them explicitly in the PCOV statement of the reference model so that the same (partial) covariance specification is transferred to the new model.

PVAR Statement

```
PVAR assignment < , assignment ... > ;
```

where *assignment* represents:

var-list <= *parameter-spec* >

The PVAR statement specifies the variance or error (partial) variance parameters in connection with the confirmatory FACTOR and PATH models.

In each *assignment* of the PVAR statement, you list the *var-list* that you want to specify for their variances or error (partial) variances. Optionally, you can provide a list of parameter specifications (*parameter-spec*) after an equal sign for each *var-list* list. The syntax of the PVAR statement is exactly the same as that of the [VARIANCE](#) statement. See the [VARIANCE statement](#) on page 1231 for details about the syntax.

The concept behind the PVAR statement is broader than that of the [VARIANCE](#) statement. The PVAR statement supports the partial variance parameter specification in addition to the variance parameter specification, which is the only type of parameters that the [VARIANCE](#) statement supports. This difference is reflected from the set of *var-list* you can use in the PVAR statement. You can specify both exogenous variables and endogenous variables in the *var-list* list of the PVAR statement, but you can specify only exogenous variables in the *var-list* list of the [VARIANCE](#) statement. This conceptualization of the PVAR statement is needed in the FACTOR and PATH modeling languages because error variables are not explicitly defined in these models. You specify the variance of a variable if the variable in the *var-list* list of the PVAR statement is an exogenous (independent) variable in the FACTOR or PATH model. You specify the error (partial) variance of a variable if the variable in the *var-list* list of the PVAR statement is an endogenous (dependent) variable in the FACTOR or PATH model.

You can specify the following five types of the parameters for the partial variances in the PVAR statement:

- an unnamed free parameter
- an initial value
- a fixed value
- a free parameter with a name provided
- a free parameter with a name and initial value provided

For example, consider a PATH model with exogenous variables x1, x2, and x3 and endogenous variables y4 and y5. The following PVAR statement illustrates the five types of specifications in five *assignments*:

```
pvar x1 ,
      x2 = (2.0) ,
      x3 = 1.0 ,
      y4 = psi1 ,
      y5 = psi2(0.6) ;
```

In this statement, the variance of x1 is specified as an unnamed free parameter. For this variance, PROC CALIS generates a parameter name with the `_Parm` prefix and appended with a unique integer (for example, `_Parm1`). The variance of x2 is an unnamed free parameter with an initial value of 2.0. PROC CALIS also generates a parameter name for this variance. The variance of x3 is a fixed value of 1.0. This value stays the same during the estimation. The error variance of endogenous variable y4 is a free parameter named `psi1`. The error variance of endogenous variable y5 is a free parameter named `psi2` with an initial value of 0.6.

The syntax of the PVAR statement is the same as the syntax of the [VARIANCE](#) statement. See the [VARIANCE](#) statement for more illustrations about the usage.

Default Partial Variance Parameters

By default, all variances of the *exogenous* manifest and latent variables and all error (partial) variances of the *endogenous* manifest and latent variables are free parameters in the FACTOR or PATH model. For these default free variance parameters, PROC CALIS generates the parameter names with the `_Add` prefix and appended with unique integer suffixes. You can also use the PVAR statement specification to override these default variance parameters in situations where you want to specify parameter constraints, provide initial or fixed values, or make parameter references.

In the FACTOR or PATH model, a variable can either be exogenous or endogenous. Therefore, the default free parameters covers all the possible variance or partial variance parameters in the model. There are no default fixed zeros for any variances or partial variances in the model.

Modifying a Variance or Partial Variance Parameter Specification from a Reference Model

If you define a new FACTOR or PATH model by using a reference (old) model in the `REFMODEL` statement, you might want to modify some parameter specifications from the PVAR statement of the reference model before transferring the specifications to the new model. To change a particular variance or partial variance specification from the reference model, you can simply respecify the same variance or partial variance with the desired parameter specification in the PVAR statement of the new model. To delete a particular variance parameter from the reference model, you can specify the desired variance or partial variance with a missing value specification in the PVAR statement of the new model.

For example, suppose that the variance of V1 is specified in the reference PATH model but you do not want this variance specification to be transferred to the new model. You can use the following PVAR statement specification in the new model:

```
pvar
    v2 = .;
```

Note that the missing value syntax is valid only when you use the `REFMODEL` statement. See the section “[Modifying a FACTOR Model from a Reference Model](#)” on page 1146 for a more detailed example of FACTOR model respecification. See the section “[Modifying a PATH Model from a Reference Model](#)” on page 1211 for a more detailed example of PATH model respecification.

As discussed the section “[Default Partial Variance Parameters](#)” on page 1216, PROC CALIS generates default free variance parameters for the exogenous variables and default free error variance parameters for the endogenous variables in the confirmatory FACTOR or PATH model. When you use the `REFMODEL` statement for defining a reference model, these default free variance parameters in the old (reference) model are not transferred to the new model. Instead, the new model generates its own set of default free variance parameters *after* the new model is resolved from the reference model, the `REFMODEL` statement options, the `RENAMEPVAR` statement, and the PVAR statement specifications in the new model. If you want any of the variance or error (partial) variance parameters to be constrained across the models by means of the `REFMODEL` specification, you must specify them explicitly in the PVAR statement of the reference model so that the same variance or error (partial) variance specification is transferred to the new model.

RAM Statement

```
RAM < VAR=variable-list | [ variable-list=number-list <, variable-list=number-list ... > ], > < ram-entry
    <, ram-entry ... > >;
```

where *variable-list* is a list of variables for the rows and columns of the `_A_` and `_P_` matrices and the rows of the `_W_` vector of the RAM model, *number-list* is a list of positive integers that denote the order of the specified variables, and *ram-entry* is a parameter specification for an element in one of the three RAM model matrices. You can specify latent variables in addition to observed variables in the VAR= option.

RAM stands for the reticular action model developed by McArdle (1980). The RAM model implemented in PROC CALIS extends the original RAM model with the specification of the mean vector in the `_W_` vector. See the section “[The RAM Model](#)” on page 1294 for details about the model.

The RAM statement specification consists of the list of the variables in the model and the parameters and their locations the RAM model matrices. For example, consider the following simple RAM model specification:

```
ram var= x1-x2 y3,
      _A_ 3 1,
      _A_ 3 2;
```

In this statement, variables x1, x2, and y3 are specified in the VAR= option. The variable order in the VAR= option is important. The same variable order applies to the rows and columns of the `_A_` matrix. Next, there are two *ram-entries*. The first *ram-entry* specifies that the third variable (y3) has a path from the first variable (x1). Similarly, the second *ram-entry* specifies that y3 has a path from x2.

Specifying the VAR= Option

In the VAR= option, you specify the list of observed and latent variables in the RAM model. There are two ways to specify the VAR= list. The first way is a simple listing of variables. For example, you specify a total of 18 variables in the RAM model in the following statement:

```
ram var= a b c x1-x5 y1-y10;
```

The order of the variables in this VAR= list is important. The same variable order applies to the rows and columns of the `_A_` and `_P_` matrices and the rows of the `_W_` matrices. Although it is not required to arrange the variables according to whether they are observed or latent in the VAR= list, you can do so for your own convenience. PROC CALIS checks each variable in the VAR= list against the associated data sets to determine whether the variable is observed or latent.

When you specify the parameters in the *ram-entries*, you represent variables by the variable numbers that refer to the VAR= list. Therefore, it is important to make correct association of the variables and their order on the VAR= list. To this end, you can add some comments in your VAR= list to make the variable numbers explicit. For example,

```
ram var= a      /* 1 */
        b      /* 2 */
        c      /* 3 */
        x1-x5  /* 4-8 */
        y1-y10 /* 9-18 */;
```

Another way to specify VAR= list is to provide the *variable-lists* together with explicit ordering indicated in the *number-lists*. For example, in the following statement you specify exactly the same variable list as that in the preceding example:

```
ram var= [x1-x5 = 4 to 8, c = 3, y1-y10 = 9 to 18, a = 1, b = 2];
```

Apart from showing how you can construct the VAR= list in a very general way with the *number-lists*, there is no particular reason why the *variable-lists* in the preceding specification are not in either an ascending or a descending order. Perhaps a more natural and useful way to use this type of explicit ordering specification is to place variables in exactly the same order as intended. For example, the following VAR= specification serves as a “key” of the variable numbers in the subsequent *ram-entries*:

```
ram var= [x1 = 1, x2 = 2, y1 = 3, y2 = 4, y3 = 5],
  _A_   1   2 ,
  _P_   2   2 ;
```

With reference to the explicit variable numbers in the VAR= list, you can interpret the `_A_[1, 2]` specification immediately as the effect from x2 to x1, and the `_P_[2, 2]` specification as the variance of x2.

If the VAR= option is not specified in the RAM statement, the *n* observed variables in the VAR statement are used as the first *n* variables in the VAR= list. If you specify neither the VAR= option in the RAM statement nor the VAR statement, all *n* numerical variables in the associated data sets serve as the first *n* variables in the RAM model matrices. If there are more than *n* variables used in the *ram-entries*, the extra variables are all treated as latent variables in the RAM model.

Latent variables generated by PROC CALIS for the RAM model are named in two different ways, depending on whether your RAM model is specified under a MODEL statement. If you do not use the MODEL statement (for example, in situations with single-group analyses), latent variables are named `_Factor1`, `_Factor2`, and so on. If your RAM model is defined within the scope of a MODEL statement, latent variables are named `_Mdlk_F1`, `_Mdlk_F2`, and so on, where *k* is substituted with the model number that is specified in the MODEL statement. For example, `_Mdl2_F1` is a latent factor that is specified under a RAM model within the scope of the MODEL statement with 2 as its model number.

Because data sets might contain nonnumerical variables, implicit variable ordering deduced from the data sets is sometimes obscured. Therefore, it is highly recommended that you use the VAR= option to list all the variables in the RAM model.

Specifying a *ram-entry*

matrix-name | *matrix-number* *row-number* *column-number* <*parameter-spec*>

A *ram-entry* is a parameter specification of a matrix element of the RAM model. In each *ram-entry*, you first specify the matrix by using either the *matrix-name* or the *matrix-number*. Then you specify the *row-number* and the *column-number* of the element of the matrix. At the end of the *ram-entry*, you can optionally specify various kinds of parameters in *parameter-spec*. You can specify as many *ram-entries* as needed in your RAM model. *Ram-entries* are separated by commas. For example, consider the following specification:

```
ram var= x1-x2 y3,
  _A_ 3 1 1.,
  _A_ 3 2;
```

You specify three variables in the VAR= option of the RAM statement. In the first *ram-entry*, variable y3 has a path from variable x1 with a fixed path coefficient 1. In the second *ram-entry*, variable y3 has a path from variable x2. Because the *parameter-spec* is blank, the corresponding path coefficient (or the effect from x2 on y3) is a free parameter by default.

Specifying the matrix-name or matrix-number

The three model matrices in the RAM model are: `_A_`, `_P_`, and `_W_`. See the section “The RAM Model” on page 1294 for the mathematical formulation of the RAM model. The *matrix-name* or *matrix-number* specifications in the *ram-entries* refer to these model matrices. You can use the following keywords for *matrix-name* or *matrix-number*:

`_A_`, `_RAMA_`, or 1 for the elements in the **A** matrix, which is for path coefficients or effects
`_P_`, `_RAMP_`, or 2 for the elements in the **P** matrix, which is for variances and covariances
`_W_`, `_RAMW_`, or 3 for the elements in the **W** vector, which is for intercepts and means

Specifying the row-number and column-number

After you specify the *matrix-name* or *matrix-number* in a *ram-entry*, you need to specify the *row-number* and *column-number* that correspond to the intended element of the matrix being specified.

Specifying the parameter-spec

You can specify three types of parameters in *parameter-spec*:

- A free parameter without an initial estimate: blank or *parameter-name*

You can specify a free parameter for the matrix element in a *ram-entry* by either omitting the *parameter-spec* (that is, leaving it blank) or specifying a *parameter-name*. For example, both of the following *ram-entries* specify that `_A_[3,1]` is a free parameter in the RAM model:

```
_A_ 3 1
```

and

```
_A_ 3 1 beta
```

The difference is that in the latter you name the effect (path coefficient) for the `_A_[3,1]` element as `beta`, while in the former PROC CALIS generates a free parameter name (prefixed with `_Parm` and followed by a unique parameter number) for the specified element. Leaving the *parameter-spec* blank is handy if you do not need to refer to this parameter in your code. But when you need to specify parameter constraints by referring to parameter names, the *parameter-name* syntax becomes necessary. For example, the following specification constrains the `_A_[3,1]` and `_A_[3,2]` paths to have equal effects (path coefficients) because they have the same *parameter-name* `beta`:

```
ram var= x1-x2 y3,
      _A_ 3 1 beta,
      _A_ 3 2 beta;
```

- A free parameter with an initial estimate: *(number)* or *parameter-name (number)*

You can specify a free parameter with an initial estimate in a *ram-entry* by either specifying the initial estimate within parentheses or specifying a *parameter-name* followed by the parenthesized initial estimate. For example, both of the following *ram-entries* specify that `_A_[3,1]` is a free parameter with an initial estimate of 0.3 in the RAM model:

```
_A_ 3 1 (0.3)
```

and

```
_A_ 3 1 beta (0.3)
```

In the latter you name the effect (path coefficient) for the `_A_[3,1]` element as `beta`, while in the former PROC CALIS generates a free parameter name (prefixed with `_Parm` and followed by a unique parameter number). The latter syntax is necessary when you need to specify parameter constraints by referring to the parameter name `beta`. The former syntax is more convenient when you do not need to refer to this parameter in other specifications.

For the latter syntax with a *parameter-name* specified, you can omit the pair of parentheses or exchange the position of *parameter-name* and *number* (or both) without changing the nature of the parameter. That is, you can use the following equivalent specifications for a named free parameter with initial values:

```
_A_ 3 1 beta 0.3
```

and

```
_A_ 3 1 .3 beta
```

- A fixed parameter value: *number*

You can specify a fixed value by simply providing it as the *parameter-spec* in a *ram-entry*. For example, in the following syntax you specify that `_A_[3,1]` is a fixed value of 0.3:

```
_A_ 3 1 0.3
```

The fixed value for `_A_[3,1]` does not change during the estimation. To distinguish this syntax from the initial value specification, notice that you do not put `0.3` inside parentheses, nor do you put a *parameter-name* before or after the provided value.

Notes and Cautions about Specifying *ram-entries*

- Older versions of PROC CALIS treat a blank *parameter-spec* in the *ram-entry* as a fixed constant 1. This is no longer the case in this version of PROC CALIS. Fixed values such as 1.0 must be specified explicitly.
- The *row-number* and *column-number* in the *ram-entries* refer to the VAR= variable list of the RAM statement. An exception is for the `_W_` vector, of which the *column-number* should always be 1 and does not refer to any particular variable.
- When a *row-number* or *column-number* in a *ram-entry* (except for the *column-number* of `_W_`) does not have any reference in the VAR= variable list (or is greater than the number of default observed variables when the VAR= option is not specified), PROC CALIS treats the corresponding row or column variable as a latent variable and generates variable names for it.

- The largest row or column number used in any *ram-entry* should not exceed the sum of observed and latent variables intended in the RAM model. Otherwise, some extraneous latent variables might be created.

Default Parameters

It is important to understand the default parameters in the RAM model. First, if you know which parameters are default free parameters, you can make your specification more efficient by omitting the specifications of those parameters that can be set by default. For example, because all exogenous variances and error variances in the RAM model are free parameters by default, you do not need to specify the diagonal elements of the *_P_* matrix if they are not constrained in the model. Second, if you know which parameters are default free parameters, you can specify your model accurately. For example, because all the error covariances in the RAM model are fixed zeros by default, you must specify the corresponding off-diagonal elements of the *_P_* matrix in the *ram-entries*. See the section “[Default Parameters in the RAM Model](#)” on page 1301 for details about the default parameters of the RAM model.

Modifying a RAM Model from a Reference Model

This section assumes that you use a **REFMODEL** statement within the scope of a **MODEL** statement and that the reference model (or base model) is also a RAM model. The reference model is called the old model, and the model that refers to this old model is called the new model. If the new model is not intended to be an exact copy of the old model, you can use the following extended RAM modeling language to make modifications on the model specification. The syntax for modifications is very much the same as the ordinary RAM modeling language (see the section “[RAM Statement](#)” on page 1216), except that you cannot specify the **VAR=** option in the RAM statement. The reason is that the **VAR=** variable list in the new RAM model should be exactly the same as the old model; otherwise, the *row-number* and *column-number* in the *ram-entries* would not have the same references and thus would make model referencing meaningless. Hence, the syntax for respecifying (modifying) the RAM model contains only the *ram-entries*:

RAM *ram-entry* <, *ram-entry* ... > ;

The syntax of the *ram-entry* is the same as that of the original RAM statement, with an addition of the missing value specification for the *parameter-spec*, which denotes the deletion of a parameter location.

The new model is formed by integrating with the old model in the following ways:

Duplication:	If you do not specify in the new model a parameter location (matrix element) that exists in the old model, the old parameter specification is duplicated in the new model.
Addition:	If you specify in the new model a parameter location (matrix element) that does not exist in the old model, the new parameter specification is added to the new model.
Deletion:	If you specify in the new model a parameter location (matrix element) that also exists in the old model and the new <i>parameter-spec</i> is denoted by the missing value ‘.’, the old parameter specification is not copied into the new model.
Replacement:	If you specify in the new model a parameter location (matrix element) that also exists in the old model and the new parameter is not denoted by the missing value ‘.’, the new parameter specification replaces the old one in the new model.

For example, consider the following two-group analysis:

```

proc calis;
  group 1 / data=d1;
  group 2 / data=d2;
  model 1 / group=1;
    ram
      var = [V1-V6 = 1 to 6, F1 = 7],
      _A_ 1 7 1.,
      _A_ 2 7 load1,
      _A_ 3 7 load2,
      _A_ 7 4 ,
      _A_ 7 5 ,
      _A_ 7 6 ,
      _P_ 1 1 ,
      _P_ 2 2 ,
      _P_ 3 3 ,
      _P_ 7 7 ,
      _P_ 4 4 ,
      _P_ 5 5 ,
      _P_ 6 6 ,
      _P_ 1 2 cve12;
  model 2 / group=2;
    refmodel 1;
    ram
      _A_ 3 7 load1,
      _P_ 1 2 .,
      _P_ 2 3 cve23;
run;

```

In this example, you specify Model 2 by referring to Model 1 in the **REFMODEL** statement. Model 2 is the new model which refers to the old model, Model 1. This example illustrates the four types of model integration process by PROC CALIS:

- Duplication: All parameter specifications, except for **_A_[3, 7]** and **_P_[1, 2]**, in the old model are duplicated in the new model.
- Addition: The new parameter **cve23** is added for the matrix element **_P_[2, 3]** in the new model.
- Deletion: The parameter location **_P_[1, 2]** and associated parameter **cve12** are not copied into the new model, as indicated by the missing value '.' in the new model specification.
- Replacement: The **_A_[3, 7]** path in the new model replaces the same path in the old model with another parameter for the path coefficient. As a result, in the new model paths specified by **_A_[3, 7]** and **_A_[2, 7]** are constrained to have the same path coefficient parameter **load1**.

PROC CALIS might have generated some default parameters (named with the '_Add' prefix) for the old (reference) model. These default parameters in the old (reference) model do *not* transfer to the new model. Only after the new model is resolved from the reference model, the **REFMODEL** statement options, the **RENAMEPARAM** statement, and the model respecification are the default parameters of the new RAM model generated. In this way, the generated parameters in the new model are not constrained to be the same as the corresponding parameters in the old (reference) model. If you want any of these default parameters to be constrained across the models, you must specify them explicitly in the *ram-entries* of the RAM statement

of the reference model so that these specifications are duplicated to the new model via the [REFMODEL](#) statement.

REFMODEL Statement

REFMODEL *model-number* *</ options>* ;

The REFMODEL statement is not a modeling language itself. It is a tool for referencing and modifying models. It is classified into one of the modeling languages because its role is similar to other modeling languages.

REFMODEL *model-number* *</ options>* ;
RENAMEPARM *parameter renaming* ;
main model specification statement ;
subsidiary model specification statements ;

In the REFMODEL statement, you specify the *model-number* (between 1 and 9,999, inclusive) of the model you are making reference to. The reference model must be well-defined in the same PROC CALIS run. In the *options*, you can rename all the parameters in the reference model by adding a prefix or suffix so that the current model has a new set of parameters. The [RENAMEPARM](#) statement renames individual parameters in the reference model to new names. In the [main model specification statement](#) and the [subsidiary model specification statements](#), you can respecify or modify the specific parts of the reference model. The specification of these statements must be compatible with the model type of the reference model.

NOTE: The REFMODEL statement does *not* simply copy model specifications from a reference model. If you do not change any of the parameter names of the reference model by any of the REFMODEL statement options, the REFMODEL statement copies only the *explicit* specifications from the reference model to the new model. However, the REFMODEL statement does not copy the default parameters from the reference model to the new model. For example, consider the following statements:

```
proc calis;
  group 1 / data=a1;
  group 2 / data=a2;
  model 1 / group=1;
    path x1 ==> x2;
  model 2 / group=2;
    refmodel 1;
run;
```

In this example, Model 2 makes reference to Model 1. This means that the path relationship between x1 and x2 as specified in Model 1 is exactly the same path relationship you want Model 2 to have. The path coefficients in these two models are constrained to be the same. However, the variance parameter of x1 and the error variance parameter for x2 are not constrained in these models. Rather, these two parameters are set by default in these models separately. If you intend to constrain all parameters in the two models, you can specify all the parameters in Model 1 explicitly and use the REFMODEL statement for Model 2, as shown in the following statements:

```
proc calis;
  group 1 / data=a1;
  group 2 / data=a2;
  model 1 / group=1;
```

```

    path x1 ==> x2;
    pvar x1 x2;
    model 2 / group=2;
    refmodel 1;
run;

```

This way Model 2 makes reference to all the explicitly specified parameters in Model 1. Hence the two models are completely constrained. However, a simpler way to fit exactly the same model to two groups is to use a single model definition, as shown in the following statements:

```

proc calis;
  group 1 / data=a1;
  group 2 / data=a2;
  model 1 / group=1,2;
    path x1 ==> x2;
run;

```

This specification has the same estimation results as those for the preceding specification.

When you also use one of the REFMODEL statement options, the REFMODEL statement is no longer a simple copy of explicit parameter specifications from the reference model. All parameters are renamed in the new model in the model referencing process. The following options are available in the REFMODEL statement:

ALLNEWPARMS

appends to the parameter names in the reference model with *_mdl* and then an integer suffix denoting the model number of the current model. For example, if *qq* is a parameter in the reference model for a current model with model number 3, then this option creates *qq_mdl3* as a new parameter name.

PARM_PREFIX=*prefix*

inserts to all parameter names in the reference model with the *prefix* provided. For example, if *qq* is a parameter in the reference model for a current model, then **PARM_PREFIX=pre_** creates *pre_qq* as a new parameter name.

PARM_SUFFIX=*suffix*

appends to all parameter names in the reference model with the *suffix* provided. For example, if *qq* is a parameter in the reference model for a current model, then **PARM_SUFFIX=_suf** creates *qq_suf* as a new parameter name.

Instead of renaming all parameters, you can also rename parameters individually by using the **RENAMEPARAM** statement within the scope of the REFMODEL statement.

You can also add the main and subsidiary model specification statements to modify a particular part from the reference model. For example, you might like to add or delete some equations or paths, or to change a fixed parameter to a free parameter or vice versa in the new model. All can be done in the respecification in the main and subsidiary model specification statements within the scope of the **MODEL** statement to which the REFMODEL statement belongs. Naturally, the modeling language used in respecification must be the same as that of the reference model. See the individual statements for modeling languages for the syntax of respecification. Note that when you respecify models by using the main and subsidiary model specification statements together with the **RENAMEPARAM** statement or the REFMODEL options for changing parameter names, the parameter name changes occur after respecifications.

RENAMEPARAM Statement

RENAMEPARAM *assignment* <, *assignment* ... >;

where *assignment* represents:

old_parameters = *parameter-spec*

You can use the RENAMEPARAM statement to rename parameters or to change the types of parameters of a reference model so that new parameters are transferred to the new model in question. The RENAMEPARAM statement is a subsidiary model specification statement that should be used together with the [REFMODEL](#) statement. The syntax of the RENAMEPARAM statement is similar to that of the [VARIANCE](#) statement—except that in the RENAMEPARAM statement, you put parameter names on the left-hand side of equal signs, whereas you put variable names on the left-hand side in the [VARIANCE](#) statement. You can use no more than one RENAMEPARAM statement within the scope of each [REFMODEL](#) statement.

In the [REFMODEL](#) statement, you transfer all the model specification information from a base model to the new model being specified. The RENAMEPARAM statement enables you to modify the parameter names or types in the base model before transferring them to the new model. For example, in the following example, you define Model 2, which is a new model, by referring it to Model 1, the base model, in the [REFMODEL](#) statement.

```
model 1;
  lineqs
    V1 =    F1 + E1,
    V2 = b2 F1 + E2,
    V3 = b3 F1 + E3,
    V4 = b4 F1 + E4;
  variance F1 = vF1,
    E1-E4 = ve1-ve4;
model 2;
  refmodel 1;
  renameparm ve1-ve4=new1-new4, b2=newb2(.2), b4=.3;
```

Basically, the LINEQS model specification in Model 1 is transferred to Model 2. In addition, you redefine some parameters in the base model by using the RENAMEPARAM statement. This example illustrates two kinds of modifications that the RENAMEPARAM statement can do:

- creating new parameters in the new model

The error variances for E1–E4 in Model 2 are different from those defined in Model 1 because new parameters new1–new4 are now used. Parameter b2 is renamed as newb2 with a starting value at 0.2 in Model 2. So the two models have distinct path coefficients for the F1-to-V2 path.

- changing free parameters into fixed constants

By using the specification **b4=.3** in the RENAMEPARAM statement, b4 is no longer a free parameter in Model 2. The path coefficient for the F1-to-V4 path in Model 2 is now fixed at 0.3.

The RENAMEPARAM statement is handy when you have just few parameters to change in the reference model defined by the [REFMODEL](#) statement. However, when there are a lot of parameters to modify, the

RENAMEPARM statement might not be very efficient. For example, to make all parameters unique to the current model, you might consider using the [ALLNEWPARMS](#), [PARM_PREFIX=](#), or [PARM_SUFFIX=](#) option in the [REFMODEL](#) statement.

SAS Programming Statements

You can use SAS programming statements to define dependent parameters, parametric functions, and equality constraints among parameters.

Several statistical procedures support the use of SAS programming statements. The syntax of SAS programming statements are common to all these procedures and can be found in the section “[Programming Statements](#)” on page 504 in Chapter 19, “[Shared Concepts and Topics](#).”

SIMTESTS Statement

SIMTESTS | SIMTEST *sim-test* < *sim-test* ... > ;

where *sim-test* represents one of the following:

- *test-name* = [*functions*]
- *test-name* = { *functions* }

and *functions* are either parameters in the model or parametric functions computed in the [SAS programming statements](#).

When the estimates in a model are asymptotically multivariate-normal, continuous and differentiable functions of the estimates are also multivariate-normally distributed. In the SIMTESTS statement, you can test these parametric functions simultaneously. The null hypothesis for the simultaneous tests is assumed to have the following form:

$$H_0 : h_1(\theta) = 0, h_2(\theta) = 0, \dots$$

where θ is the set of model parameters (independent or dependent) in the analysis and each $h_i()$ is a continuous and differentiable function of the model parameters.

To test parametric functions simultaneously in the SIMTESTS statement, you first assign a name for the simultaneously test in *test-name*. Then you put the parametric functions for the simultaneous test inside a pair of parentheses: either the ‘{’ and ‘}’ pair, or the ‘[’ and ‘]’ pair. For example, if θ_1 , θ_2 , θ_3 , and θ_4 are parameters in the model and you want to test the equality of θ_1 and θ_2 and the equality of θ_3 and θ_4 simultaneously, you can use the following statements:

```
simtests
  Equality_test = [t1_t2_diff t3_t4_diff];
t1_t2_diff     = theta1 - theta2;
t3_t4_diff     = theta3 - theta4;
```

In the SIMTESTS statement, you test two functions *t1_t2_diff* and *t3_t4_diff* simultaneously in the test named *Equality_test*. The two parametric functions *t1_t2_diff* and *t3_t4_diff* are computed in the [SAS programming statements](#) as differences of some parameters in the model.

See also the [TESTFUNC statement](#) on page 1227 for testing parametric functions individually.

STD Statement

STD *assignment* <, *assignment* ... > ;

where *assignment* represents:

var-list = *parameter-spec*

The STD statement functions exactly the same as the [VARIANCE](#) statement. The STD statement is obsolete and might not be supported in future versions of PROC CALIS. Use the [VARIANCE](#) statement instead.

STRUCTEQ Statement

STRUCTEQ *variables* </ *label*> ;

where *label* represents:

LABEL | NAME = *name*

The STRUCTEQ statement functions exactly the same as the [DETERM](#) statement.

TESTFUNC Statement

TESTFUNC *functions* ;

where *functions* are either parameters in the model or parametric functions computed in the [SAS programming statements](#).

When the estimates in a model are asymptotically multivariate-normal, any continuous and differentiable function of the estimates is also normally distributed. In the TESTFUNC statement, you can test these parametric functions using z-tests. The form of the null hypothesis is as follows:

$$H_0 : h(\theta) = 0$$

where θ is the set of model parameters (independent or dependent) in the analysis and $h()$ is a continuous and differentiable function of the model parameters.

For example, if θ_1 , θ_2 , and θ_3 are parameters in the model, and you want to test whether θ_1 and θ_2 are the same and whether θ_3 is the same as the average of θ_1 and θ_2 , you can use the following statements:

```
testfunc    t1_t2_diff t3_t1t2_diff;
t1_t2_diff  = theta1 - theta2;
t3_t1t2_diff = theta3 - (theta1 + theta2)/2;
```

In the TESTFUNC statement, you test two functions: `t1_t2_diff` and `t3_t1t2_diff`. These two functions are defined in the [SAS programming statements](#) that follow after the TESTFUNC statement. Thus, `t1_t2_diff` represents the difference between θ_1 and θ_2 , and `t3_t1t2_diff` represents the difference between θ_3 and the average of θ_1 and θ_2 .

See the [SIMTESTS](#) statement if you want to test several null hypotheses simultaneously.

VAR Statement

VAR *variables* ;

The VAR statement defines and limits the set of observed variables that are available for the corresponding model analysis. It is one of the [subsidiary group specification statements](#). You can use the VAR statement no more than once within the scope of each [GROUP](#) or the PROC CALIS statement. The set of variables in the VAR statement must be present in the data set specified in the associated [GROUP](#) or the PROC CALIS statement.

The following example shows the specification of 16 variables (x1, x2, ..., x9, x10, y, z1, z2, ..., z5) in the VAR statement:

```
var x1-x10 y z1-z5;
```

The VAR statement in PROC CALIS does not support the specification of variable lists with syntax that refers to consecutive variables in the data set. For example, if QQ, RR, SS, and TT are consecutive variables in a data set, the following specification of these four variables in the VAR statement is not supported by PROC CALIS:

```
var QQ-TT;
```

The VAR statement should not be confused with the [PARAMETERS](#) statement. In the [PARAMETERS](#) statement, you specify additional *parameters* in the model. Parameters are population quantities that characterize the functional relationships, variations, or covariation among variables. Unfortunately, parameters are sometimes referred to as *var-list* in the optimization context. You have to make sure that all variables specified in the VAR statement refer to the variables in the input data set, while the parameters specified in the [PARAMETERS](#) statement are population quantities that characterize distributions of the variables and their relationships.

In some modeling languages of PROC CALIS, you can also specify the observed variables either directly (for example, through the VAR= or similar option in some [main model specification statements](#)) or indirectly (for example, through the specification of functional relationships between observed variables). How does the VAR statement specifications interplay with the observed variables specified in the model? This depends on the types of models specified. Four different cases are considered in the following.

Case 1. Exploratory Factor Models With No VAR= option in the FACTOR statement. For exploratory factor models specified using the [FACTOR](#) statement, it is important for you to use the VAR statement to select and limit the set of the observed variables for analysis. The reason is simply that there is no other options in the [FACTOR](#) statement that will serve the same purpose. For example, you analyze only v1–v3 in the following exploratory factor model even though there might be more observed variables available in the data set:

```
proc calis;
  var v1-v3;
  factor n=1;
```

If you do not specify the VAR statement, PROC CALIS simply selects all numerical variables for analysis. However, to avoid confusions it is a good practice to specify the observed variables explicitly in the VAR statement.

Case 2. Models With a VAR= or Similar Option for Defining the Set of Observed Variables for Analysis. The classes of models considered here are: **COSAN**, **LISMOD**, **MSTRUCT**, and **RAM**. Except for the LISMOD models, in all other three classes of models you can specify the observed variables in the model by using the a VAR= option in the respective [main model specification statement](#). For the LISMOD models, you can specify all observed variables that should be included in the model in the XVAR= and YVAR= options of the LISMOD statement. Therefore, the use of the VAR statement for these models might become unnecessary. For example, the following MSTRUCT statement specifies the observed variables v1–v6 in the VAR= option:

```
proc calis;
  mstruct var=v1-v6;
```

It would have been redundant to use a VAR statement to specify v1–v6 additionally. The same conclusion applies to the **COSAN** and the **RAM** models.

Another example is when you specify a LISMOD model. In the following LISMOD specification, variables v1–v8 would be the set of observed variables for analysis:

```
proc calis;
  var v1-v8;
  lismod xvar = v1-v4,
         yvar = v5-v8,
         eta  = factor1,
         xi   = factor2;
```

Again, there is no need to add a VAR statement merely repeating the specification of variables v1–v8.

If you do specify the VAR statement in addition to the specification of variable lists in these models, PROC CALIS will check the consistency between the lists. Conflicts arise if the two lists do not match.

For example, the following statements will generate an error in model specification because v6 specified in the MSTRUCT model is not defined as an observed variable available for analysis in the VAR statement (even if v6 might indeed be present in the data set):

```
proc calis;
  var v1-v5;
  mstruct var=v1-v6;
```

So it is an error when you specify fewer observed variables in the VAR statement than in the VAR= option in the model. How about if you specify more variables in the VAR statement? PROC CALIS will also general an error because the extra variables in VAR statement will not be well-undefined in the model. For example, v7–v10 specified in the VAR statement are supposed to be included into the model, but they not listed on either the XVAR= or YVAR= list in the following LISMOD statement:

```
proc calis;
  var v1-v10;
  lismod xvar = v1-v3,
         yvar = v4-v6,
         eta  = factor1,
         xi   = factor2;
```

Therefore, if you must specify the VAR statement for these models, the specifications of the observed variables must be consistent in the VAR statement and in the relevant model options. However, to avoid

potential conflicts in these situations, you are recommended to specify the observed variables in the VAR=, XVAR=, or YVAR= lists only.

When the VAR= option is not specified in the COSAN, MSTRUCT, or RAM statement, the VAR statement specification will be used as the list of observed variables in the model. If both of the VAR= option and VAR statement specification are lacking, then all numerical variables in the associated data set will be used in the model. However, to avoid confusions the preferred method is to specify the list of observed variables explicitly on the VAR=, XVAR=, or YVAR= option of the [main model specification statements](#).

Case 3. Models With Indirect Ways to Include the Set of Observed Variables for Analysis. Two types of models are considered here: [LINEQS](#) and [PATH](#). For these models, the main use of the VAR statement is to include those observed variables that are not mentioned in model specifications.

For example, in the following statements for a LINEQS model variable v3 is not mentioned in the LINEQS statement:

```
proc calis;
  var v1-v3;
  lineqs    v1 = a1 * v2 + e1;
```

With the specification in the VAR statement, however, variable v3 is included into the model as an exogenous manifest variable. Similarly, the same applies to the following PATH model specification:

```
proc calis;
  var v1-v3;
  path     v1 <=== v2;
```

Again, variable v3 is included into the PATH model because it is specified in the VAR statement.

The two preceding examples also suggest that you do not need to use the VAR statement when your already mentions all observed variables in the model specification. For example, if your target set of observed variables are v1–v3, the use of the VAR statement in the following specification is *unnecessary*:

```
proc calis;
  var v1-v3;
  path   v1 <=== v2;
  pvar v3;
```

For the two types of models considered here, you can also use the VAR statement to define and limit the set of observed variables for analysis. For example, you might have v1, v2, v3 in your data set as observed variables for analysis; but somehow in your model v2 should be treated as a latent variable. You might use the following code to exclude v2 as an observed variable in the model:

```
proc calis;
  var v1 v3;
  path   v1 <=== v2;
  pvar v3;
```

The role of the VAR statement here is to define and limit the set of observed variables available for the model. Hence, only variables v1 and v3 are supposed to be observed variables in the model while variable v2 in the PATH model is treated as latent.

In sum, in the current situation the use of the VAR statement should depend on whether a variable should or should not be included as an observed variable in your theoretical model.

Case 4. Confirmatory Factor Model With the FACTOR statement. In this case, the VAR statement still limits the set of observed variables being analyzed in the confirmatory factor model. However, because all observed variables in a [confirmatory factor analysis](#) must be loaded on (or related to) some factors through the specification of *factor-variable-relations* in the [FACTOR](#) statement, all observed variables in the model should have been specified (or mentioned) in the [FACTOR](#) statement already, making it redundant to use the VAR statement for the same purpose.

VARIANCE Statement

VARIANCE *assignment* <, *assignment* ... > ;

where *assignment* represents:

var-list < =*parameter-spec* >

The VARIANCE statement specifies the variance parameters in connection with the [LINEQS](#) model. Notice that the VARIANCE statement is different from the [VAR](#) statement, which specifies variables for analysis. In previous versions of PROC CALIS, the STD statement name was used instead of the VARIANCE statement name. Although these two names result in the same functionalities, the VARIANCE statement name reflects the intended usages better.

In the LINEQS model, variance parameters are defined only for *exogenous* manifest and latent variables (including error and disturbance variables) in the model. Therefore, you cannot list any *endogenous* variables in the *var-list* list of the VARIANCE statement. You can specify no more than one VARIANCE statement for each LINEQS model.

In each *assignment* of the VARIANCE statement, you list the *var-list* whose variances you want to specify. Optionally, you can provide a list of parameter specifications (*parameter-spec*) after an equal sign for each *var-list* list.

You can specify the following five types of the parameters for the variances of the exogenous variables in the VARIANCE statement:

- an unnamed free parameter
- an initial value
- a fixed value
- a free parameter with a name provided
- a free parameter with a name and initial value provided

Consider a LINEQS model with exogenous variables V1, V2, F1, D2, and E3. The following VARIANCE statement illustrates the five types of parameter specifications in five *assignments*:

```
variance
  V1 ,
  V2 = (.5),
  F1 = 1.0,
```

```
D2 = dvar,
E3 = evar(0.7);
```

In this statement, the variance of V1 is specified as an unnamed free parameter. For this variance, PROC CALIS generates a parameter name with the `_Parm` prefix and appended with a unique integer (for example, `_Parm1`). The variance of V2 is an unnamed free parameter with an initial value of 0.5. PROC CALIS also generates a parameter name for this variance. The variance of F1 is a fixed value of 1.0. This value stays the same during the estimation. The variance of D2 is a free parameter named `dvar`. The variance of E3 is a free parameter named `evar` with an initial value of 0.7.

When you need to specify a long parameter name list, you can consider using the prefix-name specification for the parameter list. For example, the following statement specifies 100 unique parameter names for the variances of E1–E100:

```
variance
  E1-E100 = 100 * evar__ ; /* evar with two trailing underscores */
```

In the VARIANCE statement, `evar__` is a prefix-name with the root `evar`. The notation `100*` means this prefix-name is applied 100 times, resulting in a generation of the 100 unique parameter names `evar001`, `evar002`, ..., `evar100`.

The root of the prefix-name should have few characters so that the generated parameter name is not longer than 32 characters. To avoid unintentional equality constraints, the prefix-names should not coincide with other parameter names.

Mixed Parameter Lists

You can specify different types of parameters for the list of variances. For example, the following statement uses a list of parameters with mixed types:

```
variance
  E1-E6 = vp1 vp2(2.0) vp3 4. (.3) vp6(.4);
```

This is equivalent to the following specification:

```
variance
  E1 = vp1
  E2 = vp2(2.0) ,
  E3 = vp3 ,
  E4 = 4. ,
  E5 = (.3) ,
  E6 = vp6(.4);
```

Notice that an initial value followed after a parameter name is associated with the free parameter. For example, in the original mixed list specification, the specification `(2.0)` after `vp2` is interpreted as the initial value for the parameter `vp2`, but not as the initial estimate for the variance of E3.

However, if you indeed want to specify that `vp2` is a free parameter *without* an initial value and 2.0 is an initial estimate for the variance of E3 (while keeping all other things the same), you can use a null initial value specification for the parameter `vp2`, as shown in the following statement:

```

variance
  E1-E6 = vp1 vp2() (2.0) 4. (.3) vp6(.4);

```

This way 2.0 becomes the initial estimate for the variance of E3. Because a parameter list with mixed types might be confusing, you can break down the specifications into separate *assignments* to remove ambiguities. For example, you can use the following equivalent specification:

```

variance
  E1 = vp1
  E2 = vp2,
  E3 = (2.),
  E4 = 4. ,
  E5 = (.3),
  E6 = vp6(.4);

```

Shorter and Longer Parameter Lists

If you provide fewer parameters than the number of variances in the *var-list* list, all the remaining parameters are treated as unnamed free parameters. For example, the following specification assigns a fixed value of 1.0 to the variance of F1 while treating the other three variances as unnamed free parameters:

```

variance
  F1-F4 = 1.0;

```

This specification is equivalent to the following specification:

```

variance
  F1 = 1.0, F2-F4;

```

If you intend to fill up all values with the last parameter specification in the list, you can use the continuation syntax [...], [...], or [...], as shown in the following example:

```

variance
  E1-E100 = 1.0 psi [...];

```

This means that the variance of E1 is fixed at 1.0, while the variances of E1–E100 are all free parameter named psi. All variances except that for E1 are thus constrained to be equal by using the same parameter name.

However, you must be careful not to provide too many parameters. For example, the following specification results in an error:

```

variance
  E1-E6 = 1.0 psi2-psi6 extra;

```

The parameters after psi6 are excessive.

Default Variance Parameters

In the LINEQS model, by default all variances of exogenous manifest and latent variables (including error and disturbance variables) are free parameters. For these default free parameters, PROC CALIS generates the parameter names with the *_Add* prefix and appended with unique integer suffixes. You can also use the

VARIANCE statement specification to override these default variance parameters in situations where you want to specify parameter constraints, provide initial or fixed values, or make parameter references.

Because only exogenous variables can have variance parameters in the LINEQS model and all these exogenous variances are free parameters by default, there are no default fixed zeros for any variances in the LINEQS model.

Modifying a Variance Parameter Specification from a Reference Model

If you define a new LINEQS model by using a reference (old) model in the [REFMODEL](#) statement, you might want to modify some parameter specifications from the VARIANCE statement of the reference model before transferring the specifications to the new model. To change a particular variance specification from the reference model, you can simply respecify the same variance with the desired parameter specification in the VARIANCE statement of the new model. To delete a particular variance parameter from the reference model, you can specify the desired variance with a missing value specification in the VARIANCE statement of the new model.

For example, suppose that the variance of V1 is specified in the reference model but you do not want this variance specification to be transferred to the new model, you can use the following VARIANCE statement specification in the new model:

```
variance V1 = .;
```

Note that the missing value syntax is valid only when you use the [REFMODEL](#) statement. See the section “[Modifying a LINEQS Model from a Reference Model](#)” on page 1160 for a more detailed example of the LINEQS model respecification.

As discussed in a preceding section, PROC CALIS generates default free variance parameters for the LINEQS model if you do not specify them explicitly in the VARIANCE statement. When you use the [REFMODEL](#) statement for defining a reference model, these default free variance parameters in the old (reference) model are not transferred to the new model. Instead, the new model generates its own set of default free variance parameters *after* the new model is resolved from the reference model, the [REFMODEL](#) statement options, the [RENAMEPARM](#) statement, and the VARIANCE statement specifications in the new model. This also implies that if you want any of the variance parameters to be constrained across the models by means of the [REFMODEL](#) specification, you must specify them explicitly in the VARIANCE statement of the reference model so that the same variance specification is transferred to the new model.

VARNAMES Statement

```
VARNAMES name-assignment <, name-assignment ... > ;
```

```
VARNAME name-assignment <, name-assignment ... > ;
```

```
VNAMES name-assignment <, name-assignment ... > ;
```

where *name-assignment* represents one of the following forms:

```
matrix-name variable-names
```

```
matrix-name = [variable-names]
```

```
matrix-name = matrix-name
```

You can use the VARNAMES statement in connection with the [COSAN](#) modeling language to assign variable names for matrices. The *matrix-name* refers to any matrix you define in the [COSAN](#) statement. The *variable-names* that follow the *matrix-name* are assigned to the column variables of the matrix of interest. This applies to the first two types of VARNAMES specifications. For example,

```
varnames F f1-f3;
```

is exactly the same as

```
varnames F = [ f1-f3 ];
```

Both of these assign f1, f2, and f3 as the names for the first three column variables of matrix F.

You can also use another kind of *name-assignment* in connection with a [COSAN](#) statement. Two matrix names equated by an equal sign assign the column names of the matrix on the right-hand side to the column names of the matrix on the left-hand side. This assignment assumes that the column names of at least one of the two matrices are already defined. For example, assuming that **J** and **A** are model matrices defined in a [COSAN](#) statement, the following VARNAMES statement specification specifies that both **J** and **A** have the same set of column variable names V1–V6 and F1–F3:

```
varnames J = [ V1-V6 F1-F3 ] ,
         A = J ;
```

This is the same as the following specification:

```
varnames J = [ V1-V6 F1-F3 ] ,
         A = [ V1-V6 F1-F3 ] ;
```

The VARNAMES statement appears to enable you to specify only the column variable names for matrices. However, PROC CALIS also uses these column variable names to assign row variable names of the related matrices in the covariance and mean structure formulas for the [COSAN](#) model. PROC CALIS uses the following rules to determine the row variable names of a matrix in the model:

- If a matrix is the first matrix of any term in the covariance or mean structure formula, the row variable names are the names of the manifest variables.
- If a matrix is the central covariance matrix of any term in the covariance structure formula, the row variable names are the same as the column variable names.
- For any other matrices, the row variable names are the same as the column variable names of the preceding matrix in the multiplicative formula for the covariance or mean structures.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement specifies the weight variable for the observations. It is one of the [subsidiary group specification statements](#). You can use the WEIGHT statement no more than once within the scope of each **GROUP** statement or the PROC CALIS statement.

Weighting is often done when the error variance associated with each observation is different and the values of the weight variable are proportional to the reciprocals of the variances. The **WEIGHT** and **FREQ** statements have a similar effect, except the **WEIGHT** statement does not alter the number of observations unless **VARDEF=WGT** or **VARDEF=WDF**. An observation is used in the analysis only if the **WEIGHT** variable is greater than 0 and is not missing.

Details: CALIS Procedure

Input Data Sets

You can use four different kinds of input data sets in the CALIS procedure, and you can use them simultaneously. The **DATA=** data set contains the data to be analyzed, and it can be an ordinary SAS data set containing raw data or a special **TYPE=COV**, **TYPE=UCOV**, **TYPE=CORR**, **TYPE=UCORR**, **TYPE=SSCP**, or **TYPE=FACTOR** data set containing previously computed statistics. The **INEST=** data set specifies an input data set that contains initial estimates for the parameters used in the optimization process, and it can also contain boundary and general linear constraints on the parameters. If the model does not change too much, you can use an **OUTEST=** data set from a previous PROC CALIS analysis; the initial estimates are taken from the values of the **_TYPE_=PARMS** observation. The **INMODEL=** or **INRAM=** data set contains information of the analysis models (except for user-written programming statements). Often the **INMODEL=** data set is created as the **OUTMODEL=** data set from a previous PROC CALIS analysis. See the section “**OUTMODEL=** or **OUTRAM=** Data Set” on page 1243 for the structure of both **OUTMODEL=** and **INMODEL=** data sets. Using the **INWGT=** data set enables you to read in the weight matrix **W** that can be used in generalized least squares, weighted least squares, or diagonally weighted least squares estimation.

BASEFIT= or INBASEFIT= Data Set

The **BASEFIT=** or **INBASEFIT=** data set saves the fit function value and the degrees of freedom of a baseline model for computing various fit indices, especially the incremental fit indices. Typically, the **BASEFIT=** data set is created as an **OUTFIT=** data set from a previous PROC CALIS fitting of a customized baseline model. See the section “**OUTFIT=** Data Set” on page 1254 for details about the format of the **OUTFIT=** and **BASEFIT=** data sets.

DATA= Data Set

A **TYPE=COV**, **TYPE=UCOV**, **TYPE=CORR**, or **TYPE=UCORR** data set can be created by the **CORR** procedure or various other procedures. It contains means, standard deviations, the sample size, the covariance or correlation matrix, and possibly other statistics depending on which procedure is used.

If your data set has many observations and you plan to run PROC CALIS several times, you can save computer time by first creating a **TYPE=COV**, **TYPE=UCOV**, **TYPE=CORR**, or **TYPE=UCORR** data set and using it as input to PROC CALIS.

For example, assuming that PROC CALIS is first run with an **OUTMODEL=MODEL** option, you can run the following statements in subsequent analyses with the same model in the first run:

```

/* create TYPE=COV data set */
proc corr cov nocorr data=raw outp=cov(type=cov);
run;
/* analysis using correlations */
proc calis corr data=cov inmodel=model;
run;
/* analysis using covariances */
proc calis data=cov inmodel=model;
run;

```

Most procedures automatically set the TYPE= option of an output data set appropriately. However, the CORR procedure sets TYPE=CORR unless an explicit TYPE= option is used. Thus, (TYPE=COV) is needed in the preceding PROC CORR request, since the output data set is a covariance matrix. If you use a DATA step with a SET statement to modify this data set, you must declare the TYPE=COV, TYPE=UCOV, TYPE=CORR, or TYPE=UCORR attribute in the new data set.

You can use a [VAR](#) statement with PROC CALIS when reading a TYPE=COV, TYPE=UCOV, TYPE=CORR, TYPE=UCORR, or TYPE=SSCP data set to select a subset of the variables or change the order of the variables.

CAUTION: Problems can arise from using the CORR procedure when there are missing data. By default, PROC CORR computes each covariance or correlation from all observations that have values present for the pair of variables involved (“pairwise deletion”). The resulting covariance or correlation matrix can have negative eigenvalues. A correlation or covariance matrix with negative eigenvalues is recognized as a singular matrix in PROC CALIS, and you cannot compute (default) generalized least squares or maximum likelihood estimates. You can specify the RIDGE option to ridge the diagonal of such a matrix to obtain a positive definite data matrix. If the NOMISS option is used with the CORR procedure, observations with any missing values are completely omitted from the calculations (“listwise deletion”), and there is no possibility of negative eigenvalues (but there is still a chance for a singular matrix).

PROC CALIS can also create a TYPE=COV, TYPE=UCOV, TYPE=CORR, or TYPE=UCORR data set that includes all the information needed for repeated analyses.

If the data set DATA=RAW does not contain missing values, the following statements should give the same PROC CALIS results as the previous example:

```

/* using correlations */
proc calis corr data=raw outstat=cov inmodel=model;
run;
/* using covariances */
proc calis data=cov inmodel=model;
run;

```

You can create a TYPE=COV, TYPE=UCOV, TYPE=CORR, TYPE=UCORR, or TYPE=SSCP data set in a DATA step. Be sure to specify the TYPE= option in parentheses after the data set name in the DATA statement and include the _TYPE_ and _NAME_ variables. If you want to analyze the covariance matrix but your [DATA=](#) data set is a TYPE=CORR or TYPE=UCORR data set, you should include an observation with _TYPE_=STD giving the standard deviation of each variable. By default, PROC CALIS analyzes the recomputed covariance matrix even when a TYPE=CORR data set is provided, as shown in the following statements:

```

data correl(type=corr);
  input _type_ $ _name_ $ X1-X3;
  datalines;
std    .    4.  2.  8.
corr  X1   1.0  .   .
corr  X2   .7  1.0  .
corr  X3   .5  .4  1.0
;
proc calis inmodel=model;
run;

```

INEST= Data Set

You can use the **INEST=** (or **INVAR=**) input data set to specify the initial values of the parameters used in the optimization and to specify boundary constraints and the more general linear constraints that can be imposed on these parameters.

The variables of the **INEST=** data set must correspond to the following:

- a character variable **_TYPE_** that indicates the type of the observation
- n numeric variables with the parameter names used in the specified PROC CALIS model
- the BY variables that are used in a **DATA=** input data set
- a numeric variable **_RHS_** (right-hand side); needed only if linear constraints are used
- additional variables with names corresponding to constants used in the programming statements

The content of the **_TYPE_** variable defines the meaning of the observation of the **INEST=** data set. PROC CALIS recognizes observations with the following **_TYPE_** specifications.

PARMS	specifies initial values for parameters that are defined in the model statements of PROC CALIS. The _RHS_ variable is not used. Additional variables can contain the values of constants that are referred to in programming statements. At the beginning of each run of PROC CALIS, the values of the constants are read from the PARMS observation for initializing the constants in the SAS programming statements.
UPPERBD UB	specifies upper bounds with nonmissing values. The use of a missing value indicates that no upper bound is specified for the parameter. The _RHS_ variable is not used.
LOWERBD LB	specifies lower bounds with nonmissing values. The use of a missing value indicates that no lower bound is specified for the parameter. The _RHS_ variable is not used.
LE <= <	specifies the linear constraint $\sum_j a_{ij}x_j \leq b_i$. The n parameter values contain the coefficients a_{ij} , and the _RHS_ variable contains the right-hand-side b_i . The use of a missing value indicates a zero coefficient a_{ij} .

- GE |>=|> specifies the linear constraint $\sum_j a_{ij}x_j \geq b_i$. The n parameter values contain the coefficients a_{ij} , and the `_RHS_` variable contains the right-hand-side b_i . The use of a missing value indicates a zero coefficient a_{ij} .
- EQ |= specifies the linear constraint $\sum_j a_{ij}x_j = b_i$. The n parameter values contain the coefficients a_{ij} , and the `_RHS_` variable contains the right-hand-side b_i . The use of a missing value indicates a zero coefficient a_{ij} .

The constraints specified in the `INEST=`, `INVAR=`, or `ESTDATA=` data set are added to the constraints specified in `BOUNDS` and `LINCON` statements.

You can use an `OUTEST=` data set from a PROC CALIS run as an `INEST=` data set in a new run. However, be aware that the `OUTEST=` data set also contains the boundary and general linear constraints specified in the previous run of PROC CALIS. When you are using this `OUTEST=` data set without changes as an `INEST=` data set, PROC CALIS adds the constraints from the data set to the constraints specified by a `BOUNDS` and `LINCON` statement. Although PROC CALIS automatically eliminates multiple identical constraints, you should avoid specifying the same constraint a second time.

INMODEL= or INRAM= Data Set

This data set is usually created in a previous run of PROC CALIS. It is useful if you want to reanalyze a problem in a different way such as using a different estimation method. You can alter an existing `OUTMODEL=` data set in the DATA step to create the `INMODEL=` data set that describes a modified model. See the section “`OUTMODEL=` or `OUTRAM=` Data Set” on page 1243 for more details about the `INMODEL=` data set.

INWGT= Data Set

This data set enables you to specify a weight matrix other than the default matrix for the generalized, weighted, and diagonally weighted least squares estimation methods. If you also specify the `INWGT-INV` option (or use the `INWGT(INV)=option`), the `INWGT=` data set is assumed to contain the inverse of the weight matrix, rather than the weight matrix itself. The specification of any `INWGT=` data set for unweighted least squares or maximum likelihood estimation is ignored. For generalized and diagonally weighted least squares estimation, the `INWGT=` data set must contain a `_TYPE_` and a `_NAME_` variable as well as the manifest variables used in the analysis. The value of the `_NAME_` variable indicates the row index i of the weight w_{ij} . For weighted least squares, the `INWGT=` data set must contain `_TYPE_`, `_NAME_`, `_NAM2_`, and `_NAM3_` variables as well as the manifest variables used in the analysis. The values of the `_NAME_`, `_NAM2_`, and `_NAM3_` variables indicate the three indices i, j, k of the weight $w_{ij,kl}$. You can store information other than the weight matrix in the `INWGT=` data set, but only observations with `_TYPE_=WEIGHT` are used to specify the weight matrix **W**. This property enables you to store more than one weight matrix in the `INWGT=` data set. You can then run PROC CALIS with each of the weight matrices by changing only the `_TYPE_` observation in the `INWGT=` data set with an intermediate DATA step.

See the section “`OUTWGT=` Data Set” on page 1254 for more details about the `INWGT=` data set.

Output Data Sets

OUTEST= Data Set

The **OUTEST=** (or **OUTVAR=**) data set is of **TYPE=EST** and contains the final parameter estimates, the gradient, the Hessian, and boundary and linear constraints. For **METHOD=ML**, **METHOD=GLS**, and **METHOD=WLS**, the **OUTEST=** data set also contains the approximate standard errors, the information matrix (crossproduct Jacobian), and the approximate covariance matrix of the parameter estimates ((generalized) inverse of the information matrix). If there are linear or nonlinear equality or active inequality constraints at the solution, the **OUTEST=** data set also contains Lagrange multipliers, the projected Hessian matrix, and the Hessian matrix of the Lagrange function.

The **OUTEST=** data set can be used to save the results of an optimization by PROC CALIS for another analysis with either PROC CALIS or another SAS procedure. Saving results to an **OUTEST=** data set is advised for expensive applications that cannot be repeated without considerable effort.

The **OUTEST=** data set contains the BY variables, two character variables **_TYPE_** and **_NAME_**, t numeric variables corresponding to the parameters used in the model, a numeric variable **_RHS_** (right-hand side) that is used for the right-hand-side value b_i of a linear constraint or for the value $f = f(x)$ of the objective function at the final point x^* of the parameter space, and a numeric variable **_ITER_** that is set to zero for initial values, set to the iteration number for the OUTITER output, and set to missing for the result output.

The **_TYPE_** observations in Table 27.5 are available in the **OUTEST=** data set, depending on the request.

Table 27.5 **_TYPE_** Observations in the OUTEST= Data Set

TYPE	Description								
ACTBC	If there are active boundary constraints at the solution x^* , three observations indicate which of the parameters are actively constrained, as follows: <table border="1"> <thead> <tr> <th>_NAME_</th><th>Description</th></tr> </thead> <tbody> <tr> <td>GE</td><td>indicates the active lower bounds</td></tr> <tr> <td>LE</td><td>indicates the active upper bounds</td></tr> <tr> <td>EQ</td><td>indicates the active masks</td></tr> </tbody> </table>	_NAME_	Description	GE	indicates the active lower bounds	LE	indicates the active upper bounds	EQ	indicates the active masks
NAME	Description								
GE	indicates the active lower bounds								
LE	indicates the active upper bounds								
EQ	indicates the active masks								
COV	Contains the approximate covariance matrix of the parameter estimates; used in computing the approximate standard errors.								
COVRANK	contains the rank of the covariance matrix of the parameter estimates.								
CRPJ_LF	Contains the Hessian matrix of the Lagrange function (based on CRPJAC).								
CRPJAC	Contains the approximate Hessian matrix used in the optimization process. This is the inverse of the information matrix.								

Table 27.5 *continued*

TYPE	Description										
EQ	If linear constraints are used, this observation contains the i th linear constraint $\sum_j a_{ij}x_j = b_i$. The parameter variables contain the coefficients a_{ij} , $j = 1, \dots, n$, the _RHS_ variable contains b_i , and _NAME_ =ACTLC or _NAME_ =LDACTLC.										
GE	If linear constraints are used, this observation contains the i th linear constraint $\sum_j a_{ij}x_j \geq b_i$. The parameter variables contain the coefficients a_{ij} , $j = 1, \dots, n$, and the _RHS_ variable contains b_i . If the constraint i is active at the solution x^* , then _NAME_ =ACTLC or _NAME_ =LDACTLC.										
GRAD	Contains the gradient of the estimates.										
GRAD_LF	Contains the gradient of the Lagrange function. The _RHS_ variable contains the value of the Lagrange function.										
HESSIAN	Contains the Hessian matrix.										
HESS_LF	Contains the Hessian matrix of the Lagrange function (based on HESSIAN).										
INFORMAT	Contains the information matrix of the parameter estimates (only for METHOD =ML, METHOD =GLS, or METHOD =WLS).										
INITGRAD	Contains the gradient of the starting estimates.										
INITIAL	Contains the starting values of the parameter estimates.										
JACNLC	Contains the Jacobian of the nonlinear constraints evaluated at the final estimates.										
LAGM BC	Contains Lagrange multipliers for masks and active boundary constraints.										
<table> <tr> <th>_NAME_</th><th>Description</th></tr> <tr> <td>GE</td><td>Indicates the active lower bounds</td></tr> <tr> <td>LE</td><td>Indicates the active upper bounds</td></tr> <tr> <td>EQ</td><td>Indicates the active masks</td></tr> </table>		_NAME_	Description	GE	Indicates the active lower bounds	LE	Indicates the active upper bounds	EQ	Indicates the active masks

NLEC_VAL	Corresponding Lagrange multiplier value										
NLIC_NUM	Number of the linear inequality constraint										
NLIC_VAL	Corresponding Lagrange multiplier value										
LE	If linear constraints are used, this observation contains the i th linear constraint $\sum_j a_{ij}x_j \leq b_i$. The parameter variables contain the coefficients a_{ij} , $j = 1, \dots, n$, and the _RHS_ variable contains b_i . If the constraint i is active at the solution x^* , then _NAME_ =ACTLC or _NAME_ =LDACTLC.										
LOWERBD LB	If boundary constraints are used, this observation contains the lower bounds. Those parameters not subjected to lower bounds contain missing values. The _RHS_ variable contains a missing value, and the _NAME_ variable is blank.										
NACTBC	All parameter variables contain the number n_{abc} of active boundary constraints at the solution x^* . The _RHS_ variable contains a missing value, and the _NAME_ variable is blank.										
NACTLC	All parameter variables contain the number n_{alc} of active linear constraints at the solution x^* that are recognized as linearly independent. The _RHS_ variable contains a missing value, and the _NAME_ variable is blank.										
NLC_EQ NLC_GE NLC_LE	Contains values and residuals of nonlinear constraints. The _NAME_ variable is described as follows: <table> <tr> <th>_NAME_</th><th>Description</th></tr> <tr> <td>NLC</td><td>Inactive nonlinear constraint</td></tr> <tr> <td>NLCACT</td><td>Linear independent active nonlinear constraint</td></tr> <tr> <td>NLCACTLD</td><td>Linear dependent active nonlinear constraint</td></tr> </table>	_NAME_	Description	NLC	Inactive nonlinear constraint	NLCACT	Linear independent active nonlinear constraint	NLCACTLD	Linear dependent active nonlinear constraint		
NAME	Description										
NLC	Inactive nonlinear constraint										
NLCACT	Linear independent active nonlinear constraint										
NLCACTLD	Linear dependent active nonlinear constraint										
NLDACTBC	Contains the number of active boundary constraints at the solution x^* that are recognized as linearly dependent. The _RHS_ variable contains a missing value, and the _NAME_ variable is blank.										

Table 27.5 *continued*

TYPE	Description
NLDACTLC	Contains the number of active linear constraints at the solution x^* that are recognized as linearly dependent. The _RHS_ variable contains a missing value, and the _NAME_ variable is blank.
NOBS	Contains the number of observations.
PARMS	Contains the final parameter estimates. The _RHS_ variable contains the value of the objective function.
PCRPI_LF	Contains the projected Hessian matrix of the Lagrange function (based on CRPJAC).
PHESI_LF	Contains the projected Hessian matrix of the Lagrange function (based on HESSIAN).
PROJCRPI	Contains the projected Hessian matrix (based on CRPJAC).
PROJGRAD	If linear constraints are used in the estimation, this observation contains the $n - n_{act}$ values of the projected gradient $\mathbf{g}_z = \mathbf{Z}'\mathbf{g}$ in the variables corresponding to the first $n - n_{act}$ parameters. The _RHS_ variable contains a missing value, and the _NAME_ variable is blank.
PROJHESS	Contains the projected Hessian matrix (based on HESSIAN).
STDERR	Contains approximate standard errors (only for METHOD=ML , METHOD=GLS , or METHOD=WLS).
TERMINAT	The _NAME_ variable contains the name of the termination criterion.
UPPERBD UB	If boundary constraints are used, this observation contains the upper bounds. Those parameters not subjected to upper bounds contain missing values. The _RHS_ variable contains a missing value, and the _NAME_ variable is blank.

If the technique specified by the **OMETHOD=** option cannot be performed (for example, no feasible initial values can be computed or the function value or derivatives cannot be evaluated at the starting point), the **OUTEST=** data set can contain only some of the observations (usually only the **PARMS** and **GRAD** observations).

OUTMODEL= or OUTRAM= Data Set

The **OUTMODEL=** (or **OUTRAM=**) data set is of **TYPE=CALISMDL** and contains the model specification, the computed parameter estimates, and the standard error estimates. This data set is intended to be reused as an **INMODEL=** data set to specify good initial values in a subsequent analysis by **PROC CALIS**.

The **OUTMODEL=** data set contains the following variables:

- the **BY** variables, if any

- an `_MDLNUM_` variable for model numbers, if used
- a character variable `_TYPE_`, which takes various values that indicate the type of model specification
- a character variable `_NAME_`, which indicates the model type, parameter name, or variable name
- a character variable `_MATNR_`, which indicates the matrix number (COSAN models only)
- a character variable `_VAR1_`, which is the name or number of the first variable in the specification
- a character variable `_VAR2_`, which is the name or number of the second variable in the specification
- a numerical variable `_ESTIM_` for the final estimate of the parameter location
- a numerical variable `_STDERR_` for the standard error estimate of the parameter location
- a numerical variable `_SDEST_` for the final standardized estimate of the parameter location
- a numerical variable `_SDSE_` for the standard error of the standardized estimate of the parameter location

Although the `_SDEST_` and `_SDSE_` variables are created for COSAN models, the values for these two variables are always missing because there are no rules to carry out the standardization of COSAN models.

Each observation (record) of the `OUTMODEL=` data set contains a piece of information regarding the model specification. Depending on the type of the specification indicated by the value of the `_TYPE_` variable, the meanings of `_NAME_`, `_VAR1_`, and `_VAR2_` differ. The following tables summarize the meanings of the `_NAME_`, `_MATNR_` (COSAN models only), `_VAR1_`, and `_VAR2_` variables for each value of the `_TYPE_` variable, given the type of the model.

COSAN Models

<code>_TYPE_</code>	Description	<code>_NAME_</code>	<code>_MATNR_</code>	<code>_VAR1_</code>	<code>_VAR2_</code>
MDLTYPE	Model type	COSAN			
VAR	Variable	Variable name	Matrix number	Column location	
MATRIX	Matrix	Matrix name	Matrix number	Number of rows	Number of columns
MODEL	Model formula	COV or MEAN	Matrix number	Term number	Location in term
ESTIM	Parameters	Parameter name	Matrix number	Row number	Column number

The value of the `_NAME_` variable is COSAN for the `_TYPE_=MDLTYPE` observation.

The `_TYPE_=VAR` observations store the information about the column variables in matrices. The `_NAME_` variable stores the variable names. The value of `_VAR1_` indicates the column location of the variable in the matrix with the matrix number stored in `_MATNR_`.

The `_TYPE_=MATRIX` observations store the information about the model matrices. The `_NAME_` variable stores the matrix names. The value of `_MATNR_` indicates the corresponding matrix number. The values of `_VAR1_` and `_VAR2_` indicates the numbers of rows and columns, respectively, of the matrix.

The `_TYPE_=MODEL` observations store the covariance and mean structure formulas. The `_NAME_` variable indicates whether the mean (MEAN) or covariance (COV) structure information is stored. The value of `_MATNR_` indicates the matrix number in the mean or covariance structure formula. The `_VAR1_` variable indicates the term number, and the `_VAR2_` variable indicates the location of the matrix in the term.

The `_TYPE_=ESTIM` observations store the information about the parameters and their estimates. The `_NAME_` variable stores the parameter names. The value of `_MATNR_` indicates the matrix number. The values of `_VAR1_` and `_VAR2_` indicate the associated row and column numbers, respectively, of the parameter.

FACTOR Models

<code>_TYPE_</code>	Description	<code>_NAME_</code>	<code>_VAR1_</code>	<code>_VAR2_</code>
MDLTYPE	Model type	Model type		
FACTVAR	Variable	Variable name	Variable number	Variable type
LOADING	Factor loading	Parameter name	Manifest variable	Factor variable
COV	Covariance	Parameter name	First variable	Second variable
PVAR	(Partial) variance	Parameter name	Variable	
MEAN	Mean or intercept	Parameter name	Variable	
ADDCOV	Added covariance	Parameter name	First variable	Second variable
ADDPVAR	Added (partial) variance	Parameter name	Variable	
ADDMEAN	Added mean or intercept	Parameter name	Variable	

For factor models, the value of the `_NAME_` variable is either EFACOR (exploratory factor model) or CFACOR (confirmatory factor model) for the `_TYPE_=MDLTYPE` observation.

The `_TYPE_=FACTVAR` observations store the information about the variables in the model. The `_NAME_` variable stores the variable names. The value of `_VAR1_` indicates the variable number. The value of `_VAR2_` indicates the type of the variable: either DEPV for dependent observed variables or INDF for latent factors.

Other observations specify the parameters and their estimates in the model. The `_NAME_` values for these observations are the parameter names. Observation with `_TYPE_=LOADING`, `_TYPE_=COV`, or `_TYPE_=ADDCOV` are for parameters that are associated with two variables. The `_VAR1_` and `_VAR2_` values of these two types of observations indicate the variables involved.

Observations with `_TYPE_=PVAR`, `_TYPE_=MEAN`, `_TYPE_=ADDPVAR`, or `_TYPE_=ADDMEAN` are for parameters that are associated with a single variable. The value of `_VAR1_` indicates the variable involved.

LINEQS Models

<code>_TYPE_</code>	Description	<code>_NAME_</code>	<code>_VAR1_</code>	<code>_VAR2_</code>
MDLTYPE	Model type	LINEQS		
EQSVAR	Variable	Variable name	Variable number	Variable type
EQUATION	Path coefficient	Parameter	Outcome variable	Predictor variable
COV	Covariance	Parameter	First variable	Second variable
VARIANCE	Variance	Parameter	Variable	
MEAN	Mean	Parameter	Variable	
ADDCOV	Added covariance	Parameter	First variable	Second variable
ADDVARIA	Added variance	Parameter	Variable	
ADDINTE	Added intercept	Parameter	Variable	
ADDMEAN	Added mean	Parameter	Variable	

The value of the `_NAME_` variable is `LINEQS` for the `_TYPE_=MDLTYPE` observation.

The `_TYPE_=EQSVAR` observations store the information about the variables in the model. The `_NAME_` variable stores the variable names. The value of `_VAR1_` indicates the variable number. The value of `_VAR2_` indicates the type of the variable. There are six types of variables in the `LINEQS` model:

- `DEPV` for dependent observed variables
- `INDV` for independent observed variables
- `DEPF` for dependent latent factors
- `INDF` for independent latent factors
- `INDD` for independent error terms
- `INDE` for independent disturbance terms

Other observations specify the parameters and their estimates in the model. The `_NAME_` values for these observations are the parameter names. Observation with `_TYPE_=EQUATION`, `_TYPE_=COV`, or `_TYPE_=ADDCOV` are for parameters that are associated with two variables. The `_VAR1_` and `_VAR2_` values of these two types of observations indicate the variables involved.

Observations with `_TYPE_=VARIANCE`, `_TYPE_=MEAN`, `_TYPE_=ADDVARIA`, `_TYPE_=ADDINTE`, or `_TYPE_=ADDMEAN` are for parameters associated with a single variable. The value of `_VAR1_` indicates the variable involved.

LISMOD Models

TYPE	Description	_NAME_	_VAR1_	_VAR2_
MDLTYPE	model type	LISMOD		
XVAR	x-variable	Variable	Variable number	
YVAR	y-variable	Variable	Variable number	
ETAVAR	η -variable	Variable	Variable number	
XIVAR	ξ -variable	Variable	Variable number	
ALPHA	_ALPHA_ entry	Parameter	Row number	
BETA	_BETA_ entry	Parameter	Row number	Column number
GAMMA	_BETA_ entry	Parameter	Row number	Column number
KAPPA	_KAPPA_ entry	Parameter	Row number	
LAMBDAX	_LAMBDAX_ entry	Parameter	Row number	Column number
LAMBDAY	_LAMBDAY_ entry	Parameter	Row number	Column number
NUX	_NUX_ entry	Parameter	Row number	
NUY	_NUY_ entry	Parameter	Row number	
PHI	_PHI_ entry	Parameter	Row number	Column number
PSI	_PSI_ entry	Parameter	Row number	Column number
THETAX	_THETAX_ entry	Parameter	Row number	Column number
THETAY	_THETAY_ entry	Parameter	Row number	Column number
ADDALPHA	Added _ALPHA_ entry	Parameter	Row number	
ADDKAPPA	Added _KAPPA_ entry	Parameter	Row number	
ADDNUX	Added _NUX_ entry	Parameter	Row number	
ADDNUY	Added _NUY_ entry	Parameter	Row number	
ADDPHI	Added _PHI_ entry	Parameter	Row number	Column number
ADDPSI	Added _PSI_ entry	Parameter	Row number	Column number
ADTHETAX	Added _THETAX_ entry	Parameter	Row number	Column number
ADTHETAY	Added _THETAY_ entry	Parameter	Row number	Column number

The value of the **_NAME_** variable is LISMOD for the **_TYPE_=MDLTYPE** observation. Other observations specify either the variables or the parameters in the model.

Observations with **_TYPE_** values equal to XVAR, YVAR, ETAVAR, and XIVAR indicate the variables in the respective lists in the model. The **_NAME_** variable of these observations stores the names of the variables, and the **_VAR1_** variable stores the variable numbers in the respective list. The variable numbers in this data set are not arbitrary—that is, they define the variable orders in the rows and columns of the LISMOD model matrices. The **_VAR2_** variable of these observations is not used.

All other observations in this data set specify the parameters in the model. The **_NAME_** values of these observations are the parameter names. The corresponding **_VAR1_** and **_VAR2_** values of these observations indicate the row and column locations of the parameters in the LISMOD model matrices that are specified in the **_TYPE_** variable. For example, when the value of **_TYPE_** is ADDPHI or PHI, the parameter specified is located in the **_PHI_** matrix, with its row and column numbers indicated by the **_VAR1_** and **_VAR2_** values, respectively. Some observations for specifying parameters do not have values in the **_VAR2_** variable. This means that the associated LISMOD matrices are vectors so that the column numbers are always 1 for these observations.

MSTRUCT Models

TYPE	Description	_NAME_	_VAR1_	_VAR2_
MDLTYPE	Model type	MSTRUCT		
VAR	Variable	Variable	Variable number	
COVMAT	Covariance	Parameter	Row number	Column number
MEANVEC	Mean	Parameter	Row number	
ADCOVMAT	Added covariance	Parameter	Row number	Column number
AMEANVEC	Added mean	Parameter	Row number	

The value of the **_NAME_** variable is MSTRUCT for the **_TYPE_=MDLTYPE** observation. Other observations specify either the variables or the parameters in the model.

Observations with **_TYPE_** values equal to VAR indicate the variables in the model. The **_NAME_** variable of these observations stores the names of the variables, and the **_VAR1_** variable stores the variable numbers in the variable list. The variable numbers in this data set are not arbitrary—that is, they define the variable orders in the rows and columns of the mean and covariance matrices. The **_VAR2_** variable of these observations is not used.

All other observations in this data set specify the parameters in the model. The **_NAME_** values of these observations are the parameter names. The corresponding **_VAR1_** and **_VAR2_** values of these observations indicate the row and column locations of the parameters in the mean or covariance matrix, as specified in the **_TYPE_** model. For example, when **_TYPE_=COVMAT**, the parameter specified is located in the covariance matrix, with its row and column numbers indicated by the **_VAR1_** and **_VAR2_** values, respectively. For observations with **_TYPE_=MEANVEC**, the **_VAR2_** variable is not used because the column numbers are always 1 for parameters in the mean vector.

PATH Models

TYPE	Description	_NAME_	_VAR1_	_VAR2_
MDLTYPE	Model type	PATH		
PATHVAR	Variable	Variable name	Variable number	Variable type
LEFT	Path coefficient	Parameter	Outcome variable	Predictor variable
RIGHT	Path coefficient	Parameter	Predictor variable	Outcome variable
PCOV	(Partial) covariance	Parameter	First variable	Second variable
PCOVPATH	(Partial) covariance path	Parameter	First variable	Second variable
PVAR	(Partial) variance	Parameter	Variable	
PVARPATH	(Partial) variance path	Parameter	Variable	Variable
MEAN	Mean or intercept	Parameter	Variable	
ONEPATH	Mean or intercept path	Parameter	_ONE_	Variable
ADDPcov	Added (partial) covariance	Parameter	First variable	Second variable
ADDPVAR	Added (partial) variance	Parameter	Variable	
ADDMEAN	Added mean	Parameter	Variable	

The value of the **_NAME_** variable is PATH for the **_TYPE_=MDLTYPE** observation.

The **_TYPE_=PATHVAR** observations store the information about the variables in the model. The **_NAME_** variable stores the variable names. The value of **_VAR1_** indicates the variable number. The value of **_VAR2_** indicates the type of the variable. There are four types of variables in the PATH model:

- DEPV for dependent observed variables

- INDV for independent observed variables
- DEPF for dependent latent factors
- INDF for independent latent factors

Other observations specify the parameters in the model. The `_NAME_` values for these observations are the parameter names. Observation with `_TYPE_=LEFT`, `_TYPE_=RIGHT`, `_TYPE_=PCOV`, or `_TYPE_=ADDP` are for parameters that are associated with two variables. The `_VAR1_` and `_VAR2_` values of these two types of observations indicate the variables involved.

Observations with `_TYPE_=PVAR`, `_TYPE_=MEAN`, `_TYPE_=ADDPVAR`, or `_TYPE_=ADDMEAN` are for parameters that are associated with a single variable. The value of `_VAR1_` indicates the variable involved.

RAM Models

<code>_TYPE_</code>	Description	<code>_NAME_</code>	<code>_VAR1_</code>	<code>_VAR2_</code>
MDLTYPE	Model type	RAM		
RAMVAR	Variable name	Variable	Variable number	Variable type
<code>_A_</code>	<code>_A_</code> entry	Parameter	Row number	Column number
<code>_P_</code>	<code>_P_</code> entry	Parameter	Row number	Column number
<code>_W_</code>	<code>_W_</code> entry	Parameter	Row number	Column number
ADD_P_	Added <code>_P_</code> entry	Parameter	Row number	Column number
ADD_W_	Added <code>_W_</code> entry	Parameter	Row number	Column number

The value of the `_NAME_` variable is RAM for the `_TYPE_=MDLTYPE` observation.

For the `_TYPE_=RAMVAR` observations, the `_NAME_` variable stores the variable names, the `_VAR1_` variable stores the variable number, and the `_VAR2_` variable stores the variable type. There are four types of variables in the PATH model:

- DEPV for dependent observed variables
- INDV for independent observed variables
- DEPF for dependent latent factors
- INDF for independent latent factors

Other observations specify the parameters in the model. The `_NAME_` variable stores the parameter name. The `_TYPE_` variable indicates the associated matrix with the row number indicated in `_VAR1_` and column number indicated in `_VAR2_`.

Reading an OUTMODEL= Data Set As an INMODEL= Data Set in Subsequent Analyses

When the `OUTMODEL=` data set is treated as an `INMODEL=` data set in subsequent analyses, you need to pay attention to observations with `_TYPE_` values prefixed by “ADD”, “AD”, or “A” (for example, `ADDCOV`, `ADTHETAY`, or `AMEANVEC`). These observations represent default parameter locations that are generated by PROC CALIS in a previous run. Because the context of the new analyses might be different, these observations for added parameter locations might no longer be suitable in the new runs. Hence, these observations are *not* read as input model information. Fortunately, after reading the `INMODEL=` specification in the new

analyses, CALIS analyzes the new model specification again. It then adds an appropriate set of parameters in the new context when necessary. If you are certain that the added parameter locations in the INMODEL= data set are applicable, you can force the input of these observations by using the [READADDPARM](#) option in the PROC CALIS statement. However, you must be very careful about using the [READADDPARM](#) option. The added parameters from the INMODEL= data set might have the same parameter names as those for the generated parameters in the new run. This might lead to unnecessary constraints in the model.

OUTSTAT= Data Set

The [OUTSTAT=](#) data set is similar to the TYPE=COV, TYPE=UCOV, TYPE=CORR, or TYPE=UCORR data set produced by the CORR procedure. The [OUTSTAT=](#) data set contains the following variables:

- the BY variables, if any
- the _GPNUM_ variable for groups numbers, if used in the analysis
- two character variables, _TYPE_ and _NAME_
- the manifest and the latent variables analyzed

The [OUTSTAT=](#) data set contains the following information (when available) in the observations:

- the mean and standard deviation
- the skewness and kurtosis (if the [DATA=](#) data set is a raw data set and the [KURTOSIS](#) option is specified)
- the number of observations
- if the [WEIGHT](#) statement is used, sum of the weights
- the correlation or covariance matrix to be analyzed
- the robust covariances, standard deviations, and means for robust estimation
- the predicted correlation or covariance matrix
- the standardized or normalized residual correlation or covariance matrix
- if the model contains latent variables, the predicted covariances between latent and manifest variables and the latent variable (or factor) score regression coefficients (see the [PLATCOV](#) option on page 1112)

In addition, for FACTOR models the [OUTSTAT=](#) data set contains:

- the unrotated factor loadings, the error variances, and the matrix of factor correlations
- the standardized factor loadings and factor correlations
- the rotation matrix, rotated factor loadings, and factor correlations

- standardized rotated factor loadings and factor correlations

If effects are analyzed, the **OUTSTAT=** data set also contains:

- direct, indirect, and total effects and their standard error estimates
- standardized direct, indirect, and total effects and their standard error estimates

Each observation in the **OUTSTAT=** data set contains some type of statistic as indicated by the **_TYPE_** variable. The values of the **_TYPE_** variable are shown in the following tables:

Basic Descriptive Statistics

Value of _TYPE_	Contents
ADJCOV	Adjusted covariances
ADJSTD	Adjusted standard deviations
CORR	Correlations
COV	Covariances
KURTOSIS	Univariate kurtosis
MEAN	Means
N	Sample size
NPARTIAL	Number of partial variables
PARTCOV	Covariances after partialling
PARTCORR	Correlations after partialling
PARTMEAN	Means after partialling
PARTSTD	Standard deviations after partialling
ROBCOV	Robust covariances
ROBMEAN	Robust means
ROBSTD	Robust standard deviations
SKEWNESS	Univariate skewness
STD	Standard deviations
SUMWGT	Sum of weights (if the WEIGHT statement is used)
VARDIV	Variance divisor
VARDIVAJ	Variance divisor adjustment

For the **_TYPE_=CORR** or **COV** observations, the **_NAME_** variable contains the name of the manifest variable that corresponds to each row for the covariance or correlation. For other observations, **_NAME_** is blank.

Predicted Moments and Residuals

value of _TYPE_	Contents
METHOD=DWLS	
DWLSPRED	DWLS predicted moments
DWLSRES	DWLS raw residuals
DWLSSRES	DWLS variance standardized residuals
METHOD=GLS	
GLSASRES	GLS asymptotically standardized residuals
GLSNRES	GLS normalized residuals
GLSPRED	GLS predicted moments
GLSRES	GLS raw residuals
GLSSRES	GLS variance standardized residuals
METHOD=ML or FIML	
MAXASRES	ML asymptotically standardized residuals
MAXNRES	ML normalized residuals
MAXPRED	ML predicted moments
MAXRES	ML raw residuals
MAXSRES	ML variance standardized residuals
METHOD=ULS	
ULSPRED	ULS predicted moments
ULSRES	ULS raw residuals
ULSSRES	ULS variance standardized residuals
METHOD=WLS	
WLSASRES	WLS asymptotically standardized residuals
WLSNRES	WLS normalized residuals
WLSPRED	WLS predicted moments
WLSRES	WLS raw residuals
WLSSRES	WLS variance standardized residuals

For residuals or predicted moments of means, the **_NAME_** variable is a fixed value denoted by **_Mean_**. For residuals or predicted moments for covariances or correlations, the **_NAME_** variable is used for names of variables.

Effects and Latent Variable Scores Regression Coefficients

Value of _TYPE_	Contents
Unstandardized Effects	
DEFFECT	Direct effects
DEFF_SE	Standard error estimates for direct effects
IEFFECT	Indirect effects
IEFF_SE	Standard error estimates for indirect effects
TEFFECT	Total effects
TEFF_SE	Standard error estimates for total effects
Standardized Effects	
SDEFF	Standardized direct effects
SDEFF_SE	Standard error estimates for standardized direct effects
SIEFF	Standardized indirect effects
SIEFF_SE	Standard error estimates for standardized indirect effects
STEFF	Standardized total effects
STEFF_SE	Standard error estimates for standardized total effects
Latent Variable Scores Coefficients	
LSSCORE	Latent variable (or factor) scores regression coefficients for ULS method
SCORE	Latent variable (or factor) scores regression coefficients other than ULS method

For latent variable or factor scores coefficients, the **_NAME_** variable contains factor or latent variables in the observations. For other observations, the **_NAME_** variable contains manifest or latent variable names.

You can use the latent variable score regression coefficients with PROC SCORE to compute factor scores. If the analyzed matrix is a covariance rather than a correlation matrix, the **_TYPE_=STD** observation is not included in the **OUTSTAT=** data set. In this case, the standard deviations can be obtained from the diagonal elements of the covariance matrix. Dropping the **_TYPE_=STD** observation prevents PROC SCORE from standardizing the observations before computing the factor scores.

Factor Analysis Results

Value of _TYPE_	Contents
ERRVAR	Error variances
FCOV	Factor correlations or covariances
LOADINGS	Unrotated factor loadings
RFCOV	Rotated factor correlations or covariances
RLOADING	Rotated factor loadings
ROTMAT	Rotation matrix
STDFCOV	Standardized factor correlations
STDLOAD	Standardized factor loadings
STDRFCOV	Standardized rotated factor correlations or covariances
STDRLOAD	Standardized rotated factor loadings

For the **_TYPE_=ERRVAR** observation, the **_NAME_** variable is blank. For all other observations, the **_NAME_** variable contains factor names.

OUTWGT= Data Set

You can create an **OUTWGT=** data set that is of **TYPE=WEIGHT** and contains the weight matrix used in generalized, weighted, or diagonally weighted least squares estimation. The **OUTWGT=** data set contains the weight matrix on which the **WRIDGE=** and the **WPENALTY=** options are applied. However, if you input the inverse of the weight matrix with the **INWGT=** and **INWGTINV** options (or the **INWGT(INV)=** option alone) in the same analysis, the **OUTWGT=** data set contains the same elements of the inverse of the weight matrix. For unweighted least squares or maximum likelihood estimation, no **OUTWGT=** data set can be written. The weight matrix used in maximum likelihood estimation is dynamically updated during optimization. When the ML solution converges, the final weight matrix is the same as the predicted covariance or correlation matrix, which is included in the **OUTSTAT=** data set (observations with **_TYPE_=MAXPRED**).

For generalized and diagonally weighted least squares estimation, the weight matrices **W** of the **OUTWGT=** data set contain all elements w_{ij} , where the indices i and j correspond to all manifest variables used in the analysis. Let $varnam_i$ be the name of the i th variable in the analysis. In this case, the **OUTWGT=** data set contains n observations with the variables shown in the following table:

Variable	Contents
TYPE	WEIGHT (character)
NAME	Name of variable $varnam_i$ (character)
$varnam_1$	Weight w_{i1} for variable $varnam_1$ (numeric)
\vdots	\vdots
$varnam_n$	Weight w_{in} for variable $varnam_n$ (numeric)

For weighted least squares estimation, the weight matrix **W** of the **OUTWGT=** data set contains only the nonredundant elements $w_{ij,kl}$. In this case, the **OUTWGT=** data set contains $n(n+1)(2n+1)/6$ observations with the variables shown in the following table:

Variable	Contents
TYPE	WEIGHT (character)
NAME	Name of variable $varnam_i$ (character)
NAM2	Name of variable $varnam_j$ (character)
NAM3	Name of variable $varnam_k$ (character)
$varnam_1$	Weight $w_{ij,k1}$ for variable $varnam_1$ (numeric)
\vdots	\vdots
$varnam_n$	Weight $w_{ij,kn}$ for variable $varnam_n$ (numeric)

Symmetric redundant elements are set to missing values.

OUTFIT= Data Set

You can create an **OUTFIT=** data set that is of **TYPE=CALISFIT** and that contains the values of the fit indices of your analysis. If you use two estimation methods such as LSML or LSWLS, the fit indices are for the second analysis. An **OUTFIT=** data set contains the following variables:

- a character variable **_TYPE_** for the types of fit indices
- a numerical variable **IndexCode** for the codes of the fit indices

- a character variable `FitIndex` for the names of the fit indices
- a numerical variable `FitValue` for the numerical values of the fit indices
- a character variable `PrintChar` for the character-formatted fit index values.

The possible values of `_TYPE_` are:

`ModelInfo`: basic modeling statistics and information
`Absolute`: stand-alone fit indices
`Parsimony`: fit indices that take model parsimony into account
`Incremental`: fit indices that are based on comparison with a baseline model

Possible Values of FitIndex When _TYPE_=ModelInfo

Value of FitIndex	Description
Number of Observations	Number of observations used in the analysis
Number of Complete Observations	Number of complete observations (METHOD=FIML)
Number of Incomplete Observations	Number of incomplete observations (METHOD=FIML)
Number of Variables	Number of variables
Number of Moments	Number of mean or covariance elements
Number of Parameters	Number of parameters
Number of Active Constraints	Number of active constraints in the solution
Saturated Model Estimation	Estimation status of the saturated model (METHOD=FIML)
Saturated Model Function Value	Saturated model function value (METHOD=FIML)
Saturated Model -2 Log-Likelihood	Saturated model -2 log-likelihood function value (METHOD=FIML)
Baseline Model Estimation	Estimation status of the baseline model (METHOD=FIML)
Baseline Model Function Value	Baseline model function value
Baseline Model -2 Log-Likelihood	Baseline model -2 log-likelihood function value (METHOD=FIML)
Baseline Model Chi-Square	Baseline model chi-square value
Baseline Model Chi-Square DF	Baseline model chi-square degrees of freedom
Baseline Model DF	Baseline model degrees of freedom (METHOD=ULS or METHOD=DWLS)
Pr > Baseline Model Chi-Square	<i>p</i> value of the baseline model chi-square

Possible Values of FitIndex When _TYPE_=Absolute

Value of FitIndex	Description
Fit Function	Fit function value
-2 Log-Likelihood	-2 log-likelihood function value for the model (METHOD=FIML)
Chi-Square	Model chi-square value
Chi-Square DF	Degrees of freedom for the model chi-square test
Model DF	Degrees of freedom for model (METHOD=ULS or METHOD=DWLS)
Pr > Chi-Square	Probability of obtaining a larger chi-square than the observed value
Percent Contribution to Chi-Square	Percentage contribution to the chi-square value
Percent Contribution to Likelihood	Percentage contribution to the -2 log-likelihood function value (METHOD=FIML)
Elliptic Corrected Chi-Square	Elliptic-corrected chi-square value
Pr > Elliptic Corr. Chi-Square	Probability of obtaining a larger elliptic-corrected chi-square value
Z-test of Wilson and Hilferty	Z-test of Wilson and Hilferty
Hoelter Critical N	N value that makes a significant chi-square when multiplied to the fit function value
Root Mean Square Residual (RMR)	Root mean square residual
Standardized RMR (SRMR)	Standardized root mean square residual
Goodness of Fit Index (GFI)	Jöreskog and Sörbom goodness-of-fit index

Possible Values of FitIndex When _TYPE_=Parsimony

Value of FitIndex	Description
Adjusted GFI (AGFI)	Goodness-of-fit index adjusted for the degrees of freedom of the model
Parsimonious GFI	Mulaik et al. (1989) modification of the GFI
RMSEA Estimate	Steiger and Lind (1980) root mean square error approximation
RMSEA Lower $r\%$ Confidence Limit	Lower $r\%^1$ confidence limit for RMSEA
RMSEA Upper $r\%$ Confidence Limit	Upper $r\%^1$ confidence limit for RMSEA
Probability of Close Fit	Browne and Cudeck (1993) test of close fit
ECVI Estimate	Expected cross-validation index
ECVI Lower $r\%$ Confidence Limit	Lower $r\%^2$ confidence limit for ECVI
ECVI Upper $r\%$ Confidence Limit	Upper $r\%^2$ confidence limit for ECVI
Akaike Information Criterion	Akaike information criterion
Bozdogan CAIC	Bozdogan (1987) consistent AIC
Schwarz Bayesian Criterion	Schwarz (1978) Bayesian criterion
McDonald Centrality	McDonald and Marsh (1988) measure of centrality

1. The value of r is one minus the ALPHARMS= value. By default, $r=90$.2. The value of r is one minus the ALPHAECV= value. By default, $r=90$.

Possible Values of FitIndex When `_TYPE_=Incremental`

Value of FitIndex	Description
Bentler Comparative Fit Index	Bentler (1985) comparative fit index
Bentler-Bonett NFI	Bentler and Bonett (1980) normed fit index
Bentler-Bonett Non-normed Index	Bentler and Bonett (1980) nonnormed fit index
Bollen Normed Index Rho1	Bollen normed ρ_1
Bollen Non-normed Index Delta2	Bollen nonnormed δ_2
James et al. Parsimonious NFI	James, Mulaik, and Brett (1982) parsimonious normed fit index

Default Analysis Type and Default Parameterization

This section describes the default analysis type and default parameterization of PROC CALIS. Because various types of models supported by PROC CALIS have their own specific features, the following table outlines only those major default settings of PROC CALIS in SAS/STAT 9.22 or later:

Moment Structures Analyzed

Covariance structures	Covariance structures are analyzed by default (COVARIANCE option).
Mean structures	Not analyzed by default. Use the MEANSTR option, the ‘Intercept’ variable in the LINEQS statement, the MEAN statement, or specific MATRIX statements to specify mean or intercept parameters.

Default Parameterization

Variance parameters	Free variance parameters for independent latent factors, observed variables, and errors.
Covariance parameters	Free covariance parameters for all pairs of independent latent factors and observed variables (except for the latent factors in exploratory factor models). Fixed zero covariances for all pairs of error variables, all pairs between errors and other exogenous variables, and all pairs of latent factors in exploratory factor models.
Mean parameters	Free mean parameters for all exogenous observed variables. Fixed zero means for all exogenous latent factors and error terms.
Intercept parameters	Free intercept parameters for all endogenous observed variables; Fixed zero intercepts for all endogenous latent factors.

Role of the VAR Statement in Model Specification

Inclusion of Variables	If the VAR statement is used, observed variables that are listed in the VAR statement but not mentioned in corresponding model specification are included as exogenous variables in the model. Default variance, covariance, and mean parameterization apply to these exogenous variables.
------------------------	--

Exclusion of Variables	If the VAR statement is used, observed variables that are not listed in the VAR statement are not recognized as observed variables in model specification. They might be treated as latent variables instead.
------------------------	---

In general, the default settings of PROC CALIS in SAS/STAT 9.22 and later are more consistent with conventional practice of structural equation modeling. For example, because statistical theory of structural equation modeling is based mainly on the analysis of covariance structures, the default analysis type of PROC CALIS in SAS/STAT 9.22 or later is for covariance structures. This means that the **CORR** option must be specified if you want to analyze correlation matrices. Mean structures in PROC CALIS have also been parameterized more naturally since SAS/STAT 9.22 so that users can make statistical inferences directly on the mean and intercept estimates. Default variance and covariance parameters for all independent factors and observed variables have been implemented since SAS/STAT 9.22 to reflect the common belief that no exogenous variables are absolutely uncorrelated (except for the unrotated factors in the initial solution of exploratory FACTOR models).

For comparisons of these and other default settings before and after SAS/STAT 9.22, see the section “[Compatibility with the CALIS Procedure in SAS/STAT 9.2 or Earlier](#)” on page 1045.

For details about the default parameters in specific types of model, see the **FACTOR**, **LINEQS**, **LISMOD**, **PATH**, and **RAM** statements. Because there are no explicit latent variables and the exogenous/endogenous variable distinction is not used in the COSAN and MSTRUCT modeling languages, the default parameterization outlined in the preceding table does not apply to these two types of models. See the **COSAN** and the **MSTRUCT** statements for details. See the following sections for details about model parameterization in various types of models:

- “[The COSAN Model](#)” on page 1259
- “[The FACTOR Model](#)” on page 1263
- “[The LINEQS Model](#)” on page 1270
- “[The LISMOD Model and Submodels](#)” on page 1277
- “[The PATH Model](#)” on page 1288
- “[The RAM Model](#)” on page 1294
- “[The MSTRUCT Model](#)” on page 1285

By default, PROC CALIS in SAS/STAT 9.22 or later treats observed variables specified in the **VAR** statement as exogenous variables in the **FACTOR**, **PATH**, **LINEQS**, and **RAM** models. This minimizes the routine specifications in the **COVARIANCE**, **MEAN**, **PCOV**, **PVAR**, or **VARIANCE** for those “standalone” exogenous observed variables—observed variables that are not functionally related to any other variables in the model. Including these standalone exogenous observed variables into the model is useful during the model modification process (by the **MODIFICATION** option) where you can do Lagrange multiplier tests to see whether relating these variables to other variables can improve the model fit.

Notice that the use of the VAR statement specification is optional in PROC CALIS. If you have specified all the observed variables that you want in the model specification statements, it is not necessary to use the VAR statement specifications for the purpose of specifying the set of observed variable for analysis.

The COSAN Model

The original COSAN (covariance structure analysis) model is proposed by McDonald (1978, 1980) for analyzing general covariance structure models. PROC CALIS enables you to analyze a generalized form of the original COSAN model. The generalized COSAN model extends the original COSAN model with the inclusion of addition terms in the covariance structure formula and the associated mean structure formula.

The covariance structure formula of the generalized COSAN model is

$$\Sigma = \mathbf{F}_1 \mathbf{P}_1 \mathbf{F}_1' + \cdots + \mathbf{F}_m \mathbf{P}_m \mathbf{F}_m'$$

and the corresponding mean structure formula of the generalized COSAN model is

$$\mu = \mathbf{F}_1 \mathbf{v}_1 + \cdots + \mathbf{F}_m \mathbf{v}_m$$

where Σ is a symmetric correlation or covariance matrix for the observed variables, μ is a vector for the observed variable means, each \mathbf{P}_k is a symmetric matrix, each \mathbf{v}_k is a mean vector, and each \mathbf{F}_k ($k = 1, \dots, m$) is the product of $n(k)$ matrices $\mathbf{F}_{k_1}, \dots, \mathbf{F}_{k_{n(k)}}$; that is,

$$\mathbf{F}_k = \mathbf{F}_{k_1} \cdots \mathbf{F}_{k_{n(k)}}, \quad k = 1, \dots, m$$

The matrices \mathbf{F}_{k_j} and \mathbf{P}_k in the model can be one of the forms

$$\mathbf{F}_{k_j} = \begin{cases} \mathbf{G}_{k_j} \\ \mathbf{G}_{k_j}^{-1} \\ (\mathbf{I} - \mathbf{G}_{k_j})^{-1} \end{cases} \quad j = 1, \dots, n(k) \quad \text{and} \quad \mathbf{P}_k = \begin{cases} \mathbf{Q}_k \\ \mathbf{Q}_k^{-1} \end{cases}$$

where \mathbf{G}_{k_j} and \mathbf{Q}_k are basic model matrices that are not expressed as functions of other matrices.

The COSAN model matrices and vectors are \mathbf{G}_{k_j} , \mathbf{Q}_k , and \mathbf{v}_k (when the mean structures are analyzed). The elements of these model matrices and vectors are either parameters (free or constrained) or fixed values. Matrix \mathbf{P}_k is referred to as the central covariance matrix for the k th term in the covariance structure formula.

Essentially, the COSAN modeling language enables you to define the covariance and mean structure formulas of the generalized COSAN model, the basic COSAN model matrices \mathbf{G}_{k_j} , \mathbf{Q}_k , and \mathbf{v}_k , and the parameters and fixed values in the model matrices.

You can also specify a generalized COSAN model without using an explicit central covariance matrix in any term. For example, you can define the k th term in the covariance structure formula as

$$\mathbf{F}_k \mathbf{F}_k' = \mathbf{F}_{k_1} \cdots \mathbf{F}_{k_{n-1}} \mathbf{F}_{k_n} \mathbf{F}_{k_n}' \mathbf{F}_{k_{n-1}}' \cdots \mathbf{F}_{k_1}'$$

The corresponding term for the mean structure becomes

$$\mathbf{F}_{k_1} \cdots \mathbf{F}_{k_{n-1}} \mathbf{v}_m$$

In the covariance structure formula, $\mathbf{F}_{k_n} \mathbf{F}_{k_n}'$ serves as an implicit central covariance matrix in this term of the covariance structure formula. Because of this, \mathbf{F}_{k_n} does not appear in the corresponding mean structure formula.

To take advantage of the modeling flexibility of the COSAN model specifications, you are required to provide the correct covariance and mean structure formulas for the analysis problem. If you are not familiar with the mathematical formulations of structural equation models, you can consider using simpler modeling languages such as PATH or LINEQS.

An Example: Specifying a Second-Order Factor Model

This example illustrates how to specify the covariance structures in the COSAN statement. Consider a second-order factor analysis model with the following formula for the covariance structures of observed variables v_1 – v_9

$$\Sigma = \mathbf{F}_1(\mathbf{F}_2\mathbf{P}_2\mathbf{F}_2' + \mathbf{U}_2)\mathbf{F}_1' + \mathbf{U}_1$$

where \mathbf{F}_1 is a 9×3 first-order factor matrix, \mathbf{F}_2 is a 3×2 second-order factor matrix, \mathbf{P}_2 is a 2×2 covariance matrix for the second-order factors, \mathbf{U}_2 is a 3×3 diagonal matrix for the unique variances of the first-order factors, and \mathbf{U}_1 is a 9×9 diagonal matrix for the unique variances of the observed variables.

To fit this covariance structure model, you first rewrite the covariance structure formula in the form of the generalized COSAN model as

$$\Sigma = \mathbf{F}_1\mathbf{F}_2\mathbf{P}_2\mathbf{F}_2'\mathbf{F}_1' + \mathbf{F}_1\mathbf{U}_2\mathbf{F}_1' + \mathbf{U}_1$$

You can specify the list of observed variables and the three terms for the covariance structure formula in the following COSAN statement:

```
cosan var= v1-v9,
      F1(3) * F2(2) * P2(2,SYM) + F1(3) * U2(3,DIA) + U1(9,DIA);
```

The VAR= option specifies the nine observed variables in the model. Next, the three terms of the covariance structure formula are specified. Because each term in the covariance structure formula is a symmetric product, you only need to specify each term up to the central covariance matrix. For example, although the first term in the covariance structure formula is $\mathbf{F}_1\mathbf{F}_2\mathbf{P}_2\mathbf{F}_2'\mathbf{F}_1'$, you only need to specify **F1(3) * F2(2) * P2(2,SYM)**. PROC CALIS generates the redundant information for the term. Similarly, you specify the other two terms of the covariance structure formula.

In each matrix specification of the COSAN statement, you can specify the following three matrix properties as the arguments in the trailing parentheses: the number of columns, the matrix type, and the transformation of the matrix. For example, **F1(3)** means that the number of columns of \mathbf{F}_1 is 3 (while the number of rows is 9 because this number has to match the number of observed variables specified in the VAR= option), **F2(2)** means that the number of columns of \mathbf{F}_2 is 2 (while the number of rows is 3 because the number has to match the number of columns of the preceding matrix, \mathbf{F}_1). You can specify the type of the matrix in the second argument. For example, **P2(2,SYM)** means that \mathbf{P}_2 is a symmetric (SYM) matrix and **U2(2,DIA)** means that \mathbf{U}_2 is a diagonal (DIA) matrix. You can also specify the transformation of the matrix in the third argument. Because there is no transformation needed in the current second-order factor model, this argument is omitted in the specification. See the [COSAN](#) statement for details about the matrix types and transformation that are supported by the COSAN modeling language.

Suppose now you also want to analyze the mean structures of the second-order factor model. The corresponding mean structure formula is

$$\mu = \mathbf{F}_1\mathbf{F}_2\mathbf{v} + \mathbf{u}$$

where \mathbf{v} is a 2×1 mean vector for the second-order factors and \mathbf{u} is a 6×1 vector for the intercepts of the observed variables. To analyze the mean and covariance structures simultaneously, you can use the following COSAN statement:

```
cosan var= v1-v9,
          F1(3) * F2(2) * P2(2,SYM) [mean = v] + F1(3) * U2(3,DIA)
          + U1(9,DIA) [mean = u];
```

In addition to the covariance structure specified, you now add the trailing MEAN= options in the first and the third terms. PROC CALIS then generates the mean structure formula by the following steps:

- Remove the last matrix (that is, the central covariance matrix) in each term of the covariance structure formula.
- Append to each term the vector that is specified in the MEAN= option of the term, or if no MEAN= option is specified in a term, that term becomes a zero vector in the mean structure formula.

Following these steps, the mean structure formula generated for the second-order factor model is

$$\boldsymbol{\mu} = \mathbf{F}_1 \mathbf{F}_2 \mathbf{v} + \mathbf{0} + \mathbf{u}$$

which is what you expect for the mean structures of the second-order factor model. To complete the COSAN model specification, you can use **MATRIX** statements to specify the parameters and fixed values in the COSAN model matrices. See [Example 27.29](#) for a complete example.

Special Cases of the Generalized COSAN Model

It is illustrative to see how you can view different types of models as a special case of the generalized COSAN model. This section describes two such special cases.

The Original COSAN Model

The original COSAN (covariance structure analysis) model (McDonald 1978, 1980) specifies the following covariance structures:

$$\boldsymbol{\Sigma} = \mathbf{F}_1 \cdots \mathbf{F}_n \mathbf{P} \mathbf{F}_n' \cdots \mathbf{F}_1'$$

This is the generalized COSAN with only one term for the covariance structure model formula. Hence, using the COSAN statement to specify the original COSAN model is straightforward.

Reticular Action Model

The RAM (McArdle 1980; McArdle and McDonald 1984) model fits the covariance structures

$$\boldsymbol{\Sigma}_a = (\mathbf{I} - \mathbf{A})^{-1} \mathbf{P} (\mathbf{I} - \mathbf{A})^{-1'}$$

where $\boldsymbol{\Sigma}_a$ is the symmetric covariance for all latent and observed variables in the RAM model, \mathbf{A} is a square matrix for path coefficients, \mathbf{I} is an identity matrix with the same dimensions as \mathbf{A} , and \mathbf{P} is a symmetric covariance matrix. For details about the RAM model, see the section “[The RAM Model](#)” on page 1294.

Correspondingly, the RAM model fits the mean structure formula

$$\boldsymbol{\mu}_a = (\mathbf{I} - \mathbf{A})^{-1} \mathbf{w}$$

where μ_a is the mean vector for all latent and observed variables in the RAM model and \mathbf{w} is a vector for mean or intercepts of the variables.

To extract the covariance and mean structures for the observed variables, a selection matrix \mathbf{G} is used. The selection matrix \mathbf{G} contains zeros and ones as its elements. Each row of \mathbf{G} has exactly one nonzero element at the position that corresponds to the location of a manifest row variable in Σ_a or μ_a . The covariance structure formula for the observed variables in the RAM model becomes

$$\Sigma = \mathbf{G}(\mathbf{I} - \mathbf{A})^{-1}\mathbf{P}(\mathbf{I} - \mathbf{A})^{-1'}\mathbf{G}'$$

The mean structure formula for the observed variables in the RAM model becomes

$$\mu = \mathbf{G}(\mathbf{I} - \mathbf{A})^{-1}\mathbf{w}$$

These formulas suggest that the RAM model is special case of the generalized COSAN model with one term. For example, suppose that there are 10 observed variables (var1–var10) and 3 latent variables in a RAM model. The following COSAN statement represents the RAM model:

```
cosan var= v1-v10,
      G(13,GEN) * A(13,GEN,IMI) * P(13,SYM) [Mean = w];
```

In the COSAN statement, you define the 10 variables in the VAR= option. Next, you provide the formulas for the mean and covariance structures. \mathbf{G} is 10×13 general matrix (GEN), \mathbf{A} is a 13×13 general matrix with the IMI transformation (that is, $(\mathbf{I} - \mathbf{A})^{-1}$), \mathbf{P} is a 13×13 symmetric matrix (SYM), and \mathbf{w} is a 13×1 vector. With these COSAN statement specifications, your mean and covariance structure formulas represent exactly those of the RAM model. To complete the entire model specification, your next step is to use the **MATRIX** statements to specify the parameters and fixed values in the model matrices \mathbf{G} , \mathbf{A} , \mathbf{P} , and \mathbf{w} .

Similarly, it is possible to use the COSAN modeling language to represent any other model types such as models defined by the FACTOR, LINEQS, LISMOD, MSTRUCT, PATH, and RAM statements. But this is not an automatic recommendation of using the COSAN modeling languages in all situations. When an analysis can be specified by either the COSAN or a more specific modeling language (for example, PATH), you should consider using the specific modeling language because the specific modeling language can exploit specific model features so that it does the following:

- enables more supplemental analysis (effect analysis, standardized solutions, and so on), which COSAN has no general way to display
- supports better initial estimation methods (the COSAN model can only set initial estimates to certain default or random values)
- leads to more efficient computations due to the availability of more specific formulas and algorithms

Certainly, the COSAN modeling language is still very useful when you fit some nonstandard model structures that cannot be handled otherwise by the more specific modeling languages.

Naming Variables in the COSAN Model

Although you can define the list of observed (manifest) variables in the VAR= option of the COSAN statement, the COSAN modeling language does not support a direct specification of the latent or error variables in the model. In the COSAN statement, you can define the model matrices and how they multiply together

to form the covariance and mean structures. However, except for the row variables of the first matrix in each term, you do not need to *identify* the row and column variables in all other matrices. However, you can use the **VARNAME**s statement to *label* the column variables of the matrices. The names in the **VARNAME**s statement follow the general naming rules required by the general SAS system. They should not contain special characters and cannot be longer than 32 characters. Also, they do not need to use certain prefixes like what the LINEQS modeling language requires. It is important to realize that the **VARNAME**s statement only *labels*, but does not *identify*, the column variables (and the row variables, by propagation). This means that while keeping all other things equal, changing the names in the **VARNAME**s statements does not change the mathematical model or the estimation of the model. For example, you can label all columns of a COSAN matrix with the same name but it does not mean that these columns refer to the same variable in the model. See the section “**Naming Variables and Parameters**” on page 1302 for the general rules about naming variables and parameters.

Default Parameters in the COSAN Model

The default parameters of the COSAN model matrices depend on the types of the matrices. Each element of the IDE or ZID matrix (identity matrix with or without an additional zero matrix) is either a fixed one or a fixed zero. You cannot override the default parameter values of these fixed matrices. For COSAN model matrices with types other than IDE or ZID, all elements are fixed zeros by default. You can override these default zeros by specifying them explicitly in the **MATRIX** statements.

The FACTOR Model

The FACTOR modeling language is used for specifying exploratory and confirmatory factor analysis models. You can use other general modeling languages such as LINEQS, LISMOD, PATH, and RAM to specify a factor model. But the FACTOR modeling language is more convenient for specifying factor models and is more specialized in displaying factor-analytic results. For convenience, models specified by the FACTOR modeling language are called FACTOR models.

Types of Variables in the FACTOR Model

Each variable in the FACTOR model is either manifest or latent. Manifest variables are those variables that are measured in the research. They must be present in the input data set. Latent variables are not directly observed. Each latent variable in the FACTOR model can be either a factor or an error term.

Factors are unmeasured hypothetical constructs for explaining the covariances among manifest variables, while errors are the unique parts of the manifest variables that are not explained by the (common) factors.

In the FACTOR model, all manifest variables are endogenous, which means that they are predicted from the latent variables. In contrast, all latent variables in the FACTOR model are exogenous, which means that they serve as predictors only.

Naming Variables in the FACTOR Model

Manifest variables in the FACTOR model are referenced in the input data set. In the FACTOR model specification, you use their names as they appear in the input data set. Manifest variable names must not be longer than 32 characters. There are no further restrictions on these names beyond those required by the SAS System.

Error variables in the FACTOR model are not named explicitly, although they are assumed in the model. You can name latent factors only in confirmatory FACTOR models. Factor names must not be longer than 32 characters and must be distinguishable from the manifest variable names in the same analysis. You do not need to name factors in exploratory FACTOR models, however. Latent factors named Factor1, Factor2, and so on are generated automatically in exploratory FACTOR models.

Model Matrices in the FACTOR Model

Suppose in the FACTOR model that there are p manifest variables and n factors. The FACTOR model matrices are described in the following subsections.

Matrix \mathbf{F} ($p \times n$) : Factor Loading Matrix

The rows of \mathbf{F} represent the p manifest variables, while the columns represent the n factors. Each row of \mathbf{F} contains the factor loadings of a variable on all factors in the model.

Matrix \mathbf{P} ($n \times n$) : Factor Covariance Matrix

The \mathbf{P} matrix is a symmetric matrix for the variances of and covariances among the n factors.

Matrix \mathbf{U} ($p \times p$) : Error Covariance Matrix

The \mathbf{U} matrix represents a $p \times p$ diagonal matrix for the error variances for the manifest variables. Elements in this matrix are the parts of variances of the manifest variables that are not explained by the common factors. Note that all off-diagonal elements of \mathbf{U} are fixed zeros in the FACTOR model.

Vector \mathbf{a} ($p \times 1$) : Intercepts

If the mean structures are analyzed, vector \mathbf{a} represents the intercepts of the manifest variables.

Vector \mathbf{v} ($n \times 1$) : Factor Means

If the mean structures are analyzed, vector \mathbf{v} represents the means of the factors.

Matrix Representation of the FACTOR Model

Let \mathbf{y} be a $p \times 1$ vector of manifest variables, $\boldsymbol{\xi}$ be an $n \times 1$ vector of latent factors, and \mathbf{e} be a $p \times 1$ vector of errors. The factor model is written as

$$\mathbf{y} = \mathbf{a} + \mathbf{F}\boldsymbol{\xi} + \mathbf{e}$$

With the model matrix definitions in the previous section, the covariance matrix $\boldsymbol{\Sigma}$ ($p \times p$) of manifest variables is structured as

$$\boldsymbol{\Sigma} = \mathbf{F}\mathbf{P}\mathbf{F}' + \mathbf{U}$$

The mean vector $\boldsymbol{\mu}$ ($p \times p$) of manifest variables is structured as

$$\boldsymbol{\mu} = \mathbf{a} + \mathbf{F}\mathbf{v}$$

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

and

$$\mathbf{U} = \begin{pmatrix} * & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & * & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & * & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & * & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & * & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & * & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & * & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & * & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & * \end{pmatrix}$$

If METHOD=FIML or METHOD=LSFIML, the elements of the intercept vector \mathbf{a} are all free parameters, as shown in the following:

$$\mathbf{a} = \begin{pmatrix} * \\ * \\ * \\ * \\ * \\ * \\ * \\ * \\ * \end{pmatrix}$$

The factor mean vector \mathbf{v} is a fixed zero vector.

If an initial factor solution is rotated afterward, some of these matrix patterns are changed. In general, rotating a factor solution eliminates the fixed zero pattern in the upper triangle of the factor loading matrix \mathbf{F} . If you apply an orthogonal rotation, the factor covariance matrix \mathbf{P} does not change. It is an identity matrix before and after rotation. However, if you apply an oblique rotation, in general the rotated factor covariance matrix \mathbf{P} is not an identity matrix and the off-diagonal elements are not zeros.

The error covariance matrix \mathbf{U} remains unchanged after rotation. That is, it would still be a diagonal matrix. For the FIML estimation, the rotation does not affect the estimation of the intercept vector \mathbf{a} and the fixed factor mean vector \mathbf{v} .

Confirmatory Factor Analysis Models

In confirmatory FACTOR models, there are no imposed patterns on the \mathbf{F} , \mathbf{P} , \mathbf{a} , and \mathbf{v} model matrices. All elements in these model matrices can be specified. However, for model identification, you might need to specify some factor loadings or factor variances as constants.

The only model restriction in confirmatory FACTOR models is placed on \mathbf{U} , which must be a diagonal matrix, as in exploratory FACTOR models too.

For example, for a confirmatory factor analysis with nine variables and three factors, you might specify the following patterns for the model matrices, where * denotes free parameters in the model matrices:

$$\mathbf{F} = \begin{pmatrix} 1 & 0 & 0 \\ * & 0 & 0 \\ * & 0 & 0 \\ 0 & 1 & 0 \\ 0 & * & 0 \\ 0 & * & 0 \\ 0 & 0 & 1 \\ 0 & 0 & * \\ 0 & 0 & * \end{pmatrix}$$

$$\mathbf{P} = \begin{pmatrix} * & * & * \\ * & * & * \\ * & * & * \end{pmatrix}$$

and

$$\mathbf{U} = \begin{pmatrix} * & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & * & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & * & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & * & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & * & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & * & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & * & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & * & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & * \end{pmatrix}$$

In this confirmatory factor model, mean structures are not modeled. In addition, there are some distinctive features that underscore the differences between confirmatory and exploratory models:

- Factor loading matrix \mathbf{F} contains mostly zero elements and few nonzero free parameters, a pattern which is seen in most confirmatory factor models. In contrast, in exploratory factor models most elements in the \mathbf{F} matrix are nonzero parameters.
- Factor loading matrix \mathbf{F} contains fixed values of ones. These fixed values are used for model identification purposes (that is, identifying the scales of the latent variables). In general, you always have to make sure that your confirmatory factor models are identified by putting fixed values in appropriate parameter locations in the model matrices. However, this is not a concern in exploratory FACTOR models because identification has been ensured by imposing certain patterns on the model matrices.
- The nonzero off-diagonal parameters in the factor covariance matrix \mathbf{P} indicate that correlated factors are hypothesized in the confirmatory factor model. This cannot be the case with the initial model of exploratory FACTOR models, where the \mathbf{P} matrix must be an identity matrix before rotation.

Summary of Matrices in the FACTOR Model

Let p be the number of manifest variables and n be the number of factors in the FACTOR model. The names, roles, and dimensions of the FACTOR model matrices are shown in the following table.

Matrix	Name	Description	Dimensions
F	_FACTLOAD_	Factor loading matrix	$p \times n$
P	_FACTFCOV_	Factor covariance matrix	$n \times n$
U	_FACTERRV_	Error covariance matrix	$p \times p$
a	_FACTINTE_	Intercepts	$p \times 1$
v	_FACTMEAN_	Factor means	$n \times 1$

Specification of the Exploratory Factor Model

Because all initial model matrices of exploratory FACTOR models are predefined in PROC CALIS, you do not need to specify any other parameters in the model matrices. To obtain desired factor solutions, you can use various options for exploratory factor analysis in the **FACTOR** statement. These options are the *EFA-options* in the **FACTOR** statement. Two main types of *EFA-options* are shown as follows:

- options for factor extraction: COMPONENT, HEYWOOD, and N=.
- options for factor rotation: GAMMA=, NORM=, RCONVERGE=, RITER=, ROTATE=, and TAU=.

For example, the following statement requests that three factors be extracted, followed by a varimax rotation of the initial factor solution:

```
factor n=3 rotate=varimax;
```

See the **FACTOR** statement on page 1138 for details about the *EFA-options*.

Specification of the Confirmatory Factor Model

To specify a confirmatory FACTOR model, you specify the factor-variable relationships in the **FACTOR** statement, the factor variances and error variances in the **PVAR** statement, the factor covariances in the **COV** statement, and the means and intercepts in the **MEAN** statement.

Specification of Factor-Variable Relationships

The *CFA-spec* in the **FACTOR** statement is for specifying the factor-variables relationships. For example, in the following statement you specify three factors F1, F2, and F3 that are related to different clusters of observed variables V1–V9:

```
factor
  F1 ==> V1-V3 = 1. parm1 (.4) parm2 (.4),
  F2 ==> V4-V6 = 1. parm3 parm4,
  F3 ==> V7-V9 = 1. parm5 parm6 (.3);
```

In the specification, variable V1 has a fixed loading of 1.0 on F1. Variables V2 and V3 have loadings on F1 also. These two loadings are free parameters named parm1 and parm2, respectively. Initial estimates can be set in parentheses after the free parameters. For example, both parm1 and parm2 have initial values at 0.4. Similarly, relationships of factor F2 with V4–V6 and of factor F3 with V7–V9 are defined in the same

FACTOR statement. Providing initial estimates for parameters is optional. In this example, `parm3`, `parm4`, and `parm5` are all free parameters without initial values provided. PROC CALIS can determine appropriate initial estimates for these parameters. See the descriptions of *CFA-spec* in the **FACTOR** statement on page 1138 for more details about the syntax.

Specification of Factor Variances and Error Variances

You can specify the factor variances and error variances in the **PVAR** statement. For example, consider the following statement:

```
pvar F1-F3 = fvar1-fvar3,
      V1-V9 = evar1-evar9 (9*10.);
```

In the **PVAR** statement, you specify the variances of factors F1, F2, and F3 as free parameters `fvar1`, `fvar2`, and `fvar3`, respectively, and the error variances for manifest variables V1–V9 as free parameters `evar1`–`evar9`, respectively. Each of the error variance parameters is given a starting value at 10. See the **PVAR** statement on page 1214 for more details about the syntax.

Specification of Factor Covariances

You can specify the factor covariances in the **COV** statement. For example, you specify the covariances among factors F1, F2, and F3 in the following statement:

```
cov F1 F2 = cov12,
     F1 F3 = cov13,
     F2 F3 = cov23;
```

The covariance parameters are named `cov12`, `cov13`, and `cov23`, respectively. They represent the lower triangular elements of the factor covariance matrix **P**. See the **COV** statement on page 1132 for more details about the syntax.

Specification of Means and Intercepts

If mean structures are of interest, you can also specify the factor means and the intercepts for the manifest variables in the **MEAN** statement. For example, consider the following statement:

```
mean F1-F3 = fmean1-fmean3,
      V1-V9 = 9*12.;
```

In this statement, you specify the factor means of F1, F2, and F3 as free parameters `fmean1`, `fmean2`, and `fmean3`, respectively, and the intercepts for variables V1–V9 as fixed parameters at 12. See the **MEAN** statement on page 1189 for more details about the syntax.

Naming the Factors

For the exploratory FACTOR model, PROC CALIS generates the names for the factors automatically. For the confirmatory FACTOR model, you can specify the names for the factors. Unlike the LINEQS model, in the confirmatory FACTOR model you do not need to use the ‘F’ or ‘f’ prefix to denote factors in the model. You can use any valid SAS variable names for the factors, especially those names that reflect the nature of the factors. To avoid confusions with other names in the model, some general rules are recommended. See the section “Naming Variables and Parameters” on page 1302 for these general rules about naming variables and parameters.

Default Parameters in the FACTOR Model

Default parameters in the FACTOR model are different for exploratory and confirmatory factor models.

For the exploratory FACTOR model, all fixed and free parameters of the model are prescribed. These prescribed parameters include a fixed pattern for the factor loading matrix **F**, a diagonal pattern for the error variance matrix **U**, and an identity matrix for factor covariance matrix **P**. This means that factors are uncorrelated in the estimation. However, if you specify an oblique rotation after the estimation of the factor solution, the factors could become correlated. See the section “[Exploratory Factor Analysis Models](#)” on page 1265 for more details about the patterns of the exploratory FACTOR model. Because all these patterns are prescribed, you cannot override any of these parameters for the exploratory FACTOR model.

For the confirmatory FACTOR model, the set of default free parameters of the confirmatory FACTOR model includes the following:

- the error variances of the observed variables; these correspond to the diagonal elements of the uniqueness matrix **U**
- the variances and covariances among the factors; these correspond to all elements of the factor covariance matrix **P**
- the intercepts of the observed variables if the mean structures are modeled; these correspond to all elements of the intercept vector **a**

PROC CALIS names the default free parameters with the `_Add` prefix (or the `_a` prefix for the case of default intercept parameters in `a` for exploratory factor models), followed by a unique integers for each parameter. Except for the exploratory factor model, you can override the default free parameters by explicitly specifying them as free, constrained, or fixed parameters in the `COV`, `MEAN`, or `PVAR` statement.

In addition to default free parameters, another type of default parameter is the fixed zeros applied to the unspecified parameters in the loading matrix **F** and the factor means in the **ν** vector. Certainly, you use the `FACTOR` and `MEAN` specifications to override those default zero loadings or factor means and set them to free, constrained, or fixed parameters. Notice that the uniqueness matrix **U** in the confirmatory factor model is a diagonal element. You cannot specify any of its off-diagonal elements—they are always fixed zeros by the model restriction.

The LINEQS Model

The LINEQS modeling language is adapted from the EQS (equations) program by Bentler (1995). The statistical models that LINEQS or EQS analyzes are essentially the same as other general modeling languages such as LISMOD, RAM, and PATH. However, the terminology and approach of the LINEQS or EQS modeling language are different from other languages. They are based on the theoretical model developed by Bentler and Weeks (1980). For convenience, models that are analyzed using the LINEQS modeling language are called LINEQS models. Note that these so-called LINEQS models can also be analyzed by other general modeling languages in PROC CALIS.

In the LINEQS (or the original EQS) model, relationships among variables are represented by a system of equations. For example:

$$Y_1 = a_0 + a_1X_1 + a_2X_2 + E_1$$

$$Y_2 = b_0 + b_1X_1 + b_2Y_1 + E_2$$

On the left-hand side of each equation, an outcome variable is hypothesized to be a linear function of one or more predictor variables and an error, which are all specified on the right-hand side of the equation. The parameters specified in an equation are the effects (or regression coefficients) of the predictor variables. For example, in the preceding equations, Y_1 and Y_2 are outcome variables; E_1 and E_2 are error variables; a_1 , a_2 , b_1 , and b_2 are effect parameters (or regression coefficients); and a_0 and b_0 are intercept parameters. Variables X_1 and X_2 serve as predictors in the first equation, while variables X_1 and Y_1 serve as predictors in the second equation.

This is almost the same representation as in multiple regression models. However, the LINEQS model entails more. It supports a system of equations that can also include latent variables, measurement errors, and correlated errors.

Types of Variables in the LINEQS Model

The distinction between dependent and independent variables is important in the LINEQS model.

A variable is dependent if it appears on the left-hand side of an equation in the model. A dependent variable might be observed (manifest) or latent. It might or might not appear on the right-hand side of other equations, but it cannot appear on the left-hand sides of two or more equations. Error variables cannot be dependent in the LINEQS model.

A variable in the LINEQS model is independent if it is not dependent. Independent variables can be observed (manifest) or latent. All error variables must be independent in the LINEQS model.

Dependent variables are also referred to as endogenous variables; these names are interchangeable. Similarly, independent variables are interchangeable with exogenous variables.

Whereas an outcome variable in any equation must be a dependent variable, a predictor variable in an equation is not necessarily an independent variable in the entire LINEQS model. For example, Y_1 is a predictor variable in the second equation of the preceding example, but it is a dependent variable in the LINEQS model. In summary, the predictor-outcome nature of a variable is determined within a single equation, while the exogenous-endogenous (independent-dependent) nature of variable is determined within the entire system of equations.

In addition to the dependent-independent variable distinction, variables in the LINEQS model are distinguished according to whether they are observed in the data. Variables that are observed in research are called observed or manifest variables. Hypothetical variables that are not observed in the LINEQS model are latent variables.

Two types of latent variables should be distinguished: one is error variables; the other is non-error variables. An error variable is unique to an equation. It serves as the unsystematic source of effect for the outcome variable in an equation. If the outcome variable in the equation is latent, the corresponding error variable is also called disturbance. In contrast, non-error or systematic latent variables are called factors. Factors are unmeasured hypothetical constructs in your model. They are systematic sources that explain or describe functional relationships in your model.

Both manifest variables and latent factors can be dependent or independent. However, error or disturbance terms must be independent (or exogenous) variables in your model.

Naming Variables in the LINEQS Model

Whether a variable in each equation is an outcome or a predictor variable is prescribed by the modeler. Whether a variable is independent or dependent can be determined by analyzing the entire system of equations in the model. Whether a variable is observed or latent can be determined if it is referenced in your data set. However, whether a latent variable serves as a factor or an error can be determined only if you provide the specific information.

To distinguish latent factors from errors and both from manifest variables, the following rules for naming variables in the LINEQS model are followed:

- Manifest variables are referenced in the input data set. You use their names in the LINEQS model specification directly. There is no additional naming rule for the manifest variables in the LINEQS model beyond those required by the SAS System.
- Latent factor variables must start with letter F or f (for factor).
- Error variables must start with letter E or e (for error), or D or d (for disturbance). Although you might enforce the use of D- (or d-) variables for disturbances, it is not required. For flexibility, disturbance variables can also start with letter E or e in the LINEQS model.
- The names of latent variables, errors, and disturbances (F-, E-, and D-variables) should not coincide with the names of manifest variables.
- You should not use `Intercept` as a name for any variable. This name is reserved for the intercept specification in LINEQS model equations.

See the section “[Naming Variables and Parameters](#)” on page 1302 for the general rules about naming variables and parameters.

Matrix Representation of the LINEQS Model

As a programming language, the LINEQS model uses equations to describes relationships among variables. But as a mathematical model, the LINEQS model is more conveniently described by matrix terms. In this section, the LINEQS matrix model is described.

Suppose in a LINEQS model that there are n_i independent variables and n_d dependent variables. The vector of the independent variables is denoted by ξ , in the order of manifest variables, latent factors, and error variables. The vector of dependent variables is denoted by η , in the order of manifest variables and latent factors. The LINEQS model matrices are defined as follows:

α ($n_d \times 1$) :	intercepts of dependent variables
β ($n_d \times n_d$) :	effects of dependent variables (in columns) on dependent variables (in rows)
γ ($n_d \times n_i$) :	effects of independent variables (in columns) on dependent variables (in rows)
Φ ($n_i \times n_i$) :	covariance matrix of independent variables
ν ($n_i \times 1$) :	means of independent variables

The model equation of the LINEQS model is

$$\eta = \alpha + \beta\eta + \gamma\xi$$

Assuming that $(\mathbf{I} - \beta)$ is invertible, under the model the covariance matrix of all variables $(\eta', \xi')'$ is structured as

$$\Sigma_a = \begin{pmatrix} (\mathbf{I} - \beta)^{-1} \gamma \Phi \gamma' (\mathbf{I} - \beta)^{-1'} & (\mathbf{I} - \beta)^{-1} \gamma \Phi \\ \Phi \gamma' (\mathbf{I} - \beta)^{-1'} & \Phi \end{pmatrix}$$

The mean vector of all variables $(\eta', \xi')'$ is structured as

$$\mu_a = \begin{pmatrix} (\mathbf{I} - \beta)^{-1} (\alpha + \gamma \nu) \\ \nu \end{pmatrix}$$

As is shown in the structured covariance and mean matrices, the means \mathbf{G} and covariances of independent variables are direct model parameters in ν and Φ ; whereas the means and covariances of dependent variables are functions of various model matrices and hence functions of model parameters.

The covariance and mean structures of all observed variables are obtained by selecting the elements in Σ_a and μ_a . Mathematically, define a selection matrix \mathbf{G} of dimensions $n \times (n_d + n_i)$, where n is the number of observed variables in the model. The selection matrix \mathbf{G} contains zeros and ones as its elements. Each row of \mathbf{G} has exactly one nonzero element at the position that corresponds to the location of an observed row variable in Σ_a or μ_a . With each row of \mathbf{G} selecting a distinct observed variable, the structured covariance matrix of all observed variables is represented by

$$\Sigma = \mathbf{G} \Sigma_a \mathbf{G}'$$

The structured mean vector of all observed variables is represented by

$$\mu = \mathbf{G} \mu_a$$

Partitions of Some LINEQS Model Matrices and Their Restrictions

There are some restrictions in some of the LINEQS model matrices. Although these restrictions do not affect the derivation of the covariance and mean structures, they are enforced in the LINEQS model specification.

Model Restrictions on the β Matrix

The diagonal of the β matrix must be zeros. This prevents the direct regression of dependent variables on themselves. Hence, in the LINEQS statement you cannot specify the same variable on both the left-hand and the right-hand sides of the same equation.

Partitions of the γ Matrix and the Associated Model Restrictions

The columns of the γ matrix refer to the variables in ξ , in the order of manifest variables, latent factors, and error variables. In the LINEQS model, the following partition of the γ matrix is assumed:

$$\gamma = (\gamma_0 \quad \mathbf{E})$$

where γ_0 is an $n_d \times (n_i - n_d)$ matrix for the effects of independent manifest variables and latent factors on the dependent variables and \mathbf{E} is an $n_d \times n_d$ permutation matrix for the effects of errors on the dependent variables.

The dimension of submatrix \mathbf{E} is $n_d \times n_d$ because in the LINEQS model each dependent variable signifies an equation with an error term. In addition, because \mathbf{E} is a permutation matrix (which is formed by exchanging rows of an identity matrix of the same order), the partition of the $\boldsymbol{\gamma}$ matrix ensures that each dependent variable is associated with a *unique* error term and that the effect of each error term on its associated dependent variable is 1.

As a result of the error term restriction, in the **LINEQS** statement you must specify a unique error term in each equation. The coefficient associated with the error term can only be a fixed value at one, either explicitly (with 1.0 inserted immediately before the error term) or implicitly (with no coefficient specified).

Partitions of the $\boldsymbol{\nu}$ Vector and the Associated Model Restrictions

The $\boldsymbol{\nu}$ vector contains the means of independent variables, in the order of the manifest, latent factor, and error variables. In the LINEQS model, the following partition of the $\boldsymbol{\nu}$ vector is assumed:

$$\boldsymbol{\nu} = \begin{pmatrix} \boldsymbol{\nu}_0 \\ 0 \end{pmatrix}$$

where $\boldsymbol{\nu}_0$ is an $(n_i - n_d) \times 1$ vector for the means of independent manifest variables and latent factors and 0 is a null vector of dimension n_d for the means of errors or disturbances. Again, the dimension of the null vector is n_d because each dependent variable is associated uniquely with an error term. This partition restricts the means of errors or disturbances to zeros.

Hence, when specifying a LINEQS model, you cannot specify the means of errors (or disturbances) as free parameter or fixed values other than zero in the **MEAN** statement.

Partitions of the Φ matrix

The Φ matrix is for the covariances of the independent variables, in the order of the manifest, latent factor, and error variables. The following partition of the Φ matrix is assumed:

$$\Phi = \begin{pmatrix} \Phi_{11} & \Phi'_{21} \\ \Phi_{21} & \Phi_{22} \end{pmatrix}$$

where Φ_{11} is an $(n_i - n_d) \times (n_i - n_d)$ covariance matrix for the independent manifest variables and latent factors, Φ_{22} is an $n_d \times n_d$ covariance matrix for the errors, and Φ_{21} is an $n_d \times (n_i - n_d)$ covariance matrix for the errors with other independent variables in the LINEQS model. Because Φ is symmetric, Φ_{11} and Φ_{22} are also symmetric.

There are actually no model restrictions placed on the submatrices of the partition. However, in most statistical applications, errors represent unsystematic sources of effects and therefore they are not to be correlated with other systematic sources. This implies that submatrix Φ_{21} is a null matrix. However, Φ_{21} being null is not enforced in the LINEQS model specification. If you ever specify a covariance between an error variable and a non-error independent variable in the **COV** statement, as a workaround trick or otherwise, you should provide your own theoretical justifications.

Summary of Matrices and Submatrices in the LINEQS Model

Let n_d be the number of dependent variables and n_i be the number of independent variables. The names, roles, and dimensions of the LINEQS model matrices and submatrices are summarized in the following table.

Matrix	Name	Description	Dimensions
Model Matrices			
α	_EQSALPHA_	Intercepts of dependent variables	$n_d \times 1$
β	_EQSBETA_	Effects of dependent (column) variables on dependent (row) variables	$n_d \times n_d$
γ	_EQSGAMMA_	Effects of independent (column) variables on dependent (row) variables	$n_d \times n_i$
ν	_EQSNU_	Means of independent variables	$n_i \times 1$
Φ	_EQSPHI_	Covariance matrix of independent variables	$n_i \times n_i$
Submatrices			
γ_0	_EQSGAMMA_SUB_	Effects of independent variables, excluding errors, on dependent variables	$n_d \times (n_i - n_d)$
ν_0	_EQSNU_SUB_	Means of independent variables, excluding errors	$(n_i - n_d) \times 1$
Φ_{11}	_EQSPHI11_	Covariance matrix of independent variables, excluding errors	$(n_i - n_d) \times (n_i - n_d)$
Φ_{21}	_EQSPHI21_	Covariances of errors with other independent variables	$n_d \times (n_i - n_d)$
Φ_{22}	_EQSPHI22_	Covariance matrix of errors	$n_d \times n_d$

Specification of the LINEQS Model

Specification in Equations

In the **LINEQS** statement, you specify intercepts and effect parameters (or regression coefficients) along with the variable relationships in equations. In terms of model matrices, you specify the α vector and the β and γ matrices in the **LINEQS** statement without using any matrix language.

For example:

$$Y = b_0 + b_1 * X_1 + b_2 * F_2 + E_1$$

In this equation, you specify Y as an outcome variable, X_1 and F_2 as predictor variables, and E_1 as an error variable. The parameters in the equation are the intercept b_0 and the path coefficients (or effects) b_1 and b_2 .

This kind of model equation is specified in the **LINEQS** statement. For example, the previous equation translates into the following **LINEQS** statement specification:

```
lineqs Y = b0 * Intercept + b1 * X1 + b2 * F2 + E1;
```

If the mean structures of the model are not of interest, the intercept term can be omitted. The specification becomes:

```
lineqs Y = b1 * X1 + b2 * F2 + E1;
```

See the [LINEQS statement](#) on page 1156 for the details about the syntax.

Because of the LINEQS model restrictions (see the section “[Partitions of Some LINEQS Model Matrices and Their Restrictions](#)” on page 1273), you must also follow these rules when specifying LINEQS model equations:

- A dependent variable can appear only on the left-hand side of an equation once. In other words, you must put all predictor variables for a dependent variable in one equation. This is different from some econometric models where a dependent variable can appear on the left-hand sides of two equations to represent an equilibrium point. However, this limitation can be resolved by reparameterization in some cases. See [Example 27.18](#).
- A dependent variable that appears on the left-hand side of an equation cannot appear on the right-hand side of the same equation. If you measure the same characteristic at different time points and the previous measurement serves as a predictor of the next measurement, you should use different variable names for the measurements so as to comply with this rule.
- An error term must be specified in each equation and must be unique. The same error name cannot appear in two or more equations. When an equation is truly intended to have no error term, it should be represented equivalently in the LINEQS equation by introducing an error term with zero variance (specified in the [VARIANCE](#) statement).
- The regression coefficient (effect) that is associated with an error term must be fixed at one (1.0). This is done automatically by omitting any fixed constants or parameters that are associated with the error terms. Inserting a parameter or a fixed value other than 1 immediately before an error term is not allowed.

Mean, Variance, and Covariance Parameter Specification

In addition to the intercept and effect parameters that are specified in equations, the means, variances, and covariances among all independent variables are parameters in the LINEQS model. An exception is that the means of all error variables are restricted to fixed zeros in the LINEQS model. To specify the mean, variance, and covariance parameters, you use the [MEAN](#), [VARIANCE](#), and the [COV](#) statements, respectively.

The means, variances, and covariances among dependent variables are not parameters themselves in the model. Rather, they are complex functions of the model parameters. See the section “[Matrix Representation of the LINEQS Model](#)” on page 1272 for mathematical details.

Default Parameters in the LINEQS Model

There are two types of default parameters of the LINEQS model, as implemented in PROC CALIS. One is the free parameters; the other is the fixed constants.

The following sets of parameters are free parameters by default:

- the variances of all exogenous (independent) observed or latent variables (*including* error and disturbance variables)

- the covariances among all exogenous (independent) manifest or latent variables (*excluding* error and disturbance variances)
- the means of all exogenous (independent) observed variables if the mean structures are modeled
- the intercepts of all endogenous (dependent) manifest variables if the mean structures are modeled

PROC CALIS names the default free parameters with the `_Add` prefix and a unique integer suffix. You can override the default free parameters by explicitly specifying them as free, constrained, or fixed parameters in the COV, LINEQS, MEAN, or VARIANCE statement.

Parameters that are not default free parameters in the LINEQS model are fixed constants by default. You can override almost all of the default fixed constants of the LINEQS model by using the COV, LINEQS, MEAN, or VARIANCE statement. You cannot override the following two sets of fixed constants:

- fixed zero parameters for the direct effects (path coefficients) of variables on their own. You cannot have an equation in the LINEQS statement that has the same variable specified on the left-hand and the right-hand sides.
- fixed one effects from the error or disturbance variables. You cannot set the path coefficient (effect) of the error or disturbance term to any value other than 1 in the LINEQS statement.

These two sets of fixed parameters reflect the LINEQS model restrictions so that they cannot be modified. Other than these two sets of default fixed parameters, all other default fixed parameters are zeros. You can override these default zeros by explicitly specifying them as free, constrained, or fixed parameters in the COV, LINEQS, MEAN, or VARIANCE statement.

The LISMOD Model and Submodels

As a statistical model, the LISMOD modeling language is derived from the LISREL model proposed by Jöreskog and others (see Keesling 1972; Wiley 1973; Jöreskog 1973). But as a computer language, the LISMOD modeling language is quite different from the LISREL program. To maintain the consistence of specification syntax within the CALIS procedure, the LISMOD modeling language departs from the original LISREL programming language. In addition, to make the programming a little easier, some terminological changes from LISREL are made in LISMOD.

For brevity, models specified by the LISMOD modeling language are called LISMOD models, although you can also specify these LISMOD models by other general modeling languages that are supported in PROC CALIS.

The following descriptions of LISMOD models are basically the same as those of the original LISREL models. The main modifications are the names for the model matrices.

The LISMOD model is described by three component models. The first one is the structural equation model that describes the relationships among latent constructs or factors. The other two are measurement models that relate latent factors to manifest variables.

Structural Equation Model

The structural equation model for latent factors is

$$\eta = \alpha + \beta\eta + \Gamma\xi + \zeta$$

where:

η is a random vector of n_η endogenous latent factors

ξ is a random vector of n_ξ exogenous latent factors

ζ is a random vector of errors

α is a vector of intercepts

β is a matrix of regression coefficients of η variables on other η variables

Γ is a matrix of regression coefficients of η on ξ

There are some assumptions in the structural equation model. To prevent a random variable in η from regressing directly on itself, the diagonal elements of β are assumed to be zeros. Also, $(I - \beta)^{-1}$ is assumed to be nonsingular, and ζ is uncorrelated with ξ .

The covariance matrix of ζ is denoted by Ψ and its expected value is a null vector. The covariance matrix of ξ is denoted by Φ and its expected value is denoted by κ .

Because variables in the structural equation model are not observed, to analyze the model these latent variables must somehow relate to the manifest variables. The measurement models, which are discussed in the subsequent sections, provide such relations.

Measurement Model for y

$$y = v_y + \Lambda_y\eta + \epsilon$$

where:

y is a random vector of n_y manifest variables

ϵ is a random vector of errors for y

v_y is a vector of intercepts for y

Λ_y is a matrix of regression coefficients of y on η

It is assumed that ϵ is uncorrelated with either η or ζ . The covariance matrix of ϵ is denoted by Θ_y and its expected value is the null vector.

Measurement Model for x

$$x = v_x + \Lambda_x\xi + \delta$$

where:

x is a random vector of n_x manifest variables

δ is a random vector of errors for x

v_x is a vector of intercepts for x

Λ_x is a matrix of regression coefficients of x on ξ

It is assumed that δ is uncorrelated with ξ , ϵ , or ζ . The covariance matrix of δ is denoted by Θ_x and its expected value is a null vector.

Covariance and Mean Structures

Under the structural and measurement equations and the model assumptions, the covariance structures of the manifest variables $(\mathbf{y}', \mathbf{x}')'$ are expressed as

$$\Sigma = \begin{pmatrix} \Lambda_y(I - \beta)^{-1}(\Gamma\Phi\Gamma' + \Psi)(I - \beta')^{-1}\Lambda_y' + \Theta_y & \Lambda_y(I - \beta)^{-1}\Gamma\Phi\Lambda_x' \\ \Lambda_x\Phi\Gamma'(I - \beta')^{-1}\Lambda_y' & \Lambda_x\Phi\Lambda_x' + \Theta_x \end{pmatrix}$$

The mean structures of the manifest variables $(\mathbf{y}', \mathbf{x}')'$ are expressed as

$$\mu = \begin{pmatrix} \nu_y + \Lambda_y(I - \beta)^{-1}(\alpha + \Gamma\kappa) \\ \nu_x + \Lambda_x\kappa \end{pmatrix}$$

Model Matrices in the LISMOD Model

The parameters of the LISMOD model are elements in the model matrices, which are summarized as follows.

Matrix	Name	Description	Dimensions	Row Variables	Column Variables
α	_ALPHA_	Intercepts for η	$n_\eta \times 1$	η (ETAVAR=)	N/A
β	_BETA_	Effects of η on η	$n_\eta \times n_\eta$	η (ETAVAR=)	η (ETAVAR=)
Γ	_GAMMA_	Effects of ξ on η	$n_\eta \times n_\xi$	η (ETAVAR=)	ξ (XIVAR=)
Ψ	_PSI_	Error covariance matrix for η	$n_\eta \times n_\eta$	η (ETAVAR=)	η (ETAVAR=)
Φ	_PHI_	Covariance matrix for ξ	$n_\xi \times n_\xi$	ξ (XIVAR=)	ξ (XIVAR=)
κ	_KAPPA_	Mean vector for ξ	$n_\xi \times 1$	ξ (XIVAR=)	N/A
ν_y	_NUY_	Intercepts for y	$n_y \times 1$	y (YVAR=)	N/A
Λ_y	_LAMBDAY_	Effects of η on y	$n_y \times n_\eta$	y (YVAR=)	η (ETAVAR=)
Θ_y	_THETAY_	Error covariance matrix for y	$n_y \times n_y$	y (YVAR=)	y (YVAR=)
ν_x	_NUX_	Intercepts for x	$n_x \times 1$	x (XVAR=)	N/A
Λ_x	_LAMBDAX_	Effects of ξ on x	$n_x \times n_\xi$	x (XVAR=)	ξ (XIVAR=)
Θ_x	_THETAX_	Error covariance matrix for x	$n_x \times n_x$	x (XVAR=)	x (XVAR=)

There are twelve model matrices in the LISMOD model. Not all of them are used in all situations. See the section “[LISMOD Submodels](#)” on page 1282 for details. In the preceding table, each model matrix is given a name in the column Name, followed by a brief description of the parameters in the matrix, the dimensions, and the row and column variables being referred to. In the second column of the table, the LISMOD matrix

names are used in the **MATRIX** statements when specifying the LISMOD model. In the last two columns of the table, following the row or column variables is the variable list (for example, ETAVAR=, YVAR=, and so on) in parentheses. These lists are used in the LISMOD statement for defining variables.

Specification of the LISMOD Model

The LISMOD specification consists of two tasks. The first task is to define the variables in the model. The second task is to specify the parameters in the LISMOD model matrices.

Specifying Variables

The first task is accomplished in the **LISMOD** statement. In the **LISMOD** statement, you define the lists of variables of interest: YVAR=, XVAR=, ETAVAR=, and XIVAR= lists, respectively for the y-variables, x-variables, η -variables, and the ξ -variables. While you provide the names of variables in these lists, you also define implicitly the numbers of four types of variables: n_y , n_x , n_η , and n_ξ . The variables in the YVAR= and XVAR= lists are manifest variables and therefore must be present in the analyzed data set. The variables in the ETAVAR= and XIVAR= lists are latent factors, the names of which are assigned by the researcher to represent their roles in the substantive theory. After these lists are defined, the dimensions of the model matrices are also defined by the number of variables on various lists. In addition, the variable orders in the lists are referred to by the row and column variables of the model matrices.

Unlike the LINEQS model, in the LISMOD model you do not need to use the ‘F’ or ‘f’ prefix to denote factors in the ETAVAR= or XIVAR= list. You can use any valid SAS variable names for the factors, especially those names that reflect the nature of the factors. To avoid confusion with other names in the model, some general rules are recommended. See the section “[Naming Variables and Parameters](#)” on page 1302 for these general rules about naming variables and parameters.

Specifying Parameters in Model Matrices

The second task is accomplished by the **MATRIX** statements. In each **MATRIX** statement, you specify the model matrix by using the matrix names described in the previous table. Then you specify the parameters (free or fixed) in the locations of the model matrix. You can use as many **MATRIX** statements as needed for defining your model. But each model matrix can be specified only in one **MATRIX** statement, and each **MATRIX** statement is used for specifying only one model matrix.

An Example

In the section “[LISMOD Model](#)” on page 1072, the LISMOD modeling language is used to specify the model described in the section “[A Structural Equation Example](#)” on page 1067. In the **LISMOD** statement, you define four lists of variables, as shown in the following statement:

```
lismod
  yvar = Anomie67 Powerless67 Anomie71 Powerless71,
  xvar = Education SEI,
  etav = Alien67 Alien71,
  xivar = SES;
```

Endogenous latent factors are specified in the ETAVAR= list. Exogenous latent factors are specified in the XIVAR= list. In this case, Alien67 and Alien71 are the η -variables, and SES is the only ξ -variable in the model. Manifest variables that are indicators of endogenous latent factors in η are specified in the YVAR= list. In this case, they are the Anomie and Powerless variables, measured at two different time points. Manifest variables that are indicators of exogenous latent factors in ξ are specified in the XVAR= list. In this case, they are the Education and the SEI variables. Implicitly, the dimensions of the model matrices are defined by these lists already; that is, $n_y = 4$, $n_x = 2$, $n_\eta = 2$, and $n_\xi = 1$.

The **MATRIX** statements are used to specify parameters in the model matrices. For example, in the following statement you define the **_LAMBDA_** (Λ_x) matrix with two nonzero entries:

```
matrix _LAMBDA_ [1,1] = 1.0,
                [2,1] = lambda;
```

The first parameter location is for [1,1], which is the effect of SES (the first variable in the XIVAR= list) on Education (the first element in the XVAR= list). A fixed value of 1.0 is specified there. The second parameter location is for [2,1], which is the effect of SES (the first variable in the XIVAR= list) on SEI (the second variable in the XVAR= list). A parameter named lambda without an initial value is specified there.

Another example is shown as follows:

```
matrix _THETAY_ [1,1] = theta1,
                [2,2] = theta2,
                [3,3] = theta1,
                [4,4] = theta2,
                [3,1] = theta5,
                [4,2] = theta5;
```

In this **MATRIX** statement, the error variances and covariances (that is, the Θ_y matrix) for the y-variables are specified. The diagonal elements of the **_THETAY_** matrix are specified by parameters theta1, theta2, theta1, and theta2, respectively, for the four y-variables Anomie67, Powerless67, Anomie71, and Powerless71. By using the same parameter name theta1, the error variances for Anomie67 and Anomie71 are implicitly constrained. Similarly, the error variances for Powerless67 and Powerless71 are also implicitly constrained. Two more parameter locations are specified. The error covariance between Anomie67 and Anomie71 and the error covariance between Powerless67 and Powerless71 are both represented by the parameter theta5. Again, this is an implicit constraint on the covariances. All other unspecified elements in the **_THETAY_** matrix are treated as fixed zeros.

In this example, no parameters are specified for matrices **_ALPHA_**, **_KAPPA_**, **_NUY_**, or **_NUX_**. Therefore, mean structures are not modeled.

LISMOD Submodels

It is not necessary to specify all four lists of variables in the **LISMOD** statement. When some lists are unspecified in the **LISMOD** statement, PROC CALIS analyzes submodels derived logically from the specified lists of variables. For example, if only y- and x-variable lists are specified, the submodel being analyzed would be a multivariate regression model with manifest variables only. Not all combinations of lists lead to meaningful submodels, however. To determine whether and how a submodel (which is formed by a certain combination of variable lists) can be analyzed, the following three principles in the LISMOD modeling language are applied:

- Submodels with at least one of the YVAR= and XVAR= lists are required.
- Submodels that have an ETAVAR= list but no YVAR= list cannot be analyzed.
- When a submodel has a YVAR= (or an XVAR=) list but without an ETAVAR= (or a XIVAR=) list, it is assumed that the set of y-variables (x-variables) is equivalent to the η -variables (ξ -variables). Hereafter, this principle is referred to as an equivalence interpretation.

Apparently, the third principle is the same as the situation where the latent factors η (or ξ) are perfectly measured by the manifest variables y (or x). That is, in such a perfect measurement model, Λ_y (Λ_x) is an identity matrix and Θ_y (Θ_x) and ν_y (ν_x) are both null. This can be referred to as a perfect measurement interpretation. However, the equivalence interpretation stated in the last principle presumes that there are actually no measurement equations at all. This is important because under the equivalence interpretation, matrices Λ_y (Λ_x), Θ_y (Θ_x) and ν_y (ν_x) are nonexistent rather than fixed quantities, which is assumed under the perfect measurement interpretation. Hence, the x-variables are treated as *exogenous* variables with the equivalence interpretation, but they are still treated as *endogenous* with the perfect measurement interpretation. Ultimately, whether x-variables are treated as exogenous or endogenous affects the default or automatic parameterization. See the section “[Default Parameters](#)” on page 1164 for more details.

By using these three principles, the models and submodels that PROC CALIS analyzes are summarized in the following table, followed by detailed descriptions of these models and submodels.

Presence of Lists	Description	Model Equations	Nonfixed Model Matrices
Presence of Both x- and y-variables			
1 YVAR=, ETAVAR=, XVAR=, XIVAR=	Full model	$y = v_y + \Lambda_y \eta + \epsilon$ $x = v_x + \Lambda_x \xi + \delta$ $\eta = \alpha + \beta \eta + \Gamma \xi + \zeta$	v_y, Λ_y, Θ_y $v_x, \Lambda_x, \Theta_x, \kappa, \Phi$ $\alpha, \beta, \Gamma, \Psi$
2 YVAR=, XVAR=, XIVAR=	Full model with $y \equiv \eta$	$x = v_x + \Lambda_x \xi + \delta$ $y = \alpha + \beta y + \Gamma \xi + \zeta$	$v_x, \Lambda_x, \Theta_x, \kappa, \Phi$ $\alpha, \beta, \Gamma, \Psi$
3 YVAR=, ETAVAR=, XVAR=	Full model with $x \equiv \xi$	$y = v_y + \Lambda_y \eta + \epsilon$ $\eta = \alpha + \beta \eta + \Gamma x + \zeta$	v_y, Λ_y, Θ_y $\alpha, \beta, \Gamma, \Psi, \kappa, \Phi$
4 YVAR=, XVAR=	Regression ($y \equiv \eta$) ($x \equiv \xi$)	$y = \alpha + \beta y + \Gamma x + \zeta, \text{ or}$ $(\mathbf{I} - \beta)^{-1} y = \alpha + \Gamma x + \zeta$	$\alpha, \beta, \Gamma, \Psi, \kappa, \Phi$
Presence of x-variables and Absence of y-variables			
5 XVAR=, XIVAR=	Factor model for x	$x = v_x + \Lambda_x \xi + \delta$	$v_x, \Lambda_x, \Theta_x, \kappa, \Phi$
6 XVAR=	x-structures ($x \equiv \xi$)		κ, Φ
Presence of y-variables and Absence of x-variables			
7 YVAR=, ETAVAR=	Factor model for y	$y = v_y + \Lambda_y \eta + \epsilon$ $\eta = \alpha + \beta \eta + \zeta$	v_y, Λ_y, Θ_y α, β, Ψ
8 YVAR=	y-structures ($y \equiv \eta$)	$y = \alpha + \beta y + \zeta, \text{ or}$ $(\mathbf{I} - \beta)^{-1} y = \alpha + \zeta$	α, β, Ψ
9 YVAR=, ETAVAR=, XIVAR=	Second-order factor model	$y = v_y + \Lambda_y \eta + \epsilon$ $\eta = \alpha + \beta \eta + \Gamma \xi + \zeta$	v_y, Λ_y, Θ_y $\alpha, \beta, \Gamma, \Psi, \kappa, \Phi$
10 YVAR=, XIVAR=	Factor model ($y \equiv \eta$)	$y = \alpha + \beta y + \Gamma \xi + \zeta, \text{ or}$ $(\mathbf{I} - \beta)^{-1} y = \alpha + \Gamma \xi + \zeta$	$\alpha, \beta, \Gamma, \Psi, \kappa, \Phi$

Models 1, 2, 3, and 4—Presence of Both x- and y-Variables

Submodels 1, 2, 3, and 4 are characterized by the presence of both x- and y-variables in the model. In fact, Model 1 is the full model with the presence of all four types of variables. All twelve model matrices are parameter matrices in this model.

Depending on the absence of the latent factor lists, manifest variables can replace the role of the latent factors in Models 2–4. For example, the absence of the ETAVAR= list in Model 2 means y is equivalent to η ($y \equiv \eta$). Consequently, you cannot, nor do you need to, use the **MATRIX** statement to specify parameters in the **_LAMBDAY_**, **_THETAY_**, or **_NUY_** matrices under this model. Similarly, because x is equivalent to ξ ($x \equiv \xi$) in Model 3, you cannot, nor do you need to, use the **MATRIX** statement to specify the parameters in the **_LAMBDAX_**, **_THETAX_**, or **_NUX_** matrices. In Model 4, y is equivalent to η ($y \equiv \eta$) and x is equivalent to ξ ($x \equiv \xi$). None of the six model matrices in the measurement equations are defined in the

model. Matrices in which you can specify parameters by using the **MATRIX** statement are listed in the last column of the table.

Describing Model 4 as a regression model is a simplification. Because y can regress on itself in the model equation, the regression description is not totally accurate for Model 4. Nonetheless, if β is a null matrix, the equation describes a multivariate regression model with outcome variables y and predictor variables x . This model is the TYPE 2A model in LISREL VI (Jöreskog and Sörbom 1985).

You should also be aware of the changes in meaning of the model matrices when there is an equivalence between latent factors and manifest variables. For example, in Model 4 the Φ and κ are now the covariance matrix and mean vector, respectively, of manifest variables x , while in Model 1 (the complete model) these matrices are of the latent factors ξ .

Models 5 and 6 — Presence of x -Variables and Absence of y -Variables

Models 5 and 6 are characterized by the presence of the x -variables and the absence of y -variables.

Model 5 is simply a factor model for measured variables x , with Λ_x representing the factor loading matrix, Θ_x the error covariance matrix, and Φ the factor covariance matrix. If mean structures are modeled, κ represents the factor means and ν_x is the intercept vector. This is the TYPE 1 submodel in LISREL VI (Jöreskog and Sörbom 1985).

Model 6 is a special case where there is no model equation. You specify the mean and covariance structures (in κ and Φ , respectively) for the manifest variables x directly. The x -variables are treated as exogenous variables in this case. Because this submodel uses direct mean and covariance structures for measured variables, it can also be handled more easily by the MSTRUCT modeling language. See the **MSTRUCT** statement and the section “**The MSTRUCT Model**” on page 1285 for more details.

Note that because η -variables cannot exist in the absence of y -variables (see one of the three aforementioned principles for deriving submodels), adding the ETAVAR= list alone to these two submodels does not generate new submodels that can be analyzed by PROC CALIS.

Models 7, 8, 9 and 10—Presence of y -Variables and Absence of x -Variables

Models 7–10 are characterized by the presence of the y -variables and the absence of x -variables.

Model 7 is a factor model for y -variables (TYPE 3B submodel in LISREL VI). It is similar to Model 5, but with regressions among latent factors allowed. When β is null, Model 7 functions the same as Model 5. It becomes a factor model for y -variables, with Λ_y representing the factor loading matrix, Θ_y the error covariance matrix, Ψ the factor covariance matrix, α the factor means, and ν_y the intercept vector.

Model 8 (TYPE 2B submodel in LISREL VI) is a model for studying the mean and covariance structures of y -variables, with regression among y -variables allowed. When β is null, the mean structures of y are specified in α and the covariance structures are specified in Ψ . This is similar to Model 6. However, there is an important distinction. In Model 6, the x -variables are treated as exogenous (no model equation at all). But the y -variables are treated as endogenous in Model 8 (with or without $\beta = 0$). Consequently, the default parameterization would be different for these two submodels. See the section “**Default Parameters**” on page 1164 for details about the default parameterization.

Model 9 represents a modified version of the second-order factor model for y . It would be a standard second-order factor model when β is null. This is the TYPE 3A submodel in LISREL VI. With β being null, η represents the first-order factors and ξ represents the second-order factors. The first- and second-order factor loading matrices are Λ_y and Γ , respectively.

Model 10 is another form of factor model when β is null, with factors represented by ξ and manifest variables represented by y . However, if β is indeed a null matrix in applications, you might want to use Model 5, in which the factor model specification is more direct and intuitive.

Default Parameters in the LISMOD Model

When a model matrix is defined in a LISMOD model, you can specify fixed values or free parameters for the elements of the matrix by the **MATRIX** statement. All other unspecified elements in the matrix are set by default. There are two types of default parameters for the LISMOD model matrices: one is free parameters; the other is fixed zeros.

The following sets of parameters are free parameters by default:

- the diagonal elements of the `_THETAX_`, `_THETAY_`, and `_PSI_` matrices; these elements represent the error variances in the model
- all elements of the `_PHI_` matrix; these elements represent the variances and covariance among exogenous variables in the model
- all elements in the `_NUX_` and `_NUY_` vectors if the mean structures are modeled; these elements represent the intercepts of the observed variables
- all elements in the `_ALPHA_` vector if a `YVAR=` list is specified but an `ETAVAR=` list is not specified and the mean structures are modeled; these elements represent the intercepts of the y -variables
- all elements in the `_KAPPA_` vector if an `XVAR=` list is specified but an `XIVAR=` list is not specified and the mean structures are modeled; these elements represent the means of the x -variables

PROC CALIS names the default free parameters with the `_Add` prefix and a unique integer suffix. You can override the default free parameters by explicitly specifying them as free, constrained, or fixed parameter in the **MATRIX** statements for the matrices.

Parameters that are not default free parameters in the LISMOD model are fixed zeros by default. You can override almost all of these default fixed zeros of the LISMOD model by using the **MATRIX** statements for the matrices. The only set of default fixed zeros that you cannot override is the set of the diagonal elements of the `_BETA_` matrix. These fixed zeros reflect a model restriction that precludes variables from having direct effects on themselves.

The MSTRUCT Model

In contrast to other modeling languages where the mean and covariance structures are implied from the specification of equations, paths, variable-factor relations, mean parameters, variance parameters, or covariance parameters, the MSTRUCT modeling language is supported in PROC CALIS for modeling mean and covariance structures directly.

A simple example for using the MSTRUCT modeling language is the testing of a covariance model with equal variances and covariances. Suppose that a variable was measured five times in an experiment. The covariance matrix of these five measurements is hypothesized to have the structure

$$\Sigma = \Sigma(\theta)$$

where

$$\theta = (\phi, \tau)$$

and

$$\Sigma(\theta) = \begin{pmatrix} \phi & \tau & \tau & \tau & \tau \\ \tau & \phi & \tau & \tau & \tau \\ \tau & \tau & \phi & \tau & \tau \\ \tau & \tau & \tau & \phi & \tau \\ \tau & \tau & \tau & \tau & \phi \end{pmatrix}$$

For model structures that are hypothesized directly in the covariance matrix, the MSTRUCT modeling language is the most convenient to use. You can also use other general modeling languages such as LINEQS, PATH, or RAM to fit the same model structures, but the specification is less straightforward and more error-prone. For convenience, models that are specified using the MSTRUCT modeling language are called MSTRUCT models.

Model Matrices in the MSTRUCT Model

Suppose that there are p observed variables. The two model matrices, their names, their roles, and their dimensions are summarized in the following table.

Matrix	Name	Description	Dimensions
Σ	<code>_COV_</code> or <code>_MSTRUCTCOV_</code>	Structured covariance matrix	$p \times p$
μ	<code>_MEAN_</code> or <code>_MSTRUCTMEAN_</code>	Structured mean vector	$p \times 1$

Specification of the MSTRUCT Model

Specifying Variables

In the **MSTRUCT** statement, you specify the list of p manifest variables of interest in the `VAR=` list. For example, you specify `v1-v5` as the variables to be analyzed in your MSTRUCT model by this statement:

```
mstruct VAR= v1 v2 v3 v4 v5;
```

See the **MSTRUCT** statement on page 1194 for details about the syntax.

The manifest variables in the `VAR=` list must be referenced in the input set. The number of variables in the `VAR=` list determines the dimensions of the `_COV_` and the `_MEAN_` matrices in the model. In addition, the order of variables determines the order of row and column variables in the model matrices.

Specifying Parameters in Model Matrices

Denote the parameter vector in the MSTRUCT model as θ . The dimension of θ depends on your hypothesized model. In the preceding example, θ contains two parameters in ϕ and τ . You can use the **MATRIX** statement to specify these parameters in the `_COV_` matrix:

```
matrix _COV_ [1,1] = 5*phi, /* phi for all diagonal elements */
              [2, ] = tau,  /* tau for all off-diagonal elements */
              [3, ] = 2*tau,
              [4, ] = 3*tau,
              [5, ] = 4*tau;
```

In this **MATRIX** statement, the five diagonal elements, starting from the [1,1] element of the covariance matrix, are fitted by the phi parameter. The specification **5*phi** is a shorthand for specifying phi five times, once for each of the five diagonal elements in the covariance matrix. All other lower triangular elements are fitted by the tau parameter, as shown in the **MATRIX** statement. For example, with [3,1] the elements starting from the first element of the third row of the **_COV_** matrix are parameterized by the tau parameter. The specification **2*tau** repeats the specification two times, meaning that the [3,1] and [3,2] elements are both fitted by the same parameter tau. Similarly, all lower triangular elements (not including the diagonal elements) of the **_COV_** matrix are fitted by the tau parameter. The specification of the upper triangular elements (diagonal excluded) of the **_COV_** matrix is not needed because the **_COV_** matrix is symmetric. The specification in the lower triangular elements is transferred automatically to the upper triangular elements. See the **MATRIX statement** on page 1175 for details about the syntax.

Default Parameters in the MSTRUCT Model

By using the **MATRIX** statements, you can specify either fixed values or free parameters (with or without initial values) for the elements in the **_COV_** and **_MEAN_** model matrices. If some or all elements are not specified, default parameters are applied to the **MSTRUCT**. There are two types of default parameters: one is free parameters; the other is fixed zeros. They are applied in different situations.

If you do not specify *any* elements of the **_COV_** matrix with the **MATRIX** statement, all elements of the **_COV_** matrix are free parameters by default. **PROC CALIS** names the default free parameters with the **_Add** prefix and a unique integer suffix. However, if you specify *at least one* fixed or free parameter of the **_COV_** matrix with the **MATRIX** statement, then all other unspecified elements of the **_COV_** matrix are fixed zeros by default.

If the mean structures are modeled, the same treatment applies to the **_MEAN_** vector. That is, if you do not specify any elements of the **_MEAN_** vector with the **MATRIX** statement, all elements of the **_MEAN_** vector are free parameters by default. However, if you specify *at least one* fixed or free parameter of the **_MEAN_** vector with the **MATRIX** statement, then all other unspecified elements of the **_MEAN_** vector are fixed zeros by default.

How and Why the Default Parameters Are Treated Differently in the MSTRUCT Model

Notice that the default parameter treatment of the **MSTRUCT** model is quite different from other types of models such as **FACTOR**, **LINEQS**, **LISMOD**, **RAM**, or **PATH**. For these models, unspecified variances and covariances among exogenous variables are all free parameters by default. However, for the **MSTRUCT** model, either default free parameters or fixed zeros are generated depending on whether at least one element of the covariance matrix is specified. The reason for this different treatment is that you fit the covariance structure directly by using the **MSTRUCT** modeling language. Hence, in an **MSTRUCT** model there is no information regarding the functional relationships among the variables that indicates whether the variables are exogenous or endogenous in the model. Hence, **PROC CALIS** cannot assume default free parameters based on the exogenous or endogenous variable types.

Because of this special default parameter treatment, when fitting an **MSTRUCT** model you must make sure that each diagonal element in your **_COV_** matrix is set as a free, constrained, or fixed parameter, in accordance with your theoretical model. If you specify some elements in the model matrix but omit the specification of other diagonal elements, the default fixed zero variances would lead to a nonpositive definite **_COV_** model matrix, making the model fitting problematic.

The PATH Model

The PATH modeling language is supported in PROC CALIS as a more intuitive modeling tool. It is designed so that specification by using the PATH modeling language translates effortlessly from the path diagram. For example, consider the following simple path diagram:

You can use the following PATH statement to specify the paths easily:

```
path    A ==> B ,
        C ==> B ;
```

There are two path entries in the PATH statement: one is for the path **A ==> B**, and the other is for the path **C ==> B**. Sometimes you might want to name the effect parameters in the path diagram, as shown in the following:

You can specify the paths and the parameters together in the following statement:

```
path    A ==> B    = effect1,
        C ==> B    = effect2;
```

In the first entry of the PATH statement, the path **A ==> B** is specified together with the path coefficient (effect) **effect1**. Similarly, in the second entry, the **C ==> B** path is specified together with the effect parameter **effect2**. In addition to the path coefficients (effects) in the path diagram, you can also specify other types of parameters by using the **PVAR** and **PCOV** statements. See the section “[A Structural Equation Example](#)” on page 1067 for a more detailed example of the PATH model specification.

Despite its simple representation of the path diagram, the PATH modeling language is general enough to handle a wide class of structural models that can also be handled by other general modeling languages such as LINEQS, LISMOD, or RAM. For brevity, models specified by the PATH modeling language are called PATH models.

Types of Variables in the PATH Model

When you specify the paths in the PATH model, you typically use arrows (such as **<==** or **==>**) to denote “causal” paths. For example, in the preceding path diagram or the PATH statement, you specify that **B** is an outcome variable with predictors **A** and **C**, respectively, in two paths. An outcome variable is the variable being pointed to in a path specification, while the predictor variable is the one where the arrow starts from.

Whereas the outcome–predictor relationship describes the roles of variables in each single path, the endogenous–exogenous relationship describes the roles of variables in the entire system of paths. In a

system of path specification, a variable is endogenous if it is pointed to by at least one single-headed arrow or it serves as an outcome variable in at least one path. Otherwise, it is exogenous. In the preceding path diagram, for example, variable B is endogenous and both variables A and C are exogenous. Note that although any variable that serves as an outcome variable at least in one path must be endogenous, it does not mean that all endogenous variables must serve only as outcome variables in all paths. An endogenous variable in a model might also serve as a predictor variable in a path. For example, variable B in the following PATH statement is an endogenous variable, and it serves as an outcome variable in the first path but as a predictor variable in the second path.

```
path      A ==> B      = effect1,
          B ==> C      = effect2;
```

A variable is a manifest or observed variable in the PATH model if it is measured and exists in the input data set. Otherwise, it is a latent variable. Because error variables are not explicitly defined in the PATH modeling language, all latent variables that are named in the PATH model are *factors*, which are considered to be the systematic source of effects in the model. Each manifest variable in the PATH model can be endogenous or exogenous. The same is true for any latent factor in the PATH model.

Because you do not name error variables in the PATH model, you do not need to specify paths from errors to any endogenous variables. Error terms are implicitly assumed for all endogenous variables in the PATH model. Although error variables are not named in the PATH model, the error variances are expressed equivalently as partial variances of the associated endogenous variables. These partial variances are set by default in the PATH modeling language. Therefore, you do not need to specify error variance parameters explicitly unless constraints on these parameters are desirable in the model. You can use the [PVAR](#) statement to specify the error variance or partial variance parameters explicitly.

Naming Variables in the PATH Model

Manifest variables in the PATH model are referenced in the input data set. Their names must not be longer than 32 characters. There are no further restrictions beyond those required by the SAS System. You use the names of manifest variables directly in the PATH model specification.

Because you do not name error variables in the PATH model, all latent variables named in the PATH model specification are factors (non-errors). Factor names in the PATH model must not be longer than 32 characters, and they should be different from the manifest variables. Unlike the LINEQS model, you do not need to use ‘F’ or ‘f’ prefix to denote latent factors in the PATH model. As a general naming convention, you should not use Intercept as either a manifest or latent variable name. See the section “[Naming Variables and Parameters](#)” on page 1302 for these general rules about naming variables and parameters.

Specification of the PATH Model

(1) Specification of Effects or Paths

You specify the “causal” paths or linear functional relationships among variables in the PATH statement. For example, if there is a path from v2 to v1 in your model and the effect parameter is named parm1 with a starting value at 0.5, you can use either of these specifications:

```
path      v1 <=== v2      = parm1 (0.5) ;
```

```
path      v2 ==> v1      = parm1(0.5);
```

If you have more than one path in your model, path specifications should be separated by commas, as shown in the following [PATH](#) statement:

```
path
  v1 <=== v2      = parm1(0.5),
  v2 <=== v3      = parm2(0.3);
```

Because the [PATH](#) statement can be used only once in each model specification, all paths in the model must be specified together in a single [PATH](#) statement. See the [PATH statement](#) on page 1202 for more details about the syntax.

(2) Specification of Variances and Partial (Error) Variances

If *v2* is an exogenous variable in the [PATH](#) model and you want to specify its variance as a parameter named *parm2* with a starting value at 10, you can use the following [PVAR](#) statement specification:

```
pvar      v2 = parm2(10.);
```

If *v1* is an endogenous variable in the [PATH](#) model and you want to specify its partial variance or error variance as a parameter named *parm3* with a starting value at 5.0, you can also use the following [PVAR](#) statement specification:

```
pvar      v1 = parm3(5.0);
```

Therefore, the [PVAR](#) statement can be used for both exogenous and endogenous variables. When a variable in the statement is exogenous (which can be automatically determined by PROC CALIS), you are specifying the variance parameter of the variable. Otherwise, you are specifying the partial or error variance for an endogenous variable.

You do not need to supply the parameter names for the variances or partial variances if these parameters are not constrained. For example, the following statement specifies the unnamed free parameters for variances or partial variances of *v1* and *v2*:

```
pvar      v1 v2;
```

If you have more than one variance or partial variance parameter to specify in your model, you can put a variable list on the left-hand side of the equal sign, and a parameter list on the right-hand side, as shown in the following [PVAR](#) statement specification:

```
pvar
  v1 v2 v3 = parm1(0.5) parm2 parm3;
```

In the specification, variance or partial variance parameters for variables *v1*–*v3* are *parm1*, *parm2*, and *parm3*, respectively. Only *parm1* is given an initial value at 0.5. The initial values for other parameters are generated by PROC CALIS.

You can also separate the specifications into several entries in the [PVAR](#) statement. Entries should be separated by commas. For example, the preceding specification is equivalent to the following specification:

```

pvar
  v1 = parm1 (0.5) ,
  v2 = parm2 ,
  v3 = parm3 ;

```

Because the **PVAR** statement can be used only once in each model specification, all variance and partial variance parameters in the model must be specified together in a single **PVAR** statement. See the **PVAR statement** on page 1214 for more details about the syntax.

(3) Specification of Covariances and Partial Covariances

If you want to specify the (partial) covariance between two variables *v3* and *v4* as a parameter named *parm4* with a starting value at 3, you can use the following **PCOV** statement specification:

```

pcov  v3  v4 = parm4 (5.) ;

```

Whether *parm4* is a covariance or partial covariance parameter depends on the variable types of *v3* and *v4*. If both *v3* and *v4* are exogenous variables (manifest or latent), *parm4* is a covariance parameter between *v3* and *v4*. If both *v3* and *v4* are endogenous variables (manifest or latent), *parm4* is a parameter for the covariance between the errors for *v3* and *v4*. In other words, it is a partial covariance or error covariance parameter for *v3* and *v4*.

A less common case is when one of the variables is exogenous and the other is endogenous. In this case, *parm4* is a parameter for the partial covariance between the endogenous variable and the exogenous variable, or the covariance between the error for the endogenous variable and the exogenous variable. Fortunately, such covariances are relatively uncommon in statistical modeling. Their uses confuse the roles of systematic and unsystematic sources in the model and lead to difficulties in interpretations. Therefore, you should almost always avoid this kind of partial covariance.

Like the syntax of the **PVAR** statement, you can specify a list of (partial) covariance parameters in the **PCOV** statement. For example, consider the following statement:

```

pcov
  v1 v2 = parm4 ,
  v1 v3 = parm5 ,
  v2 v3 = parm6 ;

```

In the specification, three (partial) covariance parameters *parm4*, *parm5*, and *parm6* are specified, respectively, for the variable pairs (*v1*,*v2*), (*v1*,*v3*), and (*v2*,*v3*). Entries for (partial) covariance specification are separated by commas.

Again, if all these covariances are not constrained, you can omit the names for the parameters. For example, the preceding specification can be specified as the following statement when the three covariances are free parameters in the model:

```

pcov
  v1 v2 ,
  v1 v3 ,
  v2 v3 ;

```

Or, you can simply use the following within-list covariance specification:

```
pcov
  v1 v2 v3;
```

Three covariance parameters are generated by this specification.

Because the **PCOV** statement can be used only once in each model specification, all covariance and partial covariance parameters in the model must be specified together in a single **PCOV** statement. See the **PCOV statement** on page 1212 for more details about the syntax.

(4) Specification of Means and Intercepts

Means and intercepts are specified when the mean structures of the model are of interest. You can specify mean and intercept parameters in the **MEAN** statement. For example, consider the following statement:

```
mean      V5 = parm5(11.);
```

If V5 is an exogenous variable (which is determined by PROC CALIS automatically), you are specifying parm5 as the mean parameter of V5. If V5 is an endogenous variable, you are specifying parm5 as the intercept parameter for V5.

Because each named variable in the PATH model is either exogenous or endogenous (exclusively), each variable in the PATH model would have either a mean or an intercept parameter (but not both) to specify in the **MEAN** statement. Like the syntax of the **PVAR** statement, you can specify a list of mean or intercept parameters in the **MEAN** statement. For example, in the following statement you specify a list of mean or intercept parameters for variables v1–v4:

```
mean
  v1-v4 = parm6-parm9;
```

This specification is equivalent to the following specification with four entries of parameter specifications:

```
mean
  v1 = parm6,
  v2 = parm7,
  v3 = parm8,
  v4 = parm9;
```

Again, entries in the **MEAN** statement must be separated by commas, as shown in the preceding statement.

Because the **MEAN** statement can be used only once in each model specification, all mean and intercept parameters in the model must be specified together in a single **MEAN** statement. See the **MEAN statement** on page 1189 for more details about the syntax.

Specifying Parameters without Initial Values

If you do not have any knowledge about the initial value for a parameter, you can omit the initial value specification and let PROC CALIS compute it. For example, you can provide just the parameter locations and parameter names as in the following specification:

```
path      v1 <=== v2      = parm1;
pvar      v2 = parm2,
          v1 = parm3;
```

Specifying Fixed Parameter Values

If you want to specify a fixed parameter value, you do not need to provide a parameter name. Instead, you provide the fixed value (without parentheses) in the specification.

For example, in the following statement the path coefficient for the path is fixed at 1.0 and the (partial) variance of F1 is also fixed at 1.0:

```
path    v1 <=== F1  = 1.;
pvar
    F1 = 1.;
```

A Complete PATH Model Specification Example

The following specification shows a more complete PATH model specification:

```
path    v1 <=== v2 ,
        v1 <=== v3 ;
pvar    v1,
        v2 = parm3,
        v3 = parm3;
pcov    v3 v2 = parm5(5.);
```

The two paths specified in the PATH statement have unnamed free effect parameters. These parameters are named by PROC CALIS with the `_Parm` prefix and unique integer suffixes. The error variance of v1 is an unnamed parameter, while the variances of v2 and v3 are constrained by using the same parameter parm3. The covariance between v2 and v3 is a free parameter named parm5, with a starting value of 5.0.

Default Parameters in the PATH Model

There are two types of default parameters of the PATH model. One is the free parameters; the other is the fixed constants.

The following sets of parameters are free parameters by default:

- the variances or partial (or error) variances of all variables, manifest or latent
- the covariances among all exogenous (independent) manifest or latent variables
- the means of all exogenous (independent) manifest variables if the mean structures are modeled
- the intercepts of all endogenous (dependent) manifest variables if the mean structures are modeled

For each of the default free parameters, PROC CALIS generates a parameter name with the `_Add` prefix and a unique integer suffix. Parameters that are not default free parameters in the PATH model are fixed zeros by default. You can override almost all of the default zeros of the PATH model by using the MEAN, PATH, PCOV, and MEAN statements. The only exception is the single-headed path that has the same variable on both sides. That is, the following specification is not accepted by PROC CALIS:

```
path    v1 <=== v1    = parm;
```

This path should always has a zero coefficient, which is treated as a model restriction that prevents a variable from having a direct effect on itself.

Relating the PATH Model to the RAM Model

Mathematically, the PATH model is essentially the RAM model. You can consider the PATH model to share exactly the same set of model matrices as in the RAM model. See the section “[Model Matrices in the RAM Model](#)” on page 1295 and the section “[Summary of Matrices and Submatrices in the RAM Model](#)” on page 1298 for details about the RAM model matrices. In the RAM model, the **A** matrix contains effects or path coefficients for describing relationships among variables. In the PATH model, you specify these effect or coefficient parameters in the **PATH** statement. The **P** matrix in the RAM model contains (partial) variance and (partial) covariance parameters. In the PATH model, you use the **PVAR** and **PCOV** statements to specify these parameters. The **W** vector in the RAM model contains the mean and intercept parameters, while in the PATH model you use the **MEAN** statement to specify these parameters. By using these model matrices in the PATH model, the covariance and mean structures are derived in the same way as they are derived in the RAM model. See the section “[The RAM Model](#)” on page 1294 for derivations of the model structures.

The RAM Model

The RAM modeling language is adapted from the basic RAM model developed by McArdle (1980). For brevity, models specified by the RAM modeling language are called RAM models. You can also specify these so-called RAM models by other general modeling languages that are supported in PROC CALIS.

Types of Variables in the RAM Model

A variable in the RAM model is manifest if it is observed and is defined in the input data set. A variable in the RAM model is latent if it is not manifest. Because error variables are not explicitly named in the RAM model, all latent variables in the RAM model are considered as factors (non-error-type latent variables).

A variable in the RAM model is endogenous if it ever serves as an outcome variable in the RAM model. That is, an endogenous variable has at least one path (or an effect) from another variable in the model. A variable is exogenous if it is not endogenous. Endogenous variables are also referred to as dependent variables, while exogenous variables are also referred to as independent variables.

In the RAM model, distinctions between exogenous and endogenous and between latent and manifest for variables are not essential to the definitions of model matrices, although they are useful for conceptual understanding when the model matrices are partitioned.

Naming Variables in the RAM Model

Manifest variables in the RAM model are referenced in the input data set. Their names must not be longer than 32 characters. There are no further restrictions beyond those required by the SAS System.

Latent variables in the RAM model are those not being referenced in the input data set. Their names must not be longer than 32 characters. Unlike the LINEQS model, you do not need to use any specific prefix (for example, ‘F’ or ‘f’) for the latent factor names. The reason is that error or disturbance variables in the RAM model are not named explicitly in the RAM model. Thus, any variable names that are not referenced in the input data set are for latent factors.

As a general naming convention, you should not use `Intercept` as either a manifest or latent variable name.

Model Matrices in the RAM Model

In terms of the number of model matrices involved, the RAM model is the simplest among all the general structural equations models that are supported by PROC CALIS. Essentially, there are only three model matrices in the RAM model: one for the interrelationships among variables, one for the variances and covariances, and one for the means and intercepts. These matrices are discussed in the following subsections.

Matrix \mathbf{A} ($n_a \times n_a$): Effects of Column Variables on Row Variables

The row and column variables of matrix \mathbf{A} are the set of manifest and latent variables in the RAM model. Unlike the LINEQS model, the set of latent variables in the RAM model matrix does not include the error or disturbance variables. Each entry or element in the \mathbf{A} matrix represents an effect of the associated column variable on the associated row variable or a path coefficient from the associated column variable to the associated row variable. A zero entry means an absence of a path or an effect.

The pattern of matrix \mathbf{A} determines whether a variable is endogenous or exogenous. A variable in the RAM model is endogenous if its associated row in the \mathbf{A} matrix has at least one nonzero entry. Any other variable in the RAM model is exogenous.

Mathematically, you do not need to arrange the set of variables for matrix \mathbf{A} in a particular order, as long as the order of variables is the same for the rows and the columns. However, arranging the variables according to whether they are endogenous or exogenous is useful for showing the partitions of the model matrices and certain mathematical properties. See the section “Partitions of the RAM Model Matrices and Some Restrictions” on page 1296 for details.

Matrix \mathbf{P} ($n_a \times n_a$): Variances, Covariances, Partial Variances, and Partial Covariances

The row and column variables of matrix \mathbf{P} refer to the same set of manifest and latent variables that are defined in the RAM model matrix \mathbf{A} . The diagonal entries of \mathbf{P} contain variances or partial variances of variables. If a variable is exogenous, then the corresponding diagonal element in the \mathbf{P} matrix represents its variance. Otherwise, the corresponding diagonal element in the \mathbf{P} matrix represents its partial variance. This partial variance is an unsystematic source of variance that is not explained by the interrelationships of variables in the model. In most cases, you can interpret a partial variance as the error variance for an endogenous variable.

The off-diagonal elements of \mathbf{P} contain covariances or partial covariances among variables. An off-diagonal element in \mathbf{P} that is associated with exogenous row and column variables represents covariance between the two exogenous variables. An off-diagonal element in \mathbf{P} that is associated with endogenous row and column variables represents *partial* covariance between the two variables. This partial covariance is unsystematic, in the sense that it is not explained by the interrelationships of variables in the model. In most cases, you can interpret a partial covariance as the error covariance between the two endogenous variables involved. An off-diagonal element in \mathbf{P} that is associated with one exogenous variable and one endogenous variable in the row and column represents the covariance between the exogenous variable and the error of the endogenous variable. While this interpretation sounds a little awkward and inelegant, this kind of covariance, fortunately, is rare in most applications.

Vector \mathbf{W} ($n_a \times 1$): Intercepts and Means

The row variables of vector \mathbf{W} refer to the same set of manifest and latent variables that are defined in the RAM model matrix \mathbf{A} . Elements in \mathbf{W} represent either intercepts or means. An element in \mathbf{W} that is associated with an exogenous row variable represents the mean of the variable. An element in \mathbf{W} that is associated with an endogenous row variable represents the intercept term for the variable.

Covariance and Mean Structures

Assuming that $(\mathbf{I} - \mathbf{A})$ is invertible, where \mathbf{I} is an identity matrix of the same dimension as \mathbf{A} , the structured covariance matrix of all variables (including latent variables) in the RAM model is shown as follows:

$$\Sigma_a = (\mathbf{I} - \mathbf{A})^{-1} \mathbf{P} (\mathbf{I} - \mathbf{A})^{-1'}$$

The structured mean vector of all variables is shown as follows:

$$\mu_a = (\mathbf{I} - \mathbf{A})^{-1} \mathbf{W}$$

The covariance and mean structures of all manifest variables are obtained by selecting the elements in Σ_a and μ_a . This can be achieved by defining a selection matrix \mathbf{G} of dimensions $n \times n_a$, where n is the number of manifest variables in the model. The selection matrix \mathbf{G} contains zeros and ones as its elements. Each row of \mathbf{G} has exactly one nonzero element at the position that corresponds to the location of a manifest row variable in Σ_a or μ_a . With each row of \mathbf{G} selecting a distinct manifest variable, the structured covariance matrix of all manifest variables is expressed as the following:

$$\Sigma = \mathbf{G} \Sigma_a \mathbf{G}'$$

The structured mean vector of all observed variables is expressed as the following:

$$\mu = \mathbf{G} \mu_a$$

Partitions of the RAM Model Matrices and Some Restrictions

There are some model restrictions in the RAM model matrices. Although these restrictions do not affect the derivation of the covariance and mean structures, they are enforced in the RAM model specification.

For convenience, it is useful to assume that n_a variables are arranged in the order of n_d endogenous (or dependent) variables and the n_i exogenous (independent) variables in the rows and columns of the model matrices.

Model Restrictions on the \mathbf{A} Matrix

The \mathbf{A} matrix is partitioned as

$$\mathbf{A} = \begin{pmatrix} \boldsymbol{\beta} & \boldsymbol{\gamma} \\ 0 & 0 \end{pmatrix}$$

where $\boldsymbol{\beta}$ is an $n_d \times n_d$ matrix for paths or effects from (column) endogenous variables to (row) endogenous variables and $\boldsymbol{\gamma}$ is an $n_d \times n_i$ matrix for paths (effects) from (column) exogenous variables to (row) endogenous variables.

As shown in the matrix partitions, there are four submatrices. The two submatrices at the lower parts are seemingly structured to zeros. However, this should not be interpreted as restrictions imposed by the model. The zero submatrices are artifacts created by the exogenous-endogenous arrangement of the row and column variables. The only restriction on the \mathbf{A} matrix is that the diagonal elements must all be zeros. This implies that the diagonal elements of the submatrix $\boldsymbol{\beta}$ are also zeros. This restriction prevents a direct path from any endogenous variable to itself. There are no restrictions on the pattern of $\boldsymbol{\gamma}$.

It is useful to denote the lower partitions of the \mathbf{A} matrix by \mathbf{A}_{LL} (lower left) and \mathbf{A}_{LR} (lower right) so that

$$\mathbf{A} = \begin{pmatrix} \boldsymbol{\beta} & \boldsymbol{\gamma} \\ \mathbf{A}_{LL} & \mathbf{A}_{LR} \end{pmatrix}$$

Although they are zero matrices in the initial model specification, their entries could become non-zero (paths) in an improved model when you modify your model by using the Lagrange multiplier statistics (see the section “[Modification Indices](#)” on page 1346 or the [MODIFICATION](#) option). Hence, you might need to reference these two submatrices when you apply the customized LM tests on them during the model modification process (see the [LMTESTS](#) statement).

For the purposes of defining specific parameter regions in customized LM tests, you might also partition the \mathbf{A} matrix in other ways. First, you can partition \mathbf{A} into the left and right portions,

$$\mathbf{A} = (\mathbf{A}_{Left} \quad \mathbf{A}_{Right})$$

where \mathbf{A}_{Left} is top-down concatenation of the $\boldsymbol{\beta}$ and \mathbf{A}_{LL} matrices and \mathbf{A}_{Right} is the top-down concatenation of the $\boldsymbol{\gamma}$ and \mathbf{A}_{LR} matrices. Second, you can partition \mathbf{A} into the upper and lower portions,

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}_{Upper} \\ \mathbf{A}_{Lower} \end{pmatrix}$$

where \mathbf{A}_{Upper} is the side-by-side concatenation of the $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ matrices and \mathbf{A}_{Lower} is the side-by-side concatenation of the \mathbf{A}_{LL} and \mathbf{A}_{LR} matrices.

In your initial model, because of the arrangement of the endogenous and exogenous variables \mathbf{A}_{Lower} is a null matrix. But if you improve your model by applying the LM tests on the entries in \mathbf{A}_{Lower} , some of these entries might become free paths in your improved model. Hence, some exogenous variables in your initial model now become endogenous variables in your improved model. For this reason, \mathbf{A}_{Lower} is also designated as a parameter region for *new* endogenous variables, which is exactly what the NEWENDO region means in the [LMTESTS](#) statement.

Partition of the P Matrix

The \mathbf{P} matrix is partitioned as

$$\mathbf{P} = \begin{pmatrix} \mathbf{P}_{11} & \mathbf{P}'_{21} \\ \mathbf{P}_{21} & \mathbf{P}_{22} \end{pmatrix}$$

where \mathbf{P}_{11} is an $n_d \times n_d$ partial covariance matrix for the endogenous variables, \mathbf{P}_{22} is an $n_i \times n_i$ covariance matrix for the exogenous variables, and \mathbf{P}_{21} is an $n_i \times n_d$ covariance matrix between the exogenous variables and the error terms for the endogenous variables. Because \mathbf{P} is symmetric, \mathbf{P}_{11} and \mathbf{P}_{22} are also symmetric.

There are virtually no model restrictions placed on these submatrices. However, in most statistical applications, errors for endogenous variables represent unsystematic sources of effects and therefore they are not to be correlated with other systematic sources such as the exogenous variables in the RAM model. This means that in most practical applications \mathbf{P}_{21} would be a null matrix, although this is not enforced in PROC CALIS.

Partition of the W Vector

The \mathbf{W} vector is partitioned as

$$\mathbf{W} = \begin{pmatrix} \boldsymbol{\alpha} \\ \boldsymbol{\nu} \end{pmatrix}$$

where $\boldsymbol{\alpha}$ is an $n_d \times 1$ vector for intercepts of the endogenous variables and $\boldsymbol{\nu}$ is an $n_i \times 1$ vector for the means of the exogenous variables. There is no model restriction on these subvectors.

Summary of Matrices and Submatrices in the RAM Model

Let n_a be the total number of manifest and latent variables in the RAM model. Of these n_a variables, n_d are endogenous and n_i are exogenous. Suppose that the rows and columns of the RAM model matrices **A** and **P** and the rows of **W** are arranged in the order of n_d endogenous variables and then n_i exogenous variables. The names, roles, and dimensions of the RAM model matrices and submatrices are summarized in the following table.

Matrix	Name	Description	Dimensions
Model Matrices			
A	<code>_A_</code> or <code>_RAMA_</code>	Effects of column variables on row variables, or paths from the column variables to the row variables	$n_a \times n_a$
P	<code>_P_</code> or <code>_RAMP_</code>	(Partial) variances and covariances	$n_a \times n_a$
W	<code>_W_</code> or <code>_RAMW_</code>	Intercepts and means	$n_a \times 1$
Submatrices			
β	<code>_RAMBETA_</code>	Effects of endogenous variables on endogenous variables	$n_d \times n_d$
γ	<code>_RAMGAMMA_</code>	Effects of exogenous variables on endogenous variables	$n_d \times n_i$
A_{LL}	<code>_RAMA_LL_</code>	The null submatrix at the lower left portion of <code>_A_</code>	$n_i \times n_d$
A_{LR}	<code>_RAMA_LR_</code>	The null submatrix at the lower right portion of <code>_A_</code>	$n_i \times n_i$
A_{Left}	<code>_RAMA_LEFT_</code>	The left portion of <code>_A_</code> , including β and A_{LL}	$n_a \times n_d$
A_{Right}	<code>_RAMA_RIGHT_</code>	The right portion of <code>_A_</code> , including γ and A_{LR}	$n_a \times n_i$
A_{Upper}	<code>_RAMA_UPPER_</code>	The upper portion of <code>_A_</code> , including β and γ	$n_d \times n_a$
A_{Lower}	<code>_RAMA_LOWER_</code>	The lower portion of <code>_A_</code> , including A_{LL} and A_{LR}	$n_i \times n_a$
P_{11}	<code>_RAMP11_</code>	Error variances and covariances for endogenous variables	$n_d \times n_d$
P_{21}	<code>_RAMP21_</code>	Covariances between exogenous variables and error terms for endogenous variables	$n_d \times n_i$
P_{22}	<code>_RAMP22_</code>	Variances and covariances for exogenous variables	$n_i \times n_i$
α	<code>_RAMALPHA_</code>	Intercepts for endogenous variables	$n_d \times 1$
ν	<code>_RAMNU_</code>	Means for exogenous variables	$n_i \times 1$

Specification of the RAM Model

In PROC CALIS, the RAM model specification is a matrix-oriented modeling language. That is, you have to define the row and column variables for the model matrices and specify the parameters in terms of matrix entries. The VAR= option specifies the variables (including manifest and latent) in the model. For example, the following statement specifies five variables in the model:

RAM

```
var= v1 v2 v3;
```

The order of variables in the VAR= option is important. The same order is used for the row and column variables in the model matrices. After you specify the variables in the model, you can specify three types of parameters, which correspond to the elements in the three model matrices. The three types of RAM entries are described in the following.

(1) Specification of Effects or Paths in Model Matrix A

If there is a path from V2 to V1 in your model and the associated effect parameter is named parm1 with 0.5 as the starting value, you can use the following RAM statement:

RAM

```
var= v1 v2 v3,
_A_ 1 2 parm1(0.5);
```

The *ram-entry* that starts with *_A_* means that an element of the ram matrix A is being specified. The row number and the column number of this element are 1 and 2, respectively. With reference to the VAR= list, the row number 1 refers to variable v1, and the column number 2 refers to variable v2. Therefore, the effect of V2 on V1 is a parameter named parm1, with an initial value of 0.5.

You can specify fixed values in the *ram-entries* too. Suppose the effect of v3 on v1 is fixed at 1.0. You can use the following specification:

RAM

```
var= v1 v2 v3,
_A_ 1 2 parm1(0.5),
_A_ 1 3 1.0;
```

(2) Specification of the Latent Factors in the Model

In the RAM model, you specify the list of variables in VAR= list of the RAM statement. The list of variables can include the latent variables in the model. Because observed variables have references in the input data sets, those variables that do not have references in the data sets are treated as latent factors automatically. Unlike the LINEQS model, you do not need to use 'F' or 'f' prefix to denote latent factors in the RAM model. It is recommended that you use meaningful names for the latent factors. See the section “[Naming Variables and Parameters](#)” on page 1302 for the general rules about naming variables and parameters.

For example, suppose that SES_Factor and Education_Factor are names that are not used as variable names in the input data set. These two names represent two latent factors in the model, as shown in the following specification:

RAM

```
var= v1 v2 v3 SES_FACTOR Education_Factor,
_A_ 1 4 b1,
_A_ 2 5 b2,
_A_ 3 5 1.0;
```

This specification shows that the effect of SES_Factor on v1 is a free parameter named b1, and the effects of Education_Factor on v2 and v3 are a free parameter named b2 and a fixed value of 1.0, respectively.

However, naming latent factors is not compulsory. The preceding specification is equivalent to the following specification:

```

RAM
var= v1 v2 v3,
_A_  1   4   b1,
_A_  2   5   b2,
_A_  3   5   1.0;

```

Although you do not name the fourth and the fifth variables in the VAR= list, PROC CALIS generates the names for these two latent variables. In this case, the fourth variable is named `_Factor1` and the fifth variable is named `_Factor2`.

(3) Specification of (Partial) Variances and (Partial) Covariances in Model Matrix P

Suppose now you want to specify the variance of v2 as a free parameter named `parm2`. You can add a new *ram-entry* for this variance parameter, as shown in the following statement:

```

RAM
var= v1 v2 v3,
_A_  1   2   parm1(0.5),
_A_  1   3   1.0,
_P_  2   2   parm2;

```

The *ram-entry* that starts with `_P_` means that an element of the RAM matrix **P** is being specified. The (2,2) element of **P**, which is the variance of v2, is a parameter named `parm2`. You do not specify an initial value for this parameter.

You can also specify the error variance of v1 similarly, as shown in the following statement:

```

RAM
var= v1 v2 v3,
_A_  1   2   parm1(0.5),
_A_  1   3   1.0,
_P_  2   2   parm2,
_P_  1   1;

```

In the last *ram-entry*, the (1,1) element of **P**, which is the error variance of v1, is an unnamed free parameter.

Covariance parameters are specified in the same manner. For example, the following specification adds a *ram-entry* for the covariance parameter between v2 and v3:

```

RAM
var= v1 v2 v3,
_A_  1   2   parm1(0.5),
_A_  1   3   1.0,
_P_  2   2   parm2,
_P_  1   1,
_P_  2   3   (.5);

```

The covariance between v2 and v3 is an unnamed parameter with an initial value of 0.5.

(4) Specification of Means and Intercepts in Model Matrix W

To specifying means or intercepts, you need to start the *ram-entries* with the `_W_` keyword. For example, the last two entries of following statement specify the intercept of v1 and the mean of v2, respectively:

RAM

```

var= v1 v2 v3,
_A_  1  2  parm1(0.5),
_A_  1  3  1.0,
_P_  2  2  parm2,
_P_  1  1  ,
_P_  2  3  (.5),
_W_  1  1  int_v1,
_W_  2  2  mean_v2;

```

The intercept of v1 is a free parameter named `int_v1`, and the mean of v2 is a free parameter named `mean_v2`.

Default Parameters in the RAM Model

There are two types of default of parameters of the RAM model in PROC CALIS. One is the free parameters; the other is the fixed zeros.

By default, certain sets of model matrix elements in the RAM model are free parameters. These parameters are set automatically by PROC CALIS, although you can also specify them explicitly in the *ram-entries*. In general, default free parameters enable you to specify only what are absolutely necessary for defining your model. PROC CALIS automatically sets those commonly assumed free parameters so that you do not need to specify them routinely. The sets of default free parameters of the RAM model are as follows:

- Diagonal elements of the `_P_` matrix—this includes the variance of exogenous variables (latent or observed) and error variances of all endogenous variables (latent or observed)
- The off-diagonal elements that pertain to the exogenous variables of the `_P_` matrix—this includes all the covariances among exogenous variables, latent or observed
- If the mean structures are modeled, the elements that pertain to the observed variables (but not the latent variables) in the `_W_` vector— this includes all the means of exogenous observed variables and the intercepts of all endogenous observed variables

For example, suppose you are fitting a RAM model with three observed variables x1, x2, and y3, you specify a simple multiple-regression model with x1 and x2 predicting y3 by the following statements:

```

proc calis meanstr;
  ram var= x1-x2 y3,
      _A_ 3 1 ,
      _A_ 3 2 ;

```

In the RAM statement, you specify that path coefficients represented by `_A_[3,1]` and `_A_[3,2]` are free parameters in the model. In addition to these free parameters, PROC CALIS sets several other free parameters by default. `_P_[1,1]`, `_P_[2,2]`, and `_P_[3,3]` are set as free parameters for the variance of x1, the variance of x2, and the error variance of x3, respectively. `_P_[2,1]` (and hence `_P_[1,2]`) is set as a free parameter for the covariance between the exogenous variables x1 and x2. Because the mean structures are also analyzed by the `MEANSTR` option in the PROC CALIS statement, `_W_[1,1]`, `_W_[2,1]`, and `_W_[3,1]` are also set as free parameters for the mean of x1, the mean of x2, and the intercept of x3, respectively. In the current situation, this default parameterization is consistent with using PROC REG for multiple regression analysis, where you only need to specify the functional relationships among variables.

If a matrix element is not a default free parameter in the RAM model, then it is a fixed zero by default. You can override almost all default fixed zeros in the RAM model matrices by specifying the *ram-entries*. The diagonal elements of the *_A_* matrix are exceptions. These elements are always fixed zeros. You cannot set these elements to free parameters or other fixed values—this reflects a model restriction that prevents a variable from having a direct effect on itself.

Naming Variables and Parameters

Follow these rules when you name your variables:

- Use the usual naming conventions of the SAS System.
- Variable names are not more than 32 characters.
- When you create latent variable names, make sure that they are not used in the input data set that is being analyzed.
- For the LINEQS model, error or disturbance variables must start with ‘E’, ‘e’, ‘D’, or ‘d’.
- For the LINEQS model, non-error-type latent variables (that is, factors) must start with ‘F’ or ‘f’.
- For modeling languages other than LINEQS, names for errors or disturbances are not needed. As a result, you do not need to distinguish latent factors from errors or disturbances by using particular prefixes. Variable names that are not referenced in the analyzed data set are supposed to be latent factors.
- You should not use Intercept (case-insensitive) as a variable name in your data set or as a latent variable name in your model.

Follow these rules when you name your parameters:

- Use the usual naming conventions of the SAS System.
- Parameter names are not more than 32 characters.
- Use a prefix-name when you want to generate new parameter names automatically. A prefix-name contains a short string of characters called a “root,” followed by double underscores ‘__’. Each occurrence of such a prefix-name generates a new parameter name by replacing the two trailing underscores with a unique integer. For example, occurrences of Gen__ generate Gen1, Gen2, and so on.
- A special prefix-name is the one without a root—that is, it contains only double underscores ‘__’. Occurrences of ‘__’ generate _Parm1, _Parm2, and so on.
- PROC CALIS generates parameter names for default parameters to safeguard ill-defined models. These generated parameter names start with the _Add prefix and unique integer suffixes. For example, _Add1, _Add2, and so on.
- Avoid using parameter names that start with either __, _Add, or _Parm. These names might get confused with the names generated by PROC CALIS. The confusion might lead to unintended constraints to your model if the parameter names that you use match those generated by PROC CALIS.

- Avoid using parameter names that are roots of prefix-names. For example, you should not use `Gen` as a parameter name if `Gen__` is also used in the same model specification. Although violation of this rule might not distort the model specification, it might cause ambiguities and confusion.

Finally, parameter names and variable names in PROC CALIS are not distinguished by explicit declarations. That is, a valid SAS name can be used as a parameter name or a variable name in any model that is supported by PROC CALIS. Whether a name in a model specification is for a parameter or a variable is determined by the syntactic structure. For example, consider the following path specification:

```
proc calis;
  path
    a ==> b    = c;
run;
```

PROC CALIS parses the path specification according to the syntactic structure of the PATH statement and determines that `a` and `b` are variable names and `c` is a parameter name. Consider another specification as follows:

```
proc calis;
  path
    a ==> b    = b;
run;
```

This is a syntactically correct specification. Variables `a` and `b` are defined in a path relationship with a path coefficient parameter also named `b`. While such a name conflict between parameter and variable names would not confuse PROC CALIS in terms of model specification and fitting, it would create unnecessary confusion in programming and result interpretations. Hence, using parameter names that match variable names exactly is a bad practice and should be avoided.

Setting Constraints on Parameters

The CALIS procedure offers a very flexible way to constrain parameters. There are two main methods for specifying constraints. One is explicit specification by using specially designed statements for constraints. The other is implicit specification by using the [SAS programming statements](#).

Explicit Specification of Constraints

Explicit constraints can be set in the following ways:

- specifying boundary constraints on independent parameters in the [BOUNDS](#) statement
- specifying general linear equality and inequality constraints on independent parameters in the [LIN-CON](#) statement
- specifying general nonlinear equality and inequality constraints on parametric functions in the [NLIN-CON](#) statement

BOUNDS Statement

You can specify one-sided or two-sided boundaries on independent parameters in the **BOUNDS** statement. For example, in the following statement you constrain parameter `var1` to be nonnegative and parameter `effect` to be between 0 and 5.

```
bounds    var1 >= 0,
          0. <= effect <= 5.;
```

Note that if your upper and lower bounds are the same for a parameter, it effectively sets a fixed value for that parameter. As a result, PROC CALIS will reduce the number of independent parameters by one automatically. Note also that only independent parameters are allowed to be bounded in the **BOUNDS** statement.

LINCON Statement

You can specify equality or inequality linear constraints on independent parameters in the **LINCON** statement. For example, in the following statement you specify a linear inequality constraint on parameters `beta1`, `beta2`, and `beta3` and an equality constraint on parameters `gamma1` and `gamma2`.

```
lincon    beta1 - .5 * beta2 - .5 * beta3 >= 0.,
          gamma1 - gamma2 = 0.;
```

In the inequality constraint, `beta1` is set to be at least as large as the average of `beta2` and `beta3`. In the equality constraint, `gamma1` and `gamma2` are set to be equal. Note that in PROC CALIS a nonredundant linear equality constraint on independent parameters effectively reduces the number of parameters by one.

NLINCON Statement

You can specify equality or inequality nonlinear constraints for parameters in the **NLINCON** statement. While you can only constrain the independent parameters in the **BOUNDS** and the **LINCON** statements, you can constrain any of the following in the **NLINCON** statement:

- independent parameters
- dependent parameters
- parametric functions computed by the [SAS programming statements](#)

For example, consider the following statements:

```
nlincon
  IndParm >= 0,          /* constraint 1 */
  0 <= DepParm <= 10,   /* constraint 2 */
  ParmFunc1 >= 3,       /* constraint 3 */
  0 <= ParmFunc2 <= 8;  /* constraint 4 */

/* SAS Programming statements in the following */
DepParm   = Indparm1 + IndParm5;
ParmFunc1 = IndParm1 - .5 * IndParm2 - .5 * IndParm3;
ParmFunc2 = (IndParm1 - 7. )**2 + SQRT(DepParm * IndParm4) * ParmFunc1;
```

You specify four nonlinear constraints by using the **NLINCON** statement. Labeled in a comment as “constraint 1” is a one-sided boundary constraint for independent parameter `IndParm`. Labeled in a comment as “constraint 2” is a two-sided boundary constraint for dependent parameter `DepParm`. Labeled in a comment as “constraint 3” is a one-sided inequality constraint on parametric function named `ParmFunc1`. Finally, labeled in a comment as “constraint 4” is a two-sided inequality constraint on parametric function named `ParmFunc2`. Parametric functions `ParmFunc1` and `ParmFunc2` are defined and computed in the **SAS programming statements** after the **NLINCON** statement specification.

Constraint 1 could have been set in the **BOUNDS** statement because it is just a simple boundary constraint on an independent parameter. Constraint 3 could have been set in the **LINCON** statement because the definition of `ParmFunc1` in a SAS programming statement shows that it is a linear function of independent parameters. The purpose of including these special cases of “nonlinear constraints” in this example is to show the flexibility of the **NLINCON** statement. However, whenever possible, the **BOUNDS** or the **LINCON** statement specification should be considered first because computationally they are more efficient than the equivalent specification in the **NLINCON** statement.

Specification in the **NLINCON** statement becomes necessary when you want to constrain dependent parameters or nonlinear parametric functions. For example, constraint 2 is a two-sided boundary constraint on the dependent parameter `DepParm`, which is defined as a linear function of independent parameters in a SAS programming statement. Constraints on dependent parameters are not allowed in the **BOUNDS** statement. Constraint 4 is a two-sided inequality constraint on the nonlinear parametric function `ParmFunc2`, which is defined as a nonlinear function of other parametric functions and parameters in the **SAS programming statements**. Again, you cannot use the **LINCON** statement to specify nonlinear constraints.

Implicit Constraint Specification

An implicit way to specify constraints is to use your own **SAS programming statements** together with the **PARAMETERS** statement to express special properties of the parameter estimates. This kind of reparameterization tool is also present in McDonald’s COSAN implementation (McDonald 1978) but is considerably easier to use in the CALIS procedure. PROC CALIS is able to compute analytic first- and second-order derivatives that you would have to specify using the COSAN program.

Some traditional ways to enforce parameter constraints by using reparameterization or parameter transformation (McDonald 1980) are considered in the following:

- **one-sided boundary constraints of the form:**

$$q \geq a \quad \text{or} \quad q \leq b$$

where the parameter of interest is q , which should be at least as large as (or at most as small as) a given constant value a (or b). This inequality constraint can be expressed as an equality constraint:

$$q = a + x^2 \quad \text{or} \quad q = b - x^2$$

in which the new parameter x is unconstrained.

For example, inequality constraint $q \geq 7$ can be accomplished by the following statements:

```
parameters x (0.);
q = 7 + x * x;
```

In this specification, you essentially redefine q as a parametric function of x , which is not constrained and has a starting value at 0.

- **two-sided boundary constraints of the form:**

$$a \leq q \leq b$$

where the parameter of interest is q , which should be located between two given constant values a and b , with $a < b$. This inequality constraint can be expressed as the following equality constraint:

$$q = a + (b - a) \frac{\exp(x)}{1 + \exp(x)}$$

where the new parameter x is unconstrained.

For example, to implement $1 \leq q \leq 5$ in PROC CALIS, you can use the following statements:

```
parameters x (0.);
u = exp(x);
q = 1 + 4 * u / (1 + u);
```

In this specification, q becomes a dependent parameter which is nonlinearly related to independent parameter x , which is an independent parameter defined in the [PARAMETERS](#) statement with a starting value of 0.

- **one-sided order constraints of the form:**

$$q_1 \leq q_2, \quad q_1 \leq q_3, \quad \dots, \quad q_1 \leq q_k$$

where q_1, \dots, q_k are the parameters of interest. These inequality constraints can be expressed as the following set of equality constraints:

$$q_1 = x_1, \quad q_2 = x_1 + x_2^2, \quad \dots, \quad q_k = x_1 + x_k^2$$

where the new parameters x_1, \dots, x_k are unconstrained.

For example, to implement $q_1 \leq q_2$, $q_1 \leq q_3$, and $q_1 \leq q_4$ simultaneously, you can use the following statements:

```
parameters x1-x4 (4*0.);
q1 = x1;
q2 = x1 + x2 * x2;
q3 = x1 + x3 * x3;
q4 = x1 + x4 * x4;
```

In this specification, you essentially redefine $q_1 - q_4$ as dependent parameters that are functions of $x_1 - x_4$, which are defined as independent parameters in the [PARAMETERS](#) statement with starting values of zeros. No constraints on x_i 's are needed. The way that q_i 's are computed in the SAS programming statements guarantees the required order constraints on q_i 's are satisfied.

- **two-sided order constraints of the form:**

$$q_1 \leq q_2 \leq q_3 \leq \dots \leq q_k$$

These inequality constraints can be expressed as the following set of equality constraints:

$$q_1 = x_1, \quad q_2 = q_1 + x_2^2, \quad \dots \quad q_k = q_{k-1} + x_k^2$$

where the new parameters x_1, \dots, x_k are unconstrained.

For example, to implement $q_1 \leq q_2 \leq q_3 \leq q_4$ simultaneously, you can use the following statements:

```
parameters x1-x4 (4*0.);
q1 = x1;
q2 = q1 + x2 * x2;
q3 = q2 + x3 * x3;
q4 = q3 + x4 * x4;
```

In this specification, you redefine $q_1 - q_4$ as dependent parameters that are functions of $x_1 - x_4$, which are defined as independent parameters in the **PARAMETERS** statement. Each x_i has a starting value of zero without being constrained in estimation. The order relation of q_i 's are satisfied by the way they are computed in the **SAS programming statements**.

- **linear equation constraints of the form:**

$$\sum_i^k b_i q_i = a$$

where q_i 's are the parameters of interest, b_i 's are constant coefficients, a is a constant, and k is an integer greater than one. This linear equation can be expressed as the following system of equations with unconstrained new parameters x_1, x_2, \dots, x_k :

$$\begin{aligned} q_i &= x_i / b_i & (i < k) \\ q_k &= (a - \sum_j^{k-1} x_j) / b_k \end{aligned}$$

For example, consider the following linear constraint on independent parameters $q_1 - q_3$:

$$3q_1 + 2q_2 - 5q_3 = 8$$

You can use the following statements to implement the linear constraint:

```
parameters x1-x2 (2*0.);
q1 = x1 / 3;
q2 = x2 / 2;
q3 = -(8 - x1 - x2) / 5;
```

In this specification, $q_1 - q_3$ become dependent parameters that are functions of x_1 and x_2 . The linear constraint on q_1 and q_3 are satisfied by the way they are computed. In addition, after reparameterization the number of independent parameters drops to two.

See McDonald (1980) and Browne (1982) for further notes on reparameterization techniques.

Explicit or Implicit Specification of Constraints?

Explicit and implicit constraint techniques differ in their specifications and lead to different computational steps in optimizing a solution. The explicit constraint specification that uses the supported statements incurs additional computational routines within the optimization steps. In contrast, the implicit reparameterization method does not incur additional routines for evaluating constraints during the optimization. Rather, it changes the constrained problem to a non-constrained one. This costs more in computing function derivatives and in storing parameters.

If the optimization problem is small enough to apply the Levenberg-Marquardt or Newton-Raphson algorithm, use the **BOUNDS** and the **LINCON** statements to set explicit boundary and linear constraints. If the problem is so large that you must use a quasi-Newton or conjugate gradient algorithm, reparameterization techniques might be more efficient than the **BOUNDS** and **LINCON** statements.

Automatic Variable Selection

When you specify your model, you use the **main** and **subsidiary** model statements to define variable relationships and parameters. PROC CALIS checks the variables mentioned in these statements against the variable list of the input data set. If a variable in your model is also found in your data set, PROC CALIS knows that it is a manifest variable. Otherwise, it is either a latent variable or an invalid variable.

To save computational resources, only manifest variables defined in your model are automatically selected for analysis. For example, even if you have 100 variables in your input data set, only a covariance matrix of 10 manifest variables is computed for the analysis of the model if only 10 variables are selected for analysis.

In some special circumstances, the automatic variable selection performed for the analysis might be a drawback. For example, if you are interested in modification indices connected to some of the variables that are not used in the model, automatic variable selection in the specification stage will exclude those variables from consideration in computing modification indices. Fortunately, a little trick can be done. You can use the **VAR** statement to include as many exogenous manifest variables as needed. Any variables in the **VAR** statement that are defined in the input data set but are not used in the main and subsidiary model specification statements are included in the model as exogenous manifest variables.

For example, the first three steps in a stepwise regression analysis of the Werner Blood Chemistry data (Jöreskog and Sörbom 1988, p. 111) can be performed as follows:

```
proc calis data=dixon method=glS nobs=180 print mod;
  var    x1-x7;
  lineqs y = e;
  variance    e = var;
run;
proc calis data=dixon method=glS nobs=180 print mod;
  var    x1-x7;
  lineqs y = g1 x1 + e;
  variance    e = var;
run;
proc calis data=dixon method=glS nobs=180 print mod;
  var    x1-x7;
  lineqs y = g1 x1 + g6 x6 + e;
  variance    e = var;
run;
```

In the first analysis, no independent manifest variables are included in the regression equation for dependent variable y . However, x_1 – x_7 are specified in the **VAR** statement so that in computing the Lagrange multiplier tests these variables would be treated as potential predictors in the regression equation for dependent variable y . Similarly, in the next analysis, x_1 is already a predictor in the regression equation, while x_2 – x_7 are treated as potential predictors in the LM tests. In the last analysis, x_1 and x_6 are predictors in the regression equation, while other x -variables are treated as potential predictors in the LM tests.

Estimation Criteria

The following seven estimation methods are available in PROC CALIS:

- unweighted least squares (ULS)
- full information maximum likelihood (FIML)
- generalized least squares (GLS)
- normal-theory maximum likelihood (ML)
- weighted least squares (WLS, ADF)
- diagonally weighted least squares (DWLS)
- robust estimation (ROBUST) under the normal theory (ML)

Default weight matrices \mathbf{W} are computed for GLS, WLS, and DWLS estimation. You can also provide your own weight matrices by using an **INWGT=** data set. The weight matrices in these estimation methods provide weights for the moment matrices. In contrast, weights that are applied to individual observations are computed in robust estimation. These observation weights are updated during iteration steps of robust estimation. The ULS, GLS, ML, WLS, ADF, and DWLS methods can analyze sample moment matrices as well as raw data, while the FIML and robust methods must analyze raw data.

PROC CALIS does not implement all estimation methods in the field. As mentioned in the section “**Overview: CALIS Procedure**” on page 1040, partial least squares (PLS) is not implemented. The PLS method is developed under less restrictive statistical assumptions. It circumvents some computational and theoretical problems encountered by the existing estimation methods in PROC CALIS; however, PLS estimates are less efficient in general. When the statistical assumptions of PROC CALIS are tenable (for example, large sample size, correct distributional assumptions, and so on), ML, GLS, or WLS methods yield better estimates than the PLS method. Note that there is a SAS/STAT procedure called PROC PLS that employs the partial least squares technique, but for a different class of models than those of PROC CALIS. For example, in a PROC CALIS model each latent variable is typically associated with only a subset of manifest variables (predictor or outcome variables). However, in PROC PLS latent variables are not prescribed with subsets of manifest variables. Rather, they are extracted from linear combinations of all manifest predictor variables. Therefore, for general path analysis with latent variables you should use PROC CALIS.

ULS, GLS, and ML Discrepancy Functions

In each estimation method, the parameter vector is estimated iteratively by a nonlinear optimization algorithm that minimizes a discrepancy function F , which is also known as the fit function in the literature. With p denoting the number of manifest variables, \mathbf{S} the sample $p \times p$ covariance matrix for a sample with size N , $\bar{\mathbf{x}}$ the $p \times 1$ vector of sample means, $\boldsymbol{\Sigma}$ the fitted covariance matrix, and $\boldsymbol{\mu}$ the vector of fitted means, the discrepancy function for unweighted least squares (ULS) estimation is:

$$F_{ULS} = 0.5\text{Tr}[(\mathbf{S} - \boldsymbol{\Sigma})^2] + (\bar{\mathbf{x}} - \boldsymbol{\mu})'(\bar{\mathbf{x}} - \boldsymbol{\mu})$$

The discrepancy function for generalized least squares estimation (GLS) is:

$$F_{GLS} = 0.5\text{Tr}[(\mathbf{W}^{-1}(\mathbf{S} - \boldsymbol{\Sigma}))^2] + (\bar{\mathbf{x}} - \boldsymbol{\mu})'\mathbf{W}^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu})$$

By default, $\mathbf{W} = \mathbf{S}$ is assumed so that F_{GLS} is the normal theory generalized least squares discrepancy function.

The discrepancy function for normal-theory maximum likelihood estimation (ML) is:

$$F_{ML} = \text{Tr}(\mathbf{S}\boldsymbol{\Sigma}^{-1}) - p + \ln(|\boldsymbol{\Sigma}|) - \ln(|\mathbf{S}|) + (\bar{\mathbf{x}} - \boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu})$$

In each of the discrepancy functions, \mathbf{S} and $\bar{\mathbf{x}}$ are considered to be given and $\boldsymbol{\Sigma}$ and $\boldsymbol{\mu}$ are functions of model parameter vector $\boldsymbol{\Theta}$. That is:

$$F = F(\boldsymbol{\Sigma}(\boldsymbol{\Theta}), \boldsymbol{\mu}(\boldsymbol{\Theta}); \mathbf{S}, \bar{\mathbf{x}})$$

Estimating $\boldsymbol{\Theta}$ by using a particular estimation method amounts to choosing a vector $\boldsymbol{\theta}$ that minimizes the corresponding discrepancy function F .

When the mean structures are not modeled or when the mean model is saturated by parameters, the last term of each fit function vanishes. That is, they become:

$$F_{ULS} = 0.5\text{Tr}[(\mathbf{S} - \boldsymbol{\Sigma})^2]$$

$$F_{GLS} = 0.5\text{Tr}[(\mathbf{W}^{-1}(\mathbf{S} - \boldsymbol{\Sigma}))^2]$$

$$F_{ML} = \text{Tr}(\mathbf{S}\boldsymbol{\Sigma}^{-1}) - p + \ln(|\boldsymbol{\Sigma}|) - \ln(|\mathbf{S}|)$$

If, instead of being a covariance matrix, \mathbf{S} is a correlation matrix in the discrepancy functions, $\boldsymbol{\Sigma}$ would naturally be interpreted as the fitted correlation matrix. Although whether \mathbf{S} is a covariance or correlation matrix makes no difference in minimizing the discrepancy functions, correlational analyses that use these functions are problematic because of the following issues:

- The diagonal of the fitted correlation matrix $\boldsymbol{\Sigma}$ might contain values other than ones, which violates the requirement of being a correlation matrix.
- Whenever available, standard errors computed for correlation analysis in PROC CALIS are straightforward generalizations of those of covariance analysis. In very limited cases these standard errors are good approximations. However, in general they are not even asymptotically correct.
- The model fit chi-square statistic for correlation analysis might not follow the theoretical distribution, thus making model fit testing difficult.

Despite these issues in correlation analysis, if your primary interest is to obtain the estimates in the correlation models, you might still find PROC CALIS results for correlation analysis useful.

The statistical techniques used in PROC CALIS are primarily developed for the analysis of covariance structures, and hence **COVARIANCE** is the default option. Depending on the nature of your research, you can add the mean structures in the analysis by specifying mean and intercept parameters in your models. However, you cannot analyze mean structures simultaneously with correlation structures (see the **CORRELATION** option) in PROC CALIS.

FIML Discrepancy Function

The full information maximum likelihood method (FIML) assumes multivariate normality of the data. Suppose that you analyze a model that contains p observed variables. The discrepancy function for FIML is

$$F_{FIML} = \frac{1}{N} \sum_{j=1}^N (\ln(|\Sigma_j|) + (\mathbf{x}_j - \boldsymbol{\mu}_j)' \Sigma_j^{-1} (\mathbf{x}_j - \boldsymbol{\mu}_j) + K_j)$$

where \mathbf{x}_j is a data vector for observation j , and K_j is a constant term (to be defined explicitly later) independent of the model parameters $\boldsymbol{\Theta}$. In the current formulation, \mathbf{x}_j 's are not required to have the same dimensions. For example, \mathbf{x}_1 could be a complete vector with all p variables present while \mathbf{x}_2 is a $(p-1) \times 1$ vector with one missing value that has been excluded from the original $p \times 1$ data vector. As a consequence, subscript j is also used in $\boldsymbol{\mu}_j$ and Σ_j to denote the submatrices that are extracted from the entire $p \times 1$ structured mean vector $\boldsymbol{\mu}$ ($\boldsymbol{\mu} = \boldsymbol{\mu}(\boldsymbol{\Theta})$) and $p \times p$ covariance matrix Σ ($\Sigma = \Sigma(\boldsymbol{\Theta})$). In other words, in the current formulation $\boldsymbol{\mu}_j$ and Σ_j do not mean that each observation is fitted by distinct mean and covariance structures (although theoretically it is possible to formulate FIML in such a way). The notation simply signifies that the dimensions of \mathbf{x}_j and of the associated mean and covariance structures could vary from observation to observation.

Let p_j be the number of variables without missing values for observation j . Then \mathbf{x}_j denotes a $p_j \times 1$ data vector, $\boldsymbol{\mu}_j$ denotes a $p_j \times 1$ vector of means (structured with model parameters), Σ_j is a $p_j \times p_j$ matrix for variances and covariances (also structured with model parameters), and K_j is defined by the following formula, which is a constant term independent of model parameters:

$$K_j = \ln(2\pi) * p_j$$

As a general estimation method, the FIML method is based on the same statistical principle as the ordinary maximum likelihood (ML) method for multivariate normal data—that is, both methods maximize the normal theory likelihood function given the data. In fact, F_{FIML} used in PROC CALIS is related to the log-likelihood function L by the following formula:

$$F_{FIML} = \frac{-2L}{N}$$

Because the FIML method can deal with observations with various levels of information available, it is primarily developed as an estimation method that could deal with data with random missing values. See the section “[Relationships among Estimation Criteria](#)” on page 1318 for more details about the relationship between FIML and ML methods.

Whenever you use the FIML method, the mean structures are automatically assumed in the analysis. This is due to fact that there is no closed-form formula to obtain the saturated mean vector in the FIML discrepancy function if missing values are present in the data. You can certainly provide explicit specification of the

mean parameters in the model by specifying intercepts in the **LINEQS** statement or means and intercepts in the **MEAN** or **MATRIX** statement. However, usually you do not need to do the explicit specification if all you need to achieve is to saturate the mean structures with p parameters (that is, the same number as the number of observed variables in the model). With **METHOD=FI**ML, PROC CALIS uses certain default parameterizations for the mean structures automatically. For example, all intercepts of endogenous observed variables and all means of exogenous observed variables are default parameters in the model, making the explicit specification of these mean structure parameters unnecessary.

WLS and ADF Discrepancy Functions

Another important discrepancy function to consider is the weighted least squares (WLS) function. Let $\mathbf{u} = (\mathbf{s}, \bar{\mathbf{x}})$ be a $p(p+3)/2$ vector containing all nonredundant elements in the sample covariance matrix \mathbf{S} and sample mean vector $\bar{\mathbf{x}}$, with $\mathbf{s} = \text{vecs}(\mathbf{S})$ representing the vector of the $p(p+1)/2$ lower triangle elements of the symmetric matrix \mathbf{S} , stacking row by row. Similarly, let $\boldsymbol{\eta} = (\boldsymbol{\sigma}, \boldsymbol{\mu})$ be a $p(p+3)/2$ vector containing all nonredundant elements in the fitted covariance matrix $\boldsymbol{\Sigma}$ and the fitted mean vector $\boldsymbol{\mu}$, with $\boldsymbol{\sigma} = \text{vecs}(\boldsymbol{\Sigma})$ representing the vector of the $p(p+1)/2$ lower triangle elements of the symmetric matrix $\boldsymbol{\Sigma}$.

The WLS discrepancy function is:

$$F_{WLS} = (\mathbf{u} - \boldsymbol{\eta})' \mathbf{W}^{-1} (\mathbf{u} - \boldsymbol{\eta})$$

where \mathbf{W} is a positive definite symmetric weight matrix with $(p(p+3)/2)$ rows and columns. Because $\boldsymbol{\eta}$ is a function of model parameter vector $\boldsymbol{\Theta}$ under the structural model, you can write the WLS function as:

$$F_{WLS} = (\mathbf{u} - \boldsymbol{\eta}(\boldsymbol{\Theta}))' \mathbf{W}^{-1} (\mathbf{u} - \boldsymbol{\eta}(\boldsymbol{\Theta}))$$

Suppose that \mathbf{u} converges to $\boldsymbol{\eta}_o = (\boldsymbol{\sigma}_o, \boldsymbol{\mu}_o)$ with increasing sample size, where $\boldsymbol{\sigma}_o$ and $\boldsymbol{\mu}_o$ denote the population covariance matrix and mean vector, respectively. By default, the WLS weight matrix \mathbf{W} in PROC CALIS is computed from the raw data as a consistent estimate of the asymptotic covariance matrix $\boldsymbol{\Gamma}$ of $\sqrt{N}(\mathbf{u} - \boldsymbol{\eta}_o)$, with $\boldsymbol{\Gamma}$ partitioned as

$$\boldsymbol{\Gamma} = \begin{pmatrix} \boldsymbol{\Gamma}_{ss} & \boldsymbol{\Gamma}'_{\bar{x}s} \\ \boldsymbol{\Gamma}_{\bar{x}s} & \boldsymbol{\Gamma}_{\bar{x}\bar{x}} \end{pmatrix}$$

where $\boldsymbol{\Gamma}_{ss}$ denotes the $(p(p+1)/2) \times (p(p+1)/2)$ asymptotic covariance matrix for $\sqrt{N}(\mathbf{s} - \boldsymbol{\sigma}_o)$, $\boldsymbol{\Gamma}_{\bar{x}\bar{x}}$ denotes the $p \times p$ asymptotic covariance matrix for $\sqrt{N}(\bar{\mathbf{x}} - \boldsymbol{\mu}_o)$, and $\boldsymbol{\Gamma}_{\bar{x}s}$ denotes the $p \times (p(p+1)/2)$ asymptotic covariance matrix between $\sqrt{N}(\bar{\mathbf{x}} - \boldsymbol{\mu}_o)$ and $\sqrt{N}(\mathbf{s} - \boldsymbol{\sigma}_o)$.

To compute the default weight matrix \mathbf{W} as a consistent estimate of $\boldsymbol{\Gamma}$, define a similar partition of the weight matrix \mathbf{W} as:

$$\mathbf{W} = \begin{pmatrix} \mathbf{W}_{ss} & \mathbf{W}'_{\bar{x}s} \\ \mathbf{W}_{\bar{x}s} & \mathbf{W}_{\bar{x}\bar{x}} \end{pmatrix}$$

Each of the submatrices in the partition can now be computed from the raw data. First, define the biased sample covariance for variables i and j as:

$$t_{ij} = \frac{1}{N} \sum_{r=1}^N (x_{ri} - \bar{x}_i)(x_{rj} - \bar{x}_j)$$

and the sample fourth-order central moment for variables i, j, k , and l as:

$$t_{ij,kl} = \frac{1}{N} \sum_{r=1}^N (x_{ri} - \bar{x}_i)(x_{rj} - \bar{x}_j)(x_{rk} - \bar{x}_k)(x_{rl} - \bar{x}_l)$$

The submatrices in \mathbf{W} are computed by:

$$[\mathbf{W}_{ss}]_{ij,kl} = t_{ij,kl} - t_{ij}t_{kl}$$

$$[\mathbf{W}_{\bar{x}s}]_{i,kl} = \frac{1}{N} \sum_{r=1}^N (x_{ri} - \bar{x}_i)(x_{rk} - \bar{x}_k)(x_{rl} - \bar{x}_l)$$

$$[\mathbf{W}_{\bar{x}\bar{x}}]_{ij} = t_{ij}$$

Assuming the existence of finite eighth-order moments, this default weight matrix \mathbf{W} is a consistent but biased estimator of the asymptotic covariance matrix $\mathbf{\Gamma}$.

By using the `ASYCOV=` option, you can use Browne's unbiased estimator (Browne 1984, formula (3.8)) of $\mathbf{\Gamma}_{ss}$ as:

$$\begin{aligned} [\mathbf{W}_{ss}]_{ij,kl} &= \frac{N(N-1)}{(N-2)(N-3)}(t_{ij,kl} - t_{ij}t_{kl}) \\ &\quad - \frac{N}{(N-2)(N-3)}(t_{ik}t_{jl} + t_{il}t_{jk} - \frac{2}{N-1}t_{ij}t_{kl}) \end{aligned}$$

There is no guarantee that \mathbf{W}_{ss} computed this way is positive semidefinite. However, the second part is of order $O(N^{-1})$ and does not destroy the positive semidefinite first part for sufficiently large N . For a large number of independent observations, default settings of the weight matrix \mathbf{W} result in asymptotically distribution-free parameter estimates with unbiased standard errors and a correct χ^2 test statistic (Browne 1982, 1984).

With the default weight matrix \mathbf{W} computed by PROC CALIS, the WLS estimation is also called as the asymptotically distribution-free (ADF) method. In fact, as options in PROC CALIS, `METHOD=WLS` and `METHOD=ADF` are totally equivalent, even though WLS in general might include cases with special weight matrices other than the default weight matrix.

When the mean structures are not modeled, the WLS discrepancy function is still the same quadratic form statistic. However, with only the elements in covariance matrix being modeled, the dimensions of \mathbf{u} and $\boldsymbol{\eta}$ are both reduced to $p(p+1)/2 \times 1$, and the dimension of the weight matrix is now $(p(p+1)/2) \times (p(p+1)/2)$. That is, the WLS discrepancy function for covariance structure models is:

$$F_{WLS} = (\mathbf{s} - \boldsymbol{\sigma})' \mathbf{W}_{ss}^{-1} (\mathbf{s} - \boldsymbol{\sigma})$$

If \mathbf{S} is a correlation rather than a covariance matrix, the default setting of the \mathbf{W}_{ss} is a consistent estimator of the asymptotic covariance matrix $\mathbf{\Gamma}_{ss}$ of $\sqrt{N}(\mathbf{s} - \boldsymbol{\sigma}_o)$ (Browne and Shapiro 1986; DeLeeuw 1983), with \mathbf{s} and $\boldsymbol{\sigma}_o$ representing vectors of sample and population correlations, respectively. Elementwise, \mathbf{W}_{ss} is expressed as:

$$\begin{aligned} [\mathbf{W}_{ss}]_{ij,kl} &= r_{ij,kl} - \frac{1}{2}r_{ij}(r_{ii,kl} + r_{jj,kl}) - \frac{1}{2}r_{kl}(r_{kk,ij} + r_{ll,ij}) \\ &\quad + \frac{1}{4}r_{ij}r_{kl}(r_{ii,kk} + r_{ii,ll} + r_{jj,kk} + r_{jj,ll}) \end{aligned}$$

where

$$r_{ij} = \frac{t_{ij}}{\sqrt{t_{ii}t_{jj}}}$$

and

$$r_{ij,kl} = \frac{t_{ij,kl}}{\sqrt{t_{ii}t_{jj}t_{kk}t_{ll}}}$$

The asymptotic variances of the diagonal elements of a correlation matrix are 0. That is,

$$[\mathbf{W}_{ss}]_{ii,ii} = 0$$

for all i . Therefore, the weight matrix computed this way is always singular. In this case, the discrepancy function for weighted least squares estimation is modified to:

$$\begin{aligned} F_{WLS} = & \sum_{i=2}^p \sum_{j=1}^{i-1} \sum_{k=2}^p \sum_{l=1}^{k-1} [\mathbf{W}_{ss}]^{ij,kl} ([\mathbf{S}]_{ij} - [\boldsymbol{\Sigma}]_{ij})([\mathbf{S}]_{kl} - [\boldsymbol{\Sigma}]_{kl}) \\ & + r \sum_i^p ([\mathbf{S}]_{ii} - [\boldsymbol{\Sigma}]_{ii})^2 \end{aligned}$$

where r is the penalty weight specified by the **WPENALTY**= r option and the $[\mathbf{W}_{ss}]^{ij,kl}$ are the elements of the inverse of the reduced $(p(p-1)/2) \times (p(p-1)/2)$ weight matrix that contains only the nonzero rows and columns of the full weight matrix \mathbf{W}_{ss} .

The second term is a penalty term to fit the diagonal elements of the correlation matrix \mathbf{S} . The default value of $r = 100$ can be decreased or increased by the **WPENALTY**= option. The often used value of $r = 1$ seems to be too small in many cases to fit the diagonal elements of a correlation matrix properly.

Note that when you model correlation structures, no mean structures can be modeled simultaneously in the same model.

DWLS Discrepancy Functions

Storing and inverting the huge weight matrix \mathbf{W} in WLS estimation requires considerable computer resources. A compromise is found by implementing the diagonally weighted least squares (DWLS) method that uses only the diagonal of the weight matrix \mathbf{W} from the WLS estimation in the following discrepancy function:

$$\begin{aligned} F_{DWLS} &= (\mathbf{u} - \boldsymbol{\eta})' [\text{diag}(\mathbf{W})]^{-1} (\mathbf{u} - \boldsymbol{\eta}) \\ &= \sum_{i=1}^p \sum_{j=1}^i [\mathbf{W}_{ss}]_{ij,ij}^{-1} ([\mathbf{S}]_{ij} - [\boldsymbol{\Sigma}]_{ij})^2 + \sum_{i=1}^p [\mathbf{W}_{\bar{x}\bar{x}}]_{ii}^{-1} (\bar{x}_i - \mu_i)^2 \end{aligned}$$

When only the covariance structures are modeled, the discrepancy function becomes:

$$F_{DWLS} = \sum_{i=1}^p \sum_{j=1}^i [\mathbf{W}_{ss}]_{ij,ij}^{-1} ([\mathbf{S}]_{ij} - [\boldsymbol{\Sigma}]_{ij})^2$$

For correlation models, the discrepancy function is:

$$F_{DWLS} = \sum_{i=2}^p \sum_{j=1}^{i-1} [\mathbf{W}_{ss}]_{ij,ij}^{-1} ([\mathbf{S}]_{ij} - [\mathbf{\Sigma}]_{ij})^2 + r \sum_{i=1}^p ([\mathbf{S}]_{ii} - [\mathbf{\Sigma}]_{ii})^2$$

where r is the penalty weight specified by the **WPENALTY**= r option. Note that no mean structures can be modeled simultaneously with correlation structures when using the DWLS method.

As the statistical properties of DWLS estimates are still not known, standard errors for estimates are not computed for the DWLS method.

Input Weight Matrices

In GLS, WLS, or DWLS estimation you can change from the default settings of weight matrices \mathbf{W} by using an **INWGT**= data set. The CALIS procedure requires a positive definite weight matrix that has positive diagonal elements.

Multiple-Group Discrepancy Function

Suppose that there are k independent groups in the analysis and N_1, N_2, \dots, N_k are the sample sizes for the groups. The overall discrepancy function $F(\boldsymbol{\Theta})$ is expressed as a weighted sum of individual discrepancy functions F_i 's for the groups:

$$F(\boldsymbol{\Theta}) = \sum_{i=1}^k t_i F_i(\boldsymbol{\Theta})$$

where

$$t_i = \frac{N_i - 1}{N - k}$$

is the weight of the discrepancy function for group i , and

$$N = \sum_{i=1}^k N_i$$

is the total number of observations in all groups. In PROC CALIS, all discrepancy function F_i 's in the overall discrepancy function must belong to the same estimation method. You cannot specify different estimation methods for the groups in a multiple-group analysis. In addition, the same analysis type must be applied to all groups—that is, you can analyze either covariance structures, covariance and mean structures, and correlation structures for all groups.

Robust Estimation

Two robust estimation methods that are proposed by Yuan and Zhong (2008) and Yuan and Hayashi (2010) are implemented in PROC CALIS. The first method is the two-stage robust method, which estimates robust covariance and mean matrices in the first stage and then feeds the robust covariance and mean matrices (in place of the ordinary sample covariance and mean matrices) for ML estimation in the second stage. Weighting of the observations is done only in the first stage. The **ROBUST**=**SAT** option invokes the two-stage robust estimation. The second method is the direct robust method, which iteratively estimates

model parameters with simultaneous weightings of the observations. The **ROBUST**, **ROBUST=RES(E)**, or **ROBUST=RES(F)** option invokes the direct robust estimation method.

The procedural difference between the two robust methods results in differential treatments of model outliers and leverage observations (or leverage points). In producing the robust covariance and mean matrices in the first stage, the two-stage robust method downweights outlying observations in all variable dimensions without regard to the model structure. This method downweights potential model outliers and leverage observations (which are not necessarily model outliers) in essentially the same way before the ML estimation in the second stage.

However, the direct robust method downweights the model outliers only. “Good” leverage observations (those that are not outliers at the same time) are not downweighted for model estimation. Therefore, it could be argued that the direct robust method is more desirable if you can be sure that the model is a reasonable one. The reason is that the direct robust method can retain the information from the “good” leverage observations for estimation, while the two-stage robust method downweights all leverage observations indiscriminately during its first stage. However, if the model is itself uncertain, the two-stage robust estimation method might be more foolproof.

Both robust methods employ weights on the observations. Weights are functions of the Mahalanobis distances (M-distances) of the observations and are computed differently for the two robust methods. The following two sections describe the weighting scheme and the estimation procedure of the two robust methods in more detail.

Two-Stage Robust Method

For the two-stage robust method, the following conventional M-distance d_s for an observed random vector \mathbf{x} is computed as

$$d_s = \sqrt{(\mathbf{x} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{x} - \boldsymbol{\mu})}$$

where $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are the unstructured mean and covariance matrices, respectively.

Two sets of weights are computed as functions of the M-distances of the observations. The weighting functions are essentially the same form as that of Huber (see, for example, Huber 1981). Let d_i be the M-distance of observation i , computed from the d_s formula. The first set of weights $w_1(d_i)$ applies to the first moments of the data and is defined as

$$\begin{aligned} w_1(d_i) &= 1 && \text{(if } d_i \leq \rho) \\ &= \rho/d_i && \text{(if } d_i > \rho) \end{aligned}$$

where ρ is the critical value corresponding to the $(1 - \varphi) \times 100$ quantile of the $\chi_r = \sqrt{\chi_r^2}$ distribution, with r being the degrees of freedom. For the two-stage robust method, r is simply the number of observed variables in the analysis. The tuning parameter φ controls the approximate proportion of observations to be downweighted (that is, with $w_1(d_i)$ less than 1). The default φ value is set to 0.05. You can override this value by using the **ROBPHI=** option.

The second set of weights $w_2(d_i)$ applies to the second moments of the data and is defined as

$$w_2(d_i) = (w_1(d_i))^2 / \kappa$$

where κ is a constant that adjusts the sum $\sum_{i=1}^N w_2(d_i)$ to 1 approximately. After the tuning parameter φ is determined, the critical value ρ and the adjustment κ are computed automatically by PROC CALIS.

With these two sets of weights, the two-stage robust method (ROBUST=SAT) estimates the mean and covariance by the so-called iteratively reweighted least squares (IRLS) algorithm. Specifically, the updating formulas at the $j+1$ iteration are

$$\begin{aligned}\boldsymbol{\mu}^{(j+1)} &= \frac{\sum_{i=1}^N w_1(d_i^{(j)}) \mathbf{x}_i}{\sum_{i=1}^N w_1(d_i^{(j)})} \\ \boldsymbol{\Sigma}^{(j+1)} &= \frac{1}{N} \sum_{i=1}^N w_2(d_i^{(j)}) (\mathbf{x}_i - \boldsymbol{\mu}^{(j)}) (\mathbf{x}_i - \boldsymbol{\mu}^{(j)})'\end{aligned}$$

where $d_i^{(j)}$ is the M-distance evaluated at $\boldsymbol{\mu}^{(j)}$ and $\boldsymbol{\Sigma}^{(j)}$ obtained in the j th iteration. Carry out the iterations until $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ converge. The final iteration yields the robust estimates of mean and covariance matrices. PROC CALIS uses the relative parameter convergence criterion for the IRLS algorithm. The default criterion is $1\text{E}-8$. See the **XCONV=** option for the definition of the relative parameter convergence criterion. After the IRLS algorithm converges in the first stage, the two-stage robust method proceeds to treat the robust mean and covariance estimates as if they were sample mean and covariance matrices for a maximum likelihood estimation (METHOD=ML) of the model.

Direct Robust Method

The direct robust method computes the following residual M-distance d_r for an observation with residual random vector $\hat{\mathbf{e}}$ (say, of dimension $h \times 1$, where h is the number of dependent observed variables \mathbf{y}):

$$d_r = \sqrt{(\mathbf{L}\hat{\mathbf{e}})'(\mathbf{L}\boldsymbol{\Omega}_{\hat{\mathbf{e}}}\mathbf{L}')^{-1}(\mathbf{L}\hat{\mathbf{e}})}$$

where \mathbf{L} ($(h - q) \times h$) is a loading matrix that reduces $\hat{\mathbf{e}}$ to $(h - q)$ independent components and q is the number of independent factors to be estimated from the dependent observed variables \mathbf{y} . The reduction of the residual vector into independent components is necessary when the number of factors q is not zero in the model. For $q > 0$, the residual covariance matrix $\boldsymbol{\Omega}_{\hat{\mathbf{e}}}$ is not invertible and cannot be used in computing the residual M-distances. Hence, the covariance matrix $\mathbf{L}\boldsymbol{\Omega}_{\hat{\mathbf{e}}}\mathbf{L}'$ of independent components $\mathbf{L}\hat{\mathbf{e}}$ is used instead. See Yuan and Hayashi (2010) for details about the computation of the residuals in the context of structural equation modeling.

The direct robust method also computes two sets of weights as functions of the residual M-distances. Let d_i be the M-distance of observation i , computed from the d_r formula. The first set of weights $w_1(d_i)$ applies to parameters in the first moments and is defined as

$$\begin{aligned}w_1(d_i) &= 1 \quad (\text{if } d_i \leq \rho) \\ &= \rho/d_i \quad (\text{if } d_i > \rho)\end{aligned}$$

The second set of weights $w_2(d_i)$ applies to the parameters in the second moments and is defined as

$$w_2(d_i) = (w_1(d_i))^2 / \kappa$$

These are essentially the same Huber-type weighting functions as those for the two-stage robust method. The only difference is that the d_r , instead of the d_s , formula is used in the weighting functions for the direct robust method. The definition of ρ is also the same as that in the two-stage robust method, but it is now based on a different theoretical chi-square distribution. That is, in the direct robust method, ρ is the critical value that corresponds to the $(1 - \varphi) \times 100$ quantile of the $\chi_r = \sqrt{\chi_r^2}$ distribution, with $r = (h - q)$ being

the degrees of freedom. Again, φ is a tuning parameter and is set to 0.05 by default. You can override this value by using the **ROBPHI=** option. The calculation of the number of “independent factors” q depends on the variants of the direct robust estimation that you choose. With the **ROBUST=RES(E)** option, q is the same as the number of exogenous factors specified in the model. With the **ROBUST=RES(F)** option, the disturbances of the endogenous factors in the model are also treated as “independent factors,” so q is the total number of latent factors specified in the model.

The direct robust method (**ROBUST=RES(E)** or **ROBUST=RES(F)**) employs the IRLS algorithm in model estimation. Let the following expression be a vector of nonredundant first and second moments structured in terms of model parameters θ :

$$\mathbf{m}(\theta) = \begin{pmatrix} \mu(\theta) \\ \text{vech}(\Sigma(\theta)) \end{pmatrix}$$

where $\text{vech}()$ extracts the lower-triangular nonredundant elements in $\Sigma(\theta)$. The updating formulas for θ at the $j+1$ iteration is

$$\theta^{(j+1)} = \theta^{(j)} + \Delta\theta^{(j)}$$

where $\theta^{(j)}$ is the parameter values at the j th iteration and $\Delta\theta^{(j)}$ is defined by the following formula:

$$\Delta\theta^{(j)} = (\dot{\mathbf{m}}'(\theta^{(j)})\mathbf{W}(\theta^{(j)})\dot{\mathbf{m}}(\theta^{(j)}))^{-1}\dot{\mathbf{m}}'(\theta^{(j)})\mathbf{W}(\theta^{(j)})\mathbf{g}_j$$

where $\dot{\mathbf{m}}(\theta) = \frac{\partial \mathbf{m}(\theta)}{\partial \theta}$ is the model Jacobian, $\mathbf{W}(\theta)$ is the (normal theory) weight matrix for the moments (see Yuan and Zhong 2008 for the formula of the weight matrix), and \mathbf{g}_j is defined as

$$\mathbf{g}_j = \begin{pmatrix} \frac{1}{\sum_{i=1}^N w_1(d_i)} \sum_{i=1}^N w_1(d_i) \mathbf{x}_i - \mu(\theta^{(j)}) \\ \frac{1}{N} \sum_{i=1}^N w_2(d_i) \text{vech}[(\mathbf{x}_i - \mu(\theta^{(j)}))(\mathbf{x}_i - \mu(\theta^{(j)}))'] - \Sigma(\theta^{(j)}) \end{pmatrix}$$

Starting with some reasonable initial estimates for θ , PROC CALIS iterates the updating formulas until the relative parameter convergence criterion of the IRLS algorithm is satisfied. The default criterion value is 1E–8. This essentially means that the IRLS algorithm converges when $\Delta\theta$ is sufficiently small. See the **XCONV=** option for the definition of the relative parameter convergence criterion.

Although the iterative formulas and the IRLS steps for robust estimation have been presented for single-group analysis, they are easily generalizable to multiple-group analysis. For the two-stage robust method, you only need to repeat the robust estimation of the means and covariances for the groups and then apply the obtained robust moments as if they were sample moments for regular maximum likelihood estimation (**METHOD=ML**). For the direct robust method, you need to expand the dimensions of the model Jacobian matrix $\dot{\mathbf{m}}(\theta)$, the weight matrix $\mathbf{W}(\theta)$, and the vector \mathbf{g} to include moments from several groups/models. Therefore, the multiple-group formulas are conceptually quite simple but tedious to present. For this reason, they are omitted here.

Relationships among Estimation Criteria

There is always some arbitrariness to classify the estimation methods according to certain mathematical or numerical properties. The discussion in this section is not meant to be a thorough classification of the estimation methods available in PROC CALIS. Rather, classification is done here with the purpose of clarifying the uses of different estimation methods and the theoretical relationships of estimation criteria.

Assumption of Multivariate Normality

GLS, ML, and FIML assume multivariate normality of the data, while ULS, WLS, and DWLS do not. Although the ML method with covariance structure analysis alone can also be based on the Wishart distribution of the sample covariance matrix, for convenience GLS, ML, and FIML are usually classified as normal-theory based methods, while ULS, WLS, and DWLS are usually classified as distribution-free methods.

An intuitive or even naive notion is usually that methods without distributional assumptions such as WLS and DWLS are preferred to normal theory methods such as ML and GLS in practical situations where multivariate normality is doubtful. This notion might need some qualifications because there are simply more factors to consider in judging the quality of estimation methods in practice. For example, the WLS method might need a very large sample size to enjoy its purported asymptotic properties, while the ML might be robust against the violation of multi-normality assumption under certain circumstances. No recommendations regarding which estimation criterion should be used are attempted here, but you should make your choice based more than the assumption of multivariate normality.

Contribution of the Off-Diagonal Elements to the Estimation of Covariance or Correlation Structures

If only the covariance or correlation structures are considered, the six estimation functions, F_{ULS} , F_{GLS} , F_{ML} , F_{FIML} , F_{WLS} , and F_{DWLS} , belong to the following two groups:

- The functions F_{ULS} , F_{GLS} , F_{ML} , and F_{FIML} take into account all n^2 elements of the symmetric residual matrix $\mathbf{S} - \mathbf{\Sigma}$. This means that the off-diagonal residuals contribute twice to the discrepancy function F , as lower and as upper triangle elements.
- The functions F_{WLS} and F_{DWLS} take into account only the $n(n + 1)/2$ lower triangular elements of the symmetric residual matrix $\mathbf{S} - \mathbf{\Sigma}$. This means that the off-diagonal residuals contribute to the discrepancy function F only once.

The F_{DWLS} function used in PROC CALIS differs from that used by the LISREL 7 program. Formula (1.25) of the LISREL 7 manual (Jöreskog and Sörbom 1985, p. 23) shows that LISREL groups the F_{DWLS} function in the first group by taking into account all n^2 elements of the symmetric residual matrix $\mathbf{S} - \mathbf{\Sigma}$.

- Relationship between DWLS and WLS:
PROC CALIS: The F_{DWLS} and F_{WLS} discrepancy functions deliver the same results for the special case that the weight matrix $\mathbf{W} = \mathbf{W}_{ss}$ used by WLS estimation is a diagonal matrix.
LISREL 7: This is not the case.
- Relationship between DWLS and ULS:
LISREL 7: The F_{DWLS} and F_{ULS} estimation functions deliver the same results for the special case that the diagonal weight matrix $\mathbf{W} = \mathbf{W}_{ss}$ used by DWLS estimation is an identity matrix.
PROC CALIS: To obtain the same results with F_{DWLS} and F_{ULS} estimation, set the diagonal weight matrix $\mathbf{W} = \mathbf{W}_{ss}$ used in DWLS estimation to:

$$[\mathbf{W}_{ss}]_{ik,ik} = \begin{cases} 1. & \text{if } i = k \\ 0.5 & \text{otherwise} \end{cases} \quad (k \leq i)$$

Because the reciprocal elements of the weight matrix are used in the discrepancy function, the off-diagonal residuals are weighted by a factor of 2.

ML and FIML Methods

Both the ML and FIML methods can be derived from the log-likelihood function for multivariate normal data. The preceding section “[Estimation Criteria](#)” on page 1309 mentions that F_{FIML} is essentially the same as $\frac{-2L}{N}$, where L is the log-likelihood function for multivariate normal data. For the ML estimation, you can also consider $\frac{-2L}{N}$ as a part of the F_{ML} discrepancy function that contains the information regarding the model parameters (while the rest the F_{ML} function contains some constant terms given the data). That is, with some algebraic manipulations and assuming that there is no missing value in the analysis (so that all μ_j and Σ_j are the same as μ and Σ , respectively), it can be shown that

$$\begin{aligned} F_{FIML} &= \frac{-2L}{N} \\ &= \frac{1}{N} \sum_{j=1}^n (\ln(|\Sigma|) + (\mathbf{x}_j - \mu)' \Sigma^{-1} (\mathbf{x}_j - \mu) + K) \\ &= \ln(|\Sigma|) + \text{Tr}(\mathbf{S}_N \Sigma^{-1}) + (\bar{\mathbf{x}} - \mu)' \Sigma^{-1} (\bar{\mathbf{x}} - \mu) + K \end{aligned}$$

where $\bar{\mathbf{x}}$ is the sample mean and \mathbf{S}_N is the biased sample covariance matrix. Compare this FIML function with the ML function shown in the following expression, which shows that both functions are very similar:

$$F_{ML} = \ln(|\Sigma|) + \text{Tr}(\mathbf{S} \Sigma^{-1}) + (\bar{\mathbf{x}} - \mu)' \Sigma^{-1} (\bar{\mathbf{x}} - \mu) - p - \ln(|\mathbf{S}|)$$

The two expressions differ only in the constant terms, which are independent of the model parameters, and in the formulas for computing the sample covariance matrix. While the FIML method assumes the biased formula (with N as the divisor, by default) for the sample covariance matrix, the ML method (as implemented in PROC CALIS) uses the unbiased formula (with $N - 1$ as the divisor, by default).

The similarity (or dissimilarity) of the ML and FIML discrepancy functions leads to some useful conclusions here:

- Because the constant terms in the discrepancy functions play no part in parameter estimation (except for shifting the function values), overriding the default ML method with `VARDEF=N` (that is, using N as the divisor in the covariance matrix formula) leads to the same estimation results as that of the FIML method, given that there are no missing values in the analysis.
- Because the FIML function is evaluated at the level of individual observations, it is much more expensive to compute than the ML function. As compared with ML estimation, FIML estimation takes longer and uses more computing resources. Hence, for data without missing values, the ML method should always be chosen over the FIML method.
- The advantage of the FIML method lies solely in its ability to handle data with random missing values. While the FIML method uses the information maximally from each observation, the ML method (as implemented in PROC CALIS) simply throws away any observations with at least one missing value. If it is important to use the information from observations with random missing values, the FIML method should be given consideration over the ML method.

See [Example 27.15](#) for an application of the FIML method and [Example 27.16](#) for an empirical comparison of the ML and FIML methods.

Gradient, Hessian, Information Matrix, and Approximate Standard Errors

For a single-sample setting with a discrepancy function $F = F(\Sigma(\Theta), \mu(\Theta); \mathbf{S}, \bar{\mathbf{x}})$, the gradient is defined as the first partial derivatives of the discrepancy function with respect to the model parameters Θ :

$$g(\Theta) = \frac{\partial}{\partial \Theta} F(\Theta)$$

The Hessian is defined as the second partial derivatives of the discrepancy function with respect to the model parameters Θ :

$$H(\Theta) = \frac{\partial^2}{\partial \Theta \partial \Theta'} F(\Theta)$$

Suppose that the mean and covariance structures fit perfectly with $\Theta = \Theta_o$ in the population. The information matrix is defined as

$$I(\Theta_o) = \frac{1}{2} \mathcal{E}(H(\Theta_o))$$

where the expectation $\mathcal{E}(\cdot)$ is taken over the sampling space of $\mathbf{S}, \bar{\mathbf{x}}$.

The information matrix plays a significant role in statistical theory. Under certain regularity conditions, the inverse of the information matrix $I^{-1}(\Theta_o)$ is the asymptotic covariance matrix for $\sqrt{N}(\hat{\Theta} - \Theta_o)$, where N denotes the sample size and $\hat{\Theta}$ is an estimator.

In practice, Θ_o is never known and can only be estimated. The information matrix is therefore estimated by the so-called empirical information matrix:

$$I(\hat{\Theta}) = \frac{1}{2} H(\hat{\Theta})$$

which is evaluated at the values of the sample estimates $\hat{\Theta}$. Notice that this empirical information matrix, rather than the unknown $I(\Theta_o)$, is the “information matrix” displayed in PROC CALIS output.

Taking the inverse of the empirical information matrix with sample size adjustment, PROC CALIS approximates the estimated covariance matrix of $\hat{\Theta}$ by:

$$((N - 1)I(\hat{\Theta}))^{-1} = ((N - 1)\frac{1}{2}H(\hat{\Theta}))^{-1} = \frac{2}{N - 1} H^{-1}(\hat{\Theta})$$

Approximate standard errors for $\hat{\Theta}$ can then be computed as the square roots of the diagonal elements of the estimated covariance matrix. The theory about the empirical information matrix, the approximate covariance matrix of the parameter estimates, and the approximate standard errors applies to all but the ULS and DWLS estimation methods. Standard errors are therefore not computed with the ULS and DWLS estimation methods.

If a given Hessian or information matrix is singular, PROC CALIS offers two ways to compute a generalized inverse of the matrix and, therefore, two ways to compute approximate standard errors of implicitly constrained parameter estimates, t values, and modification indices. Depending on the `G4=` specification, either a Moore-Penrose inverse or a G2 inverse is computed. The expensive Moore-Penrose inverse computes an estimate of the null space by using an eigenvalue decomposition. The cheaper G2 inverse is produced by sweeping the linearly independent rows and columns and zeroing out the dependent ones.

Multiple-Group Extensions

In the section “Multiple-Group Discrepancy Function” on page 1315, the overall discrepancy function for multiple-group analysis is defined. The same notation is applied here. To begin with, the overall discrepancy function $F(\Theta)$ is expressed as a weighted sum of individual discrepancy functions F_i ’s for the groups as follows:

$$F(\Theta) = \sum_{i=1}^k t_i F_i(\Theta)$$

where

$$t_i = \frac{N_i - 1}{N - k}$$

is the weight for group i ,

$$N = \sum_{i=1}^k N_i$$

is the total sample size, and N_i is the sample size for group i .

The gradient $g(\Theta)$ and the Hessian $H(\Theta)$ are now defined as weighted sum of individual functions. That is,

$$g(\Theta) = \sum_{i=1}^k t_i g_i(\Theta) = \sum_{i=1}^k t_i \frac{\partial}{\partial \Theta} F_i(\Theta)$$

and

$$H(\Theta) = \sum_{i=1}^k t_i H_i(\Theta) = \sum_{i=1}^k t_i \frac{\partial^2}{\partial \Theta \partial \Theta'} F_i(\Theta)$$

Suppose that the mean and covariance structures fit perfectly with $\Theta = \Theta_o$ in the population. If each t_i converges to a fixed constant τ_i ($\tau_i > 0$) with increasing total sample size, the information matrix can be written as:

$$I(\Theta_o) = \frac{1}{2} \sum_{i=1}^k \tau_i \mathcal{E}(H_i(\Theta_o))$$

To approximate this information matrix, an empirical counterpart is used:

$$I(\hat{\Theta}) = \frac{1}{2} \sum_{i=1}^k t_i H_i(\hat{\Theta})$$

which is evaluated at the values of the sample estimates $\hat{\Theta}$. Again, this empirical information matrix, rather than the unknown $I(\Theta_o)$, is the “information matrix” output in PROC CALIS results.

Taking the inverse of the empirical information matrix with sample size adjustment, PROC CALIS approximates the estimated covariance matrix of $\hat{\Theta}$ in multiple-group analysis by:

$$((N - k)I(\hat{\Theta}))^{-1} = ((N - k)\frac{1}{2}H(\hat{\Theta}))^{-1} = \frac{2}{N - k} \sum_{i=1}^k t_i H_i^{-1}(\hat{\Theta})$$

Approximate standard errors for $\hat{\Theta}$ can then be computed as the square roots of the diagonal elements of the estimated covariance matrix. Again, for ULS and DWLS estimation, the theory does not apply and so there are no standard errors computed in these cases.

Testing Rank Deficiency in the Approximate Covariance Matrix for Parameter Estimates

When computing the approximate covariance matrix and hence the standard errors for the parameter estimates, inversion of the scaled information matrix or Hessian matrix is involved. The numerical condition of the information matrix can be very poor in many practical applications, especially for the analysis of unscaled covariance data. The following four-step strategy is used for the inversion of the information matrix.

1. The inversion (usually of a normalized matrix $\mathbf{D}^{-1}\mathbf{H}\mathbf{D}^{-1}$) is tried using a modified form of the Bunch and Kaufman (1977) algorithm, which allows the specification of a different singularity criterion for each pivot. The following three criteria for the detection of rank loss in the information matrix are used to specify thresholds:

- *ASING* specifies absolute singularity.
- *MSING* specifies relative singularity depending on the whole matrix norm.
- *VSING* specifies relative singularity depending on the column matrix norm.

If no rank loss is detected, the inverse of the information matrix is used for the covariance matrix of parameter estimates, and the next two steps are skipped.

2. The linear dependencies among the parameter subsets are displayed based on the singularity criteria.
3. If the number of parameters t is smaller than the value specified by the **G4=** option (the default value is 60), the Moore-Penrose inverse is computed based on the eigenvalue decomposition of the information matrix. If you do not specify the **NOPRINT** option, the distribution of eigenvalues is displayed, and those eigenvalues that are set to zero in the Moore-Penrose inverse are indicated. You should inspect this eigenvalue distribution carefully.
4. If PROC CALIS did not set the right subset of eigenvalues to zero, you can specify the **COVSING=** option to set a larger or smaller subset of eigenvalues to zero in a further run of PROC CALIS.

Counting the Degrees of Freedom

When fitting covariance and mean structure models, the population moments are hypothesized to be functions of model parameters Θ . The population moments refer to the first-order moments (means) and the second-order central moments (variances of and covariances among the variables). Usually, the number of nonredundant population moments is greater than the number of model parameters for a structural model. The difference between the two is the degrees of freedom (df) of your model.

Formally, define a multiple-group situation where you have k independent groups in your model. The set of variables in each group might be different so that you have p_1, p_2, \dots, p_k manifest or observed variables for the k groups. It is assumed that the primary interest is to study the covariance structures. The inclusion of mean structures is optional for each of these groups. Define $\delta_1, \delta_2, \dots, \delta_k$ as zero-one indicators of the

mean structures for the groups. If δ_i takes the value of one, it means that the mean structures of group i is modeled. The total number of nonredundant elements in the moment matrices is thus computed by:

$$q = \sum_{i=1}^k (p_i(p_i + 1)/2 + \delta_i p_i)$$

The first term in the summation represents the number of lower triangular elements in the covariance or correlation matrix, while the second term represents the number of elements in the mean matrix. Let t be the total number of independent parameters *in the model*. The degrees of freedom is:

$$df = q - (t - c)$$

where c represents the number of linear equality constraints imposed on the independent parameters in the model. In effect, the $(t - c)$ expression means that each nonredundant linear equality constraint reduces one independent parameter.

Counting the Number of Independent Parameters

To count the number of independent parameters in the model, first you have to distinguish them from the dependent parameters. Dependent parameters are expressed as functions of other parameters in the [SAS programming statements](#). That is, a parameter is dependent if it appears at the left-hand side of the equal sign in a SAS programming statement.

A parameter is independent if it is not dependent. An independent parameter can be specified in the [main](#) or [subsidiary](#) model specification statements or the [PARAMETERS](#) statement, or it is generated automatically by PROC CALIS as additional parameters. Quite intuitively, all independent parameter specified in the main or subsidiary model specification statements are independent parameters *in the model*. All automatic parameters added by PROC CALIS are also independent parameters *in the model*.

Intentionally or not, some independent parameters specified in the PARMS statement might not be counted as independent parameters in the model. Independent parameters in the PARMS statement belong in the model only when they are used to define at least one dependent parameter specified in the main or subsidiary model specification statements. This restriction eliminates the counting of superfluous independent parameters which have no bearing of model specification.

Note that when counting the number of independent parameters, you are counting the number of distinct independent parameter names but not the number of distinct parameter locations for independent parameters. For example, consider the following statement for defining the error variances in a LINEQS model:

```
variance    E1-E3 = vare1 vare2 vare3;
```

You define three variance parameter locations with three independent parameters vare1, vare2, and vare3. However, in the following specification:

```
variance    E1-E3 = vare vare vare;
```

you still have three variance parameter locations to define, but the number of independent parameter is only one, which is the parameter named vare.

Counting the Number of Linear Equality Constraints

The linear equality constraints refer to those specified in the **BOUNDS** or **LINCON** statement. For example, consider the following specification:

```
bounds 3 <= parm01 <= 3;
lincon 3 * parm02 + 2 * parm03 = 12;
```

In the **BOUNDS** statement, `parm01` is constrained to a fixed number 3, and in the **LINCON** statement, `parm02` and `parm03` are constrained linearly. In effect, these two statements reduce two independent parameters from the model. In the degrees of freedom formula, the value of c is 2 for this example.

Adjustment of Degrees of Freedom

In some cases, computing degrees of freedom for model fit is not so straightforward. Two important cases are considered in the following.

The first case is when you set linear inequality or boundary constraints in your model, and these inequality or boundary constraints become “active” in your final solution. For example, you might have set inequality boundary and linear constraints as:

```
bounds 0 <= var01;
lincon 3 * beta1 + 2 * beta2 >= 7;
```

The optimal solution occurs at the boundary point so that you observe in the final solution the following two equalities:

```
var01 = 0,
3 * beta1 + 2 * beta2 = 7
```

These two active constraints reduce the number of independent parameters of your original model. As a result, PROC CALIS will automatically increase the degrees of freedom by the number of active linear constraints. Adjusting degrees of freedom not only affects the significance of the model fit chi-square statistic, but it also affects the computation of many fit statistics and indices. See Dijkstra (1992) for a discussion of the validity of statistical inferences with active boundary constraints.

Automatically adjusting df in such a situation might not be totally justified in all cases. Statistical estimation is subject to sampling fluctuation. Active constraints might not occur when fitting the same model in new samples. If the researcher believes that those linear inequality and boundary constraints have a small chance of becoming active in repeated sampling, it might be more suitable to turn off the automatic adjustment by using the **NOADJDF** option in the PROC CALIS statement.

Another case where you need to pay attention to the computation of degrees of freedom is when you fit correlation models. The degrees-of-freedom calculation in PROC CALIS applies mainly to models with covariance structures with or without mean structures. When you model correlation structures, the degrees of freedom calculation in PROC CALIS is a straightforward generalization of the covariance structures. It does not take the fixed ones at the diagonal elements of the sample correlation matrix into account. Some might argue that with correlation structures, the degrees of freedom should be reduced by the total number of diagonal elements in the correlation matrices in the model. While PROC CALIS does not do this automatically, you can use the **DFREDUCE= i** option to specify the adjustment, where i can be any positive or negative integer. The df value is reduced by the **DFREDUCE=** value.

A Different Type of Degrees of Freedom

The degrees of freedom for model fitting has to be distinguished from another type of degrees of freedom. In a regression problem, the number of degrees of freedom for the error variance estimate is the number of observations in the data set minus the number of parameters. The **NOBS=**, **DFR=** (**RDF=**), and **DFE=** (**EDF=**) options refer to degrees of freedom in this sense. However, these values are not related to the degrees of freedom for the model fit statistic. The **NOBS=**, **DFR=**, and **DFE=** options should be used in PROC CALIS to specify the effective number of observations in the input data set only.

Assessment of Fit

In PROC CALIS, there are three main tools for assessing model fit:

- residuals for the fitted means or covariances
- overall model fit indices
- squared multiple correlations and determination coefficients

This section contains a collection of formulas for these assessment tools. The following notation is used:

- N for the total sample size
- k for the total number of independent groups in analysis
- p for the number of manifest variables
- t for the number of parameters to estimate
- Θ for the t -vector of parameters, $\hat{\Theta}$ for the estimated parameters
- $S = (s_{ij})$ for the $p \times p$ input covariance or correlation matrix
- $\bar{x} = (\bar{x}_i)$ for the p -vector of sample means
- $\hat{\Sigma} = \Sigma(\hat{\Theta}) = (\hat{\sigma}_{ij})$ for the predicted covariance or correlation matrix
- $\hat{\mu} = (\hat{\mu}_i)$ for the predicted mean vector
- δ for indicating the modeling of the mean structures
- W for the weight matrix
- f_{min} for the minimized function value of the fitted model
- d_{min} for the degrees of freedom of the fitted model

In multiple-group analyses, subscripts are used to distinguish independent groups or samples. For example, $N_1, N_2, \dots, N_r, \dots, N_k$ denote the sample sizes for k groups. Similarly, notation such as $p_r, S_r, \bar{x}_r, \hat{\Sigma}_r, \hat{\mu}_r, \delta_r$, and W_r is used for multiple-group situations.

Residuals in the Moment Matrices

Residuals indicate how well each entry or element in the mean or covariance matrix is fitted. Large residuals indicate bad fit.

PROC CALIS computes four types of residuals and writes them to the **OUTSTAT=** data set when requested.

- **raw residuals**

$$s_{ij} - \hat{\sigma}_{ij}, \quad \bar{x}_i - \hat{\mu}_i$$

for the covariance and mean residuals, respectively. The raw residuals are displayed whenever the **PALL**, **PRINT**, or **RESIDUAL** option is specified.

- **variance standardized residuals**

$$\frac{s_{ij} - \hat{\sigma}_{ij}}{\sqrt{s_{ii}s_{jj}}}, \quad \frac{\bar{x}_i - \hat{\mu}_i}{\sqrt{s_{ii}}}$$

for the covariance and mean residuals, respectively. The variance standardized residuals are displayed when you specify one of the following:

- the **PALL**, **PRINT**, or **RESIDUAL** option and **METHOD=NONE**, **METHOD=ULS**, or **METHOD=DWLS**
- **RESIDUAL=VARSTAND**

The variance standardized residuals are equal to those computed by the EQS 3 program (Bentler 1995).

- **asymptotically standardized residuals**

$$\frac{s_{ij} - \hat{\sigma}_{ij}}{\sqrt{v_{ij,ij}}}, \quad \frac{\bar{x}_i - \hat{\mu}_i}{\sqrt{u_{ii}}}$$

for the covariance and mean residuals, respectively; with

$$v_{ij,ij} = (\hat{\Gamma}_1 - \mathbf{J}_1 \widehat{\text{Cov}}(\hat{\Theta}) \mathbf{J}_1')_{ij,ij}$$

$$u_{ii} = (\hat{\Gamma}_2 - \mathbf{J}_2 \widehat{\text{Cov}}(\hat{\Theta}) \mathbf{J}_2')_{ii}$$

where $\hat{\Gamma}_1$ is the $p^2 \times p^2$ estimated asymptotic covariance matrix of sample covariances, $\hat{\Gamma}_2$ is the $p \times p$ estimated asymptotic covariance matrix of sample means, \mathbf{J}_1 is the $p^2 \times t$ Jacobian matrix $d\mathbf{\Sigma}/d\mathbf{\Theta}$, \mathbf{J}_2 is the $p \times t$ Jacobian matrix $d\mathbf{\mu}/d\mathbf{\Theta}$, and $\widehat{\text{Cov}}(\hat{\Theta})$ is the $t \times t$ estimated covariance matrix of parameter estimates, all evaluated at the sample moments and estimated parameter values. See the next section for the definitions of $\hat{\Gamma}_1$ and $\hat{\Gamma}_2$. Asymptotically standardized residuals are displayed when one of the following conditions is met:

- The **PALL**, the **PRINT**, or the **RESIDUAL** option is specified, and **METHOD=ML**, **METHOD=GLS**, or **METHOD=WLS**, and the expensive information and Jacobian matrices are computed for some other reason.
- **RESIDUAL=ASYSTAND** is specified.

The asymptotically standardized residuals are equal to those computed by the LISREL 7 program (Jöreskog and Sörbom 1988) except for the denominator in the definition of matrix $\hat{\Gamma}_1$.

• **normalized residuals**

$$\frac{s_{ij} - \hat{\sigma}_{ij}}{\sqrt{(\hat{\Gamma}_1)_{ij,ij}}}, \quad \frac{\bar{x}_i - \hat{\mu}_i}{\sqrt{(\hat{\Gamma}_2)_{ii}}}$$

for the covariance and mean residuals, respectively; with $\hat{\Gamma}_1$ as the $p^2 \times p^2$ estimated asymptotic covariance matrix of sample covariances; and $\hat{\Gamma}_2$ as the $p \times p$ estimated asymptotic covariance matrix of sample means.

Diagonal elements of $\hat{\Gamma}_1$ and $\hat{\Gamma}_2$ are defined for the following methods:

- **GLS**: $(\hat{\Gamma}_1)_{ij,ij} = \frac{1}{(N-1)}(s_{ii}s_{jj} + s_{ij}^2)$ and $(\hat{\Gamma}_2)_{ii} = \frac{1}{(N-1)}s_{ii}$
- **ML**: $(\hat{\Gamma}_1)_{ij,ij} = \frac{1}{(N-1)}(\hat{\sigma}_{ii}\hat{\sigma}_{jj} + \hat{\sigma}_{ij}^2)$ and $(\hat{\Gamma}_2)_{ii} = \frac{1}{(N-1)}\hat{\sigma}_{ii}$
- **WLS**: $(\hat{\Gamma}_1)_{ij,ij} = \frac{1}{(N-1)}W_{ij,ij}$ and $(\hat{\Gamma}_2)_{ii} = \frac{1}{(N-1)}s_{ii}$

where **W** in the **WLS** method is the weight matrix for the second-order moments.

Normalized residuals are displayed when one of the following conditions is met:

- The **PALL**, **PRINT**, or **RESIDUAL** option is specified, and **METHOD=ML**, **METHOD=GLS**, or **METHOD=WLS**, and the expensive information and Jacobian matrices are **not** computed for some other reasons.
- **RESIDUAL=NORM** is specified.

The normalized residuals are equal to those computed by the LISREL VI program (Jöreskog and Sörbom 1985) except for the definition of the denominator in computing matrix $\hat{\Gamma}_1$.

For estimation methods that are not “best” generalized least squares estimators (Browne 1982, 1984), such as **METHOD=NONE**, **METHOD=ULS**, or **METHOD=DWLS**, the assumption of an asymptotic covariance matrix Γ_1 of sample covariances does not seem to be appropriate. In this case, the normalized residuals should be replaced by the more relaxed variance standardized residuals. Computation of asymptotically standardized residuals requires computing the Jacobian and information matrices. This is computationally very expensive and is done only if the Jacobian matrix has to be computed for some other reasons—that is, if at least one of the following items is true:

- The default, **PRINT**, or **PALL** displayed output is requested, and neither the **NOMOD** nor **NOSTDERR** option is specified.
- Either the **MODIFICATION** (included in **PALL**), **PCOVES**, or **STDERR** (included in default, **PRINT**, and **PALL** output) option is requested or **RESIDUAL=ASYSTAND** is specified.
- The **LEVMar** or **NEWRAp** optimization technique is used.
- An **OUTMODEL=** data set is specified without using the **NOSTDERR** option.
- An **OUTEST=** data set is specified without using the **NOSTDERR** option.

Since normalized residuals use an overestimate of the asymptotic covariance matrix of residuals (the diagonals of $\mathbf{\Gamma}_1$ and $\mathbf{\Gamma}_2$), the normalized residuals cannot be greater than the asymptotically standardized residuals (which use the diagonal of the form $\mathbf{\Gamma} - \mathbf{J}\widehat{\text{Cov}}(\hat{\boldsymbol{\Theta}})\mathbf{J}'$).

Together with the residual matrices, the values of the average residual, the average off-diagonal residual, and the rank order of the largest values are displayed. The distributions of the normalized and standardized residuals are displayed also.

Overall Model Fit Indices

Instead of assessing the model fit by looking at a number of residuals of the fitted moments, an overall model fit index measures model fit by a single number. Although an overall model fit index is precise and easy to use, there are indeed many choices of overall fit indices. Unfortunately, researchers do not always have a consensus on the best set of indices to use in all occasions.

PROC CALIS produces a large number of overall model fit indices in the fit summary table. If you prefer to display only a subset of these fit indices, you can use the `ONLIST(ONLY)=` option of the `FITINDEX` statement to customize the fit summary table.

Fit indices are classified into three classes in the fit summary table of PROC CALIS:

- absolute or standalone Indices
- parsimony indices
- incremental indices

Absolute or Standalone Indices

These indices are constructed so that they measure model fit without comparing with a baseline model and without taking the model complexity into account. They measure the absolute fit of the model.

- **fit function or discrepancy function**

The fit function or discrepancy function F is minimized during the optimization. See the section “[Estimation Criteria](#)” on page 1309 for definitions of various discrepancy functions available in PROC CALIS. For a multiple-group analysis, the fit function can be written as a weighted average of discrepancy functions for k independent groups as:

$$F = \sum_{r=1}^k a_r F_r$$

where $a_r = \frac{(N_j-1)}{(N-k)}$ and F_r are the group weight and the discrepancy function for the r th group, respectively. Notice that although the groups are assumed to be independent in the model, in general F_r 's are not independent when F is being minimized. The reason is that F_r 's might have shared parameters in $\boldsymbol{\Theta}$ during estimation.

The minimized function value of F will be denoted as f_{min} , which is always positive, with small values indicating good fit.

- **χ^2 test statistic**

For the ML, GLS, and the WLS estimation, the overall χ^2 measure for testing model fit is:

$$\chi^2 = (N - k) * f_{min}$$

where f_{min} is the function value at the minimum, N is the total sample size, and k is the number of independent groups. The associated degrees of freedom is denoted by d_{min} .

For the ML estimation, this gives the likelihood ratio test statistic of the specified structural model in the null hypothesis against an unconstrained saturated model in the alternative hypothesis. The χ^2 test is valid only if the observations are independent and identically distributed, the analysis is based on the unstandardized sample covariance matrix S , and the sample size N is sufficiently large (Browne 1982; Bollen 1989b; Jöreskog and Sörbom 1985). For ML and GLS estimates, the variables must also have an approximately multivariate normal distribution.

In the output fit summary table of PROC CALIS, the notation “Prob > Chi-Square” means “the probability of obtaining a greater χ^2 value than the observed value under the null hypothesis.” This probability is also known as the p -value of the chi-square test statistic.

- **adjusted χ^2 value (Browne 1982)**

If the variables are p -variate elliptic rather than normal and have significant amounts of multivariate kurtosis (leptokurtic or platykurtic), the χ^2 value can be adjusted to:

$$\chi_{ell}^2 = \frac{\chi^2}{\eta_2}$$

where η_2 is the multivariate relative kurtosis coefficient.

- **Z-test (Wilson and Hilferty 1931)**

The Z-test of Wilson and Hilferty assumes a p -variate normal distribution:

$$Z = \frac{\sqrt[3]{\frac{\chi^2}{d}} - (1 - \frac{2}{9d})}{\sqrt{\frac{2}{9d}}}$$

where d is the degrees of freedom of the model. See McArdle (1988) and Bishop, Fienberg, and Holland (1975, p. 527) for an application of the Z-test.

- **critical N index (Hoelter 1983)**

The critical N (Hoelter 1983) is defined as

$$CN = \text{int}\left(\frac{\chi_{crit}^2}{f_{min}}\right)$$

where χ_{crit}^2 is the critical chi-square value for the given d degrees of freedom and probability $\alpha = 0.05$, and $\text{int}()$ takes the integer part of the expression. See Bollen (1989b, p. 277). Conceptually, the CN value is the largest number of observations that could still make the chi-square model fit statistic insignificant if it were to apply to the actual sample fit function value f_{min} . Hoelter (1983) suggests that CN should be at least 200; however, Bollen (1989b) notes that the CN value might lead to an overly pessimistic assessment of fit for small samples.

Note that when you have a perfect model fit for your data (that is, $f_{min} = 0$) or a zero degree of freedom for your model (that is, $d = 0$), CN is not computable.

- **root mean square residual (RMR)**

For a single-group analysis, the RMR is the root of the mean squared residuals:

$$\text{RMR} = \sqrt{\frac{1}{b} \left[\sum_i^p \sum_j^i (s_{ij} - \hat{\sigma}_{ij})^2 + \delta \sum_i^p (\bar{x}_i - \hat{\mu}_i)^2 \right]}$$

where

$$b = \frac{p(p+1+2\delta)}{2}$$

is the number of distinct elements in the covariance matrix and in the mean vector (if modeled).

For multiple-group analysis, PROC CALIS uses the following formula for the overall RMR:

$$\text{overall RMR} = \sqrt{\sum_{r=1}^k \frac{w_r}{\sum_{r=1}^k w_r} \left[\sum_i^p \sum_j^i (s_{ij} - \hat{\sigma}_{ij})^2 + \delta \sum_i^p (\bar{x}_i - \hat{\mu}_i)^2 \right]}$$

where

$$w_r = \frac{N_r - 1}{N - k} b_r$$

is the weight for the squared residuals of the r th group. Hence, the weight w_r is the product of group size weight $\frac{N_r - 1}{N - k}$ and the number of distinct moments b_r in the r th group.

- **standardized root mean square residual (SRMR)**

For a single-group analysis, the SRMR is the root of the mean of the standardized squared residuals:

$$\text{SRMR} = \sqrt{\frac{1}{b} \left[\sum_i^p \sum_j^i \frac{(s_{ij} - \hat{\sigma}_{ij})^2}{s_{ii} s_{jj}} + \delta \sum_i^p \frac{(\bar{x}_i - \hat{\mu}_i)^2}{s_{ii}} \right]}$$

where b is the number of distinct elements in the covariance matrix and in the mean vector (if modeled). The formula for b is defined exactly the same way as it appears in the formula for RMR.

Similar to the calculation of the overall RMR, an overall measure of SRMR in a multiple-group analysis is a weighted average of the standardized squared residuals of the groups. That is,

$$\text{overall SRMR} = \sqrt{\sum_{r=1}^k \frac{w_r}{\sum_{r=1}^k w_r} \left[\sum_i^p \sum_j^i \frac{(s_{ij} - \hat{\sigma}_{ij})^2}{s_{ii} s_{jj}} + \delta \sum_i^p \frac{(\bar{x}_i - \hat{\mu}_i)^2}{s_{ii}} \right]}$$

where w_r is the weight for the squared residuals of the r th group. The formula for w_r is defined exactly the same way as it appears in the formula for SRMR.

- **goodness-of-fit index (GFI)**

For a single-group analysis, the goodness-of-fit index for the ULS, GLS, and ML estimation methods is:

$$\text{GFI} = 1 - \frac{\text{Tr}((\mathbf{W}^{-1}(\mathbf{S} - \hat{\Sigma}))^2) + \delta(\bar{\mathbf{x}} - \hat{\boldsymbol{\mu}})' \mathbf{W}^{-1}(\bar{\mathbf{x}} - \hat{\boldsymbol{\mu}})}{\text{Tr}((\mathbf{W}^{-1}\mathbf{S})^2) + \delta \bar{\mathbf{x}}' \mathbf{W}^{-1} \bar{\mathbf{x}}}$$

with $\mathbf{W} = \mathbf{I}$ for ULS, $\mathbf{W} = \mathbf{S}$ for GLS, and $\mathbf{W} = \hat{\mathbf{\Sigma}}$. For WLS and DWLS estimation,

$$\text{GFI} = 1 - \frac{(\mathbf{u} - \hat{\boldsymbol{\eta}})' \mathbf{W}^{-1} (\mathbf{u} - \hat{\boldsymbol{\eta}})}{\mathbf{u}' \mathbf{W}^{-1} \mathbf{u}}$$

where \mathbf{u} is the vector of observed moments and $\hat{\boldsymbol{\eta}}$ is the vector of fitted moments. When the mean structures are modeled, vectors \mathbf{u} and $\hat{\boldsymbol{\eta}}$ contains all the nonredundant elements $\text{vecs}(\mathbf{S})$ in the covariance matrix and all the means. That is,

$$\mathbf{u} = (\text{vecs}'(\mathbf{S}), \bar{\mathbf{x}}')', \quad \hat{\boldsymbol{\eta}} = (\text{vecs}'(\hat{\mathbf{\Sigma}}), \hat{\boldsymbol{\mu}}')'$$

and the symmetric weight matrix \mathbf{W} is of dimension $p \times (p + 3)/2$. When the mean structures are not modeled, vectors \mathbf{u} and $\hat{\boldsymbol{\eta}}$ contains all the nonredundant elements $\text{vecs}(\mathbf{S})$ in the covariance matrix only. That is,

$$\mathbf{u} = \text{vecs}(\mathbf{S}), \quad \hat{\boldsymbol{\eta}} = \text{vecs}(\hat{\mathbf{\Sigma}})$$

and the symmetric weight matrix \mathbf{W} is of dimension $p \times (p + 1)/2$. In addition, for the DWLS estimation, \mathbf{W} is a diagonal matrix.

For a constant weight matrix \mathbf{W} , the goodness-of-fit index is 1 minus the ratio of the minimum function value and the function value before any model has been fitted. The GFI should be between 0 and 1. The data probably do not fit the model if the GFI is negative or much greater than 1.

For a multiple-group analysis, individual GFI_r 's are computed for groups. The overall measure is a weighted average of individual GFI_r 's, using weight $a_r = \frac{N_r - 1}{N - k}$. That is,

$$\text{overall GFI} = \sum_{r=1}^k a_r \text{GFI}_r$$

Parsimony Indices

These indices are constructed so that the model complexity is taken into account when assessing model fit. In general, models with more parameters (fewer degrees of freedom) are penalized.

- **adjusted goodness-of-fit index (AGFI)**

The AGFI is the GFI adjusted for the degrees of freedom d of the model,

$$\text{AGFI} = 1 - \frac{c}{d} (1 - \text{GFI})$$

where

$$c = \sum_{r=1}^k \frac{p_k(p_k + 1 + 2\delta_k)}{2}$$

computes the total number of elements in the covariance matrices and mean vectors for modeling. For single-group analyses, the AGFI corresponds to the GFI in replacing the total sum of squares by the mean sum of squares.

CAUTION:

- Large p and small d can result in a negative AGFI. For example, $GFI=0.90$, $p=19$, and $d=2$ result in an AGFI of -8.5 .
- AGFI is not defined for a saturated model, due to division by $d = 0$.
- AGFI is not sensitive to losses in d .

The AGFI should be between 0 and 1. The data probably do not fit the model if the AGFI is negative or much greater than 1. For more information, see Mulaik et al. (1989).

- **parsimonious goodness-of-fit index (PGFI)**

The PGFI (Mulaik et al. 1989) is a modification of the GFI that takes the parsimony of the model into account:

$$PGFI = \frac{d_{min}}{d_0} GFI$$

where d_{min} is the model degrees of freedom and d_0 is the degrees of freedom for the independence model. See the section “**Incremental Indices**” on page 1335 for the definition of independence model. The PGFI uses the same parsimonious factor as the parsimonious normed Bentler-Bonett index (James, Mulaik, and Brett 1982).

- **RMSEA index (Steiger and Lind 1980; Steiger 1998)**

The root mean square error approximation (RMSEA) coefficient is:

$$\epsilon = \sqrt{k} \sqrt{\max\left(\frac{f_{min}}{d_{min}} - \frac{1}{(N-k)}, 0\right)}$$

The lower and upper limits of the $(1 - \alpha)\%$ -confidence interval are computed using the cumulative distribution function of the noncentral chi-square distribution $\Phi(x|\lambda, d)$. With $x = (N - k)f_{min}$, λ_L satisfying $\Phi(x|\lambda_L, d_{min}) = 1 - \frac{\alpha}{2}$, and λ_U satisfying $\Phi(x|\lambda_U, d_{min}) = \frac{\alpha}{2}$:

$$(\epsilon_{\alpha_L}; \epsilon_{\alpha_U}) = \left(\sqrt{k} \sqrt{\frac{\lambda_L}{(N-k)d_{min}}}; \sqrt{k} \sqrt{\frac{\lambda_U}{(N-k)d_{min}}} \right)$$

See Browne and Du Toit (1992) for more details. The size of the confidence interval can be set by the option **ALPHARMS**= α , $0 \leq \alpha \leq 1$. The default is $\alpha = 0.1$, which corresponds to the 90% confidence interval for the RMSEA.

- **probability for test of close fit (Browne and Cudeck 1993)**

The traditional exact χ^2 test hypothesis $H_0: \epsilon = 0$ is replaced by the null hypothesis of close fit $H_0: \epsilon \leq 0.05$ and the exceedance probability P is computed as:

$$P = 1 - \Phi(x|\lambda^*, d_{min})$$

where $x = (N - k)f_{min}$ and $\lambda^* = 0.05^2(N - k)d_{min}/k$. The null hypothesis of close fit is rejected if P is smaller than a prespecified level (for example, $P < 0.05$).

- **ECVI: expected cross validation index (Browne and Cudeck 1993)**

The following formulas for ECVI are limited to the case of single-sample analysis without mean structures and with either the GLS, ML, or WLS estimation method. For other cases, ECVI is not defined in PROC CALIS. For GLS and WLS, the estimator c of the ECVI is linearly related to AIC, Akaike's Information Criterion (Akaike 1974, 1987):

$$c = f_{min} + \frac{2t}{N-1}$$

For ML estimation, c_{ML} is used:

$$c_{ML} = f_{min} + \frac{2t}{N-p-2}$$

For GLS and WLS, the confidence interval $(c_L; c_U)$ for ECVI is computed using the cumulative distribution function $\Phi(x|\lambda, d_{min})$ of the noncentral chi-square distribution,

$$(c_L; c_U) = \left(\frac{\lambda_L + p(p+1)/2 + t}{(N-1)}; \frac{\lambda_U + p(p+1)/2 + t}{(N-1)} \right)$$

with $x = (N-1)f_{min}$, $\Phi(x|\lambda_U, d_{min}) = \frac{\alpha}{2}$, and $\Phi(x|\lambda_L, d_{min}) = 1 - \frac{\alpha}{2}$.

For ML, the confidence interval $(c_L^*; c_U^*)$ for ECVI is:

$$(c_L^*; c_U^*) = \left(\frac{\lambda_L^* + p(p+1)/2 + t}{N-p-2}; \frac{\lambda_U^* + p(p+1)/2 + t}{N-p-2} \right)$$

where $x = (N-p-2)f_{min}$, $\Phi(x|\lambda_U^*, d_{min}) = \frac{\alpha}{2}$ and $\Phi(x|\lambda_L^*, d_{min}) = 1 - \frac{\alpha}{2}$. See Browne and Cudeck (1993). The size of the confidence interval can be set by the option `ALPHAECV= α` , $0 \leq \alpha \leq 1$. The default is $\alpha = 0.1$, which corresponds to the 90% confidence interval for the ECVI.

- **Akaike's information criterion (AIC) (Akaike 1974, 1987)**

This is a criterion for selecting the best model among a number of candidate models. The model that yields the smallest value of AIC is considered the best.

$$AIC = h + 2t$$

where h is the -2 times the likelihood function value for the FIML method or the χ^2 value for other estimation methods.

- **consistent Akaike's information criterion (CAIC) (Bozdogan 1987)**

This is another criterion, similar to AIC, for selecting the best model among alternatives. The model that yields the smallest value of CAIC is considered the best. CAIC is preferred by some people to AIC or the χ^2 test.

$$CAIC = h + (\ln(N) + 1)t$$

where h is the -2 times the likelihood function value for the FIML method or the χ^2 value for other estimation methods. Notice that N includes the number of incomplete observations for the FIML method while it includes only the complete observations for other estimation methods.

- **Schwarz's Bayesian criterion (SBC) (Schwarz 1978; Sclove 1987)**

This is another criterion, similar to AIC, for selecting the best model. The model that yields the smallest value of SBC is considered the best. SBC is preferred by some people to AIC or the χ^2 test.

$$\text{SBC} = h + \ln(N)t$$

where h is the -2 times the likelihood function value for the FIML method or the χ^2 value for other estimation methods. Notice that N includes the number of incomplete observations for the FIML method while it includes only the complete observations for other estimation methods.

- **McDonald's measure of centrality (McDonald and Marsh 1988)**

$$\text{CENT} = \exp\left(-\frac{(\chi^2 - d_{\min})}{2N}\right)$$

Incremental Indices

These indices are constructed so that the model fit is assessed through the comparison with a baseline model. The baseline model is usually the independence model where all covariances among manifest variables are assumed to be zeros. The only parameters in the independence model are the diagonals of covariance matrix. If modeled, the mean structures are saturated in the independence model. For multiple-group analysis, the overall independence model consists of component independence models for each group.

In the following, let f_0 and d_0 denote the minimized discrepancy function value and the associated degrees of freedom, respectively, for the independence model; and f_{\min} and d_{\min} denote the minimized discrepancy function value and the associated degrees of freedom, respectively, for the model being fitted in the null hypothesis.

- **Bentler comparative fit index (Bentler 1995)**

$$\text{CFI} = 1 - \frac{\max((N - k)f_{\min} - d_{\min}, 0)}{\max((N - k)f_{\min} - d_{\min}, \max((N - k)f_0 - d_0, 0))}$$

- **Bentler-Bonett normed fit index (NFI) (Bentler and Bonett 1980)**

$$\Delta = \frac{f_0 - f_{\min}}{f_0}$$

Mulaik et al. (1989) recommend the parsimonious weighted form called parsimonious normed fit index (PNFI) (James, Mulaik, and Brett 1982).

- **Bentler-Bonett nonnormed coefficient (Bentler and Bonett 1980)**

$$\rho = \frac{f_0/d_0 - f_{\min}/d_{\min}}{f_0/d_0 - 1/(N - k)}$$

See Tucker and Lewis (1973).

- **normed index ρ_1 (Bollen 1986)**

$$\rho_1 = \frac{f_0/d_0 - f_{\min}/d_{\min}}{f_0/d_0}$$

ρ_1 is always less than or equal to 1; $\rho_1 < 0$ is unlikely in practice. See the discussion in Bollen (1989a).

- **nonnormed index Δ_2 (Bollen 1989a)**

$$\Delta_2 = \frac{f_0 - f_{\min}}{f_0 - \frac{d_{\min}}{(N-k)}}$$

is a modification of Bentler and Bonett's Δ that uses d and “lessens the dependence” on N . See the discussion in (Bollen 1989b). Δ_2 is identical to the IFI2 index of Mulaik et al. (1989).

- **parsimonious normed fit index (James, Mulaik, and Brett 1982)**

The PNFI is a modification of Bentler-Bonett's normed fit index that takes parsimony of the model into account,

$$\text{PNFI} = \frac{d_{\min}}{d_0} \frac{(f_0 - f_{\min})}{f_0}$$

The PNFI uses the same parsimonious factor as the parsimonious GFI of Mulaik et al. (1989).

Fit Indices and Estimation Methods

Note that not all fit indices are reasonable or appropriate for all estimation methods set by the **METHOD=** option of the PROC CALIS statement. The availability of fit indices is summarized as follows:

- Adjusted (elliptic) chi-square and its probability are available only for **METHOD=ML** or **GLS** and with the presence of raw data input.
- For **METHOD=ULS** or **DWLS**, probability of the chi-square value, RMSEA and its confidence intervals, probability of close fit, ECVI and its confidence intervals, critical N index, Z-test, AIC, CAIC, SBC, and measure of centrality are not appropriate and therefore not displayed.

Individual Fit Indices for Multiple Groups

When you compare the fits of individual groups in a multiple-group analysis, you can examine the residuals of the groups to gauge which group is fitted better than the others. While examining residuals is good for knowing specific locations with inadequate fit, summary measures like fit indices for individual groups would be more convenient for overall comparisons among groups.

Although the overall fit function is a weighted sum of individual fit functions for groups, these individual functions are not statistically independent. Therefore, in general you cannot partition the degrees of freedom or χ^2 value according to the groups. This eliminates the possibility of breaking down those fit indices that are functions of degrees of freedom or χ^2 for group comparison purposes. Bearing this fact in mind, PROC CALIS computes only a limited number of descriptive fit indices for individual groups.

- **fit function**

The overall fit function is:

$$F = \sum_{r=1}^k a_r F_r$$

where $a_r = \frac{(N_j - 1)}{(N - k)}$ and F_r are the group weight and the discrepancy function for group r , respectively. The value of unweighted fit function F_r for the r th group is denoted by:

$$f_r$$

This f_r value provides a measure of fit in the r th group without taking the sample size into account. The larger the f_r , the worse the fit for the group.

- **percentage contribution to the chi-square**

The percentage contribution of group r to the chi-square is:

$$\text{percentage contribution} = a_r f_r / f_{\min} \times 100\%$$

where f_r is the value of F_r with F minimized at the value f_{\min} . This percentage value provides a descriptive measure of fit of the moments in group r , weighted by its sample size. The group with the largest percentage contribution accounts for the most lack of fit in the overall model.

- **root mean square residual (RMR)**

For the r th group, the total number of moments being modeled is:

$$g = \frac{p_r(p_r + 1 + 2\delta_r)}{2}$$

where p_r is the number of variables and δ_r is the indicator variable of the mean structures in the r th group. The root mean square residual for the r th group is:

$$\text{RMR}_r = \sqrt{\frac{1}{g} \left[\sum_i^{p_r} \sum_j^i ([S_r]_{ij} - [\hat{\Sigma}_r]_{ij})^2 + \delta_r \sum_i^{p_r} ([\bar{x}_r]_i - [\hat{\mu}_r]_i)^2 \right]}$$

- **standardized root mean square residual (SRMR)**

For the r th group, the standardized root mean square residual is:

$$\text{SRMR} = \sqrt{\frac{1}{g} \left[\sum_i^{p_r} \sum_j^i \frac{([S_r]_{ij} - [\hat{\Sigma}_r]_{ij})^2}{[S_r]_{ii}[S_r]_{jj}} + \delta_r \sum_i^{p_r} \frac{([\bar{x}_r]_i - [\hat{\mu}_r]_i)^2}{[S_r]_{ii}} \right]}$$

- **goodness-of-fit index (GFI)**

For the ULS, GLS, and ML estimation, the goodness-of-fit index (GFI) for the r th group is:

$$\text{GFI} = 1 - \frac{\text{Tr}((\mathbf{W}_r^{-1}(\mathbf{S}_r - \hat{\Sigma}_r))^2) + \delta_r (\bar{\mathbf{x}}_r - \hat{\mathbf{u}}_r)' \mathbf{W}_r^{-1} (\bar{\mathbf{x}}_r - \hat{\mathbf{u}}_r)}{\text{Tr}((\mathbf{W}_r^{-1} \mathbf{S}_r)^2) + \delta_r \bar{\mathbf{x}}_r' \mathbf{W}_r^{-1} \bar{\mathbf{x}}_r}$$

with $\mathbf{W}_r = \mathbf{I}$ for ULS, $\mathbf{W}_r = \mathbf{S}_r$ for GLS, and $\mathbf{W}_r = \hat{\Sigma}_r$. For the WLS and DWLS estimation,

$$\text{GFI} = 1 - \frac{(\mathbf{u}_r - \hat{\eta}_r)' \mathbf{W}_r^{-1} (\mathbf{u}_r - \hat{\eta}_r)}{\mathbf{u}_r' \mathbf{W}_r^{-1} \mathbf{u}_r}$$

where \mathbf{u}_r is the vector of observed moments and $\hat{\eta}_r$ is the vector of fitted moments for the r th group ($r = 1, \dots, k$).

When the mean structures are modeled, vectors \mathbf{u}_r and $\hat{\eta}_r$ contain all the nonredundant elements $\text{vecs}(\mathbf{S}_r)$ in the covariance matrix and all the means, and \mathbf{W}_r is the weight matrix for covariances and means. When the mean structures are not modeled, \mathbf{u}_r , $\hat{\eta}_r$, and \mathbf{W}_r contain elements pertaining to the covariance elements only. Basically, formulas presented here are the same as the case for a single-group GFI. The only thing added here is the subscript r to denote individual group measures.

- **Bentler-Bonett normed fit index (NFI)**

For the r th group, the Bentler-Bonett NFI is:

$$\Delta_r = \frac{f_{0r} - f_r}{f_{0r}}$$

where f_{0r} is the function value for fitting the independence model to the r th group. The larger the value of Δ_r , the better is the fit for the group. Basically, the formula here is the same as the overall Bentler-Bonett NFI. The only difference is that the subscript r is added to denote individual group measures.

Squared Multiple Correlations and Determination Coefficients

In the section, squared multiple correlations for endogenous variables are defined. Squared multiple correlation is computed for all of these five estimation methods: ULS, GLS, ML, WLS, and DWLS. These coefficients are also computed as in the LISREL VI program of Jöreskog and Sörbom (1985). The DETAE, DETSE, and DETMV determination coefficients are intended to be multivariate generalizations of the squared multiple correlations for different subsets of variables. These coefficients are displayed only when you specify the **PDETERM** option.

- **R^2 values corresponding to endogenous variables**

$$R^2 = 1 - \frac{\widehat{\text{Evar}}(y)}{\widehat{\text{Var}}(y)}$$

where y denotes an endogenous variable, $\widehat{\text{Var}}(y)$ denotes its variance, and $\widehat{\text{Evar}}(y)$ denotes its error (or unsystematic) variance. The variance and error variance are estimated under the model.

- **total determination of all equations**

$$\text{DETAE} = 1 - \frac{|\widehat{\text{Ecov}}(\mathbf{y}, \boldsymbol{\eta})|}{|\widehat{\text{Cov}}(\mathbf{y}, \boldsymbol{\eta})|}$$

where the \mathbf{y} vector denotes all manifest dependent variables, the $\boldsymbol{\eta}$ vector denotes all latent dependent variables, $\widehat{\text{Cov}}(\mathbf{y}, \boldsymbol{\eta})$ denotes the covariance matrix of \mathbf{y} and $\boldsymbol{\eta}$, and $\widehat{\text{Ecov}}(\mathbf{y}, \boldsymbol{\eta})$ denotes the error covariance matrix of \mathbf{y} and $\boldsymbol{\eta}$. The covariance matrices are estimated under the model.

- **total determination of latent equations**

$$\text{DETSE} = 1 - \frac{|\widehat{\text{Ecov}}(\boldsymbol{\eta})|}{|\widehat{\text{Cov}}(\boldsymbol{\eta})|}$$

where the $\boldsymbol{\eta}$ vector denotes all latent dependent variables, $\widehat{\text{Cov}}(\boldsymbol{\eta})$ denotes the covariance matrix of $\boldsymbol{\eta}$, and $\widehat{\text{Ecov}}(\boldsymbol{\eta})$ denotes the error covariance matrix of $\boldsymbol{\eta}$. The covariance matrices are estimated under the model.

- **total determination of the manifest equations**

$$\text{DETMV} = 1 - \frac{|\widehat{\text{Ecov}}(\mathbf{y})|}{|\widehat{\text{Cov}}(\mathbf{y})|}$$

where the \mathbf{y} vector denotes all manifest dependent variables, $\widehat{\text{Cov}}(\mathbf{y})$ denotes the covariance matrix of \mathbf{y} , $\widehat{\text{Ecov}}(\mathbf{y})$ denotes the error covariance matrix of \mathbf{y} , and $|\mathbf{A}|$ denotes the determinant of matrix \mathbf{A} . All the covariance matrices in the formula are estimated under the model.

You can also use the **DETERM** statement to request the computations of determination coefficients for any subsets of dependent variables.

Case-Level Residuals, Outliers, Leverage Observations, and Residual Diagnostics

Residual M-Distances and Outlier Detection

In structural equation modeling, residual analysis has been developed traditionally for the elements in the moment matrices such as mean vector and covariance matrix. See the section “[Residuals in the Moment Matrices](#)” on page 1327 for a detailed description of this type of residual. In fact, almost all fit indices in the field were developed more or less based on measuring the overall magnitude of the residuals in the moment matrices. See the section “[Assessment of Fit](#)” on page 1326 for examples of fit indices such as standardized root mean square residual (SRMR), adjusted goodness-of-fit index (AGFI), and so on.

However, recent research advances make it possible to study case-level or observational-level residuals. Although case-level residuals have not yet been used to assess overall model fit, they are quite useful as model diagnostic tools. This section describes how case-level residuals are computed and applied to the detection of outliers, the identification of leverage observations, and various residual diagnostics.

The main difficulty of case-level residual analysis in general structural equation modeling is the presence of latent variables in the model. Another difficulty is the involvement of multivariate responses. Both are nonissues in multiple regression analysis because there is no latent variable and there is only a single response variable. Hence, a good starting point for this section is to explain how PROC CALIS handles these two issues in general structural equation modeling. The residual diagnostic techniques described in the following draw heavily from Yuan and Hayashi (2010).

Latent variables in models are not observed, and their values must be predicted from the data. Although the indeterminacy of factor scores is a well-known issue, it does not mean that factor scores cannot be reasonably derived or predicted from the observed data. One of the factor score estimation methods is Bartlett’s method. Suppose for a factor model that Λ represents a $p \times m$ factor matrix and Ψ represents a $p \times p$ error covariance matrix, where p is the number of manifest variables and m is the number of factors. Bartlett’s factor scores are defined by the formula

$$\mathbf{f} = (\Lambda' \Psi^{-1} \Lambda)^{-1} \Lambda' \Psi^{-1} \mathbf{y}$$

where \mathbf{f} represents an $m \times 1$ random vector of factors and \mathbf{y} represents a $p \times 1$ random vector of manifest variables. Yuan and Hayashi (2010) generalize Bartlett’s formulas to a certain class of structural equation models. Essentially, they provide formulas that the quantities Λ and Ψ are computable functions from the parameter estimates of the structural equation models. PROC CALIS adopts their formulas. With the estimation of factor scores, residuals in structural equation models can be computed as if all values of factors are present. Hence, case-level residual analysis becomes possible.

With the possibility of a multivariate residual vector in structural equation models, a summary measure for the overall magnitude of the residuals in observations is needed. Yuan and Hayashi (2010) consider

the Mahalanobis distance (M-distance) of case-level residuals. For observation i with residual vector \hat{e}_i of dimension $h \times 1$, the residual M-distance of observation i is defined as

$$d_{r_i} = \sqrt{(\mathbf{L}\hat{e}_i)'(\mathbf{L}\Omega_{\hat{e}}\mathbf{L}')^{-1}(\mathbf{L}\hat{e}_i)}$$

where \mathbf{L} ($(h - q) \times h$) is a matrix that reduces \hat{e} to $(h - q)$ independent components, q is the number of independent factors to be estimated in the structural equation model, and $\Omega_{\hat{e}}$ is the covariance matrix of \hat{e} . The reduction of the residual vector into independent components is necessary when the number of factors q is not zero in the model. For $q > 0$, $\Omega_{\hat{e}}$ is not invertible and cannot be used in computing the M-distances for residuals. Hence, the covariance matrix $\mathbf{L}\Omega_{\hat{e}}\mathbf{L}'$ of independent components $\mathbf{L}\hat{e}$ is used instead. In practice, \hat{e}_i and $\Omega_{\hat{e}}$ are evaluated at the estimated parameter values. \mathbf{L} can be computed after $\Omega_{\hat{e}}$ is estimated.

Because the residual M-distance d_{r_i} is nonnegative and is a distance measure, the interpretation of d_{r_i} is straightforward—the larger it is, the farther away observation i is from the origin of the residuals. Therefore, the residual M-distance d_{r_i} can be used to detect outliers. The criterion for defining outliers is based on a selection of an α -level for the residual M-distance distribution. Under the multivariate normality distribution of the residuals, Yuan and Hayashi (2010) find that d_{r_i} is distributed as a χ_r variate (that is, the square root of the corresponding χ_r^2 variate), where $r = h - q$ is the degrees of freedom of the distribution. Therefore, a probability-based criterion for outlier detection can be used. An observation is an outlier according to the α -level criterion if its residual M-distance d_{r_i} is located within the upper $\alpha \times 100\%$ region of the χ_r distribution. Mathematically, an observation with d_{r_i} satisfying the following criterion is an outlier if

$$\text{prob}(\chi_r \geq d_{r_i}) < \alpha$$

The larger the α , the more liberal the criterion for detecting outliers. By default, PROC CALIS sets α to 0.01. You can override this value by using the **ALPHAOUT=** option.

Leverage Observations

Leverage observations are those with large M-distances in the exogenous variables of the model. For example, in the context of a confirmatory factor model, Yuan and Hayashi (2010) define the M-distance of exogenous latent factors d_{f_i} by the formula

$$d_{f_i} = \sqrt{\mathbf{f}_i'(\Omega_f)^{-1}\mathbf{f}_i}$$

where \mathbf{f}_i is the Bartlett's factor scores for observation i and Ω_f is the covariance matrix of the factor scores. See Yuan and Hayashi (2010) for the formulas for \mathbf{f}_i and Ω_f . PROC CALIS uses a more general formula to compute the M-distance of exogenous observed variables \mathbf{x}_i and latent variables \mathbf{f}_i in structural equation models. That is, with exogenous variables $\mathbf{v}_i = (\mathbf{x}_i \mathbf{f}_i)'$, the leverage M-distance d_{v_i} is computed as

$$d_{v_i} = \sqrt{\mathbf{v}_i'(\Omega_v)^{-1}\mathbf{v}_i}$$

where Ω_v is the covariance matrix of the exogenous variables. Leverage observations are those judged to have large leverage M-distances.

As with outlier detection, you need to set a criterion for declaring leverage observations. Specifically, an observation with d_{v_i} satisfying the following criterion is a leverage observation (or leverage point):

$$\text{prob}(\chi_c \geq d_{v_i}) < \alpha$$

where χ_c is the square root of the χ_c^2 variate, with c being the dimension of \mathbf{v}_i . The larger the α , the more liberal the criterion for declaring leverage observations. The default α value is 0.01. You can override this value by using the `ALPHALEV=` option.

Unlike the outliers that are usually judged as undesirable in models, leverage observations might or might not be bad for model estimation. Simply stated, a leverage observation is bad if it is also an outlier according to its residual M-distance value d_{ri} . Otherwise, it is a “good” leverage observation and should not be removed in model estimation.

Residual Diagnostics

Case-level residuals analysis can be very useful in detecting outliers, anomalies in residual distributions, and nonlinear functional relationships. All these techniques are graphical in nature and can be found in most textbooks in regression analysis (see, for example, Belsley, Kuh, and Welsch 1980). PROC CALIS provides these graphical analyses in the context of structural equation modeling. However, because PROC CALIS deals with multivariate responses and predictors in general, in some residual analysis the residuals are measured in terms of M-distances, which are always positive. PROC CALIS can produce the following graphical plots (with their ODS graph names in parentheses) for residual diagnostics:

- Residual histogram (CaseResidualHistogram): the distribution of residual M-distances is shown as a histogram. The residual M-distances are theoretically distributed as a χ -variate. Use the `PLOTS=CRESHIST` option to request this plot.
- Residual by leverage plot (ResidualByLeverage): the observations are plotted in a two-dimensional space according to their M-distances for residuals and leverages. Criteria for classifying outliers and leverage observations are shown in the plot so that outliers and leverage observations are located in well-defined regions of the two-dimensional space. Use the `PLOTS=RESBYLEV` option to request this plot.
- Residual by predicted values (ResidualByPredicted): the residuals (not the M-distances) of a dependent observed variable are plotted against the predicted values. This is also called the residual on fit plot. If the relationship of the dependent variable to the predictors is truly linear in the model, the residuals should be randomly dispersed in the plot. If the residuals show some systematic pattern with the predicted values, unexplained nonlinear relationships of the dependent observed variable with other variables or heteroscedasticity of error variance might exist. Use the `PLOTS=RESBYPRED` option to request this plot.
- Residual by quantile plot or Q-Q plot (ResidualByQuantile): the residual M-distances are plotted against their theoretical quantiles. Observations that depart significantly from the theoretical line (with slope=1) are problematic observations. Use the `PLOTS=QQPLOT` option to request this plot.
- Residual percentile by theoretical percentile plot or P-P plot (ResPercentileByExpPercentile): the observed residual M-distance percentiles are plotted against the theoretical percentiles. Observations that depart significantly from the theoretical line (with slope=1) are problematic observations. Use the `PLOTS=PPPLOT` option to request this plot.

Residual Diagnostics with Robust Estimation

With the presence of multiple outliers in a data set, estimation might suffer from the so-called masking effect. This problem refers to the fact that some prominent outliers in the data might have biased the estimation so that usual residual diagnostic tools might fail to detect some less prominent outliers. As a result, subsequent analyses that are based on the data set with outliers removed might actually not be free from the effects of the outliers.

Robust estimation deals with the outliers differently. Instead of relying on diagnostic tools for detection and removal of outliers, robust methods downweight the outliers during the estimation so that the undesirable outlier effect on estimation is minimized effectively. No outliers need to be removed during or after the robust estimation. Hence, the masking effect is not an issue. In addition, with the use of robust estimation, residual diagnostics for the purpose of outlier removal become a redundant concept. In such a scenario, outlier diagnostics are more important for the purpose of identification than for removal. You can use the ROBUST=RES option (or the default ROBUST option) to downweight the outliers during model estimation.

Similarly, detecting leverage observations might also suffer from the masking effect. That is, some leverage observations might not be detected if the diagnostic results are based on model estimation that includes the leverage observations themselves. Unfortunately, the ROBUST=RES option downweights only the residual outliers and does not downweight the leverage observations during estimation. However, the ROBUST=SAT option does downweight outlying observations in all variable dimensions, and hence it could be used if the masking effect of leverage observations is a concern.

Following the recommendation by Yuan and Hayashi (2010), PROC CALIS uses an eclectic approach to compute the residual and leverage M-distances. That is, when a robust estimation is requested (using either the ROBUST=SAT or ROBUST=RES option) with case-level residual analysis (using the RESIDUAL option), the residual M-distances are computed from the robust estimation results that downweight the model outliers only (that is, the procedure invoked by the ROBUST=RES(E) or RES(F) option); but the leverage M-distances are computed from the robust estimation results that downweight the outlying observations in all variable dimensions (that is, the procedure invoked by the ROBUST=SAT option). Consequently, both the residual M-distances and the leverage M-distances calculated from this eclectic approach are free from the respective masking effects—and this is true for any robust estimation methods implemented in PROC CALIS.

It is important to note that this eclectic approach applies only to the computations of the residual and leverage M-distances. The parameter estimates, fit statistics, and the case-level residuals that are displayed in the residual on fit plots are still obtained from the specific robust method requested. Table 27.7 summarizes the robust methods that PROC CALIS uses to compute the parameter estimates, fit statistics, case-level residuals, and residual and leverage M-distances with different robust options.

Table 27.7 Robust Methods for the Computations of Various Results

	Robust Option Specified		
	ROBUST=SAT	ROBUST=RES(E)	ROBUST=RES(F)
Estimates	ROBUST=SAT	ROBUST=RES(E)	ROBUST=RES(F)
Model fit	ROBUST=SAT	ROBUST=RES(E)	ROBUST=RES(F)
Case-level residuals	ROBUST=SAT	ROBUST=RES(E)	ROBUST=RES(F)
Residual M-distances	ROBUST=RES(E)	ROBUST=RES(E)	ROBUST=RES(F)
Leverage M-distances	ROBUST=SAT	ROBUST=SAT	ROBUST=SAT

One important implication from this table is that ROBUST=SAT and ROBUST=RES(E) lead to the same residual and leverage diagnostic results, which are all free from masking effects.

In conclusion, even though outlier removal is unnecessary with robust estimation, case-level residual diagnostics are still useful for identifying outliers and leverage observations. Needless to say, other residual diagnostics such as residual M-distance distribution, Q-Q plots, P-P plots, and residual on fit plots are useful whether you use robust estimation or not.

Total, Direct, and Indirect Effects

Most structural equation models involve the specification of the effects of variables on each other. Whenever you specify equations in the LINEQS model, paths in the PATH model, path coefficient parameters in the RAM model, variable-factor relations in the FACTOR model, or regression coefficients in model matrices of the LISMOD model, you are specifying direct effects of predictor variables on outcome variables. All direct effects are represented by the associated regression coefficients, either fixed or free, in the specifications. You can examine the direct effect estimates easily in the output for model estimation.

However, direct effects are not the only effects that are important. In some cases, the indirect effects or total effects are of interest too. For example, suppose Self-Esteem is an important factor of Job Performance in your theory. Although it does not have a direct effect on Job Performance, it affects Job Performance through its influences on Motivation and Endurance. Also, Motivation has a direct effect on Endurance in your theory. The following path diagram summarizes such a theory:

Figure 27.3 Direct and Indirect Effects of Self-Esteem on Job Performance

Clearly, each path in the diagram represents a direct effect of a predictor variable on an outcome variable. Less apparent are the total and indirect effects implied by the same path diagram. Despite this, interesting theoretical questions regarding the total and indirect effects can be raised in such a model. For example, even though there is no direct effect of Self-Esteem on Job Performance, what is its indirect effect on Job Performance? In addition to its direct effect on Job Performance, Motivation also has an indirect effect on Job Performance via its effect on Endurance. So, what is the total effect of Motivation on Job Performance and what portion of this total effect is indirect? The **TOTEFF** option of the CALIS statement and the **EFFPART** statement are designed to address these questions. By using the **TOTEFF** option or the **EFFPART** statement, PROC CALIS can compute the total, direct, and indirect effects of any sets of predictor variables on any sets of outcome variables. In this section, formulas for computing these effects are presented.

Formulas for Computing Total, Direct and Indirect Effects

No matter which modeling language is used, variables in a model can be classified into three groups. The first group is the so-called dependent variables, which serve as outcome variables at least once in the model. The other two groups consist of the remaining independent variables, which never serve as outcome variables in the model. The second group consists of independent variables that are unsystematic sources such as error and disturbance variables. The third group consists of independent variables that are systematic sources only.

Any variable, no matter which group it falls into, can have effects on the first group of variables. By definition, however, effects of variables in the first group on the other two groups do not exist. Because the effects of unsystematic sources in the second group are treated as residual effects on the first group of dependent variables, these effects are trivial in the sense that they always serve as direct effects only. That is, the effects from the second group of unsystematic sources partition trivially—total effects are always the same as the direct effects for this group. Therefore, for the purpose of effect analysis or partitioning, only the first group (dependent variables) and the third group (systematic independent variables) are considered.

Define \mathbf{u} to be the set of n_u dependent variables in the first group and \mathbf{w} to be the set of n_w systematic independent variables in the third group. Variables in both groups can be manifest or latent. All variables in the effect analysis is thus represented by the vector $(\mathbf{u}', \mathbf{w}')'$.

The $(n_u + n_w) \times (n_u + n_w)$ matrix \mathbf{D} of *direct* effects refers to the path coefficients from all column variables to the row variables. This matrix is represented by:

$$\mathbf{D} = \begin{pmatrix} \boldsymbol{\beta} & \boldsymbol{\gamma} \\ \mathbf{0} & \mathbf{0} \end{pmatrix}$$

where $\boldsymbol{\beta}$ is an $(n_u \times n_u)$ matrix for direct effects of dependent variables on dependent variables and $\boldsymbol{\gamma}$ is an $(n_u \times n_w)$ matrix for direct effects of systematic independent variables on dependent variables. By definition, there should not be any direct effects on independent variables, and therefore the lower submatrices of \mathbf{D} are null. In addition, by model restrictions the diagonal elements of matrix $\boldsymbol{\beta}$ must be zeros.

Correspondingly, the $(n_u + n_w) \times (n_u + n_w)$ matrix \mathbf{T} of *total* effects of column variables on the row variables is computed by:

$$\mathbf{T} = \begin{pmatrix} (\mathbf{I} - \boldsymbol{\beta})^{-1} - \mathbf{I} & (\mathbf{I} - \boldsymbol{\beta})^{-1} \boldsymbol{\gamma} \\ \mathbf{0} & \mathbf{0} \end{pmatrix}$$

Finally, the $(n_u + n_w) \times (n_u + n_w)$ matrix $\boldsymbol{\mu}$ of *indirect* effects of column variables on the row variables is computed by the difference between \mathbf{T} and \mathbf{D} as:

$$\boldsymbol{\mu} = \begin{pmatrix} (\mathbf{I} - \boldsymbol{\beta})^{-1} - \mathbf{I} - \boldsymbol{\beta} & (\mathbf{I} - \boldsymbol{\beta})^{-1} \boldsymbol{\gamma} - \boldsymbol{\gamma} \\ \mathbf{0} & \mathbf{0} \end{pmatrix}$$

In PROC CALIS, any subsets of \mathbf{D} , \mathbf{T} , and $\boldsymbol{\mu}$ can be requested via the specification in the [EFFPART](#) statement. All you need to do is to specify the sets of column variables (variables that have effects on others) and row variables (variables that receive the effects, direct or indirect). Specifications of the column and row variables are done conveniently by specifying variable names—no matrix terminology is needed. This feature is very handy if you have some focused subsets of effects that you want to analyze a priori. See the [EFFPART statement](#) on page 1137 for details about specifications.

Stability Coefficient of Reciprocal Causation

For recursive models (that is, models without cyclical paths of effects), using the preceding formulas for computing the total effect and the indirect effect is appropriate without further restrictions. However, for non-recursive models (that is, models with reciprocal effects or cyclical effects) the appropriateness of the preceding formulas for effect computations is restricted to situations with the convergence of the total effects.

A necessary and sufficient condition for the convergence of total effects (with or without cyclical paths) is when all eigenvalues, complex or real, of the β matrix fall into a unit circle (see Bentler and Freeman 1983). Equivalently, define the stability coefficient of reciprocal causation as the largest length (modulus) of the eigenvalues of the β matrix. A stability coefficient less than one would ensure that all eigenvalues, complex or real, of the β matrix fall into a unit circle. Hence, stability coefficient that is less than one is a necessary and sufficient condition for the convergence of the total effects, which in turn substantiates the appropriateness of total and indirect effect computations. Whenever effect analysis or partitioning is requested, PROC CALIS will check the appropriateness of effect computations by evaluating the stability coefficient of reciprocal causation. If the stability coefficient is greater than one, computations of the total and indirect effects will not be done.

Standardized Solutions

Standardized solutions are useful when you want to compare parameter values that are measured on quite different scales. PROC CALIS provides standardized solutions routinely. In standardizing a solution, parameters are classified into five groups:

- **path coefficients, regression coefficients, or direct effects**

With each parameter α in this group, there is an associated outcome variable and a predictor variable. Denote the predicted variance of the outcome variable by σ_o^2 and the variance of the predictor variable by σ_p^2 , the standardized parameter α^* is:

$$\alpha^* = \alpha \frac{\sigma_p}{\sigma_o}$$

- **fixed ones for the path coefficients attached to error or disturbance terms**

These fixed values are unchanged in standardization.

- **variances and covariances among exogenous variables, excluding errors and disturbances**

Let σ_{ij} be the covariance between variables i and j . In this notation, σ_{ii} is the variance of variable i . The standardized covariance σ_{ij}^* is:

$$\sigma_{ij}^* = \frac{\sigma_{ij}}{\sqrt{\sigma_{ii}\sigma_{jj}}}$$

When $i = j$, σ_{ii}^* takes the value of 1 for all i . Also, σ_{ij}^* is the correlation between the i th and j th variables.

- **variances and covariances among errors or disturbances**

Denote the error covariance parameter as θ_{ij} so that θ_{ii} represents the variance parameter of error variable i . Associated with each error or disturbance variable i is a unique outcome variable. Let the

variance of such an outcome variable be σ_{ii} . In the standardized solution, the error covariance θ_{ij} is rescaled as:

$$\theta_{ij}^* = \frac{\theta_{ij}}{\sqrt{\sigma_{ii}\sigma_{jj}}}$$

Notice that when $i = j$, θ_{ii}^* is not standardized to 1 in general. In fact, the error (disturbance) variance is simply rescaled by the reciprocal of the variance of the associated dependent variable. As a result, the rescaled error (disturbance) variance represents the proportion of variation of the dependent variable due to the unsystematic source. By the same token, θ_{ij}^* does not represent the correlation between errors i and j . It is a rescaled covariance of the errors involved.

- **intercepts and means of variables**

These parameters are fixed zeros in the standardized solution.

While formulas for the standardized solution are useful in computing the parameter values in the standardized solution, it is conceptually more useful to explain how variables are being transformed in the standardization process. The following provides a summary of the transformation process:

- Observed and latent variables, excluding errors or disturbances, are centered and then divided by their corresponding standard deviations. Therefore, in the standardized solution, all these variables will have variance equal to 1. In other words, these variables are truly standardized.
- Errors or disturbances are divided by the standard deviations of the corresponding outcome variables. In the standardized solution, these variables will not have variance equal to 1 in general. However, the rescaled error variances represent the proportion of unexplained or unsystematic variance of the corresponding outcome variables. Therefore, errors or disturbances in the standardized solution are simply rescaled but not standardized.

Standardized total, direct, and indirect effects are computed using formulas presented in the section “[Total, Direct, and Indirect Effects](#)” on page 1343, but with the standardized parameter values substituted into the formulas.

Although parameter values associated with different scales are made more comparable in the standardized solution, a precaution should be mentioned. In the standardized solution, the original constraints on parameters in the unstandardized solution are usually lost. These constraints, however, might underscore some important theoretical position that needs to be maintained in the model. Destroying these constraints in the standardized solution means that interpretations or comparisons of parameter values in the standardized solution are made without maintaining the original theoretical position. You must judge whether such a departure from the original constraints poses conceptual difficulties for interpreting the standardized solution.

Modification Indices

While fitting structural equation models is mostly a confirmatory analytic procedure, it does not prevent you from exploring what might have been a better model given the data. After fitting your theoretical structural equation model, you might want to modify the original model in order to do one of the following:

- add free parameters to improve the model fit significantly
- reduce the number of parameters without affecting the model fit too much

The first kind of model modification can be achieved by using the Lagrange multiplier (LM) test indices. Parameters that have the largest LM indices would increase the model fit the most. In general, adding more parameters to your model improves the overall model fit, as measured by those absolute or standalone fit indices (see the section “[Overall Model Fit Indices](#)” on page 1329 for more details). However, adding parameters liberally makes your model more prone to sampling errors. It also makes your model more complex and less interpretable in most cases. A disciplined use of LM test indices is highly recommended. In addition to the model fit improvement indicated by the LM test indices, you should also consider the theoretical significance when adding particular parameters. See [Example 27.28](#) for an illustration of the use of LM test indices for improving model fit.

The second kind of model modification can be achieved by using the Wald statistics. Parameters that are not significant in your model may be removed from the model without affecting the model fit too much. In general, removing parameters from your model decreases the model fit, as measured by those absolute or standalone fit indices (see the section “[Overall Model Fit Indices](#)” on page 1329 for more details). However, for just a little sacrifice in model fit, removing non-significant parameters increases the simplicity and precision of your model, which is the virtue that any modeler should look for.

Whether adding parameters by using the LM test indices or removing unnecessary parameters by the Wald statistics, you should not treat your modified model as if it were your original hypothesized model. That is, you should not publish your modified model as if it were hypothesized a priori. It is perfectly fine to use modification indices to gain additional insights for future research. But if you want to publish your modified model together with your original model, you should report the modification process that leads to your modified model. Theoretical justifications of the modified model should be supplemented if you want to make strong statements to support your modified model. Whenever possible, the best practice is to show reasonable model fit of the modified model with new data.

To modify your model either by LM test indices or Wald statistics, you can use the [MODIFICATION](#) or [MOD](#) option in the PROC CALIS statement. To customize the LM tests by setting specific regions of parameters, you can use the [LMTESTS](#) statements. PROC CALIS computes and displays the following default set of modification indices:

- **univariate Lagrange multiplier (LM) test indices for parameters in the model**

These are second-order approximations of the decrease in the χ^2 value that would result from allowing the *fixed parameter values* in the model to be freed to estimate. LM test indices are ranked within their own parameter regions in the model. The ones that suggest greatest model improvements (that is, greatest χ^2 drop) are ranked first. Depending on the type of your model, the set of possible parameter regions varies. For example, in a RAM model, modification indices are ranked in three different parameter regions for the covariance structures: path coefficients, variances of and covariances among exogenous variables, and the error variances and covariances. In addition to the value of the Lagrange multiplier, the corresponding p -value ($df = 1$) and the approximate change of the parameter value are displayed.

If you use the LMMAT option in the [LMTESTS](#) statement, LM test indices are shown as elements in model matrices. Not all elements in a particular model matrix will have LM test indices. Elements that are already free parameters in the model do not have LM test indices. Instead, the parameter names are shown. Elements that are model restricted values (for example, direct path from a variable

to itself must be zero) are labeled Excluded in the matrix output. When you customize your own regions of LM tests, some elements might also be excluded from a custom set of LM tests. These elements are also labeled as Excluded in the matrix output. If an LM test for freeing a parameter would result in a singular information matrix, the corresponding element in the matrix is labeled as Singular.

- **univariate Lagrange multiplier test indices for releasing equality constraints**

These are second-order approximations of the decrease in the χ^2 value that would result from the release of *equality constraints*. Multiple equality constraints containing $n > 2$ parameters are tested successively in n steps, each assuming the release of one of the equality-constrained parameters. The expected change of the parameter values of the separated parameter and the remaining parameter cluster are displayed, too.

- **univariate Lagrange multiplier test indices for releasing active boundary constraints**

These are second-order approximations of the decrease in the χ^2 value that would result from the release of the *active boundary constraints* specified in the **BOUNDS** statement.

- **stepwise multivariate Wald statistics for constraining free parameters to 0**

These are second-order approximations of the increases in χ^2 value that would result from constraining free parameters to zero in a stepwise fashion. In each step, the parameter that would lead to the smallest increase in the multivariate χ^2 value is set to 0. Besides the multivariate χ^2 value and its p -value, the univariate increments are also displayed. The process stops when the univariate p -value is smaller than the specified value in the **SLMW=** option, of which the default value is 0.05.

All of the preceding tests are approximations. You can often obtain more accurate tests by actually fitting different models and computing likelihood ratio tests. For more details about the Wald and the Lagrange multiplier test, see MacCallum (1986), Buse (1982), Bentler (1986), or Lee (1985). Note that relying solely on the LM tests to modify your model can lead to unreliable models that capitalize purely on sampling errors. See MacCallum, Roznowski, and Necowitz (1992) for the use of LM tests.

For large model matrices, the computation time for the default modification indices can considerably exceed the time needed for the minimization process.

The modification indices are not computed for unweighted least squares or diagonally weighted least squares estimation.

Missing Values and the Analysis of Missing Patterns

If the **DATA=** data set contains raw data (rather than a covariance or correlation matrix), in general observations with missing values for any variables in the analysis are omitted from the computations. The only exception is with **METHOD=FIML**. Incomplete observations with at least one nonmissing variables in the analysis are also used for the estimation.

If a covariance or correlation matrix is read, missing values are allowed as long as every pair of variables has at least one nonmissing value. Unlike the raw data input, **METHOD=FIML** does not allow missing values in the covariance or correlation matrix.

When you use **METHOD=FIML**, PROC CALIS provide several analyses on the missing patterns of the raw input data sets. First, PROC CALIS shows the coverage results for the means and covariances. The

coverage results refer to the proportions of data present for computing the means and the covariances. Because distinct missing patterns in the data sets are possible, the coverage proportions for the individual means and covariances could vary. Average coverage proportions of the means and covariances give you an overall idea about the missingness (or the lack of). In order to help locate the problematic means and covariances that have the low coverage, PROC CALIS shows the rank orders of the smallest coverages of mean and covariance elements. The number of smallest coverages shown for the means is equal to half of the total number of variables. The number of smallest coverages shown for the covariances is equal to half of the total number of the distinct elements in the lower triangular of the covariance matrix. However, in both cases at most 10 smallest coverages would be shown.

Second, PROC CALIS ranks the most frequent missing patterns in the data set (the nonmissing pattern is excluded in the ranking). Because the number of missing patterns could be quite large, PROC CALIS displays only a limited number of most frequent missing patterns in the output. You can use the `MAXMISSPAT=` and the `TMISSPAT=` options to control the number of missing patterns to display. See these options for details.

Third, PROC CALIS shows the means of the most frequent missing patterns, along with the means for the nonmissing pattern for comparison.

See [Example 27.15](#) for an illustration of the use of the full information maximum likelihood method and the analysis of missing patterns.

Measures of Multivariate Kurtosis

In many applications, the manifest variables are not even approximately multivariate normal. If this happens to be the case with your data set, the default generalized least squares and maximum likelihood estimation methods are not appropriate, and you should compute the parameter estimates and their standard errors by an asymptotically distribution-free method, such as the WLS estimation method. If your manifest variables are multivariate normal, then they have a zero relative multivariate kurtosis, and all marginal distributions have zero kurtosis (Browne 1982). If your `DATA=` data set contains raw data, PROC CALIS computes univariate skewness and kurtosis and a set of multivariate kurtosis values. By default, the values of univariate skewness and kurtosis are corrected for bias (as in PROC UNIVARIATE), but using the `BIASKUR` option enables you to compute the uncorrected values also. The values are displayed when you specify the PROC CALIS statement option `KURTOSIS`.

In the following formulas, N denotes the sample size and p denotes the number of variables.

- **corrected variance for variable z_j**

$$\sigma_j^2 = \frac{1}{N-1} \sum_i^N (z_{ij} - \bar{z}_j)^2$$

- **uncorrected univariate skewness for variable z_j**

$$\gamma_{1(j)} = \frac{N \sum_i^N (z_{ij} - \bar{z}_j)^3}{\sqrt{N [\sum_i^N (z_{ij} - \bar{z}_j)^2]^3}}$$

- **corrected univariate skewness for variable z_j**

$$\gamma_{1(j)} = \frac{N}{(N-1)(N-2)} \frac{\sum_i^N (z_{ij} - \bar{z}_j)^3}{\sigma_j^3}$$

- **uncorrected univariate kurtosis for variable z_j**

$$\gamma_{2(j)} = \frac{N \sum_i^N (z_{ij} - \bar{z}_j)^4}{[\sum_i^N (z_{ij} - \bar{z}_j)^2]^2} - 3$$

- **corrected univariate kurtosis for variable z_j**

$$\gamma_{2(j)} = \frac{N(N+1)}{(N-1)(N-2)(N-3)} \frac{\sum_i^N (z_{ij} - \bar{z}_j)^4}{\sigma_j^4} - \frac{3(N-1)^2}{(N-2)(N-3)}$$

- **Mardia's multivariate kurtosis**

$$\gamma_2 = \frac{1}{N} \sum_i^N [(z_i - \bar{z})' S^{-1} (z_i - \bar{z})]^2 - p(p+2)$$

where S is the biased sample covariance matrix with N as the divisor.

- **relative multivariate kurtosis**

$$\eta_2 = \frac{\gamma_2 + p(p+2)}{p(p+2)}$$

- **normalized multivariate kurtosis**

$$\kappa_0 = \frac{\gamma_2}{\sqrt{8p(p+2)/N}}$$

- **Mardia based kappa**

$$\kappa_1 = \frac{\gamma_2}{p(p+2)}$$

- **mean scaled univariate kurtosis**

$$\kappa_2 = \frac{1}{3p} \sum_j^p \gamma_{2(j)}$$

- **adjusted mean scaled univariate kurtosis**

$$\kappa_3 = \frac{1}{3p} \sum_j^p \gamma_{2(j)}^*$$

with

$$\gamma_{2(j)}^* = \begin{cases} \gamma_{2(j)} & , \quad \text{if } \gamma_{2(j)} > \frac{-6}{p+2} \\ \frac{-6}{p+2} & , \quad \text{otherwise} \end{cases}$$

If variable Z_j is normally distributed, the uncorrected univariate kurtosis $\gamma_{2(j)}$ is equal to 0. If Z has an p -variate normal distribution, Mardia's multivariate kurtosis γ_2 is equal to 0. A variable Z_j is called *leptokurtic* if it has a positive value of $\gamma_{2(j)}$ and is called *platykurtic* if it has a negative value of $\gamma_{2(j)}$. The values of κ_1 , κ_2 , and κ_3 should not be smaller than the following lower bound (Bentler 1985):

$$\hat{\kappa} \geq \frac{-2}{p+2}$$

PROC CALIS displays a message if κ_1 , κ_2 , or κ_3 falls below the lower bound.

If weighted least squares estimates (**METHOD=WLS** or **METHOD=ADF**) are specified and the weight matrix is computed from an input raw data set, the CALIS procedure computes two more measures of multivariate kurtosis.

- **multivariate mean kappa**

$$\kappa_4 = \frac{1}{m} \sum_i^p \sum_j^i \sum_k^j \sum_l^k \hat{\kappa}_{ij,kl} - 1$$

where

$$\hat{\kappa}_{ij,kl} = \frac{s_{ij,kl}}{s_{ij}s_{kl} + s_{ik}s_{jl} + s_{il}s_{jk}}$$

and $m = p(p+1)(p+2)(p+3)/24$ is the number of elements in the vector $s_{ij,kl}$ (Bentler 1985).

- **multivariate least squares kappa**

$$\kappa_5 = \frac{s_4' s_2}{s_2' s_2} - 1$$

where s_2 is the vector of the elements in the denominator of $\hat{\kappa}$ (Bentler 1985) and s_4 is the vector of the $s_{ij,kl}$, which is defined as

$$s_{ij,kl} = \frac{1}{N} \sum_{r=1}^N (z_{ri} - \bar{z}_i)(z_{rj} - \bar{z}_j)(z_{rk} - \bar{z}_k)(z_{rl} - \bar{z}_l)$$

The occurrence of significant nonzero values of Mardia's multivariate kurtosis γ_2 and significant amounts of some of the univariate kurtosis values $\gamma_{2(j)}$ indicate that your variables are not multivariate normal distributed. Violating the multivariate normality assumption in (default) generalized least squares and maximum likelihood estimation usually leads to the wrong approximate standard errors and incorrect fit statistics based on the χ^2 value. In general, the parameter estimates are more stable against violation of the normal distribution assumption. For more details, see Browne (1974, 1982, 1984).

Initial Estimates

Each optimization technique requires a set of initial values for the parameters. To avoid local optima, the initial values should be as close as possible to the globally optimal solution. You can check for local optima

by running the analysis with several different sets of initial values; the **RANDOM=** option in the PROC CALIS statement is useful in this regard.

Except for the case of exploratory FACTOR model, you can specify initial estimates manually for all different types of models. If you do not specify some of the initial estimates and the **RANDOM=** option is not used, PROC CALIS will use a combination of good strategic methods to compute initial estimates for your model.

These initial estimation methods are used in PROC CALIS:

- two-stage least squares estimation
- instrumental variable method (Häggglund 1982; Jennrich 1987)
- approximate factor analysis method
- ordinary least squares estimation
- estimation method of McDonald (McDonald and Hartmann 1992)
- observed moments of manifest exogenous variables

The choice of initial estimation methods is dependent on the data and on the model. In general, it is difficult to tell in advance which initial estimation methods will be used for a given analysis. However, PROC CALIS displays the methods used to obtain initial estimates in the output. Notice that none of these initial estimation methods can be applied to the COSAN model because of the general formulation of the COSAN model. If you do not provide initial parameter estimates for the COSAN model, the default values or random values are used (see the **START=** and the **RANDOM=** options).

Poor initial values can cause convergence problems, especially with maximum likelihood estimation. Sufficiently large positive initial values for variance estimates (as compared with the covariance estimates) might help prevent a nonnegative definite initial predicted covariance model matrix from happening. If maximum likelihood estimation fails to converge, it might help to use **METHOD=LSML**, which uses the final estimates from an unweighted least squares analysis as initial estimates for maximum likelihood. Or you can fit a slightly different but better-behaved model and produce an **OUTMODEL=** data set, which can then be modified in accordance with the original model and used as an **INMODEL=** data set to provide initial values for another analysis.

If you are analyzing a covariance or scalar product matrix, be sure to take into account the scales of the variables. The default initial values might be inappropriate when some variables have extremely large or small variances.

Use of Optimization Techniques

No algorithm for optimizing general nonlinear functions exists that can always find the global optimum for a general nonlinear minimization problem in a reasonable amount of time. Since no single optimization technique is invariably superior to others, PROC CALIS provides a variety of optimization techniques that work well in various circumstances. However, you can devise problems for which none of the techniques in PROC CALIS can find the correct solution. All optimization techniques in PROC CALIS use $O(n^2)$

memory except the conjugate gradient methods, which use only $O(n)$ of memory and are designed to optimize problems with many parameters.

The PROC CALIS statement NLOPTIONS can be especially helpful for tuning applications with nonlinear equality and inequality constraints on the parameter estimates. Some of the options available in NLOPTIONS can also be invoked as PROC CALIS options. The NLOPTIONS statement can specify almost the same options as the SAS/OR NLP procedure.

Nonlinear optimization requires the repeated computation of the following:

- the function value (optimization criterion)
- the gradient vector (first-order partial derivatives)
- for some techniques, the (approximate) Hessian matrix (second-order partial derivatives)
- values of linear and nonlinear constraints
- the first-order partial derivatives (Jacobian) of nonlinear constraints

For the criteria used by PROC CALIS, computing the gradient takes more computer time than computing the function value, and computing the Hessian takes *much* more computer time and memory than computing the gradient, especially when there are many parameters to estimate. Unfortunately, optimization techniques that do not use the Hessian usually require many more iterations than techniques that do use the (approximate) Hessian, and so they are often slower. Techniques that do not use the Hessian also tend to be less reliable (for example, they might terminate at local rather than global optima).

The available optimization techniques are displayed in the following table and can be chosen by the OMETHOD=*name* option.

OMETHOD=	Optimization Technique
LEVVAR	Levenberg-Marquardt method
TRUREG	Trust-region method
NEWVAR	Newton-Raphson method with line search
NRRIDG	Newton-Raphson method with ridging
QUANER	Quasi-Newton methods (DBFGS, DDFP, BFGS, DFP)
DBLDOG	Double-dogleg method (DBFGS, DDFP)
CONGRA	Conjugate gradient methods (PB, FR, PR, CD)

The following table shows, for each optimization technique, which derivatives are needed (first-order or second-order) and what kind of constraints (boundary, linear, or nonlinear) can be imposed on the parameters.

OMETHOD=	Derivatives		Constraints		
	First Order	Second Order	Boundary	Linear	Nonlinear
LEVVAR	x	x	x	x	-
TRUREG	x	x	x	x	-
NEWVAR	x	x	x	x	-
NRRIDG	x	x	x	x	-
QUANER	x	-	x	x	x
DBLDOG	x	-	x	x	-
CONGRA	x	-	x	x	-

The Levenberg-Marquardt, trust-region, and Newton-Raphson techniques are usually the most reliable, work well with boundary and general linear constraints, and generally converge after a few iterations to a precise solution. However, these techniques need to compute a Hessian matrix in each iteration. Computing the approximate Hessian in each iteration can be very time- and memory-consuming, especially for large problems (more than 200 parameters, depending on the computer used). For large problems, a quasi-Newton technique, especially with the BFGS update, can be far more efficient.

For a poor choice of initial values, the Levenberg-Marquardt method seems to be more reliable.

If memory problems occur, you can use one of the conjugate gradient techniques, but they are generally slower and less reliable than the methods that use second-order information.

There are several options to control the optimization process. You can specify various termination criteria. You can specify the `GCONV=` option to specify a relative gradient termination criterion. If there are active boundary constraints, only those gradient components that correspond to inactive constraints contribute to the criterion. When you want very precise parameter estimates, the `GCONV=` option is useful. Other criteria that use relative changes in function values or parameter estimates in consecutive iterations can lead to early termination when active constraints cause small steps to occur. The small default value for the `FCONV=` option helps prevent early termination. Using the `MAXITER=` and `MAXFUNC=` options enables you to specify the maximum number of iterations and function calls in the optimization process. These limits are especially useful in combination with the `INMODEL=` and `OUTMODEL=` options; you can run a few iterations at a time, inspect the results, and decide whether to continue iterating.

Nonlinearly Constrained QN Optimization

The algorithm used for nonlinearly constrained quasi-Newton optimization is an efficient modification of Powell's Variable Metric Constrained WatchDog (VMCWD) algorithm (Powell 1978a, b, 1982a, b). A similar but older algorithm (VF02AD) is part of the Harwell library. Both VMCWD and VF02AD use Fletcher's VE02AD algorithm (also part of the Harwell library) for positive definite quadratic programming. The PROC CALIS QUANEW implementation uses a quadratic programming subroutine that updates and down-dates the approximation of the Cholesky factor when the active set changes. The nonlinear QUANEW algorithm is not a feasible point algorithm, and the value of the objective function might not necessarily decrease (minimization) or increase (maximization) monotonically. Instead, the algorithm tries to reduce a linear combination of the objective function and constraint violations, called the *merit function*.

The following are similarities and differences between this algorithm and VMCWD:

- A modification of this algorithm can be performed by specifying `VERSION=1`, which replaces the update of the Lagrange vector μ with the original update of Powell (1978a, b), which is used in VF02AD. This can be helpful for some applications with linearly dependent active constraints.
- If the `VERSION=` option is not specified or `VERSION=2` is specified, the evaluation of the Lagrange vector μ is performed in the same way as Powell (1982a, b) describes.
- Instead of updating an approximate Hessian matrix, this algorithm uses the dual BFGS (or DFP) update that updates the Cholesky factor of an approximate Hessian. If the condition of the updated matrix gets too bad, a restart is done with a positive diagonal matrix. At the end of the first iteration after each restart, the Cholesky factor is scaled.
- The Cholesky factor is loaded into the quadratic programming subroutine, automatically ensuring positive definiteness of the problem. During the quadratic programming step, the Cholesky factor of

the projected Hessian matrix $\mathbf{Z}_k' \mathbf{G} \mathbf{Z}_k$ and the QT decomposition are updated simultaneously when the active set changes. See Gill et al. (1984) for more information.

- The line-search strategy is very similar to that of Powell (1982a, b). However, this algorithm does not call for derivatives during the line search; hence, it generally needs fewer derivative calls than function calls. The VMCWD algorithm always requires the same number of derivative and function calls. It was also found in several applications of VMCWD that Powell's line-search method sometimes uses steps that are too long during the first iterations. In those cases, you can use the **INSTEP=** option specification to restrict the step length α of the first iterations.
- The watchdog strategy is similar to that of Powell (1982a, b). However, this algorithm does not return automatically after a fixed number of iterations to a former better point. A return here is further delayed if the observed function reduction is close to the expected function reduction of the quadratic model.
- Although Powell's termination criterion still is used (as FCONV2), the QUANEW implementation uses two additional termination criteria (GCONV and ABSGCONV).

This algorithm is automatically invoked when you specify the **NLINCON** statement. The nonlinear QUANEW algorithm needs the Jacobian matrix of the first-order derivatives (constraints normals) of the constraints:

$$(\nabla c_i) = \left(\frac{\partial c_i}{\partial x_j} \right), \quad i = 1, \dots, nc, j = 1, \dots, n$$

where nc is the number of nonlinear constraints for a given point x .

You can specify two update formulas with the **UPDATE=** option:

- **UPDATE=DBFGS** performs the dual BFGS update of the Cholesky factor of the Hessian matrix. This is the default.
- **UPDATE=DDFP** performs the dual DFP update of the Cholesky factor of the Hessian matrix.

This algorithm uses its own line-search technique. All options and parameters (except the **INSTEP=** option) controlling the line search in the other algorithms do not apply here. In several applications, large steps in the first iterations are troublesome. You can specify the **INSTEP=** option to impose an upper bound for the step size α during the first five iterations. The values of the **LCSINGULAR=**, **LCEPSILON=**, and **LCDEACT=** options (which control the processing of linear and boundary constraints) are valid only for the quadratic programming subroutine used in each iteration of the nonlinear constraints QUANEW algorithm.

Optimization and Iteration History

The optimization and iteration histories are displayed by default because it is important to check for possible convergence problems. The optimization history includes the following summary of information about the initial state of the optimization:

- the number of constraints that are active at the starting point, or more precisely, the number of constraints that are currently members of the working set. If this number is followed by a plus sign, there are more active constraints, of which at least one is temporarily released from the working set due to negative Lagrange multipliers.

- the value of the objective function at the starting point
- if the (projected) gradient is available, the value of the largest absolute (projected) gradient element
- for the TRUREG and LEVMAR subroutines, the initial radius of the trust region around the starting point

The optimization history ends with some information concerning the optimization result:

- the number of constraints that are active at the final point, or more precisely, the number of constraints that are currently members of the working set. If this number is followed by a plus sign, there are more active constraints, of which at least one is temporarily released from the working set due to negative Lagrange multipliers.
- the value of the objective function at the final point
- if the (projected) gradient is available, the value of the largest absolute (projected) gradient element
- other information specific to the optimization technique

The iteration history generally consists of one line of displayed output containing the most important information for each iteration.

The iteration history always includes the following:

- the iteration number
- the number of iteration restarts
- the number of function calls
- the number of active constraints
- the value of the optimization criterion
- the difference between adjacent function values
- the maximum of the absolute gradient components that correspond to inactive boundary constraints

An apostrophe trailing the number of active constraints indicates that at least one of the active constraints is released from the active set due to a significant Lagrange multiplier.

For the Levenberg-Marquardt technique (LEVMAR), the iteration history also includes the following information:

- an asterisk trailing the iteration number when the computed Hessian approximation is singular and consequently ridged with a positive lambda value. If all or the last several iterations show a singular Hessian approximation, the problem is not sufficiently identified. Thus, there are other locally optimal solutions that lead to the same optimum function value for different parameter values. This implies that standard errors for the parameter estimates are not computable without the addition of further constraints.

- the value of the Lagrange multiplier (λ). This value is 0 when the optimum of the quadratic function approximation is inside the trust region (a trust-region-scaled Newton step can be performed) and is greater than 0 when the optimum of the quadratic function approximation is located at the boundary of the trust region (the scaled Newton step is too long to fit in the trust region and a quadratic constraint optimization is performed). Large values indicate optimization difficulties. For a nonsingular Hessian matrix, the value of λ should go to 0 during the last iterations, indicating that the objective function can be well approximated by a quadratic function in a small neighborhood of the optimum point. An increasing λ value often indicates problems in the optimization process.
- the value of the ratio ρ (rho) between the actually achieved difference in function values and the predicted difference in the function values on the basis of the quadratic function approximation. Values much less than 1 indicate optimization difficulties. The value of the ratio ρ indicates the goodness of the quadratic function approximation. In other words, $\rho \ll 1$ means that the radius of the trust region has to be reduced; a fairly large value of ρ means that the radius of the trust region does not need to be changed. And a value close to or greater than 1 means that the radius can be increased, indicating a good quadratic function approximation.

For the Newton-Raphson technique (NRRIDG), the iteration history also includes the following information:

- the value of the ridge parameter. This value is 0 when a Newton step can be performed, and it is greater than 0 when either the Hessian approximation is singular or a Newton step fails to reduce the optimization criterion. Large values indicate optimization difficulties.
- the value of the ratio ρ (rho) between the actually achieved difference in function values and the predicted difference in the function values on the basis of the quadratic function approximation. Values much less than 1.0 indicate optimization difficulties.

For the Newton-Raphson with line-search technique (NEWRAP), the iteration history also includes the following information:

- the step size α (alpha) computed with one of the line-search algorithms
- the slope of the search direction at the current parameter iterate. For minimization, this value should be significantly negative. Otherwise, the line-search algorithm has difficulty reducing the function value sufficiently.

For the trust-region technique (TRUREG), the iteration history also includes the following information:

- an asterisk after the iteration number when the computed Hessian approximation is singular and consequently ridged with a positive λ value.
- the value of the Lagrange multiplier (λ). This value is zero when the optimum of the quadratic function approximation is inside the trust region (a trust-region-scaled Newton step can be performed) and is greater than zero when the optimum of the quadratic function approximation is located at the boundary of the trust region (the scaled Newton step is too long to fit in the trust region and a quadratically constrained optimization is performed). Large values indicate optimization difficulties. As in Gay (1983), a negative λ value indicates the special case of an indefinite Hessian matrix (the smallest eigenvalue is negative in minimization).

- the value of the radius Δ of the trust region. Small trust-region radius values combined with large lambda values in subsequent iterations indicate optimization problems.

For the quasi-Newton (QUANEW) and conjugate gradient (CONGRA) techniques, the iteration history also includes the following information:

- the step size (alpha) computed with one of the line-search algorithms
- the descent of the search direction at the current parameter iterate. This value should be significantly smaller than 0. Otherwise, the line-search algorithm has difficulty reducing the function value sufficiently.

Frequent update restarts (rest) of a quasi-Newton algorithm often indicate numerical problems related to required properties of the approximate Hessian update, and they decrease the speed of convergence. This can happen particularly if the ABSGCONV= termination criterion is too small—that is, when the requested precision cannot be obtained by quasi-Newton optimization. Generally, the number of automatic restarts used by conjugate gradient methods are much higher.

For the nonlinearly constrained quasi-Newton technique, the iteration history also includes the following information:

- the maximum value of all constraint violations,

$$\text{conmax} = \max(|c_i(x)| : c_i(x) < 0)$$

- the value of the predicted function reduction used with the GCONV and FCONV2 termination criteria,

$$\text{pred} = |g(x^{(k)})^T s(x^{(k)})| + \sum_{i=1}^m |\lambda_i c_i(x^{(k)})|$$

- the step size α of the quasi-Newton step. Note that this algorithm works with a special line-search algorithm.
- the maximum element of the gradient of the Lagrange function,

$$\begin{aligned} \text{lfgmax} &= \nabla_x L(x^{(k)}, \lambda^{(k)}) \\ &= \nabla_x f(x^{(k)}) - \sum_{i=1}^m \lambda_i^{(k)} \nabla_x c_i(x^{(k)}) \end{aligned}$$

For the double dogleg technique, the iteration history also includes the following information:

- the parameter λ of the double-dogleg step. A value $\lambda = 0$ corresponds to the full (quasi) Newton step.
- the slope of the search direction at the current parameter iterate. For minimization, this value should be significantly negative.

Line-Search Methods

In each iteration k , the (dual) quasi-Newton, hybrid quasi-Newton, conjugate gradient, and Newton-Raphson minimization techniques use iterative line-search algorithms that try to optimize a linear, quadratic, or cubic approximation of the nonlinear objective function f of n parameters x along a feasible descent search direction $s^{(k)}$ as follows:

$$f(x^{(k+1)}) = f(x^{(k)} + \alpha^{(k)} s^{(k)})$$

by computing an approximately optimal scalar $\alpha^{(k)} > 0$. Since the outside iteration process is based only on the approximation of the objective function, the inside iteration of the line-search algorithm does not have to be perfect. Usually, it is satisfactory that the choice of α significantly reduces (in a minimization) the objective function. Criteria often used for termination of line-search algorithms are the Goldstein conditions (Fletcher 1987).

Various line-search algorithms can be selected by using the **LIS= option** on page 1100. The line-search methods **LIS=1**, **LIS=2**, and **LIS=3** satisfy the left-hand-side and right-hand-side Goldstein conditions (Fletcher 1987).

The line-search method **LIS=2** seems to be superior when function evaluation consumes significantly less computation time than gradient evaluation. Therefore, **LIS=2** is the default value for Newton-Raphson, (dual) quasi-Newton, and conjugate gradient optimizations.

Restricting the Step Length

Almost all line-search algorithms use iterative extrapolation techniques that can easily lead to feasible points where the objective function f is no longer defined (resulting in indefinite matrices for ML estimation) or is difficult to compute (resulting in floating point overflows). Therefore, PROC CALIS provides options that restrict the step length or trust region radius, especially during the first main iterations.

The inner product $g's$ of the gradient g and the search direction s is the slope of $f(\alpha) = f(x + \alpha s)$ along the search direction s with step length α . The default starting value $\alpha^{(0)} = \alpha^{(k,0)}$ in each line-search algorithm ($\min_{\alpha > 0} f(x + \alpha s)$) during the main iteration k is computed in three steps:

1. Use either the difference $df = |f^{(k)} - f^{(k-1)}|$ of the function values during the last two consecutive iterations or the final stepsize value α^- of the previous iteration $k - 1$ to compute a first value $\alpha_1^{(0)}$.

- Using the **DAMPSTEP<r>** option:

$$\alpha_1^{(0)} = \min(1, r\alpha^-)$$

The initial value for the new step length can be no greater than r times the final step length α^- of the previous iteration. The default is $r = 2$.

- Not using the **DAMPSTEP** option:

$$\alpha_1^{(0)} = \begin{cases} step & \text{if } 0.1 \leq step \leq 10 \\ 10 & \text{if } step > 10 \\ 0.1 & \text{if } step < 0.1 \end{cases}$$

with

$$step = \begin{cases} df/|g's| & \text{if } |g's| \geq \epsilon \max(100df, 1) \\ 1 & \text{otherwise} \end{cases}$$

This value of $\alpha_1^{(0)}$ can be too large and can lead to a difficult or impossible function evaluation, especially for highly nonlinear functions such as the EXP function.

2. During the first five iterations, the second step enables you to reduce $\alpha_1^{(0)}$ to a smaller starting value $\alpha_2^{(0)}$ using the **INSTEP=*r*** option:

$$\alpha_2^{(0)} = \min(\alpha_1^{(0)}, r)$$

After more than five iterations, $\alpha_2^{(0)}$ is set to $\alpha_1^{(0)}$.

3. The third step can further reduce the step length by

$$\alpha_3^{(0)} = \min(\alpha_2^{(0)}, \min(10, u))$$

where u is the maximum length of a step inside the feasible region.

The **INSTEP=*r*** option lets you specify a smaller or larger radius of the trust region used in the first iteration by the trust-region, double-dogleg, and Levenberg-Marquardt algorithms. The default initial trust region radius is the length of the scaled gradient (Moré 1978). This default length for the initial trust region radius corresponds to the default radius factor of $r = 1$. This choice is successful in most practical applications of the TRUREG, DBLDOG, and LEVMAR algorithms. However, for bad initial values used in the analysis of a covariance matrix with high variances or for highly nonlinear constraints (such as using the EXP function) in your SAS programming statements, the default start radius can result in arithmetic overflows. If this happens, you can try decreasing values of **INSTEP=*r*** ($0 < r < 1$), until the iteration starts successfully. A small factor r also affects the trust region radius of the next steps because the radius is changed in each iteration by a factor $0 < c \leq 4$ depending on the ρ ratio. Reducing the radius corresponds to increasing the ridge parameter λ that produces smaller steps directed closer toward the gradient direction.

Computational Problems

First Iteration Overflows

Analyzing a covariance matrix that includes high variances in the diagonal and using bad initial estimates for the parameters can easily lead to arithmetic overflows in the first iterations of the minimization algorithm. The line-search algorithms that work with cubic extrapolation are especially sensitive to arithmetic overflows. If this occurs with quasi-Newton or conjugate gradient minimization, you can specify the **INSTEP=** option to reduce the length of the first step. If an arithmetic overflow occurs in the first iteration of the Levenberg-Marquardt algorithm, you can specify the **INSTEP=** option to reduce the trust region radius of the first iteration. You also can change the minimization technique or the line-search method. If none of these help, you can consider doing the following:

- scaling the covariance matrix
- providing better initial values
- changing the model

No Convergence of Minimization Process

If convergence does not occur during the minimization process, perform the following tasks:

- If there are *negative variance estimates*, you can do either of the following:
 - Specify the **BOUNDS** statement to obtain nonnegative variance estimates.
 - Specify the **HEYWOOD** option, if the **FACTOR** statement is specified.
- Change the estimation method to obtain a better set of initial estimates. For example, if you use **METHOD=ML**, you can do either of the following:
 - Change to **METHOD=LSML**.
 - Run some iterations with **METHOD=DWLS** or **METHOD=GLS**, write the results in an **OUTMODEL=** data set, and use the results as initial values specified by an **INMODEL=** data set in a second run with **METHOD=ML**.
- Change the optimization technique. For example, if you use the default **OMETHOD=LEVMAR**, you can do either of the following:
 - Change to **OMETHOD=QUANEW** or to **OMETHOD=NEWRAP**.
 - Run some iterations with **OMETHOD=CONGRA**, write the results in an **OUTMODEL=** data set, and use the results as initial values specified by an **INMODEL=** data set in a second run with a different **OMETHOD=** technique.
- Change or modify the update technique or the line-search algorithm or both when using **OMETHOD=QUANEW** or **OMETHOD=CONGRA**. For example, if you use the default update formula and the default line-search algorithm, you can do any or all of the following:
 - Change the update formula with the **UPDATE=** option.
 - Change the line-search algorithm with the **LIS=** option.
 - Specify a more precise line search with the **LSPRECISION=** option, if you use **LIS=2** or **LIS=3**.
- Add more iterations and function calls by using the **MAXIT=** and **MAXFU=** options.
- Change the initial values. For many categories of model specifications, PROC CALIS computes an appropriate set of initial values automatically. However, for some of the model specifications (for example, structural equations with latent variables on the left-hand side and manifest variables on the right-hand side), PROC CALIS might generate very obscure initial values. In these cases, you have to set the initial values yourself.
 - Increase the initial values of the variance parameters by one of the following ways:
 - * Set the variance parameter values in the model specification manually.
 - * Use the **DEMPHAS=** option to increase all initial variance parameter values.
 - Use a slightly different, but more stable, model to obtain preliminary estimates.
 - Use additional information to specify initial values, for example, by using other SAS software like the **FACTOR**, **REG**, **SYSLIN**, and **MODEL (SYSNLIN)** procedures for the modified, unrestricted model case.

Unidentified Model

The parameter vector Θ in the structural model

$$\Sigma = \Sigma(\Theta)$$

is said to be identified in a parameter space G , if

$$\Sigma(\Theta) = \Sigma(\tilde{\Theta}), \quad \tilde{\Theta} \in G$$

implies $\Theta = \tilde{\Theta}$. The parameter estimates that result from an unidentified model can be very far from the parameter estimates of a very similar but identified model. They are usually machine dependent. Do not use parameter estimates of an unidentified model as initial values for another run of PROC CALIS.

Singular Predicted Covariance Model Matrix

Sometimes you might inadvertently specify models with singular predicted covariance model matrices (for example, by fixing diagonal elements to zero). In such cases, you cannot compute maximum likelihood estimates (the ML function value F is not defined). Since singular predicted covariance model matrices can also occur temporarily in the minimization process, PROC CALIS tries in such cases to change the parameter estimates so that the predicted covariance model matrix becomes positive definite. This process does not always work well, especially if there are fixed instead of free diagonal elements in the predicted covariance model matrices. A famous example where you cannot compute ML estimates is a component analysis with fewer components than given manifest variables. See the section “[FACTOR Statement](#)” on page 1138 for more details. If you continue to obtain a singular predicted covariance model matrix after changing initial values and optimization techniques, then your model might be specified so that ML estimates cannot be computed.

Saving Computing Time

For large models, the most computing time is needed to compute the modification indices. If you do not really need the Lagrange multipliers or multiple Wald test indices (the univariate Wald test indices are the same as the t values), using the [NOMOD](#) option can save a considerable amount of computing time.

Predicted Covariance Matrices with Negative Eigenvalues

A covariance matrix cannot have negative eigenvalues, since a negative eigenvalue means that some linear combination of the variables has negative variance. PROC CALIS displays a warning if the predicted covariance matrix has negative eigenvalues but does not actually compute the eigenvalues. Sometimes this warning can be triggered by 0 or very small positive eigenvalues that appear negative because of numerical error. If you want to be sure that the predicted covariance matrix you are fitting can be considered to be a variance-covariance matrix, you can use the SAS/IML command `VAL=EIGVAL(U)` to compute the vector `VAL` of eigenvalues of matrix `U`.

Negative R^2 Values

The estimated squared multiple correlations R^2 of the endogenous variables are computed using the estimated error variances:

$$R_i^2 = 1 - \frac{\widehat{var}(\xi_i)}{\widehat{var}(\eta_i)}$$

When $\widehat{var}(\zeta_i) > \widehat{var}(\eta_i)$, R_i^2 is negative. This might indicate poor model fit or R square is an inappropriate measure for the model. For the latter case, for example, negative R square might be due to cyclical (nonrecursive) paths in the model so that the R square interpretation is not appropriate.

Displayed Output

The output of PROC CALIS includes the following:

- a list of basic modeling information such as: the data set, the number of records read and used in the raw data set, the number of observations assumed by the statistical analysis, and the model type. When a multiple-group analysis is specified, the groups and their corresponding models are listed. This output assumes at least the **PSHORT** option.
- a list of all variables in the models. This output is displayed by default or by the **PINITIAL** option. It will not be displayed when you use the **PSHORT** or the **PSUMMARY** option.

Depending on the modeling language, the variable lists vary, as shown in the following:

- **FACTOR**: a list of the variables and the factors
- **LINEQS**, **PATH**, and **RAM**: a list of the endogenous and exogenous variables specified in the model
- **LISMOD**: a list of x -, y -, ξ -, and η - variables specified in the model
- **MSTRUCT**: a list of the manifest variables specified in the model
- initial model specification. This output is displayed by default or by the **PINITIAL** option. It will not be displayed when you use the **PSHORT** or the **PSUMMARY** option.

Depending on the modeling language, the sets of output vary, as shown in the following:

- **FACTOR**: factor loading matrix, factor covariance matrix, intercepts, factor means, and error variances as specified initially in the model. The initial values for free parameters, the fixed values, and the parameter names are also displayed.
- **LINEQS**: linear equations, variance and covariance parameters, and mean parameters as specified initially in the model. The initial values for free parameters, the fixed values, and the parameter names are also displayed.
- **LISMOD**: all model matrices as specified initially in the model. The initial values for free parameters, the fixed values, and the parameter names are also displayed.
- **MSTRUCT**: initial covariance matrix and mean vectors, with parameter names and initial values displayed.
- **PATH**: the path list, variance and covariance parameters, intercept and mean parameters as specified initially in the model. The initial values for free parameters, the fixed values, and the parameter names are also displayed.
- **RAM**: a list of parameters, their types, names, and initial values.

- mean and standard deviation of each manifest variable if you specify the **SIMPLE** option, as well as skewness and kurtosis if the **DATA=** data set is a raw data set and you specify the **KURTOSIS** option.
- various coefficients of multivariate kurtosis and the numbers of observations that contribute most to the normalized multivariate kurtosis if the **DATA=** data set is a raw data set and the **KURTOSIS** option is used or you specify at least the **PRINT** option. See the section “[Measures of Multivariate Kurtosis](#)” on page 1349 for more information.
- covariance coverage, variable coverage, average coverage of covariances and means, rank orders of the variable (mean) and covariance coverage, most frequent missing patterns in the input data set, and the means of the missing patterns when there are incomplete observations (with some missing values in the analysis variables) in the input raw data set and when you use **METHOD=FIML** or **METHOD=LSFIML** for estimation.
- covariance or correlation matrix to be analyzed and the value of its determinant if you specify the output option **PCORR** or **PALL**. A zero determinant indicates a singular data matrix. In this case, the generalized least squares estimates with default weight matrix **S** and maximum likelihood estimates cannot be computed.
- robust covariance matrix and its determinant and robust mean vector if you specify the output option **PCORR** or **PALL** for robust estimation with the **ROBUST** option. Raw data input is required.
- the weight matrix **W** or its inverse is displayed if GLS, WLS, or DWLS estimation is used and you specify the **PWEIGHT** or **PALL** option.
- initial estimation methods for generating initial estimates. This output is displayed by default. It will not be displayed when you use the **PSHORT** or the **PSUMMARY** option.
- vector of parameter names and initial values and gradients. This output is displayed by default, unless you specify the **PSUMMARY** or **NOPRINT** option.
- special features of the optimization technique chosen if you specify at least the **PSHORT** option.
- optimization history if at least the **PSHORT** option is specified. For more details, see the section “[Use of Optimization Techniques](#)” on page 1352.
- specific output requested by options in the **NLOPTIONS** statement; for example, parameter estimates, gradient, constraints, projected gradient, Hessian, projected Hessian, Jacobian of nonlinear constraints, estimated covariance matrix of parameter estimates, and information matrix. Note that the estimated covariance of parameter estimates and the information matrix are not printed for the ULS and DWLS estimation methods.
- fit summary table with various model fit test statistics or fit indices, and some basic modeling information. For the listing of fit indices and their definitions, see the section “[Overall Model Fit Indices](#)” on page 1329. Note that for ULS and DWLS estimation methods, many of those fit indices that are based on model fit χ^2 are not displayed. See the section “[Overall Model Fit Indices](#)” on page 1329 for details. This output can be suppressed by the **NOPRINT** option.
- fit comparison for multiple-group analysis. See the section “[Individual Fit Indices for Multiple Groups](#)” on page 1336 for the fit indices for group comparison. This output can be suppressed by the **NOPRINT** option.

- the predicted covariance matrix and its determinant and mean vector, if you specify the output option **PCORR** or **PALL**.
- outlier, leverage, and case-level residual analysis if you specify the **RESIDUAL** option (or at least the **PRINT** option) with raw data input.
- leverage and outlier plot, quantile and percentile plots of residual M-distances, distribution of residual M-distances, and residual on fit plots if you request ODS Graphics by using the relevant **PLOTS=** option.
- residual and normalized residual matrix if you specify the **RESIDUAL** option or at least the **PRINT** option. The variance standardized or asymptotically standardized residual matrix can be displayed also. The average residual and the average off-diagonal residual are also displayed. Note that normalized or asymptotically standardized residuals are not applicable for the ULS and DWLS estimation methods.

See the section “[Residuals in the Moment Matrices](#)” on page 1327 for more details.

- rank order of the largest normalized residuals if you specify the **RESIDUAL** option or at least the **PRINT** option.
- bar chart of the normalized residuals if you specify the **RESIDUAL** option or at least the **PRINT** option.
- plotting of smoothed density functions of residuals if you request ODS Graphics by the relevant **PLOTS=** option.
- equations of linear dependencies among the parameters used in the model specification if the information matrix is recognized as singular at the final solution.
- the estimation results and the standardized results. Except for ULS or DWLS estimates, the approximate standard errors and *t* values are also displayed. This output is displayed by default or if you specify the **PESTIM** option or at least the **PSHORT** option.

Depending on the modeling language, the sets of output vary, as shown in the following:

- **FACTOR**: factor loading matrix, rotation matrix, rotated factor loading matrix (if rotation requested), factor covariance matrix, intercepts, factor means, and error variances in the model. Factor rotation matrix is printed for the unstandardized solution.
- **LINEQS**: linear equations, variance and covariance parameters, and mean parameters in the model.
- **LISMOD**: all model matrices in the model.
- **MSTRUCT**: covariance matrix and mean vectors.
- **PATH**: the path list, variance and covariance parameters, intercept and mean parameters.
- **RAM**: a list of parameters, their types, names, and initial values.
- squared multiple correlations table which displays the error variance, total variance, and the squared multiple correlation of each endogenous variable in the model. The total variances are the diagonal elements of the predicted covariance matrix. This output is displayed if you specify the **PESTIM** option or at least the **PSHORT** option.

- the total determination of all equations, the total determination of the latent equations, and the total determination of the manifest equations if you specify the **PDETERM** or the **PALL** option. See the section “Assessment of Fit” on page 1326 for more details. If you specify subsets of variables in the **DETERM** statements, the corresponding determination coefficients will also be shown. If one of the determinants in the formula for computing the determination coefficient is zero, the corresponding coefficient is displayed as the missing value ‘.’.
- the matrix of estimated covariances among the latent variables in the model if you specify the **PLATCOV** option or at least the **PRINT** option.
- the matrix of estimated covariances between latent and manifest variables in the model if you specify the **PLATCOV** option or at least the **PRINT** option.
- the vector of estimated means for the latent and manifest variables in the model if you specify the **PLATCOV** option or at least the **PRINT** option.
- the matrix **FSR** of latent variable scores regression coefficients if you specify the **PLATCOV** option or at least the **PRINT** option. The **FSR** matrix is a generalization of Lawley and Maxwell (1971, p. 109) factor scores regression matrix,

$$\mathbf{FSR} = \hat{\Sigma}_{yx} \hat{\Sigma}_{xx}^{-1}$$

where $\hat{\Sigma}_{xx}$ is the $p \times p$ predicted covariance matrix among manifest variables and $\hat{\Sigma}_{yx}$ is the $m \times p$ matrix of the predicted covariances between latent and manifest variables, with p being the number of manifest variables, and m being the number of latent variables. You can multiply the observed values by this matrix to estimate the scores of the latent variables used in your model.

- stability coefficient of reciprocal causation if you request the effect analysis by using the **EFFPART** or **TOTEFF** option, and you must not use the **NOPRINT** option.
- the matrices for the total, direct, and indirect effects if you specify the **EFFPART** or **TOTEFF** option or at least the **PRINT** option, and you must not use the **NOPRINT** option. Unstandardized and standardized effects are printed in separate tables. Standard errors for the all estimated effects are also included in the output. Additional tables for effects are available if you request specialized effect analysis in the **EFFPART** statements.
- the matrix of rotated factor loadings and the orthogonal transformation matrix if you specify the **ROTATE=** and **PESTIM** options or at least the **PSHORT** options. This output is available for the **FACTOR** models.

- factor scores regression matrix, if you specify the **PESTIM** option or at least the **PSHORT** option. The determination of manifest variables is displayed only if you specify the **PDETERM** option.
- univariate Lagrange multiplier indices if you specify the **MODIFICATION** (or **MOD**) or the **PALL** option. The value of a Lagrange multiplier (LM) index indicates the approximate drop in χ^2 when the corresponding fixed parameter in the original model is freely estimated. The corresponding probability (with $df = 1$) and the estimated change of the parameter value are printed. Ranking of the LM indices is automatically done for prescribed parameter subsets of the original model. The LM indices with greatest improvement of χ^2 model fit appear in the beginning of the ranking list. Note that LM indices are not applicable to the ULS and the DWLS estimation methods. See the section “**Modification Indices**” on page 1346 for more detail.
- matrices of univariate Lagrange multiplier (LM) indices if you specify the **MODIFICATION** (or **MOD**) or the **PALL** option, and the **LMMAT** option in the **LMTESTS** statement. These matrices are predefined in **PROC CALIS**, or you can specify them in the **LMTESTS** statements. If releasing a fixed parameter in the matrix would result in a singular information matrix, the string ‘Singular’ is displayed instead of the Lagrange multiplier index. If a fixed entry in the matrix is restricted by the model (for example, fixed ones for coefficients associated with error terms) or being excluded in the specified subsets in the **LMTESTS** statement, the string ‘Excluded’ is displayed. Note that matrices for LM indices are not printed for the ULS and the DWLS estimation methods. See the section “**Modification Indices**” on page 1346 for more detail.
- univariate Lagrange multiplier test indices for releasing equality constraints if you specify the **MODIFICATION** (or **MOD**) or the **PALL** option. Note that this output is not applicable to the ULS and the DWLS estimation methods. See the section “**Modification Indices**” on page 1346 for more detail.
- univariate Lagrange multiplier test indices for releasing active boundary constraints specified by the **BOUNDS** statement if you specify the **MODIFICATION** (or **MOD**) or the **PALL** option. Note that this output is not applicable to the ULS and the DWLS estimation methods. See the section “**Modification Indices**” on page 1346 for more detail.
- the stepwise multivariate Wald test for constraining estimated parameters to zero constants if the **MODIFICATION** (or **MOD**) or the **PALL** option is specified and the univariate probability is greater than the value specified in the **PMW=** option (default **PMW=0.05**). Note that this output is not applicable to the ULS and the DWLS estimation methods. See the section “**Modification Indices**” on page 1346 for more details.

ODS Table Names

PROC CALIS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

There are numerous ODS tables in the CALIS procedure. The conditions for these ODS tables to display vary a lot. For convenience in presentation, the ODS tables for the PROC CALIS procedure are organized in the following categories:

- ODS tables for [descriptive statistics, missing patterns, and residual analysis](#)
- ODS tables for [model specification and results](#)
- ODS tables for [supplementary model analysis](#)
- ODS tables for [modification indices](#)
- ODS tables for [optimization control and results](#)

Many ODS tables are displayed when you set either a specialized option in a certain statement or a [global display option](#) in the PROC CALIS statement. Rather than requesting displays by setting specialized options separately, you can request a group of displays by using a global display option.

There are five global display levels, represented by five options: [PALL](#) (highest), [PRINT](#), *default*, [PSHORT](#), and [PSUMMARY](#). The higher the level, the more output requested. The *default* printing level is in effect when you do not specify any other global printing options in the PROC CALIS statement. See the section “Global Display Options” on page 1085 for details.

In the following description of ODS tables whenever applicable, the lowest level of global printing options for an ODS table to print is listed. It is understood that global printing options at higher levels can also be used. For example, if [PSHORT](#) is the global display option to print an ODS table, you can also use [PALL](#), [PRINT](#), or *default*.

ODS Tables for Descriptive Statistics, Missing Patterns, and Residual Analysis

These ODS tables are group-oriented, meaning that each group has its own set of tables in the output. To display these tables in your output, you can set a specialized option in either the PROC CALIS or [GROUP](#) statement. If the specialized option is set in the PROC CALIS statement, it will apply to all groups. If the option is set in the [GROUP](#) statement, it will apply to the associated group only. Alternatively, you can set a global printing option in the PROC CALIS statement to print these tables. Either a specialized or a global printing option is sufficient to print the tables.

Table Names for Descriptive Statistics

ODS Table Name	Description	Specialized Option	Global Display Option
ContKurtosis	Contributions to kurtosis from observations	KURTOSIS	PRINT
CovRobust	Robust covariance matrix, with raw data input	PCORR ¹	PRINT
CovDetRobust	Determinant of the robust covariance matrix, with raw data input	PCORR ¹	PRINT
InCorr	Input correlation matrix	PCORR	PALL
InCorrDet	Determinant of the input correlation matrix	PCORR	PALL
InCov	Input covariance matrix	PCORR	PALL
InCovDet	Determinant of the input covariance matrix	PCORR	PALL
InMean	Input mean vector	PCORR	PALL
Kurtosis	Kurtosis, with raw data input	KURTOSIS	PRINT
MeanRobust	Robust mean vector, with raw data input	PCORR ¹	PRINT
PredCorr	Predicted correlation matrix	PCORR	PALL
PredCorrDet	Determinant of the predicted correlation matrix	PCORR	PALL
PredCov	Predicted covariance matrix	PCORR	PALL
PredCovDet	Determinant of the predicted covariance matrix	PCORR	PALL
PredMean	Predicted mean vector	PCORR	PALL
RidgedCovRobust	Ridged robust covariance matrix, with raw data input	PCORR ¹	PRINT
RidgedCovDetRobust	Determinant of the ridged robust covariance matrix, with raw data input	PCORR ¹	PRINT
RidgedInCorr	Ridged input correlation matrix	PCORR	PALL
RidgedInCorrDet	Determinant of the ridged input correlation matrix	PCORR	PALL
RidgedInCov	Ridged input covariance matrix	PCORR	PALL
RidgedInCovDet	Determinant of the ridged input covariance matrix	PCORR	PALL
SimpleStatistics	Simple statistics, with raw data input	SIMPLE	Default
Weights	Weight matrix	PWEIGHT	PALL
WeightsDet	Determinant of the weight matrix	PWEIGHT	PALL

1. Robust estimation with the **ROBUST** option is required.

Table Names for Missing Pattern Analysis

ODS Table Name	Description	Specialized Option	Global Display Option
AveCoverage	Average proportion coverages of means (variances) and covariances	SIMPLE or PCORR ¹	Default ²
MeanCovCoverage	Proportions of data present for means (variances) and covariances	SIMPLE or PCORR ¹	Default ²
MissPatternsMeans	Means of the nonmissing and the most frequent missing patterns	SIMPLE or PCORR ¹	Default ²
RankCovCoverage	Rank order of the covariance coverages	SIMPLE or PCORR ¹	Default ²
RankMissPatterns	Rank order of the most frequent missing patterns	SIMPLE or PCORR ¹	Default ²
RankVariableCoverage	Rank order of the proportion coverages of the variables	SIMPLE or PCORR ¹	Default ²

1. You can use the [NOMISSPAT](#) option in the [PROC CALIS](#) statement to suppress the analytic output of the missing patterns. If you use the [NOMISSPAT](#) option in the [GROUP](#) statements, only the output of the missing pattern analysis for the corresponding groups are suppressed.

2. PROC CALIS outputs these tables by default only when there are incomplete observations in the data sets and you use [METHOD=FIML](#) or [METHOD=LSFIML](#) for estimation.

Table Names for Residual Displays

ODS Table Name	Description	Specialized Option	Global Display Option
Residuals in the Moment Matrices			
AsymStdRes	Asymptotically standardized residual matrix	RESIDUAL=ASYSTAND ¹	PALL
AveAsymStdRes	Average of absolute asymptotically standardized residual values	RESIDUAL=ASYSTAND ¹	PALL
AveNormRes	Average of absolute normalized residual values	RESIDUAL=NORM ¹	PALL
AveRawRes	Average of absolute raw residual values	RESIDUAL	PALL
AveVarStdRes	Average of absolute variance standardized residual values	RESIDUAL=VARSTAND ¹	PALL
DistAsymStdRes	Distribution of asymptotically standardized residuals	RESIDUAL=ASYSTAND ¹	PALL
DistNormRes	Distribution of normalized residuals	RESIDUAL=NORM ¹	PALL
DistRawRes	Distribution of raw residuals	RESIDUAL	PALL
DistVarStdRes	Distribution of variance standardized residuals	RESIDUAL=VARSTAND ¹	PALL
NormRes	Normalized residual matrix	RESIDUAL=NORM ¹	PALL
RawRes	Raw residual matrix	RESIDUAL ²	PALL
RankAsymStdRes	Rank order of asymptotically standardized residuals	RESIDUAL=ASYSTAND ¹	PALL
RankNormRes	Rank order of normalized residuals	RESIDUAL=NORM ¹	PALL
RankRawRes	Rank order of raw residuals	RESIDUAL	PALL
RankVarStdRes	Rank order of variance standardized residuals	RESIDUAL=VARSTAND ¹	PALL
VarStdRes	Variance standardized residual matrix	RESIDUAL=VARSTAND ¹	PALL
Case-Level Residuals³			
DepartResidualDist	Departures from the theoretical distribution for the residual M-distances	RESIDUAL	PALL
Leverage	Observations with largest leverage M-distances	RESIDUAL	PALL
Outlier	Observations with largest residual M-distances	RESIDUAL	PALL

1. The **RESIDUAL=** option specifies the **RESIDUAL** option and the type of residuals. For example, RESIDUAL=ASYSTAND requests asymptotically standardized residuals, in addition to the tables enabled by the **RESIDUAL** option. In some cases, the requested types of residuals are not available due to the specific estimation method or the data type used. When this occurs, PROC

CALIS will determine the appropriate types of normalized or standardized residuals to display.

2. Raw residuals are also printed for correlation analysis even if **RESIDUAL** or **PALL** is not specified.
3. Raw data input is required.

ODS Tables for Model Specification and Results

Some ODS tables of this group are model-oriented. Others are not. Model-oriented ODS tables are printed for each model, while others are printed no more than once no matter how many models you have.

Non-Model-Oriented ODS Tables

The ODS tables that are not model-oriented are listed in the following table:

ODS Table Name	Description	Global Display Option	Additional Specification Required
AddParms	Estimates for additional parameters	PSHORT	PARAMETERS statement
AddParmsInit	Initial values for additional parameters	PSHORT	PARAMETERS statement
Fit	Fit summary	PSUMMARY	
GroupFit	Fit comparison among groups	PSUMMARY	Multiple groups
ModelingInfo	General modeling information	PSHORT	
ModelSummary	Summary of models and their labels and types	PSHORT	Multiple models ¹
ParmFunc	Parametric function testing	PSHORT	TESTFUNC statement
Simtests	Simultaneous tests of parametric functions	PSHORT	SIMTESTS statement

1. This table is displayed when you have multiple models that have labels specified by the **LABEL=** option, or when you define a model with more than a single level of reference by using the **REFMODEL** option. Otherwise, the ModelingInfo table contains all pertinent information regarding the models in the analysis.

Model-Oriented ODS Tables

These ODS tables are model-oriented, meaning that each model has its own set of ODS tables in the output. There are three types of model specification and results printing in PROC CALIS: initial specification, (un-standardized) estimated model results, and standardized model results. To distinguish these three types of ODS tables, different suffixes for the ODS table names are used. An “Init” suffix indicates initial specification, while a “Std” suffix indicates standardized solutions. All other tables are for unstandardized solutions.

These ODS tables require some specialized options to print. If you set the specialized option in the PROC CALIS statement, it applies to all models. If you set the specialized option in the **MODEL** statement, it applies to the associated model only. Alternatively, to print *all* these ODS tables, you can use the **PSHORT** or any higher level **global printing** option in the PROC CALIS statement. Either a specialized or a global printing option is sufficient to print these ODS tables. The following is a summary of the specialized and global printing options for these three types of ODS tables:

Type of ODS Tables	Table Name Suffix	Specialized Option	Global Display Option
Initial specification	Init	PINITIAL	PSHORT
Unstandardized solutions	(none)	PESTIM	PSHORT
Standardized solutions	Std	PESTIM , and NOSTAND not used	PSHORT

In the following list of ODS tables, the prefixes of the ODS table names indicate the modeling language required for the ODS tables to print. The last column of the list indicates whether the [PRIMAT](#) option is needed to print the corresponding ODS tables in matrix formats. You can use the [PRIMAT](#) option either in the PROC CALIS or [MODEL](#) statement. If you want matrix output for all models, set this option in the PROC CALIS statement. If you want matrix output for a specific model, set this option in the associated [MODEL](#) statement only.

ODS Table Name	Description	Additional Option
COSANVariables	Variables in the COSAN model	
COSANModel	Mean and covariance structure formulas	
COSANMatrixSummary	Summary of COSAN model matrices	
COSANMatrix	Estimated model matrix	
COSANMatrixInit	Initial model matrix	
FACTORCov	Estimated factor covariances	
FACTORCovInit	Initial factor covariances	
FACTORCovStd	Factor correlations	
FACTORErrVar	Estimated error variances	
FACTORErrVarInit	Initial error variances	
FACTORErrVarStd	Standardized results for error variances	
FACTORIntercepts	Estimated intercepts	
FACTORInterceptsInit	Initial intercepts	
FACTORLoadings	Estimated factor loadings	
FACTORLoadingsInit	Initial factor loadings	
FACTORLoadingsStd	Standardized factor loadings	
FACTORMeans	Estimated factor means	
FACTORMeansInit	Initial factor means	
FACTORRotCov	Estimated rotated factor covariances	
FACTORRotCovStd	Rotated factor correlations	
FACTORRotErrVar	Error variances in rotated solution	
FACTORRotErrVarStd	Standardized results for error variances in rotated solution	
FACTORRotLoadings	Rotated factor loadings	
FACTORRotLoadingsStd	Standardized rotated factor loadings	
FACTORRotMat	Rotation matrix	
FACTORScoresRegCoef	Factor scores regression coefficients	
FACTORVariables	Variables in the analysis	
LINEQSAAlpha	Estimated intercept vector	PRIMAT
LINEQSAAlphaInit	Initial intercept vector	PRIMAT

ODS Table Name	Description	Additional Option
LINEQSBeta	Estimated _EQSBETA_ matrix	PRIMAT
LINEQSBetaInit	Initial _EQSBETA_ matrix	PRIMAT
LINEQSBetaStd	Standardized results for _EQSBETA_ matrix	PRIMAT
LINEQSCovExog	Estimated covariances among exogenous variables	
LINEQSCovExogInit	Initial covariances among exogenous variables	
LINEQSCovExogStd	Standardized results for covariances among exogenous variables	
LINEQSEq	Estimated equations	
LINEQSEqInit	Initial equations	
LINEQSEqStd	Standardized equations	
LINEQSGamma	Estimated _EQSGAMMA_ matrix	PRIMAT
LINEQSGammaInit	Initial _EQSGAMMA_ matrix	PRIMAT
LINEQSGammaStd	Standardized results for _EQSGAMMA_ matrix	PRIMAT
LINEQSMeans	Estimated means for exogenous variables	
LINEQSMeansInit	Initial means for exogenous variables	
LINEQSNu	Estimated mean vector	PRIMAT
LINEQSNuInit	Initial mean vector	PRIMAT
LINEQSPhi	Estimated _EQSPHI_ matrix	PRIMAT
LINEQSPhiInit	Initial _EQSPHI_ matrix	PRIMAT
LINEQSPhiStd	Standardized results for _EQSPHI_ matrix	PRIMAT
LINEQSVarExog	Estimated variances of exogenous variables	
LINEQSVarExogInit	Initial variances of exogenous variables	
LINEQSVarExogStd	Standardized results for variances of exogenous variables	
LINEQSVariables	Exogenous and endogenous variables	
LISMODAlpha	Estimated _ALPHA_ vector	
LISMODAlphaInit	Initial _ALPHA_ vector	
LISMODBeta	Estimated _BETA_ matrix	
LISMODBetaInit	Initial _BETA_ matrix	
LISMODBetaStd	Standardized _BETA_ matrix	
LISMODGamma	Estimated _GAMMA_ matrix	
LISMODGammaInit	Initial _GAMMA_ matrix	
LISMODGammaStd	Standardized _GAMMA_ matrix	
LISMODKappa	Estimated _KAPPA_ vector	
LISMODKappaInit	Initial _KAPPA_ vector	
LISMODLambdaX	Estimated _LAMBDAX_ matrix	
LISMODLambdaXInit	Initial _LAMBDAX_ matrix	
LISMODLambdaXStd	Standardized _LAMBDAX_ matrix	
LISMODLambdaY	Estimated _LAMBDAY_ matrix	
LISMODLambdaYInit	Initial _LAMBDAY_ matrix	
LISMODLambdaYStd	Standardized _LAMBDAY_ matrix	
LISMODNuX	Estimated _NUX_ vector	
LISMODNuXInit	Initial _NUX_ vector	
LISMODNuY	Estimated _NUY_ vector	

ODS Table Name	Description	Additional Option
LISMODNuYInit	Initial _NUY_ vector	
LISMODPhi	Estimated _PHI_ matrix	
LISMODPhiInit	Initial _PHI_ matrix	
LISMODPhiStd	Standardized _PHI_ matrix	
LISMODPsi	Estimated _PSI_ matrix	
LISMODPsiInit	Initial _PSI_ matrix	
LISMODPsiStd	Standardized _PSI_ matrix	
LISMODThetaX	Estimated _THETAX_ matrix	
LISMODThetaXInit	Initial _THETAX_ matrix	
LISMODThetaXStd	Standardized _THETAX_ matrix	
LISMODThetaY	Estimated _THETAY_ matrix	
LISMODThetaYInit	Initial _THETAY_ matrix	
LISMODThetaYStd	Standardized _THETAY_ matrix	
LISMODVariables	Variables in the model	
MSTRUCTCov	Estimated _COV_ matrix	
MSTRUCTCovInit	Initial _COV_ matrix	
MSTRUCTCovStd	Standardized _COV_ matrix	
MSTRUCTMean	Estimated _MEAN_ vector	
MSTRUCTMeanInit	Initial _MEAN_ vector	
MSTRUCTVariables	Variables in the model	
PATHCovErrors	Estimated error covariances	
PATHCovErrorsInit	Initial error covariances	
PATHCovErrorsStd	Standardized error covariances	
PATHCovVarErr	Estimated covariances between exogenous variables and errors	
PATHCovVarErrInit	Initial covariances between exogenous variables and errors	
PATHCovVarErrStd	Standardized results for covariances between exogenous variables and errors	
PATHCovVars	Estimated covariances among exogenous variables	
PATHCovVarsInit	Initial covariances among exogenous variables	
PATHCovVarsStd	Standardized results for covariances among exogenous variables	
PATHList	Estimated path list	
PATHListInit	Initial path list	
PATHListStd	Standardized path list	
PATHMeansIntercepts	Estimated intercepts	
PATHMeansInterceptsInit	Initial intercepts	
PATHVariables	Exogenous and endogenous variables	
PATHVarParms	Estimated variances or error variances	
PATHVarParmsInit	Initial variances or error variances	
PATHVarParmsStd	Standardized results for variances or error variances	
RAMAMat	Estimated _A_ matrix	PRIMAT

ODS Table Name	Description	Additional Option
RAMAMatInit	Initial $_A_$ matrix	PRIMAT
RAMAMatStd	Standardized results of $_A_$ matrix	PRIMAT
RAMList	List of RAM estimates	
RAMListInit	List of initial RAM estimates	
RAMListStd	Standardized results for RAM estimates	
RAMPMat	Estimated $_P_$ matrix	PRIMAT
RAMPMatInit	Initial $_P_$ matrix	PRIMAT
RAMPMatStd	Standardized results of $_P_$ matrix	PRIMAT
RAMVariables	Exogenous and endogenous variables	
RAMWVec	Estimated mean and intercept vector	PRIMAT
RAMWVecInit	Initial mean and intercept vector	PRIMAT

ODS Tables for Supplementary Model Analysis

These ODS tables are model-oriented. They are printed for each model in your analysis. To display these ODS tables, you can set some specialized *options* in either the PROC CALIS or **MODEL** statement. If the specialized options are used in the PROC CALIS statement, they apply to all models. If the specialized options are used in the **MODEL** statement, they apply to the associated model only. For some of these ODS tables, certain specialized *statements* for the model might also enable the printing. Alternatively, you can use the global printing options in the PROC CALIS statement to print these ODS tables. Either a specialized option (or statement) or a global printing option is sufficient to print a particular ODS table.

ODS Table Name	Description	Specialized Option or Statement	Global Display Option
Determination	Coefficients of determination	PDETERM DETERM ⁴	Default
DirectEffects	Direct effects	TOTEFF ¹	PRINT
DirectEffectsStd	Standardized direct effects	TOTEFF ^{1,3}	PRINT
EffectsOf	Effects of the listed variables	EFFPART ²	PRINT
EffectsOn	Effects on the listed variables	EFFPART ²	PRINT
IndirectEffects	Indirect effects	TOTEFF ¹	PRINT
IndirectEffectsStd	Standardized indirect effects	TOTEFF ^{1,3}	PRINT
LatentScoresRegCoef	Latent variable scores regression coefficients	PLATCOV	PRINT
PredCovLatent	Predicted covariances among latent variables	PLATCOV	PRINT
PredCovLatMan	Predicted covariances between latent and manifest variables	PLATCOV	PRINT
PredMeanLatent	Predicted means of latent variables	PLATCOV	PRINT
SqMultCorr	Squared multiple correlations	PESTIM	PSHORT
Stability	Stability coefficient of reciprocal causation	PDETERM, DETERM ⁴	Default
StdEffectsOf	Standardized effects of the listed variables	EFFPART ^{2,3}	PSHORT
StdEffectsOn	Standardized effects on the listed variables	EFFPART ^{2,3}	PSHORT
TotalEffects	Total effects	TOTEFF ¹	PRINT
TotalEffectsStd	Standardized total effects	TOTEFF ^{1,3}	PRINT

1. This refers to the **TOTEFF** or **EFFPART** option in the PROC CALIS or **MODEL** statement.

2. This refers to the **EFFPART** statement specifications.

3. **NOSTAND** option must not be specified in the **MODEL** or PROC CALIS statement.

4. **PDETERM** is an option specified in the PROC CALIS or **MODEL** statement, while **DETERM** is a statement name.

ODS Tables for Model Modification Indices

To print the ODS tables for model modification indices, you can use the **MODIFICATION** option in either the PROC CALIS or **MODEL** statement. When this option is set in the PROC CALIS statement, it applies to all models. When this option is set in the **MODEL** statement, it applies to the associated model only. Alternatively, you can also use the **PALL** option in the PROC CALIS statement to print these ODS tables.

If the **NOMOD** option is set in the PROC CALIS statement, these ODS tables are not printed for all models, unless the **MODIFICATION** is respecified in the individual **MODEL** statements. If the **NOMOD** option is set in the **MODEL** statement, then the ODS tables for modification do not print for the associated model.

For convenience in presentation, three different classes of ODS tables for model modifications are described in the following. First, ODS tables for ranking of LM indices are the default printing when the **MODIFICATION** option is specified. Second, ODS tables for LM indices in matrix forms require an additional option to print. Last, ODS tables for other modification indices, including the Wald test indices, require specific

data-analytic conditions to print. While the first two classes of ODS tables are model-oriented (that is, each model has its own sets of output), the third one is not.

ODS Table Names for Ranking of LM indices

Rankings of the LM statistics in different regions of parameter space are the default printing format when you specify the **MODIFICATION** option in the PROC CALIS or MODEL statement. You can also turn off these default printing by the **NODEFAULT** option in the **LMTESTS** statement for models. If you want to print matrices of LM test statistics rather than the rankings of LM test statistics, you can use the **NORANK** or **MAXRANK=0** option in the **LMTESTS** statement.

These ODS tables for ranking LM statistics are specific to the types of modeling languages used. This is noted in the last column of the following table.

ODS Table Name	Description	Model
LMRankCosanMatrix	Any COSAN model matrix	COSAN
LMRankCov	Covariances among variables	MSTRUCT
LMRankCovErr	Covariances among errors	LINEQS
LMRankCovErrorfVar	Covariances among errors of variables	PATH
LMRankCovExog	Covariances among existing exogenous variables	LINEQS or PATH
LMRankCovFactors	Covariance among factors	FACTOR
LMRankCustomSet	Customized sets of parameters defined in LMTESTS statements	any model
LMRankErrorVar	Error variances	FACTOR
LMRankFactMeans	Factor means	FACTOR
LMRankIntercepts	Intercepts	FACTOR, LINEQS, or PATH
LMRankLisAlpha	LISMOD _ALPHA_	LISMOD
LMRankLisBeta	LISMOD _BETA_	LISMOD
LMRankLisGamma	LISMOD _GAMMA_	LISMOD
LMRankLisKappa	LISMOD _KAPPA_	LISMOD
LMRankLisLambdaX	LISMOD _LAMBDA_X_	LISMOD
LMRankLisLambdaY	LISMOD _LAMBDA_Y_	LISMOD
LMRankLisNuX	LISMOD _NUX_	LISMOD
LMRankLisNuY	LISMOD _NUY_	LISMOD
LMRankLisPhi	LISMOD _PHI_	LISMOD
LMRankLisPsi	LISMOD _PSI_	LISMOD
LMRankLisThetaX	LISMOD _THETA_X_	LISMOD
LMRankLisThetaY	LISMOD _THETA_Y_	LISMOD
LMRankLoadings	Factor loadings	FACTOR
LMRankMeans	Means of existing variables	LINEQS, MSTRUCT, or PATH
LMRankPaths	All possible paths in the model	PATH
LMRankPathsFromEndo	Paths from existing endogenous variables	LINEQS
LMRankPathsFromExog	Paths from existing exogenous variables	LINEQS
LMRankPathsNewEndo	Paths to existing exogenous variables	LINEQS

ODS Table Name	Description	Model
LMRankRamA	_RAMA_ matrix	RAM
LMRankRamAlpha	_RAMALPHA_ matrix	RAM
LMRankRamNu	_RAMNU_ matrix	RAM
LMRankRamP11	_RAMP11_ matrix	RAM
LMRankRamP22	_RAMP22_ matrix	RAM

ODS Table Names for Lagrange Multiplier Tests in Matrix Form

To print matrices of LM test indices for a model, you must also use the LMMAT option in the **LMTESTS** statement for the model. Some of these matrices are printed by default, while others are printed only when certain regions of parameter are specified in the LM test sets. In the following tables, the ODS table names for LM test statistics in matrix form are listed for each model type.

The COSAN Model

ODS Table Name	Description	Selected Region in Test Sets
LMCosanMatrix	Any COSAN model matrix	(default)

The FACTOR Model

ODS Table Name	Description	Selected Region in Test Sets
LMFactErrv	Vector of error variances	FACTERRV (default)
LMFactFcov	Factor covariance matrix	FACTFCOV (default)
LMFactInte	Intercept vector	FACTINTE (default)
LMFactLoad	Factor loading matrix	FACTLOAD (default)
LMFactMean	Factor mean vector	FACTMEAN (default)

The LINEQS Model

ODS Table Name	Description	Selected Regions in Test Sets
LMEqsAlpha	_EQSALPHA_ vector	_EQSALPHA_ (default)
LMEqsBeta	_EQSBETA_ matrix	_EQSBETA_ (default)
LMEqsGammaSub	_EQSGAMMA_ matrix, excluding entries with error variables in columns	_EQSGAMMA_ (default)
LMEqsNewDep	New rows for expanding _EQSBETA_ and _EQSGAMMA_ matrices	NEWDEP
LMEqsNuSub	_EQSNU_ vector, excluding fixed zero means for error variables	_EQSNU_ (default)
LMEqsPhi	_EQSPHI_ matrix	_EQSPHI_ alone or _EQSPHI11_, _EQSPHI21_ and _EQSPHI22_ together
LMEqsPhi11	Upper left portion (exogenous variances and covariances) of the _EQSPHI_ matrix	_EQSPHI11_ (default)

ODS Table Name	Description	Selected Regions in Test Sets
LMEqsPhi21	Lower left portion (error variances and covariances) of the _EQSPHI_ matrix	_EQSPHI21_
LMEqsPhi22	Lower right portion (error variances and covariances) of the _EQSPHI_ matrix	_EQSPHI22_ (default)

The LISMOD Model

ODS Table Name	Description	Selected Regions in Test Sets
LMLisAlpha	LISMOD _ALPHA_ vector	_ALPHA_ (default)
LMLisBeta	LISMOD _BETA_ matrix	_BETA_ (default)
LMLisGamma	LISMOD _GAMMA_ matrix	_GAMMA_ (default)
LMLisKappa	LISMOD _KAPPA_ vector	_KAPPA_ (default)
LMLisLambdaX	LISMOD _LAMBDA_X_ matrix	_LAMBDA_X_ (default) or _LAMBDA_
LMLisLambdaY	LISMOD _LAMBDA_Y_ matrix	_LAMBDA_Y_ (default) or _LAMBDA_
LMLisNuX	LISMOD _NUX_ vector	_NUX_ (default) or _NU_
LMLisNuY	LISMOD _NUY_ vector	_NUY_ (default) or _NU_
LMLisPhi	LISMOD _PHI_ matrix	_PHI_ (default)
LMLisPsi	LISMOD _PSI_ matrix	_PSI_ (default)
LMLisThetaX	LISMOD _THETA_X_ matrix	_THETA_X_ (default) or _THETA_
LMLisThetaY	LISMOD _THETA_Y_ matrix	_THETA_Y_ (default) or _THETA_

The MSTRUCT Model

ODS Table Name	Description	Selected Regions in Test Sets
LMMstructCov	Covariance matrix	MSTRUCTCOV (default) or _COV_
LMMstructMean	Mean vector	MSTRUCTMEAN (default) or _MEAN_

The PATH Model

ODS Table Name	Description	Selected Regions in Test Sets
LMRamA	_RAMA_ matrix	ARROWS or _RAMA_ (default)
LMRamALeft	Left portion of the _RAMA_ matrix	_RAMA_LEFT_ alone or _RAMBETA_ and _RAMA_LL_ together
LMRamALL	Lower left portion of the _RAMA_ matrix	_RAMA_LL_

ODS Table Name	Description	Selected Regions in Test Sets
LMRamALower	Lower portion of the _RAMA_ matrix	NEWENDO or _RAMA_LOWER_ or _RAMA_LL_ and _RAMA_LR_ together
LMRamALR	Lower right portion of the _RAMA_ matrix	_RAMA_LR_
LMRamARight	Right portion of the _RAMA_ matrix	_RAMA_RIGHT_
LMRamAUppper	Upper portion of the _RAMA_ matrix	_RAMA_UPPER_ alone or _RAMBETA_ and _RAMGAMMA_ together
LMRamAlpha	_RAMALPHA_ matrix	INTERCEPTS (default)
LMRamBeta	Upper left portion of the _RAMA_ matrix	_RAMBETA_
LMRamGamma	Upper right portion of the _RAMA_ matrix	_RAMGAMMA_
LMRamNu	_RAMNU_ matrix	MEANS (default)
LMRamP	_RAMP_ matrix	_RAMP_ alone or _RAMP11_, _RAMP21_, and _RAMP22_ together
LMRamP11	Upper left portion of the _RAMP_ matrix	COVERR (default)
LMRamP21	Lower left portion of the _RAMP_ matrix	COVEXOGERR
LMRamP22	Lower right portion of the _RAMP_ matrix	COVEXOG (default)
LMRamW	_RAMW_ matrix	FIRSTMOMENTS alone or MEANS and INTERCEPTS together

The RAM Model

ODS Table Name	Description	Selected Regions in Test Sets
LMRamA	_RAMA_ matrix	_RAMA_ (default)
LMRamALeft	Left portion of the _RAMA_ matrix	_RAMA_LEFT_ alone or _RAMBETA_ and _RAMA_LL_ together
LMRamALL	Lower left portion of the _RAMA_ matrix	_RAMA_LL_
LMRamALower	Lower portion of the _RAMA_ matrix	NEWENDO or _RAMA_LOWER_ or _RAMA_LL_ and _RAMA_LR_ together
LMRamALR	Lower right portion of the _RAMA_ matrix	_RAMA_LR_
LMRamARight	Right portion of the _RAMA_ matrix	_RAMA_RIGHT_
LMRamAUppper	Upper portion of the _RAMA_ matrix	_RAMBETA_ and _RAMGAMMA_
LMRamAlpha	_RAMALPHA_ matrix	_RAMALPHA_ (default)
LMRamBeta	Upper left portion of the _RAMA_ matrix	_RAMBETA_
LMRamGamma	Upper right portion of the _RAMA_ matrix	_RAMGAMMA_
LMRamNu	_RAMNU_ matrix	_RAMNU_ (default)
LMRamP	_RAMP_ matrix	_RAMP_ alone or _RAMP11_, _RAMP21_, and _RAMP22_ together

ODS Table Name	Description	Selected Regions in Test Sets
LMRamP11	Upper left portion of the <code>_RAMP_</code> matrix	<code>_RAMP11_</code> (default)
LMRamP21	Lower left portion of the <code>_RAMP_</code> matrix	<code>_RAMP21_</code>
LMRamP22	Lower right portion of the <code>_RAMP_</code> matrix	<code>_RAMP22_</code> (default)
LMRamW	<code>_RAMW_</code> matrix	<code>_RAMW_</code>

ODS Table Names for Other Modification Indices

The following table shows the ODS tables for the remaining modification indices.

ODS Table Name	Description	Additional Requirement
LagrangeBoundary	LM tests for active boundary constraints	Presence of active boundary constraints
LagrangeDepParmEquality	LM tests for equality constraints in dependent parameters	Presence of equality constraints in dependent parameters
LagrangeEquality	LM tests for equality constraints	Presence of equality constraints in independent parameters
WaldTest	Wald tests for testing existing parameters equaling zeros	At least one insignificant parameter value

ODS Table for Optimization Control and Results

To display the ODS tables for optimization control and results, you must specify any of the following global display options in the PROC CALIS statement: `PRINT`, `PALL`, or default (that is, `NOPRINT` is not specified). Also, you must not use the `NOPRINT` option in the `NLOPTIONS` statement. For some of these tables, you must also specify additional options, either in the PROC CALIS or the `NLOPTIONS` statement. Some restrictions might apply. Additional options and restrictions are noted in the last column.

ODS Table Name	Description	Additional Option Required or Restriction
CovParm	Covariances of parameters	PCOVES ¹ or PALL ² , restriction ³
ConvergenceStatus	Convergence status	
DependParmsResults	Final dependent parameter estimates	Restriction ⁴
DependParmsStart	Initial dependent parameter estimates	Restriction ⁴
Information	Information matrix	PCOVES ¹ or PALL ² , restriction ³
InitEstMethods	Initial estimation methods	
InputOptions	Optimization options	PALL ²
IterHist	Iteration history	
IterStart	Iteration start	
IterStop	Iteration stop	
Lagrange	First and second order Lagrange multipliers	PALL ²
LinCon	Linear constraints	PALL ² , restriction ⁵
LinConDel	Deleted constraints	PALL ² , restriction ⁵
LinConSol	Linear constraints evaluated at solution	PALL ² , restriction ⁵
LinDep	Linear dependencies of parameter estimates	Restriction ⁶
ParameterEstimatesResults	Final estimates	
ParameterEstimatesStart	Initial estimates	
ProblemDescription	Problem description	
ProjGrad	Projected gradient	PALL ²

1. PCOVES option is specified in the PROC CALIS statement.

2. PALL option is specified in the NLOPTIONS statement.

3. Estimation method must not be ULS or DWLS.

4. Existence of dependent parameters.

5. Linear equality or boundary constraints are imposed.

6. Existence of parameter dependencies during optimization, but not due to model specification.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

In the following table, ODS graph names and the options to display the graphs are listed.

Table 27.17 Graphs Produced by PROC CALIS

ODS Graph Name	Plot Description	Option
Distribution of Residuals in the Moment Matrices		
AsymStdResidualHistogram	Asymptotically standardized residuals	PLOTS=RESIDUALS and RESIDUAL=ASYMSTD, METHOD= is not ULS or DWLS
NormResidualHistogram	Normalized residuals	PLOTS=RESIDUALS and RESIDUAL=NORM
RawResidualHistogram	Raw residuals	PLOTS=RESIDUALS
VarStdResidualHistogram	Variance standardized residuals	PLOTS=RESIDUALS and RESIDUAL=VARSTD
Case-Level Residual Diagnostics		
CaseResidualHistogram	Distribution of the residual M-distances	PLOTS=CRESHIST or CASERESIDUAL
ResidualByLeverage	Residual M-distances against the leverage M-distances	PLOTS=RESBYLEV or CASERESIDUAL
ResidualByPredicted	Residuals against the predicted values of dependent variables	PLOTS=RESBYPRED or CASERESIDUAL
ResidualByQuantile	Residual M-distances against the theoretical quantiles	PLOTS=QQ or CASERESIDUAL
ResPercentileByExpPercentile	Percentiles of residual M-distances against the theoretical percentiles	PLOTS=PP or CASERESIDUAL

Examples: CALIS Procedure

Example 27.1: Estimating Covariances and Correlations

This example shows how you can use PROC CALIS to estimate the covariances and correlations of the variables in your data set. Estimating the covariances introduces you to the most basic form of covariance structures—a saturated model with all variances and covariances as parameters in the model. To fit such a saturated model when there is no need to specify the functional relationships among the variables, you can use the **MSTRUCT** modeling language of PROC CALIS.

The following data set contains four variables q1–q4 for the quarterly sales (in millions) of a company. The 14 observations represent 14 retail locations in the country. The input data set is shown in the following DATA step:

```
data sales;
  input q1 q2 q3 q4;
  datalines;
1.03  1.54  1.11  2.22
1.23  1.43  1.65  2.12
3.24  2.21  2.31  5.15
1.23  2.35  2.21  7.17
.98   2.13  1.76  2.38
1.02  2.05  3.15  4.28
1.54  1.99  1.77  2.00
1.76  1.79  2.28  3.18
1.11  3.41  2.20  3.21
1.32  2.32  4.32  4.78
1.22  1.81  1.51  3.15
1.11  2.15  2.45  6.17
1.01  2.12  1.96  2.08
1.34  1.74  2.16  3.28
;
```

Use the following PROC CALIS specification to estimate a saturated covariance structure model with all variances and covariances as parameters:

```
proc calis data=sales pcorr;
  mstruct var=q1-q4;
run;
```

In the PROC CALIS statement, specify the data set with the DATA= option. Use the PCORR option to display the observed and predicted covariance matrix. Next, use the MSTRUCT statement to fit a covariance matrix of the variables that are provided in the VAR= option. Without further specifications such as the MATRIX statement, PROC CALIS assumes all elements in the covariance matrix are model parameters. Hence, this is a saturated model.

[Output 27.1.1](#) shows the modeling information. Information about the model is displayed: the name and location of the data set, the number of data records read and used, and the number of observations in the analysis. The number of data records read is the actual number of records (or observations) that PROC CALIS processes from the data set. The number of data records used might or might not be the same as the

actual number of records read from the data set. For example, records with missing values are read but not used in the analysis for the default maximum likelihood (ML) method. The number of observations refers to the N used for testing statistical significance and model fit. This number might or might not be the same as the number of records used for at least two reasons. First, if you use a frequency variable in the **FREQ** statement, the number of observations used is a weighted sum of the number of records, with the frequency variable being the weight. Second, if you use the **NOBS=** option in the **PROC CALIS** statement, you can override the number of observations that are used in the analysis. Because the current data set does not have any missing data and there are no frequency variables or an **NOBS=** option specified, these three numbers are all 14.

The model type is **MSTRUCT** because you use the **MSTRUCT** statement to define your model. The analysis type is covariances, which is the default. [Output 27.1.1](#) then shows the four variables in the covariance structure model.

Output 27.1.1 Modeling Information of the Saturated Covariance Structure Model for the Sales Data

```

Estimating the Covariance Matrix by the MSTRUCT Modeling Language

      The CALIS Procedure
Covariance Structure Analysis: Model and Initial Values

      Modeling Information
Maximum Likelihood Estimation

Data Set           WORK.SALES
N Records Read     14
N Records Used     14
N Obs              14
Model Type         MSTRUCT
Analysis           Covariances

      Variables in the Model

      q1  q2  q3  q4

      Number of Variables = 4

```

[Output 27.1.2](#) shows the initial covariance structure model for these four variables. All lower triangular elements (including the diagonal elements) of the covariance matrix are parameters in the model. **PROC CALIS** generates the names for these parameters: **_Add01–_Add10**. Because the covariance matrix is symmetric, all upper triangular elements of the matrix are redundant. The initial estimates for covariance are denoted by missing values no initial values were specified.

Output 27.1.2 Initial Saturated Covariance Structure Model for the Sales Data

Initial MSTRUCT _COV_ Matrix				
	q1	q2	q3	q4
q1
	[_Add01]	[_Add02]	[_Add04]	[_Add07]
q2
	[_Add02]	[_Add03]	[_Add05]	[_Add08]
q3
	[_Add04]	[_Add05]	[_Add06]	[_Add09]
q4
	[_Add07]	[_Add08]	[_Add09]	[_Add10]

The PCORR option in the PROC CALIS statement displays the sample covariance matrix in [Output 27.1.3](#). By default, PROC CALIS computes the unbiased sample covariance matrix (with variance divisor equal to $N - 1$) and uses it for the covariance structure analysis.

Output 27.1.3 Sample Covariance Matrix for the Sales Data

Covariance Matrix (DF = 13)				
	q1	q2	q3	q4
q1	0.33830	0.00020	0.03610	0.22137
q2	0.00020	0.22466	0.12653	0.24425
q3	0.03610	0.12653	0.60633	0.63012
q4	0.22137	0.24425	0.63012	2.66552

The fit summary and the fitted covariance matrix are shown in [Output 27.1.4](#) and [Output 27.1.5](#), respectively.

Output 27.1.4 Fit Summary of the Saturated Covariance Structure Model for the Sales Data

Fit Summary	
Chi-Square	0.0000
Chi-Square DF	0
Pr > Chi-Square	.

Output 27.1.5 Fitted Covariance Matrix for the Sales Data

MSTRUCT _COV_ Matrix: Estimate/StdErr/t-value				
	q1	q2	q3	q4
q1	0.3383	0.000198	0.0361	0.2214
	0.1327	0.0765	0.1260	0.2704
	2.5495	0.002587	0.2865	0.8186
q2	0.000198	0.2247	0.1265	0.2443
	0.0765	0.0881	0.1082	0.2251
	0.002587	2.5495	1.1693	1.0853
q3	0.0361	0.1265	0.6063	0.6301
	0.1260	0.1082	0.2378	0.3935
	0.2865	1.1693	2.5495	1.6012
q4	0.2214	0.2443	0.6301	2.6655
	0.2704	0.2251	0.3935	1.0455
	0.8186	1.0853	1.6012	2.5495

In [Output 27.1.4](#), the model fit chi-square is 0 ($df = 0$). The p -value cannot be computed because the degrees of freedom is zero. This fit is perfect because the model is saturated.

[Output 27.1.5](#) shows the fitted covariance matrix, along with standard error estimates and t values in each cell. The variance and covariance estimates match exactly those of the sample covariance matrix shown in [Output 27.1.3](#).

A common practice for determining statistical significance for estimates in structural equation modeling is to require the absolute value of t to be greater than 1.96, which is the critical value of a standard normal variate at $\alpha=0.05$. While all diagonal elements in [Output 27.1.5](#) show statistical significance, all off-diagonal elements are not significantly different from zero. The t values for these elements range from 0.002 to 1.601.

[Output 27.1.6](#) shows the standardized estimates of the variance and covariance elements. This is also the correlation matrix under the MSTRUCT model. Standard error estimates and t values are computed with the correlation estimates. Note that because the diagonal element values are fixed at 1, no standard errors or t values are shown.

Output 27.1.6 Standardized Covariance Matrix for the Sales Data

Standardized MSTRUCT _COV_ Matrix: Estimate/StdErr/t-value				
	q1	q2	q3	q4
q1	1.0000	0.000717 0.2773 0.002587	0.0797 0.2756 0.2892	0.2331 0.2623 0.8888
q2	0.000717 0.2773 0.002587	1.0000	0.3428 0.2448 1.4008	0.3156 0.2497 1.2640
q3	0.0797 0.2756 0.2892	0.3428 0.2448 1.4008	1.0000	0.4957 0.2092 2.3692
q4	0.2331 0.2623 0.8888	0.3156 0.2497 1.2640	0.4957 0.2092 2.3692	1.0000

Sometimes researchers do not need to estimate the standard errors that are in their models. You can suppress the standard error and *t* value computations by using the **NOSE** option in the PROC CALIS statement:

```
proc calis data=sales nose;
  mstruct var=q1-q4;
run;
```

Output 27.1.7 shows the fitted covariance matrix with the NOSE option. These values are exactly the same as in the sample covariance matrix shown in Output 27.1.3.

Output 27.1.7 Fitted Covariance Matrix without Standard Error Estimates for the Sales Data

MSTRUCT _COV_ Matrix				
	q1	q2	q3	q4
q1	0.3383	0.000198	0.0361	0.2214
q2	0.000198	0.2247	0.1265	0.2443
q3	0.0361	0.1265	0.6063	0.6301
q4	0.2214	0.2443	0.6301	2.6655

This example shows a very simple application of PROC CALIS: estimating the covariance matrix with standard error estimates. The covariance structure model is saturated. Several extensions of this very simple model are possible. To estimate the means and covariances simultaneously, see Example 27.2. To fit nonsaturated covariance structure models with certain hypothesized patterns, see Example 27.3 and Example 27.4. To fit structural models with implied covariance structures that are based on specified functional relationships among variables, see Example 27.6.

Example 27.2: Estimating Covariances and Means Simultaneously

This example uses the same data set that is used in [Example 27.1](#) and estimates the means and covariances. Use the **MSTRUCT** model specification as shown in the following statements:

```
proc calis data=sales meanstr nostand;
  mstruct var=q1-q4;
run;
```

In the PROC CALIS statement, specify the **MEANSTR** option to request the mean structure analysis in addition to the default covariance structure analysis. If you are not interested in the standardized solution, specify the **NOSTAND** option in the PROC CALIS statement to suppress computation of the standardized estimates. Without further model specification (such as the **MATRIX** statement), PROC CALIS assumes a saturated structural model with all means, variances, and covariances as model parameters.

[Output 27.2.1](#) shows the modeling information. With the **MEANSTR** option specified in the PROC CALIS statement, the current analysis type is Means and Covariances, instead of the default Covariances in [Example 27.1](#).

Output 27.2.1 Modeling Information of the Saturated Mean and Covariance Structure Model for the Sales Data

Saturated Means and Covariance Structures Using MSTRUCT	
The CALIS Procedure	
Mean and Covariance Structures: Model and Initial Values	
Modeling Information	
Maximum Likelihood Estimation	
Data Set	WORK.SALES
N Records Read	14
N Records Used	14
N Obs	14
Model Type	MSTRUCT
Analysis	Means and Covariances
Variables in the Model	
q1 q2 q3 q4	
Number of Variables = 4	

[Output 27.2.2](#) shows the fit summary of the current model. Again, this is a perfect model fit with 0 chi-square value and 0 degrees of freedom.

Output 27.2.2 Fit Summary of the Saturated Mean and Covariance Structure Model for the Sales Data

Fit Summary	
Chi-Square	0.0000
Chi-Square DF	0
Pr > Chi-Square	.

Output 27.2.3 shows the estimates of the means, together with the standard error estimates and the t values. These estimated means are exactly the same as the sample means, which are not shown here.

Output 27.2.3 Mean Estimates for the Sales Data

MSTRUCT _Mean_ Vector			
Variable	Estimate	Standard Error	t Value
q1	1.36714	0.16132	8.47491
q2	2.07429	0.13146	15.77902
q3	2.20286	0.21596	10.20008
q4	3.65500	0.45281	8.07176

Output 27.2.4 shows the variance and covariance estimates. These estimates are exactly the same as the elements in the sample covariance matrix. In addition, these estimates match the estimates in Output 27.1.5 of Example 27.1, where only the covariance structures are analyzed.

Output 27.2.4 Variance and Covariance Estimates for the Sales Data

MSTRUCT _COV_ Matrix: Estimate/StdErr/t-value				
	q1	q2	q3	q4
q1	0.3383 0.1327 2.5495	0.000198 0.0765 0.002587	0.0361 0.1260 0.2865	0.2214 0.2704 0.8186
q2	0.000198 0.0765 0.002587	0.2247 0.0881 2.5495	0.1265 0.1082 1.1693	0.2443 0.2251 1.0853
q3	0.0361 0.1260 0.2865	0.1265 0.1082 1.1693	0.6063 0.2378 2.5495	0.6301 0.3935 1.6012
q4	0.2214 0.2704 0.8186	0.2443 0.2251 1.0853	0.6301 0.3935 1.6012	2.6655 1.0455 2.5495

These estimates are essentially the same as the sample means, variances, and covariances. This kind of analysis is much easier using PROC CORR with the NOMISS option. However, the main purpose of [Example 27.1](#) and [Example 27.2](#) is to introduce the MSTRUCT modeling language and some basic but important options in PROC CALIS. You can apply the MSTRUCT modeling language to more sophisticated situations that are beyond the saturated mean and covariance structure models. [Example 27.3](#) and [Example 27.4](#) fit some patterned covariance models that are nonsaturated. Also, options such as NOSE, NOSTAND, and MEANSTR are useful for all modeling languages in PROC CALIS.

Example 27.3: Testing Uncorrelatedness of Variables

This example uses the sales data in [Example 27.1](#) and tests the uncorrelatedness of the variables in the model by using the MSTRUCT model specification. With the multivariate normality assumption, this is also the test of independence of the variables. The MATRIX statement defines the parameters in the model.

The uncorrelatedness model assumes that the correlations or covariances among the four variables are zero. Therefore, only the four diagonal elements of the covariance matrix, which represent the variances of the variables, are free parameters in the covariance structure model. To specify these parameters, use the MATRIX statement with the MSTRUCT model specification:

```
proc calis data=sales;
  mstruct var=q1-q4;
  matrix _cov_ [1,1], [2,2], [3,3], [4,4];
run;
```

[Example 27.1](#) specifies exactly the same MSTRUCT statement for the four variables. The difference here is the addition of the MATRIX statement. Without a MATRIX statement, the MSTRUCT model assumes that all nonredundant elements in the covariance matrix are model parameters. This assumption is not the case in the current specification. The MATRIX statement specification for the covariance matrix (denoted by the _cov_ keyword) specifies four free parameters on the diagonal of the covariance matrix: [1,1], [2,2], [3,3], and [4,4]. All other unspecified elements in the covariance matrix are fixed zeros by default.

The uncorrelatedness model is displayed in the output for the initial model specification. [Output 27.3.1](#) shows that all off-diagonal elements of the covariance matrix are fixed zeros while the diagonal elements are missing and labeled with _Parm1–_Parm4. PROC CALIS generates these parameter names automatically and estimates these four parameters in the analysis.

Output 27.3.1 Initial Uncorrelatedness Model for the Sales Data

Initial MSTRUCT _COV_ Matrix				
	q1	q2	q3	q4
q1	.	0	0	0
	[_Parm1]			
q2	0	.	0	0
		[_Parm2]		
q3	0	0	.	0
			[_Parm3]	
q4	0	0	0	.
				[_Parm4]

Output 27.3.2 shows the model fit chi-square test of the uncorrelatedness model. The chi-square is 6.528 ($df = 6$, $p = 0.3667$), which is not significant. This means that you fail to reject the uncorrelatedness model. In other words, the data is consistent with the uncorrelatedness model (zero covariances or correlations among the quarterly sales).

Output 27.3.2 Fit Summary of the Uncorrelatedness Model for the Sales Data

Fit Summary	
Chi-Square	6.5280
Chi-Square DF	6
Pr > Chi-Square	0.3667

Output 27.3.3 shows the estimates of the covariance matrix under the uncorrelatedness model, together with standard error estimates and t values. All off-diagonal elements are fixed zeros in the estimation results.

Output 27.3.3 Estimates of Variance under the Uncorrelatedness Model for the Sales Data

MSTRUCT _COV_ Matrix: Estimate/StdErr/t-value				
	q1	q2	q3	q4
q1	0.3383 0.1327 2.5495 [_Parm1]	0	0	0
q2	0	0.2247 0.0881 2.5495 [_Parm2]	0	0
q3	0	0	0.6063 0.2378 2.5495 [_Parm3]	0
q4	0	0	0	2.6655 1.0455 2.5495 [_Parm4]

This example shows how to specify free parameters in the MSTRUCT model by using the **MATRIX** statement. To specify the covariance matrix, use the **_COV_** keyword in the **MATRIX** statement. To specify the parameters in the mean structures, you need use an additional **MATRIX** statement with the **_MEAN_** keyword.

Two important notes regarding the MSTRUCT model specification are now in order:

- When you use the MSTRUCT statement without any MATRIX statements, *all* elements in the covariance matrix are *free parameters* in the model (for example, see [Example 27.1](#)). However, if the MATRIX statement includes at least one free or fixed parameter in the covariance matrix, PROC CALIS assumes that all other unspecified elements in the covariance matrix are *fixed zeros* (such as the current example).
- Using parameter names in the MATRIX statement specification is optional. In the context of the current example, naming the parameters is optional because there is no need to refer to them anywhere in the specification. PROC CALIS automatically generates unique names for these parameters. Alternatively, you can specify your own parameter names in the MATRIX statement. Naming parameters is not only useful for references, but is also indispensable when you need to constrain model parameters by referring to their names. See [Example 27.4](#) to use parameter names to define a covariance pattern.

Example 27.4: Testing Covariance Patterns

In the test for sphericity, a covariance matrix is hypothesized to be a constant multiple of an identity matrix. That is, the null hypothesis for the population covariance matrix is

$$\Sigma = \sigma^2 \mathbf{I}$$

where σ^2 is an unknown positive constant and \mathbf{I} is an identity matrix. When this covariance pattern is applied to the sales data in [Example 27.1](#), this hypothesis states that all four variables have the same variance σ^2 and are uncorrelated with each other. This model is more restricted than the uncorrelatedness model in [Example 27.3](#), which requires uncorrelatedness but does not require equal variances. Use the following specification to conduct a sphericity test for the sales data:

```
proc calis data=sales;
  mstruct var=q1-q4;
  matrix _cov_ [1,1] = 4*sigma_sq;
run;
```

This specification is similar to that of [Example 27.3](#). The major difference is the **MATRIX** statement specification. The current example uses a parameter name `sigma_sq` to represent the unknown variance parameter σ^2 , whereas [Example 27.3](#) specifies only the locations of the four free variance parameters.

The current **MATRIX** statement specification uses a shorthand notation. On the left-hand side of the equal sign, `[1,1]` indicates the starting location of the covariance matrix. The matrix entries automatically proceed to `[2,2]`, `[3,3]` and so on, depending on the length of the parameter list specified on the right-hand side of the equal sign. For example, if there is just one parameter on the right-hand side, the matrix specification contains only `[1,1]`. In the current example, the specification `4*sigma_sq` means that `sigma_sq` appears four times in the specification. As a result, the preceding **MATRIX** statement specification is equivalent to the following statement:

```
matrix _cov_ [1,1] = sigma_sq,
              [2,2] = sigma_sq,
              [3,3] = sigma_sq,
              [4,4] = sigma_sq;
```

This matrix is what is required by the sphericity test. Use either the expanded notation or the shorthand notation for specifying the covariance pattern. For details about various types of shorthand notation for parameter specifications, see the **MATRIX** statement.

[Output 27.4.1](#) shows the initial model specification under the test of sphericity. All the diagonal elements are labeled with the same name `sigma_sq`, indicating that they are the same parameter.

Output 27.4.1 Covariance Model under Sphericity for the Sales Data

Initial MSTRUCT _COV_ Matrix				
	q1	q2	q3	q4
q1	.	0	0	0
	[sigma_sq]			
q2	0	.	0	0
		[sigma_sq]		
q3	0	0	.	0
			[sigma_sq]	
q4	0	0	0	.
				[sigma_sq]

Output 27.4.2 shows that the model fit chi-square is 31.5951 ($df = 9$, $p = 0.0002$). This means that the covariance pattern under the sphericity hypothesis is not supported.

Output 27.4.2 Fit Summary of the Sphericity Test for the Sales Data

Fit Summary	
Chi-Square	31.5951
Chi-Square DF	9
Pr > Chi-Square	0.0002

Output 27.4.3 shows the estimated covariance matrix under the sphericity hypothesis. The variance estimate for all four diagonal elements is 0.9587 (standard error=0.1880).

Output 27.4.3 Fitted Covariance Matrix under the Sphericity Hypothesis for the Sales Data

MSTRUCT _COV_ Matrix: Estimate/StdErr/t-value				
	q1	q2	q3	q4
q1	0.9587 0.1880 5.0990 [sigma_sq]	0	0	0
q2	0	0.9587 0.1880 5.0990 [sigma_sq]	0	0
q3	0	0	0.9587 0.1880 5.0990 [sigma_sq]	0
q4	0	0	0	0.9587 0.1880 5.0990 [sigma_sq]

This example shows how you can specify a simple covariance pattern by using the **MATRIX** statement. Use the same parameter names to constrain variance parameters that are supposed to be the same under the model. Constraining parameters by using the same parameter names is applicable not only to the **MSTRUCT** models, but also to more complicated covariance structure models, such as multiple-group modeling (see [Example 27.19](#) and [Example 27.21](#)).

The **MSTRUCT** modeling language is handy when you can directly specify the covariance pattern or structures in your model. However, in most applications of structural equation modeling, it is difficult to specify such direct covariance structures. Instead, the covariance structures are usually implied from the functional relationships among the variables in the model. Using the **MSTRUCT** modeling language in such a situation is not easy. Fortunately, **PROC CALIS** supports other modeling languages that enable you to specify the functional relationships among variables. The functional relationships can be in the form of a set of path-like descriptions, a system of linear equations, or parameter specifications in matrices. See [Example 27.6](#) for an introduction to using the **PATH** modeling language for specifying path models.

Example 27.5: Testing Some Standard Covariance Pattern Hypotheses

In [Example 27.3](#), you test the uncorrelatedness of variables by using the **MSTRUCT** model specification. In [Example 27.4](#), you test the sphericity of the covariance matrix by using the same model specification technique. In both examples, you need to specify the parameters in the covariance structure model explicitly by using the **MATRIX** statements.

Some covariance patterns are well-known in multivariate statistics, including the two tests in [Example 27.3](#) and [Example 27.4](#). To facilitate the tests of these “standard” covariance patterns, **PROC CALIS** provides the

COVPATTERN= option to specify those standard covariance patterns more efficiently. With the COVPATTERN=option, you do not need to use the MSTRUCT and MATRIX statements to specify the covariance patterns explicitly. See the [COVPATTERN=](#) option for the supported covariance patterns. This example illustrates the use of the [COVPATTERN=](#) option.

In [Example 27.3](#), you conduct a test of uncorrelatedness for the four variables in the sales data (see [Example 27.1](#) for the data set). That is, the variables are hypothesized to be uncorrelated and only the four variances on the diagonal of the covariance matrix are population parameters of interest. The null hypothesis for the population covariance matrix is

$$\Sigma = \begin{pmatrix} x & 0 & 0 & 0 \\ 0 & x & 0 & 0 \\ 0 & 0 & x & 0 \\ 0 & 0 & 0 & x \end{pmatrix}$$

where each x represents a distinct parameter (that is, the diagonal elements are not constrained with each other). You can test the diagonal covariance pattern easily by the following specification:

```
proc calis data=sales covpattern=diag;
run;
```

The COVPATTERN=DIAG option specifies the required diagonal covariance pattern for the test. PROC CALIS then sets up the covariance structures automatically. [Output 27.5.1](#) shows the initial specification of the covariance pattern. As required, only the diagonal elements are parameters in the test and the other elements are fixed to zero. PROC CALIS names the variance parameters automatically—that is, `_varparm_1`–`_varparm_4` are the four parameters for the variances. This is the same pattern as shown in [Output 27.3.1](#) of [Example 27.3](#), although the parameter names are different.

Output 27.5.1 Initial Diagonal Pattern for the Covariance Matrix of the Sales Data

Initial MSTRUCT _COV_ Matrix				
	q1	q2	q3	q4
q1	.	0	0	0
	[_varparm_1]			
q2	0	.	0	0
	[_varparm_2]			
q3	0	0	.	0
	[_varparm_3]			
q4	0	0	0	.
	[_varparm_4]			

[Output 27.5.2](#) shows the results of the chi-square test of the diagonal covariance pattern. The chi-square is 5.44 ($df = 6$, $p = 0.4887$), which is not significant. You fail to reject the null hypothesis of the diagonal covariance pattern in the population.

Output 27.5.2 Fit Summary of the Diagonal Covariance Pattern Test for the Sales Data

Fit Summary		
Chi-Square		5.4400
Chi-Square DF		6
Pr > Chi-Square		0.4887

The numerical results shown in [Output 27.5.2](#) are different from those of the same test by using the MSTRUCT model specification, which is shown in [Output 27.3.2](#) of [Example 27.3](#), although you do not reject the null hypothesis in both cases. The reason is that with the use of COVPATTERN= option, PROC CALIS applies the appropriate chi-square correction to the test statistic automatically. In the current example, the chi-square correction due to Bartlett (1950) has been applied. Test results with chi-square corrections are theoretically more accurate.

To obtain the same numerical results as those in [Output 27.3.2](#), you can turn off the chi-square correction by using the **CHICORRECT=0** option, as shown in the following specification:

```
proc calis data=sales covpattern=diag chicorrect=0;
run;
```

[Output 27.5.3](#) shows the fit summary results without any chi-square correction. The numerical results match exactly to those shown in [Output 27.3.2](#) of [Example 27.3](#).

Output 27.5.3 Fit Summary of the Diagonal Covariance Pattern Test for the Sales Data: No Chi-Square Correction

Fit Summary		
Chi-Square		6.5280
Chi-Square DF		6
Pr > Chi-Square		0.3667

[Example 27.4](#) tests the sphericity of the covariance matrix of the same data set. The null hypothesis for the population covariance matrix is

$$\Sigma = \sigma^2 \mathbf{I}$$

where σ^2 is an unknown positive constant and \mathbf{I} is an identity matrix. You can use the following specification to test this hypothesis easily:

```
proc calis data=sales covpattern=sigsqi;
run;
```

[Output 27.5.4](#) shows the initial specification of the covariance pattern. As required, the diagonal elements are all the same parameter named `_varparm`, and all the off-diagonal elements are fixed to zero. This is the same pattern as shown in [Output 27.4.1](#) of [Example 27.4](#).

Output 27.5.4 Initial Covariance Pattern for the Sphericity Test on the Sales Data

Initial MSTRUCT _COV_ Matrix				
	q1	q2	q3	q4
q1	.	0	0	0
	[_varparm]			
q2	0	.	0	0
	[_varparm]			
q3	0	0	.	0
	[_varparm]			
q4	0	0	0	.
	[_varparm]			

Output 27.5.5 shows the fit summary of the sphericity test. The chi-square is 27.747 ($df = 9$, $p = 0.0011$), which is statistically significant. You reject the sphericity hypothesis for the population covariance matrix.

Output 27.5.5 Fit Summary of the Sphericity Test on the Sales Data

Fit Summary	
Chi-Square	27.7470
Chi-Square DF	9
Pr > Chi-Square	0.0011

Again, the numerical results in Output 27.5.5 are different from those shown in Output 27.4.2 of Example 27.4. This is because with the COVPATTERN=SIGSQI option, the chi-square correction due to Box (1949) has been applied in the current example. To turn off the automatic chi-square correction, you can use the following specification:

```
proc calis data=sales covpattern=sigsqi chicorrect=0;
run;
```

As expected, the numerical results in Output 27.5.6 match exactly to those of in Output 27.4.2 of Example 27.4.

Output 27.5.6 Fit Summary of the Sphericity Test on the Sales Data: No Chi-Square Correction

Fit Summary	
Chi-Square	31.5951
Chi-Square DF	9
Pr > Chi-Square	0.0002

This example shows that for the tests of some standard covariance patterns, you can use the **COVPATTERN=** option directly. As compared with the use of the explicit **MSTRUCT** model specifications, which are shown in [Example 27.3](#) and [Example 27.4](#), the use of **COVPATTERN=** option is more efficient and less error-prone in coding. In addition, it can apply chi-square corrections in appropriate situations.

PROC CALIS also provides the test of some “standard” mean patterns by the **MEANPATTERN=** option. You can use the **COVPATTERN=** and **MEANPATTERN=** options together to define the desired combinations of covariance and mean patterns. See these two options for details. See [Example 27.22](#) for a multiple-group analysis with the simultaneous use of the **COVPATTERN=** and **MEANPATTERN=** options. Certainly, the **COVPATTERN=** and **MEANPATTERN=** options are limited to the standard covariance and mean patterns provided by PROC CALIS. When you need to fit some specific (nonstandard) covariance or mean patterns, the **MSTRUCT** model specification would be indispensable. See [Example 27.19](#) and [Example 27.22](#) for applications.

Example 27.6: Linear Regression Model

This example shows how you can use PROC CALIS to fit the basic regression models. Unlike the preceding examples ([Example 27.1](#), [Example 27.2](#), [Example 27.3](#), and [Example 27.4](#)) where you specify the covariance structures directly, in this example the covariance structures being analyzed are implied by the functional relationships specified in the model. The **PATH** modeling language introduced in the current example requires you to specify only the functional or path relationships among variables. PROC CALIS analyzes the implied covariance structures that are derived from the specified functional or path relationships.

Consider the same sales data as in [Example 27.1](#). This example demonstrates a simple linear regression that uses q1 (the sales in the first quarter) to predict q4 (the sales in the fourth quarter).

In covariance structural analysis, or in general structural equation modeling, relationships among variables are usually represented by the so-called path diagram. For example, you can represent the linear regression of q4 on q1 by the following simple path diagram:

In the path diagram, q1 is an exogenous (or independent) variable and q4 is an endogenous (or dependent) variable. Formally, a variable in a path diagram is endogenous if there is at least one single-headed arrow pointing to it. Otherwise, the variable is exogenous. In some situations, researchers apply “causal” interpretations among variables in the path diagram, with the single-headed arrows indicating the causal directions. However, causal interpretations are not a requirement for using covariance structure analysis or structural equation modeling.

It is easy to transcribe the preceding path diagram into the **PATH** model specification in PROC CALIS, as shown in the following statements:

```

proc calis data=sales;
  path   q1 ==> q4;
run;
  
```

Output 27.6.1 shows the modeling information of the linear regression model. It shows that all 14 observations are used and the model type is PATH. PROC CALIS analyzes the (implied) covariance structure model for the data. In the next table of Output 27.6.1, PROC CALIS shows the nature of the variables in the model: q4 is an endogenous manifest variable and q1 is an exogenous manifest variable. There is no latent variable in this simple path model.

Output 27.6.1 Modeling Information of the Linear Regression Model for the Sales Data

Simple Linear Regression Model by the PATH Modeling Language		
The CALIS Procedure		
Covariance Structure Analysis: Model and Initial Values		
Modeling Information		
Maximum Likelihood Estimation		
Data Set	WORK.SALES	
N Records Read	14	
N Records Used	14	
N Obs	14	
Model Type	PATH	
Analysis	Covariances	
Variables in the Model		
Endogenous	Manifest	q4
	Latent	
Exogenous	Manifest	q1
	Latent	
Number of Endogenous Variables = 1		
Number of Exogenous Variables = 1		

Output 27.6.2 shows the initial model specification. The path is in the first table. A parameter name is attached to the path. The name `_Parm1`, which is generated automatically by PROC CALIS, denotes the effect parameter of q1 on q4. In the context of linear regression, `_Parm1` also denotes the regression coefficient.

Output 27.6.2 Initial Specification of the Linear Regression Model for the Sales Data

Initial Estimates for PATH List		
-----Path-----	Parameter	Estimate
q1 ==> q4	_Parm1	.

Output 27.6.2 *continued*

Initial Estimates for Variance Parameters			
Variance Type	Variable	Parameter	Estimate
Exogenous	q1	_Add1	.
Error	q4	_Add2	.
NOTE: Parameters with prefix '_Add' are added by PROC CALIS.			

Next, [Output 27.6.2](#) shows the variance parameters in the model. You do not need to specify any of these parameters in the preceding PATH model specification—because PROC CALIS adds these parameters by default. `_Add1` denotes the variance parameter for the exogenous variable `q1`. `_Add2` denotes the error variance parameter for the endogenous variable `q4`.

In the PATH model of PROC CALIS, all variances of exogenous variables and all error variances of endogenous variables are free parameters by default. In most practical applications, these parameters are usually free parameters in models and it would be laborious to specify them each time when you fit a covariance structure model. Therefore, to make the PATH model specification more efficient and easier, PROC CALIS sets these free parameters by default. In fact, with these default parameters in the PATH model, PROC CALIS produces essentially the same regression analysis results as those produced by common linear regression procedures such as PROC REG. This consistency is shown in the subsequent estimation results for the current example.

You can also explicitly specify those otherwise default parameters of the PATH model in PROC CALIS. Depending on the modeling situation, you can set any parameter in the PATH model as a free, fixed, or constrained parameter. You can also provide names for the parameters. Naming parameters is very useful for parameter referencing and for setting up parameter constraints. See [Example 27.4](#). For details, see the `PATH` statement and the section “[The PATH Model](#)” on page 1288.

[Output 27.6.3](#) shows some fit statistics from the linear regression model. The model fit chi-square is 0 with 0 degrees of freedom. This is a perfect model fit. The fit is perfect because the covariance model contains three distinct elements (variance of `q1`, variance of `q4`, and covariance between `q1` and `q4`) that are fitted perfectly by three parameters: `_Parm1` for the effect of `q1` on `q4`, `_Add1` for the variance of variable `q1`, and `_Add2` for the error variance of variable `q4`. Thus, the unconstrained linear regression model estimates are simply a transformation of the covariance elements. Hence, the model is saturated with a perfect fit and zero degrees of freedom.

Output 27.6.3 Model Fit of the Linear Regression Model for the Sales Data

Fit Summary	
Chi-Square	0.0000
Chi-Square DF	0
Pr > Chi-Square	.
Standardized RMR (SRMR)	0.0000
RMSEA Estimate	.

Output 27.6.4 shows the estimates of the model. The effect of q1 on q4 is 0.6544 (standard error=0.7571). The associated t value is 0.86433, which is not significantly different from zero. The estimated variance of q1 is 0.3383 and the estimated error variance for q4 is 2.5207. Both estimates are significant.

Output 27.6.4 Parameter Estimates of the Linear Regression Model for the Sales Data

PATH List					
-----Path-----		Parameter	Estimate	Standard Error	t Value
q1	==> q4	_Parm1	0.65436	0.75707	0.86433
Variance Parameters					
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value
Exogenous	q1	_Add1	0.33830	0.13269	2.54951
Error	q4	_Add2	2.52066	0.98869	2.54951

For a simple linear regression such as this one, you could have used PROC REG. You get essentially the same estimates by specifying the following statements:

```
proc reg data=sales;
  model q4 = q1;
run;
```

Output 27.6.5 shows the parameter estimates from PROC REG. The intercept estimate is 2.7604 (standard error=1.1643) and the regression coefficient is 0.6544 (standard error=0.7880). The regression coefficient estimate matches PROC CALIS. However, the corresponding standard error estimate in PROC CALIS is 0.7571, which is slightly different from PROC REG. This difference is due to the different variance divisors that are used in calculating the standard error estimates. PROC CALIS uses $(N - 1)$ as the divisor (by default) while PROC REG uses $(N - q - 1)$, where N is the number of observations and q is the number of regression coefficients. In the current example, q is 1 so that the variance divisor in PROC REG is 1 less than the divisor in PROC CALIS. If you have at least a moderate sample size and the number of regression parameters is relatively small compared to the sample size, the discrepancy due to using different variance divisors is of little consequence.

Output 27.6.5 Parameter Estimates from PROC REG for the Sales Data

Parameter Estimates					
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t
Intercept	1	2.76040	1.16430	2.37	0.0353
q1	1	0.65436	0.78798	0.83	0.4225

By default, PROC CALIS analyzes only the covariance structures, which are properties of the second-order moments of the data. PROC CALIS does not automatically produce intercept estimates, which are properties of the first-order moments of the data.

In order to produce the intercept estimate in the linear regression context, you can add the **MEANSTR** (mean structures) option in the PROC CALIS statement, as shown in the following statements:

```
proc calis data=sales meanstr;
  path  q1 ==> q4;
run;
```

Output 27.6.6 shows the parameter estimates of the model with the MEANSTR option added. Compared with Output 27.6.4, Output 27.6.6 produces one more table: estimates of the mean and intercept. The intercept estimate for q4 is 2.7604, which matches the intercept estimate from PROC REG. The estimated mean of q1 is 1.3671. All other estimates are the same for the analyses with and without the MEANSTR option.

Output 27.6.6 Parameter Estimates of the Linear Regression Model with the MEANSTR option for the Sales Data

PATH List						
-----Path-----		Parameter	Estimate	Standard Error	t Value	
q1	==>	q4	_Parm1	0.65436	0.75707	0.86433
Variance Parameters						
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value	
Exogenous Error	q1	_Add1	0.33830	0.13269	2.54951	
	q4	_Add2	2.52066	0.98869	2.54951	
Means and Intercepts						
Type	Variable	Parameter	Estimate	Standard Error	t Value	
Intercept	q4	_Add3	2.76040	1.12480	2.45413	
Mean	q1	_Add4	1.36714	0.16132	8.47491	

Linear regression estimates from PROC CALIS are comparable to those obtained from PROC REG, although the two procedures have different default treatments of the variance divisor in calculating the standard error estimates. With the **MEANSTR** option in the PROC CALIS statement, you can analyze the mean and covariance structures simultaneously. PROC CALIS prints the estimates of the intercepts and means when you model the mean structures.

This example shows how you can fit the linear regression model as a PATH model in PROC CALIS. You need to specify only path relationships among the variables in the PATH statement, because the implied

covariance structures are generated and analyzed by PROC CALIS. To make model specification more efficient, PROC CALIS sets default variance parameters for exogenous variables and default error variance parameters for endogenous variables. You can also overwrite these default parameters by explicit specifications. See [Example 27.7](#) for some sophisticated regression models that you can specify with PROC CALIS. See [Example 27.17](#) for a more elaborate path model specification.

Example 27.7: Multivariate Regression Models

This example shows how to analyze different types of multivariate regression models with PROC CALIS. [Example 27.6](#) fits a simple linear regression model to the sales data that are described in [Example 27.1](#). The simple linear regression model predicts the fourth quarter sales (q4) from the first quarter sales (q1). There is only one dependent (outcome) variable (q4) and one independent (predictor) variable (q1) in the analysis. Also, there are no constraints on the parameters. This example fits more sophisticated regression models. The models include more than one predictor. Some variables can serve as outcome variables and predictor variables at the same time. This example also illustrates the use of parameter constraints in model specifications and the use of the model fit statistics to search for a “best” model for the sales data.

Multiple Regression Model for the Sales Data

Consider a multiple regression model for q4. Instead of using just q1 as the predictor in the model as in [Example 27.6](#), use all previous sales q1–q3 to predict the fourth-quarter sale (q4). The path model representation is shown in the following path diagram:

You can transcribe this path diagram into the following PATH model specification:

```
proc calis data=sales;
  path   q1 q2 q3 ==> q4;
run;
```

In the path statement, the shorthand path specification

```
path   q1 q2 q3 ==> q4;
```

is equivalent to the following specification:

```
path   q1 ==> q4,
       q2 ==> q4,
       q3 ==> q4;
```

The shorthand notation provides a more convenient way to specify the path model. Some of the model fit statistics are shown in [Output 27.7.1](#). This is a saturated model with perfect fit and zero degrees of freedom.

Because the chi-square statistic is always smallest in a saturated model (with a zero chi-square value), it does not make much sense to judge the model quality solely by looking at the chi-square value. However, a saturated model is useful for serving as a baseline model with which other nonsaturated competing models are compared.

Output 27.7.1 Model Fit of the Multiple Regression Model for the Sales Data

Fit Summary	
Chi-Square	0.0000
Chi-Square DF	0
Pr > Chi-Square	.
Standardized RMR (SRMR)	0.0000
RMSEA Estimate	.
Akaike Information Criterion	20.0000
Bozdogan CAIC	36.3906
Schwarz Bayesian Criterion	26.3906

In addition to the model fit chi-square statistic, [Output 27.7.1](#) also shows Akaike's information criterion (AIC), Bozdogan's CAIC, and Schwarz's Bayesian criterion (SBC) of the saturated model. The AIC, CAIC, and SBC are derived from information theory and henceforth they are referred to as the information-theoretic fit indices. These information-theoretic fit indices measure the model quality by taking the model parsimony into account. The root mean square error of approximation (RMSEA) also takes the model parsimony into account, but it is not an information-theoretic fit index. The values of these information-theoretic fit indices themselves do not indicate the quality of the model. However, when you fit several different models to the same data, you can order the models by these fit indices. The better the model, the smaller the fit index values. Unlike the chi-square statistic, these fit indices do not always favor a saturated model because a saturated model lacks model parsimony (the saturated model uses the most parameters to explain the data). The subsequent discussion uses these fit indices to select the “best” model for the sales data.

[Output 27.7.2](#) shows the parameter estimates of the multiple regression model. In the first table, all path effect estimates are not statistically significant—that is, all t values are less than 1.96. The next table in [Output 27.7.2](#) shows the variance estimates of q_1 – q_3 and the error variance estimate for q_4 . All of these estimates are significant. The last table in [Output 27.7.2](#) shows the covariances among the exogenous variables q_1 – q_3 . These covariance estimates are small and are not statistically significant.

Output 27.7.2 Parameter Estimates of the Multiple Regression Model for the Sales Data

PATH List						
-----Path-----			Parameter	Estimate	Standard Error	t Value
q1	==>	q4	_Parm1	0.55980	0.64938	0.86205
q2	==>	q4	_Parm2	0.58946	0.84558	0.69711
q3	==>	q4	_Parm3	0.88290	0.51635	1.70988

Output 27.7.2 continued

Variance Parameters					
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value
Exogenous	q1	_Add1	0.33830	0.13269	2.54951
	q2	_Add2	0.22466	0.08812	2.54951
	q3	_Add3	0.60633	0.23782	2.54951
Error	q4	_Add4	1.84128	0.72221	2.54951
Covariances Among Exogenous Variables					
Var1	Var2	Parameter	Estimate	Standard Error	t Value
q2	q1	_Add5	0.0001978	0.07646	0.00259
q3	q1	_Add6	0.03610	0.12601	0.28649
q3	q2	_Add7	0.12653	0.10821	1.16931

In [Output 27.7.2](#), the total number of parameter estimates is 10 (_Parm1–_Parm3 and _Add1–_Add7). Under the covariance structure model, these 10 parameters explain the 10 nonredundant elements in the covariance matrix for the sales data. That is why the model has a perfect fit with zero degrees of freedom.

In [Output 27.7.2](#), notice that some parameters have the prefix ‘_Parm’, while others have the prefix ‘_Add’. Both types of parameter names are generated by PROC CALIS. The parameters named with the ‘_Parm’ prefix are those that were specified in the model, but were not named. In the current example, the parameters specified but not named are the path coefficients (effects) for the three paths in the PATH statement. The parameters named with the ‘_Add’ prefix are default parameters added by PROC CALIS. In the current multiple regression example, the variances and covariances among the predictors (q1–q3) and the error variance for the outcome variable (q4) are default parameters in the model. In general, variances and covariances among exogenous variables and error variances of endogenous variables are default parameters in the PATH model. Avoid using parameter names with the ‘_Parm’ and ‘_Add’ prefixes to avoid confusion with parameters that are generated by PROC CALIS.

Direct and Indirect Effects Model for the Sales Data

In the multiple regression model, q1–q3 are all predictors that have direct effects on q4. This example considers the possibility of adding indirect effects into the multiple regression model. Because of the time ordering, it is reasonable to assume that there is a causal sequence $q1 \implies q2 \implies q3$. To implement this idea into the model, put two more paths into the preceding path diagram to form the following new path diagram:

With the $q1 \implies q2$ and $q2 \implies q3$ paths, $q2$ and $q3$ are no longer exogenous in the model. They become endogenous. The only exogenous variable in the model is $q1$, which has a direct effect in addition to indirect effects on $q4$. The direct effect is indicated by the $q1 \implies q4$ path. The indirect effects are indicated by the following two causal chains: $q1 \implies q2 \implies q4$ and $q1 \implies q2 \implies q3 \implies q4$. Similarly, $q2$ has a direct and an indirect effect on $q4$. However, $q3$ has only a direct effect on $q4$. You can use the following statements to specify this *direct and indirect effects* model:

```

proc calis data=sales;
  path    q1      ==>  q2,
          q2      ==>  q3,
          q1 q2 q3 ==>  q4;
run;

```

Although the *direct and indirect effects* model has two more paths in the PATH statement than does the preceding multiple regression model, the current model is more precise because it has one fewer parameter. By introducing the causal paths $q1 \implies q2$ and $q2 \implies q3$, the six variances and covariances among $q1$ – $q3$ are explained by: the two causal effects, the exogenous variance of $q1$, and the error variances for $q2$ and $q3$ (that is, five parameters in the model). Hence, the current *direct and indirect effects* model has one fewer parameter than the preceding multiple regression model.

Output 27.7.3 shows some model fit indices of the direct and indirect effects model. The model fit chi-square is 0.0934 with one degree of freedom. It is not significant. Therefore, you cannot reject the model on statistical grounds. The standardized root mean squares of residuals (SRMR) is 0.028 and the root mean square error of approximation (RMSEA) is close to zero. Both indices point to a very good model fit. The AIC, CAIC, and SBC are all smaller than those of the saturated model, as shown in **Output 27.7.1**. This suggests that the *direct and indirect effects* model is better than the saturated model.

Output 27.7.3 Model Fit of the Direct and Indirect Effects Model for the Sales Data

Fit Summary	
Chi-Square	0.0934
Chi-Square DF	1
Pr > Chi-Square	0.7600
Standardized RMR (SRMR)	0.0280
RMSEA Estimate	0.0000
Akaike Information Criterion	18.0934
Bozdogan CAIC	32.8449
Schwarz Bayesian Criterion	23.8449

Output 27.7.4 shows the parameter estimates of the *direct and indirect effects* model. All the path effects are not significant, while all the variance or error variance estimates are significant. Unlike the saturated model where you have covariance estimates among several exogenous variables (as shown in Output 27.7.2), in the *direct and indirect effects* model there is only one exogenous variable (q1) and hence there is no covariance estimate in the results.

Output 27.7.4 Parameter Estimates of the Direct and Indirect Effects Model for the Sales Data

PATH List						
-----Path-----			Parameter	Estimate	Standard Error	t Value
q1	====>	q2	_Parm1	0.0005847	0.22602	0.00259
q2	====>	q3	_Parm2	0.56323	0.42803	1.31587
q1	====>	q4	_Parm3	0.55980	0.64705	0.86515
q2	====>	q4	_Parm4	0.58946	0.84524	0.69739
q3	====>	q4	_Parm5	0.88290	0.51450	1.71603
Variance Parameters						
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value	
Exogenous Error	q1	_Add1	0.33830	0.13269	2.54951	
	q2	_Add2	0.22466	0.08812	2.54951	
	q3	_Add3	0.53506	0.20987	2.54951	
	q4	_Add4	1.84128	0.72221	2.54951	

Although the current *direct and indirect effects* model is better than the saturated model and both the SRMR and RMSEA indicate a good model fit, the nonsignificant path effect estimates are unsettling. You continue to explore alternative models for the data.

Indirect Effects Model for the Sales Data

The saturated model includes only the direct effects of q1–q3 on q4, while the *direct and indirect effects* model includes both the direct and indirect effects of q1 and q2 on q4. An alternative model with only the indirect effects of q1 and q2 on q4, but without their direct effects, is possible. Such an *indirect effects* model is represented by the following path diagram:

You can easily transcribe this path diagram into the following PATH model specification:

```

proc calis data=sales;
  path    q1    ==>  q2,
          q2    ==>  q3,
          q3    ==>  q4;
run;

```

Output 27.7.5 shows some model fit indices for the *indirect effects* model. The chi-square model fit statistic is not statistically significant, so the model is not rejected. The standardized RMR is 0.0905, which is a bit higher than the conventional value of 0.05 for an acceptable good model fit. However, the RMSEA is close to zero, which shows a very good model fit. The AIC, CAIC and SBC are all smaller than the *direct and indirect effects* model. These information-theoretic fit indices suggest that the *indirect effects* model is better.

Output 27.7.5 Model Fit of the Indirect Effects Model for the Sales Data

Fit Summary	
Chi-Square	1.2374
Chi-Square DF	3
Pr > Chi-Square	0.7440
Standardized RMR (SRMR)	0.0905
RMSEA Estimate	0.0000
Akaike Information Criterion	15.2374
Bozdogan CAIC	26.7108
Schwarz Bayesian Criterion	19.7108

Output 27.7.6 shows the parameter estimates of the *indirect effects* model. All the variance and error variance estimates are statistically significant. However, only the path effect of q3 on q4 is statistically significant, and all other path effects are not. Having significant variances with nonsignificant paths raises some concerns about accepting the current model even though the AIC, CAIC, and SBC values suggest that it is the best model so far.

Output 27.7.6 Parameter Estimates of the Indirect Effects Model for the Sales Data

PATH List						
-----Path-----	Parameter	Estimate	Standard Error	t Value		
q1 ==> q2	_Parm1	0.0005847	0.22602	0.00259		
q2 ==> q3	_Parm2	0.56323	0.42803	1.31587		
q3 ==> q4	_Parm3	1.03924	0.50506	2.05765		

Variance Parameters					
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value
Exogenous Error	q1	_Add1	0.33830	0.13269	2.54951
	q2	_Add2	0.22466	0.08812	2.54951
	q3	_Add3	0.53506	0.20987	2.54951
	q4	_Add4	2.01067	0.78865	2.54951

Constrained Indirect Effects Model for the Sales Data

In the preceding *indirect effects* model, some path effects are not significant. In the current model, all the path effects are constrained to be equal. The following path diagram represents the *constrained indirect effects* model:

Except for one notable difference, this path diagram is the same as the path diagram for the preceding *indirect effects* model. The current path diagram labels all the paths with the same name (gamma) to signify that they are the same parameter. You can specify this *constrained indirect effects* model with this chosen constraint on the path effects by the using following statements:

```

proc calis data=sales;
  path   q1   ==>   q2       = gamma,
         q2   ==>   q3       = gamma,
         q3   ==>   q4       = gamma;
run;

```

In the PATH statement, append an equal sign and a parameter name gamma in each of the path entries. This specification means that all the associated path effects are the same parameter named gamma.

Output 27.7.7 shows some fit indices for the *constrained indirect effects* model. Again, the model fit chi-square statistic is not significant. However, the SRMR is 0.2115, which is too large to accept as a good model. The RMSEA is 0.0499, which still indicates a good model fit. The AIC, CAIC, and SBC values are a bit smaller than those of the preceding unconstrained *indirect effects* model. Therefore, it seems that constraining the path effects leads to a slightly better model.

Output 27.7.7 Model Fit of the Constrained Indirect Effects Model for the Sales Data

Fit Summary	
Chi-Square	5.1619
Chi-Square DF	5
Pr > Chi-Square	0.3964
Standardized RMR (SRMR)	0.2115
RMSEA Estimate	0.0499
Akaike Information Criterion	15.1619
Bozdogan CAIC	23.3572
Schwarz Bayesian Criterion	18.3572

Output 27.7.8 shows the parameter estimates of the *constrained indirect effects* model. Again, all variance and error variance estimates are significant, and all path effects are not significant. The effect estimate is 0.24 (standard error=0.19, $t = 1.25$).

Output 27.7.8 Parameter Estimates of the Constrained Indirect Effects Model for the Sales Data

PATH List					
-----Path-----	Parameter	Estimate	Standard Error	t Value

	q3	_Add3	0.55851	0.21907	2.54951
	q4	_Add4	2.39783	0.94051	2.54951

Constrained Indirect Effects and Error Variances Model for the Sales Data

In addition to constraining all the path effects in the preceding model, the current model constrains all the error variances. Before using a path diagram to represent the current constrained indirect effects and constrained error variances, it is important to realize that you have not manually defined variances and covariances in the path diagrams for all of the preceding models. The default parameterization in PROC CALIS defined those parameters.

Represent the variances and covariances in a path diagram with double-headed arrows. When a double-headed arrow points to a single variable, it represents the variance parameter. When a double-headed arrow points to two distinct variables, it represents the covariance between the two variables. Consider the unconstrained *indirect effects* model for the sales data as an example. A more complete path diagram representation is as follows:

In this path diagram, a double-headed arrow on each variable represents variance or error variance. For q1, the double-headed arrow represents the variance parameter of q1. For other variables, the double-headed arrows represent error variances because those variables are endogenous (that is, they are predicted from other variables) in the model.

In order to represent the equality-constrained parameters in the model, you can put parameter names in the respective parameter locations in the path diagram. For the current *constrained indirect effects and error variances* model, you can represent the model by the following path diagram:

In the path diagram, label all the path effects by the parameter gamma and all error variances by the parameter evar. The double-headed arrow attached to q1 is not labeled by any name. This means that it is an unnamed free parameter in the model.

You can transcribe the path diagram into the following statements:

```
proc calis data=sales;
  path    q1    ==>  q2      = gamma,
          q2    ==>  q3      = gamma,
          q3    ==>  q4      = gamma;
  pvar    q2 q3 q4 = 3 * evar;
run;
```

The specification in the PATH statement is the same as the preceding PATH model specification for the *constrained indirect effects* model. The new specification here is the **PVAR** statement. You use the PVAR statement to specify partial variances, which include the (total) variances of exogenous variables and the error variances of the endogenous variables. In the PVAR statement, you specify the variables for which you intend to define variances. If you do not specify anything after the list of variables, the variances of these variables are unnamed free parameters. If you put an equal sign after the variable lists, you can specify parameter names, initial values, or fixed parameters for the variances of the variables. See the **PVAR** statement for details. In the current model, **3*evar** means that you want to specify **evar** three times (for the error variance parameters of q2, q3, and q4).

Note that you did not specify the variance of q1 in the PVAR statement. This variance is a default parameter in the model, and therefore you do not need to specify it in the PVAR statement. Alternatively, you can specify it explicitly in the PVAR statement by giving it a parameter name. For example, you can specify the following:

```
pvar    q2 q3 q4 = 3 * evar,
        q1      = MyOwnName;
```

Or, you can specify it explicitly without giving it a parameter name, as shown in following statement:

```
pvar    q2 q3 q4 = 3 * evar,
        q1 ;
```

All these specifications lead to the same estimation results. The difference between the two specifications is the explicit parameter name for the variance of q1. Without putting q1 in the PVAR statement, the variance parameter is named with the prefix **_Add**, which is generated as a default parameter by PROC CALIS. With the explicit specification of q1, the variance parameter is named **MyOwnName**. With the explicit specification of q1, but without giving it a parameter name in the PVAR statement, the variance parameter is named with the prefix **_Parm**, which PROC CALIS generates for unnamed free parameters.

Output 27.7.9 shows some fit indices for the *constrained indirect effects and error variances* model. The model fit chi-square is 19.7843, which is significant at the 0.05 α -level. In practice, the model fit chi-square statistic is not the only criterion for judging model fit. In fact, it might not even be the most commonly used criterion for measuring model fit. Other criteria such as the SRMR and RMSEA are more popular or important. Unfortunately, the values of these two fit indices do not support the current constrained model either. The SRMR is 1.5037 and the RMSEA is 0.3748. Both are much greater than the commonly accepted 0.05 criterion.

Output 27.7.9 Model Fit of the Constrained Indirect Effects and Error Variances Model for the Sales Data

Fit Summary	
Chi-Square	19.7843
Chi-Square DF	7
Pr > Chi-Square	0.0061
Standardized RMR (SRMR)	1.5037
RMSEA Estimate	0.3748
Akaike Information Criterion	25.7843
Bozdogan CAIC	30.7015
Schwarz Bayesian Criterion	27.7015

The AIC, CAIC, and SBC values are all much greater than those of the preceding *constrained indirect effects* model. Therefore, constraining the error variances in addition to the constrained indirect effects does not lead to a better model.

Output 27.7.10 shows the parameter estimates of the *constrained indirect effects and error variances* model. All estimates are significant in the model, which is often desirable. However, because of the bad model fit, this model is not acceptable.

Output 27.7.10 Parameter Estimates of the Constrained Indirect Effects and Error Variances Model for the Sales Data

PATH List						
-----Path-----			Parameter	Estimate	Standard Error	t Value
q1	==>	q2	gamma	0.64733	0.16128	4.01368
q2	==>	q3	gamma	0.64733	0.16128	4.01368
q3	==>	q4	gamma	0.64733	0.16128	4.01368
Variance Parameters						
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value	
Error	q2	evar	1.00220	0.22695	4.41588	
	q3	evar	1.00220	0.22695	4.41588	
	q4	evar	1.00220	0.22695	4.41588	
Exogenous	q1	_Add1	0.33830	0.13269	2.54951	

Partially Constrained Model for the Sales Data

In the preceding model, constraining all error variances to be same shows that the model fit is unacceptable, even though all parameter estimates are significant. Relaxing those constraints a little might improve the model. The following path diagram represents such a *partially constrained* model:

The only difference between the current *partially constrained* model and the preceding *constrained indirect effects and error variances* model is that the error variance for q4 is no longer constrained to be equal to the error variances of q2 and q3. In the path diagram, *evar* is no longer attached to the double-headed arrow that is associated with the error variance of q4. You can transcribe this path diagram representation into the following PATH model specification:

```

proc calis data=sales;
  path   q1  ==> q2      = gamma,
         q2  ==> q3      = gamma,
         q3  ==> q4      = gamma;
  pvar   q2 q3 = 2 * evar,
         q4 q1;
run;

```

Now, the PVAR statement has only the error variances of q2 and q3 constrained to be equal. The error variance of q4 and the variance of q1 are free parameters without constraints.

[Output 27.7.11](#) shows some fit indices for the *partially constrained* model. The chi-square model fit test statistic is not significant. The SRMR is 0.3877 and the RMSEA is 0.1164. These are far from the conventional acceptance level of 0.05. However, the AIC, CAIC, and SBC values are all slightly smaller than the *constrained indirect effects* model, as shown in [Output 27.7.7](#). In fact, these information-theoretic fit indices suggest that the *partially constrained* model is the best model among all models that have been considered.

Output 27.7.11 Model Fit of the Partially Constrained Model for the Sales Data

Fit Summary	
Chi-Square	7.0575
Chi-Square DF	6
Pr > Chi-Square	0.3156
Standardized RMR (SRMR)	0.3877
RMSEA Estimate	0.1164
Akaike Information Criterion	15.0575
Bozdogan CAIC	21.6138
Schwarz Bayesian Criterion	17.6138

Output 27.7.12 shows the parameter estimates of the *partially constrained* model. Again, all variance and error variance parameters are statistically significant. However, the path effects are only marginally significant.

Output 27.7.12 Parameter Estimates of the Partially Constrained Model for the Sales Data

PATH List					
-----Path-----		Parameter	Estimate	Standard Error	t Value
q1 ==> q2		gamma	0.35546	0.18958	1.87497
q2 ==> q3		gamma	0.35546	0.18958	1.87497
q3 ==> q4		gamma	0.35546	0.18958	1.87497
Variance Parameters					
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value
Error	q2	evar	0.40601	0.11261	3.60555
	q3	evar	0.40601	0.11261	3.60555
	q4	_Parm1	2.29415	0.89984	2.54951
Exogenous	q1	_Parm2	0.33830	0.13269	2.54951

Which Model Should You Choose?

You fit various models in this example for the sales data. The fit summary of the models is shown in the following table:

	1	2	3	4	5	6
	Saturated	Direct and Indirect Effects	Indirect Effects	Constrained Indirect Effects	Constrained Indirect Effects and Error Variances	Partially Constrained
df	0	1	3	5	7	6
p-value	.	0.76	0.74	0.40	0.01	0.32
SRMR	0	0.03	0.09	0.21	1.50	0.39
RMSEA	.	0.00	0.00	0.05	0.37	0.12
AIC	20.00	18.09	15.24	15.16	25.78	15.06
CAIC	36.39	32.84	26.71	23.36	30.70	21.61
SBC	26.39	23.84	19.71	18.36	27.70	17.61

As discussed previously, the model fit chi-square test statistic always favors models with a lot of parameters. It does not take model parsimony into account. In particular, a saturated model (Model 1) always has a perfect fit. However, it does not explain the data in a concise way. Therefore, the model fit chi-square statistic is not used here for comparing the competing models.

The standardized root mean square residual (SRMR) also does not take the model parsimony into account. It tells you how the fitted covariance matrix is different from the observed covariance matrix in a certain

standardized way. Again, it always favors models with a lot of parameters. As shown in the preceding table, the more parameters (the fewer degrees of freedom) the model has, the smaller the SRMR is. A conventional criterion is to accept a model with SRMR less than 0.05. Applying this criterion, only the saturated model (Model 1) and the *direct and indirect effects* (Model 2) models are acceptable. The *indirect effects* model (Model 3) is marginally acceptable.

The root mean square error of approximation (RMSEA) fit index does take model parsimony into account. With the ‘RMSEA less than 0.05 criterion’, the *constrained indirect effects and error variances* model (Model 5) and the *partially constrained* model (Model 6) are not acceptable.

The information-theoretic fit indices such as the AIC, CAIC, and SBC also take model parsimony into account. All of these indices point to the *partially constrained* model (Model 6) as the best model among the competing models. However, because this model has a relatively bad absolute fit, as indicated by the large SRMR value (0.39), accepting this model is questionable. In addition, the information-theoretic fit indices of the *indirect effects* model (Model 3) and of the *constrained indirect effects* model (Model 4) are not too different from those of the *partially constrained* model (Model 6). The indirect effects model is especially promising because it has relatively small SRMR and RMSEA values. The drawback is that some path effect estimates in the indirect effects model are not significant. Perhaps collecting and analyzing more data might confirm these promising models with significant path effects.

You might not be able to draw a unanimous conclusion about the best model for the sales data of this example. Different fit indices in structural equation modeling do not always point to the same conclusions. The analyses in the current example show some of the complexity of structural equation modeling. Some interesting questions about model selections are:

- Do you choose a model based on a single fit criterion? Or, do you consider a set of model fit criteria to weigh competing models?
- Which fit index criterion is the most important for judging model fit?
- In selecting your “best” model, how do you take “chance” into account?
- How would you use your substantive theory to guide your model search?

The answers to these interesting research questions might depend on the context. Nonetheless, PROC CALIS can help you in the model selection process by computing various kinds of fit indices. (Only a few of these fit indices are shown in the output of this example. See the [FITINDEX](#) statement for a wide variety of fit indices that you can obtain from PROC CALIS.)

Alternative PATH Model Specifications for Variances and Covariances

The PATH modeling language of PROC CALIS is designed to map the path diagram representation into the PATH statement syntax efficiently. For any path that is denoted by a single-headed arrow in the path diagram, you can specify a path entry in the PATH statement. You can also specify double-headed arrows in the PATH statement.

Consider the preceding path diagram for the *partially constrained* model for the sales data. You use double-headed arrows to denote variances or error variances of the variables. The path diagram is shown in the following:

As discussed previously, you can use the PVAR statement to specify these variances or error variances as in following syntax:

```
pvar    q2 q3 = 2 * evar,
        q4 q1;
```

Alternatively, you can specify these double-headed arrows directly as paths in the PATH statement, as shown in the following statements:

```
proc calis data=sales;
  path    q1    ==> q2      = gamma,
          q2    ==> q3      = gamma,
          q3    ==> q4      = gamma,
          <==>  q2 q3      = 2 * evar,
          <==>  q4 q1;
run;
```

To specify the double-headed paths pointing to individual variables, you begin with the double-headed arrow notation `<==>`, followed by the list of variables. For example, in the preceding specification, the error variance of q4 and the variance of q1 are specified in the last path entry of the PATH statement. If you want to define the parameter names for the variances, you can add a parameter list after an equal sign in the path entries. For example, the error variances of q2 and q3 are denoted by the free parameter `evar` in a path entry in the PATH statement.

Alternatively, you can specify the double-headed arrow paths literally in a PATH statement, as shown in the following equivalent specification:

```
proc calis data=sales;
  path    q1    ==> q2      = gamma,
          q2    ==> q3      = gamma,
          q3    ==> q4      = gamma,
          q2    <==> q2      = evar,
          q3    <==> q3      = evar,
          q4    <==> q4,
          q1    <==> q1;
run;
```

For example, the path entry `q1 <==> q1` specifies the variance of q1. It is an unnamed free parameter in the model.

Output 27.7.13 show the parameter estimates for this alternative specification method. All these estimates match exactly those with the PVAR statement specification, as shown in Output 27.7.12. The only difference is that all estimation results are now presented under one PATH List, as shown in Output 27.7.13, instead of as two tables as shown in Output 27.7.12.

Output 27.7.13 Path Estimates of the Partially Constrained Model for the Sales Data

PATH List						
-----Path-----			Parameter	Estimate	Standard Error	t Value
q1	==>	q2	gamma	0.35546	0.18958	1.87497
q2	==>	q3	gamma	0.35546	0.18958	1.87497
q3	==>	q4	gamma	0.35546	0.18958	1.87497
q2	<==>	q2	evar	0.40601	0.11261	3.60555
q3	<==>	q3	evar	0.40601	0.11261	3.60555
q4	<==>	q4	_Parm1	2.29415	0.89984	2.54951
q1	<==>	q1	_Parm2	0.33830	0.13269	2.54951

The double-headed arrow path syntax applies to covariance specification as well. For example, the following PATH statement specifies the covariances among variables x1–x3:

```
path    x2 <==> x1,
        x3 <==> x1,
        x3 <==> x2;
```

In the beginning of the current example, you use the following path diagram to represent the multiple regression model for the sales data:

The following statements specify the multiple regression model:

```
proc calis data=sales;
  path    q1 q2 q3 ==> q4;
run;
```

You do not represent the covariances and variances among the exogenous variables explicitly in the path diagram, nor in the PATH statement specification. However, PROC CALIS generates them as free parameters by default. Some researchers might prefer to represent the exogenous variances and covariances explicitly in the path diagram, as shown in the following path diagram:

In the path diagram, there are three single-head arrows and seven double-headed arrows. These 10 paths represent the 10 parameters in the covariance structure model. To represent all these parameters in the PATH model specification, you can use the following statements:

```
proc calis data=sales;
  path   q1   ==>  q4   ,
         q2   ==>  q4   ,
         q3   ==>  q4   ,
         q1   <==> q1   ,
         q2   <==> q2   ,
         q3   <==> q3   ,
         q1   <==> q2   ,
         q2   <==> q3   ,
         q1   <==> q3   ,
         q4   <==> q4   ;
run;
```

The first three path entries in the PATH statement reflect the single-headed paths in the path diagram. The next six path entries in the PATH statement reflect the double-headed paths among the exogenous variables q1–q3 in the path diagram. The last path entry in the PATH statement reflects the double-headed path attached to the endogenous variable q4 in the path diagram. With this specification, the parameter estimates for the multiple regression model are all shown in [Output 27.7.14](#).

Output 27.7.14 Path Estimates of the Multiple Regression Model for the Sales Data

PATH List						
-----Path-----	Parameter	Estimate	Standard Error	t Value		
q1 ==> q4	_Parm01	0.55980	0.64938	0.86205		
q2 ==> q4	_Parm02	0.58946	0.84558	0.69711		
q3 ==> q4	_Parm03	0.88290	0.51635	1.70988		
q1 <==> q1	_Parm04	0.33830	0.13269	2.54951		
q2 <==> q2	_Parm05	0.22466	0.08812	2.54951		
q3 <==> q3	_Parm06	0.60633	0.23782	2.54951		
q1 <==> q2	_Parm07	0.0001978	0.07646	0.00259		
q2 <==> q3	_Parm08	0.12653	0.10821	1.16931		
q1 <==> q3	_Parm09	0.03610	0.12601	0.28649		
q4 <==> q4	_Parm10	1.84128	0.72221	2.54951		

These estimates are the same as those in [Output 27.7.2](#), where the estimates are shown in three different tables, instead of in one table for all paths as in [Output 27.7.14](#).

Sometimes, specification of some single-headed and double-headed paths can become very laborious. Fortunately, PROC CALIS provides shorthand notation for the PATH statement to make the specification more efficient. For example, a more concise way to specify the preceding multiple regression model is shown in the following statements:

```
proc calis data=sales;
  path    q1 q2 q3 ==> q4 ,
          <==> [q1-q3] ,
          <==> q4 ;
run;
```

The first path entry `q1 q2 q3 ==> q4` in the PATH statement represents the three single-headed arrows in the path diagram. The second path entry `<==> [q1-q3]` generates the variances and covariances for the set of variables specified in the rectangular brackets. The last path entry represents the error variance of `q4`. Consequently, expanding the preceding shorthand specification generates the following specification:

```
proc calis data=sales;
  path    q1    ==> q4 ,
          q2    ==> q4 ,
          q3    ==> q4 ,
          q1    <==> q1 ,
          q2    <==> q1 ,
          q2    <==> q2 ,
          q3    <==> q1 ,
          q3    <==> q2 ,
          q3    <==> q3 ,
          q4    <==> q4 ;
run;
```

Notice that the third through ninth path entries correspond to the lower triangular elements of the covariance matrix for `q1-q3`.

CAUTION: The double-headed path specification does *not* represent a reciprocal relationship. That is, the following statement specifies the covariance between `x2` and `x1`:

```
path    x2 <==> x1,
```

But the following statement specifies that `x2` and `x1` have reciprocal causal effects:

```
path    x2 <==> x1,
        x1 ==> x2;
```

The reciprocal causal effects specification reflects the following path diagram:

Example 27.8: Measurement Error Models

In this example, you use PROC CALIS to fit some measurement error models. You use latent variables to define “true” scores variables that are measured without errors. You constrain parameters by using parameter names or fixed values in the PATH model specification.

Consider a simple linear regression model with dependent variable y and predictor variable x . The path diagram for this simple linear regression model is depicted as follows:

Suppose you have the following SAS data set for the regression analysis of y on x :

```

data measures;
  input x y @@;
  datalines;
7.91736 13.8673 6.10807 11.7966 6.94139 12.2174
7.61290 12.9761 6.77190 11.6356 6.33328 11.7732
7.60608 12.8040 6.65642 12.8866 6.26643 11.9382
7.32266 13.2590 5.76977 10.7654 5.62881 11.5041
7.57418 13.2502 7.17305 13.3416 8.23123 13.9876
7.17199 13.1750 8.04604 14.5968 5.77692 11.5077
5.72741 11.3299 6.66033 12.5159 7.14944 12.4988
7.51832 12.3588 5.48877 11.2211 7.50323 13.3735
7.15814 13.1556 7.35485 13.8457 8.91648 14.4929
5.37445 9.6366 6.00419 11.7654 6.89546 13.1493
;
  
```

This data set contains 30 observations for the x and y variables. You can fit the simple linear regression model to the measures data by the PATH model specification of PROC CALIS, as shown in the following statements:

```

proc calis data=measures;
  path
    x ==> y;
run;
  
```

Output 27.8.1 shows that the regression coefficient estimate (denoted as `_Parm1` in the PATH List) is 1.1511 (standard error = 0.1002).

Output 27.8.1 Estimates of the Linear Regression Model for the Measures Data

PATH List					
-----Path-----	Parameter	Estimate	Standard Error	t Value	
x ==> y	_Parm1	1.15112	0.10016	11.49241	

Output 27.8.1 *continued*

Variance Parameters					
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value
Exogenous	x	_Add1	0.79962	0.20999	3.80789
Error	y	_Add2	0.23265	0.06110	3.80789

You can also do the simple linear regression by PROC REG by the following statement:

```
proc reg data=measures;
  model y = x;
run;
```

Output 27.8.2 shows that PROC REG essentially gives the same regression coefficient estimate with a similar standard error estimate. The discrepancy in the standard error estimates produced by the two procedures is due to the different variance divisors in computing standard errors in the two procedures. But the discrepancy is negligible when the sample size becomes large.

Output 27.8.2 PROC REG Estimates of the Linear Regression Model for the Measures Data

Parameter Estimates					
Variable	DF	Parameter Estimate	Standard Error	t Value	Pr > t
Intercept	1	4.62455	0.70790	6.53	<.0001
x	1	1.15112	0.10194	11.29	<.0001

There are two main differences between PROC CALIS and PROC REG regarding the parameter estimation results. First, PROC CALIS does not give the estimate of the intercept because by default PROC CALIS analyzes only the covariance structures. Therefore, it does not estimate the intercept. To obtain the intercept estimate, you can add the MEANSTR option in the PROC CALIS statement, as is shown in [Example 27.9](#). Second, in [Output 27.8.1](#) of PROC CALIS, the variance estimate of x and the error variance estimate of y are shown. The corresponding results are not shown as parameter estimates in the PROC REG results. In PROC CALIS, these two variances are model parameters in covariance structure analysis. PROC CALIS adds these variances as default parameters. You can also represent these two variance parameters by double-headed arrows in the path diagram, as shown in the following:

The two double-headed arrows attached to x and y represent the variances. Although it is not necessary to specify these default parameters, you can use the PVAR statement to specify them explicitly, as shown in the following statements:

```

proc calis data=measures meanstr;
  path
    x ==> y;
  pvar
    x y;
run;

```

In the PROC CALIS statement, you specify the MEANSTR option to request the analysis of mean structures together with covariance structures. [Output 27.8.3](#) shows the estimation results.

Output 27.8.3 Estimates of the Measurement Error Model with Error in x

PATH List						
-----Path-----		Parameter	Estimate	Standard Error	t Value	
x	==> y	_Parm1	1.15112	0.10016	11.49241	
Variance Parameters						
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value	
Exogenous Error	x	_Parm2	0.79962	0.20999	3.80789	
	y	_Parm3	0.23265	0.06110	3.80789	
Means and Intercepts						
Type	Variable	Parameter	Estimate	Standard Error	t Value	
Intercept	y	_Add1	4.62455	0.69578	6.64658	
Mean	x	_Add2	6.88865	0.16605	41.48504	

The regression coefficient estimate and the variance estimates are the same as those in [Output 27.8.1](#). However, in [Output 27.8.3](#), there is an additional table for the mean and intercept estimates. The intercept estimate for y is 4.6246 (standard error=0.6958), which match closely to the results obtained from PROC REG, as shown in [Output 27.8.2](#).

Measurement Error in x

PROC CALIS can also handle more complicated regression situations where the variables are measured with errors. This is beyond the application of PROC REG.

Suppose that the predictor variable x is measured with error and from prior studies you know that the size of the measurement error variance is about 0.019. You can use PROC CALIS to incorporate this information into the model. First, think of the measured variable x as composed of two components: one component is the “true” score measure F_x and the other is the measurement error e_1 . Both of these components are not

observed (that is, latent) but they sum up to yield x . That is,

$$x = Fx + e1$$

Because x is contaminated with measurement error, what you are interested in knowing is the regression effect of the true score Fx on x . The following path diagram represents this regression scenario:

In path diagrams, latent variables are usually represented by circles or ovals, while observed variables are represented by rectangles. In the current path diagram, Fx is a latent variable and is represented by a circle. The other two variables are observed variables and are represented by rectangles. There are five arrows in the path diagram. Two of them are single-headed arrows that represent functional relationships, while the other three are double-headed arrows that represent variances or error variances. Two paths are labeled with fixed values. The path effect from Fx to x is fixed at 1, as assumed in the measurement error model. The error variance for measuring x is fixed at 0.019 due to the prior knowledge about the measurement error variance. The remaining three arrows represent free parameters in the model: the regression coefficient of y on Fx , the variance of Fx , and the error variance of y . The following statements specify the model for this path diagram:

```

proc calis data=measures;
  path
    x <=== Fx = 1.,
    Fx ==> y;
  pvar
    x = 0.019,
    Fx, y;
run;

```

You specify all the single-headed paths in the PATH statement and all the double-headed arrows in the PVAR statement. For paths with fixed values, you put the equality at the back of the specifications to tell PROC CALIS about the fixed values. For example, the path coefficient in the path $x <=== Fx$ is fixed at 1 and the error variance for x is fixed at 0.019. All other specifications represent unnamed free parameters in the model.

[Output 27.8.4](#) shows the estimation results. The effect of Fx on y is 1.1791 (standard error=0.1029). This effect is slightly greater than the corresponding effect (1.1511) of x on y in the preceding model where the measurement error of x has not been taken into account, as shown in [Output 27.8.3](#).

Output 27.8.4 Estimates of the Measurement Error Model with Error in x

PATH List						
-----Path-----	Parameter	Estimate	Standard Error	t Value		
x <=== Fx		1.00000				
Fx ==> y	_Parm1	1.17914	0.10288	11.46153		

Output 27.8.4 continued

Variance Parameters					
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value
Error	x		0.01900		
Exogenous	Fx	_Parm2	0.78062	0.20999	3.71741
Error	y	_Parm3	0.20686	0.06126	3.37667

Measurement Errors in x and y

Measurement error can occur in the y variable too. Suppose that both x and y are measured with errors. From prior studies, the measurement error variance of x is known to be 0.019 (as in the preceding modeling scenario) and the measurement error variance of y is known to be 0.022. The following path diagram represents the current modeling scenario:

In the current path diagram the true score variable Fy and its measurement indicator y have the same kind of relationship as the relationship between the true score variable Fx and its measurement indicator x in the previous description. The error variance for measuring y is treated as a known constant 0.022. You can transcribe this path diagram easily to the following PROC CALIS specification:

```

proc calis data=measures;
  path
    x <== Fx = 1.,
    Fx ==> Fy ,
    Fy ==> y = 1.;
  pvar
    x = 0.019,
    y = 0.022,
    Fx Fy;
run;

```

Again, you specify all the single-headed paths in the PATH statement and the double-headed paths in the PVAR statement. You provide the fixed parameter values by appending the required equalities after the individual specifications.

Output 27.8.5 shows the estimation results of the model with measurement errors in both x and y. The effect of Fx on Fy is 1.1791 (standard error=0.1029). This is essentially the same effect of Fx on y as in the preceding measurement model in which no measurement error in y is assumed.

Output 27.8.5 Estimates of the Measurement Error Model with Errors in x and y

PATH List					
-----Path-----		Parameter	Estimate	Standard Error	t Value
x	<=== Fx		1.00000		
Fx	==> Fy	_Parm1	1.17914	0.10288	11.46153
Fy	==> y		1.00000		
Variance Parameters					
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value
Error	x		0.01900		
	y		0.02200		
Exogenous Error	Fx	_Parm2	0.78062	0.20999	3.71741
	Fy	_Parm3	0.18486	0.06126	3.01755

The estimated error variance for Fy in the current model is 0.1849 and the measurement error variance of y is fixed at 0.022, as shown in the last table of [Output 27.8.5](#). The sum is 0.2069, which is the same amount of error variance for y in the preceding model with measurement error assumed only in x. Hence, the assumption of the measurement error in y does not change the structural effect of Fx on y (same amount of effect Fx on Fy, which is 1.1791). It only changes the variance components of y. In the preceding model with measurement error assumed only in x, the total error variance in y is 0.2069. In the current model, this total error variance is partitioned into the measurement error variance (which is fixed at 0.022) and the error variance in the regression on Fx (which is estimated at 0.1849).

Linear Regression Model as a Special Case of Structural Equation Model

By using the current measurement error model as an illustration, it is easy to see that the structural equation model is a more general model that includes the linear regression model as a special case. If you restrict the measurement error variances in x and y to zero, the measurement error model (which represents the structural equation model in this example) reduces to the linear regression model. That is, the path diagram becomes:

You can then specify the PATH model by the following statements:

```

proc calis data=measures;
  path
    x <=== Fx = 1.,
    Fx ==> Fy ,
    Fy ==> y = 1.;
  pvar

```

```

      x  = 0.,
      y  = 0.,
      Fx Fy;
run;

```

Output 27.8.6 shows the estimation results of this measurement error model with zero measurement errors. The estimate of the regression coefficient is 1.1511, which is essentially the same result as in Output 27.8.2 by using PROC REG.

Output 27.8.6 Estimates of the Measurement Error Model with Zero Measurement Errors

PATH List						
-----Path-----			Parameter	Estimate	Standard Error	t Value
x	<===	Fx		1.00000

Error	x		0			
	y		0			
Exogenous	Fx	_Parm2	0.79962	0.20999	3.80789	
Error	Fy	_Parm3	0.23265	0.06110	3.80789	

This example shows that you can apply PROC CALIS to fit measurement error models. You treat true scores variables as latent variables in the structural equation model. The linear regression model is a special case of the structural equation model (or measurement error model) where measurement error variances are assumed to be zero. Structural equation modeling by PROC CALIS is not limited to this simple modeling scenario. PROC CALIS can treat more complicated measurement error models. In Example 27.9 and Example 27.10, you fit measurement error models with parameter constraints and with more than one predictor. You can also fit measurement error models with correlated errors.

Example 27.9: Testing Specific Measurement Error Models

In Example 27.8, you used the PATH modeling language of PROC CALIS to fit some basic measurement error models. In this example, you continue to fit the same kind of measurement error models but you restrict some model parameters to test some specific hypotheses.

This example uses the same data set as is used in [Example 27.8](#). This data set contains 30 observations for the x and y variables. The general measurement error model with measurement errors in both x and y is shown in the following path diagram:

In the path diagram, two paths are fixed with a path coefficient of 1. They are required in the model for representing the relationships between true scores (latent) and measured indicators (observed). In [Example 27.8](#), you consider several different modeling scenarios, all of which require you to make some parameter restrictions to estimate the models. You fix the measurement error variances to certain values that are based on prior knowledge or studies. Without those fixed error variances, those models would have been overparameterized and the parameters would not have been estimable.

For example, in the current path diagram, five of the single- or double-headed paths are not labeled with fixed numbers. Each of these paths represents a free parameter in the model. However, in the covariance structure model analysis, you fit these free parameters to the three nonredundant elements of the sample covariance matrix, which is a 2×2 symmetric matrix. Hence, to have an identified model, you can at most have three free parameters in your covariance structure model. However, the path diagram shows that you have five free parameters in the model. You must introduce additional parameter constraints to make the model identified.

If you do not have prior knowledge about the measurement error variances (as those described in [Example 27.8](#)), then you might need to make some educated guesses about how to restrict the overparameterized model. For example, if x and y are of the same kind of measurements, perhaps you can assume that they have an equal amount of measurement error variance. Furthermore, if the measurement errors have been taken into account, in some physical science studies you might be able to assume that the relationship between the true scores Fx and Fy is almost deterministic, resulting in a near zero error variance of Fy .

The assumptions here are not comparable to prior knowledge or studies about the measurement error variances. If you suppose they are reasonable enough in a particular field, you can use these assumptions to give you an identified model to work with (at least as an exploratory study) when the required prior knowledge is lacking. The following path diagram incorporates these two assumptions in the measurement error model:

In the path diagram, you use `evar` to denote the error variances of x and y . This implicitly constrains the two error variances to be equal. The error variance of Fy is labeled zero, indicating a fixed parameter value and a deterministic relationship between x and y . You can transcribe this path diagram into the following PATH modeling specification:

```

proc calis data=measures;
  path
    x <=== Fx = 1.,
    Fx ==> Fy ,
    Fy ==> y = 1.;
  pvar
    x = evar,
    y = evar,
    Fy = 0.,
    Fx;
run;

```

In the PVAR statement, you specify the same parameter name `evar` for the error variances of `x` and `y`. This way their estimates are constrained to be the same in the estimation. In addition, the error variance for `Fy` is fixed at zero, which reflects the “near-deterministic” assumption about the relationship between `Fx` and `Fy`. These two assumptions effectively reduce the overparameterized model by two parameters so that the new model is just-identified and estimable.

Output 27.9.1 shows the estimation results. The estimated effect of `Fx` on `Fy` is 1.3028 (standard error = 0.1134). The measurement error variances for `x` and `y` are both estimated at 0.0931 (standard error = 0.0244).

Output 27.9.1 Estimates of the Measurement Error Model with Equal Measurement Error Variances

PATH List						
-----Path-----			Parameter	Estimate	Standard Error	t Value
x	<===	Fx		1.00000		
Fx	==>	Fy	_Parm1	1.30275	0.11336	11.49241
Fy	==>	y		1.00000		
Variance Parameters

Error	x	evar	0.09307	0.02444	3.80789	
	y	evar	0.09307	0.02444	3.80789	
	Fy		0			
Exogenous	Fx	_Parm2	0.70655	0.20962	3.37057	

Testing the Effect of Fx on Fy

Suppose you are interested in testing the hypothesis that the effect of `Fx` on `Fy` (that is, the regression slope) is 1. The following path diagram represents the model under the hypothesis:

Now you label the path from Fx to Fy with a fixed constant 1, which reflects the hypothesis you want to test. You can transcribe the current path diagram easily into the following PROC CALIS specification:

```

proc calis data=measures;
  path
    x <=== Fx = 1.,
    Fx ==> Fy = 1., /* Testing a fixed constant effect */
    Fy ==> y = 1.;
  pvar
    x = evar,
    y = evar,
    Fy = 0.,
    Fx;
run;

```

Output 27.9.2 shows the model fit chi-square statistic. The model fit chi-square test here essentially is a test of the null hypothesis of the constant effect at 1 because the alternative hypothesis is a saturated model. The chi-square value is 8.1844 ($df = 1$, $p = .0042$), which is statistically significant. This means that the hypothesis of constant effect at 1 is rejected.

Output 27.9.2 Fit Summary for Testing Constant Effect

Fit Summary	
Chi-Square	8.1844
Chi-Square DF	1
Pr > Chi-Square	0.0042

Output 27.9.3 shows the estimates under this restricted model. In the first table of Output 27.9.3, all path effects or coefficients are fixed at 1. In the second table of Output 27.9.3, estimates of the error variances are 0.1255 (standard error = 0.0330) for both x and y. The error variance of Fy is a fixed zero, as required in the hypothesis. The variance estimate of Fx is 0.9205 (standard error = 0.2587).

Output 27.9.3 Estimates of Constant Effect Measurement Error Model

PATH List			
-----Path-----	Estimate	Standard Error	t Value
x <=== Fx	1.00000		
Fx ==> Fy	1.00000		
Fy ==> y	1.00000		

Output 27.9.3 continued

Variance Parameters					
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value
Error	x	evar	0.12545	0.03295	3.80789
	y	evar	0.12545	0.03295	3.80789
	Fy	0			
Exogenous	Fx	_Parm1	0.92046	0.25872	3.55771

Testing a Zero Intercept

Suppose you are interested in testing the hypothesis that the intercept for the regression of Fy on Fx is zero, while the regression effect is freely estimated. Because the intercept parameter belongs to the mean structures, you need to specify this parameter in PROC CALIS to test the hypothesis.

There are two ways to include the mean structure analysis. First, you can include the MEANSTR option in the PROC CALIS statement. Alternatively, you can use the MEAN statement to specify the means and intercepts in the model. The following statements specify the model under the zero intercept hypothesis:

```
proc calis data=measures;
  path
    x <=== Fx = 1.,
    Fx ==> Fy , /* regression effect is freely estimated */
    Fy ==> y = 1.;
  pvar
    x = evar,
    y = evar,
    Fy = 0.,
    Fx;
  mean
    x y = 0. 0., /* Intercepts are zero in the measurement error model */
    Fy = 0., /* Fixed to zero under the hypothesis */
    Fx; /* Mean of Fx is freely estimated */
run;
```

In the PATH statement, the regression effect of Fx on Fy is freely estimated. In the MEAN statement, you specify the means or intercepts of the variables. Each variable in your measurement error model has either a mean or an intercept (but not both) to specify. If a variable is exogenous (independent), you can specify its mean in the MEAN statement. Otherwise, you can specify its intercept in the MEAN statement. Variables x and y in the measurement error model are both endogenous. They are measured indicators of their corresponding true scores Fx and Fy. Under the measurement error model, their intercepts are fixed zeros. The intercept for Fy is zero under the current hypothesized model. The mean of Fx is freely estimated under the model. This parameter is specified in the MEAN statement but is not named.

Output 27.9.4 shows the model fit chi-square statistic. The chi-square value is 10.5397 ($df = 1$, $p = .0012$), which is statistically significant. This means that the zero intercept hypothesis for the regression of Fy on Fx is rejected.

Output 27.9.4 Fit Summary for Testing Zero Intercept

Fit Summary		
Chi-Square	10.5397	
Chi-Square DF	1	
Pr > Chi-Square	0.0012	

Output 27.9.5 shows the estimates under the hypothesized model. The effect of Fx on Fy is 1.8169 (standard error = 0.0206). In the last table of Output 27.9.5, the estimate of the mean of Fx is 6.9048 (standard error = 0.1388). The intercepts for all other variables are fixed at zero under the hypothesized model.

Output 27.9.5 Estimates of the Zero Intercept Measurement Error Model

PATH List						
-----Path-----			Parameter	Estimate	Standard Error	t Value
x	<==	Fx		1.00000

	y		0			
	Fy		0			
Mean	Fx	_Parm3	6.90483	0.13881	49.74314	

Measurement Model with Means and Intercepts Freely Estimated

In the preceding model, you fit a restricted regression model with a zero intercept. You reject the null hypothesis and conclude that this intercept is significantly different from zero. The alternative hypothesis is a saturated model with the intercept freely estimated. The model under the alternative hypothesis is specified in the following statements:

```

proc calis data=measures;
  path
    x <=== Fx = 1.,
    Fx ===> Fy ,
    Fy ===> y = 1.;
  pvar
    x = evar,
    y = evar,
    Fy = 0.,
    Fx;
  mean
    x y = 0. 0.,
    Fy Fx;
run;

```

Output 27.9.6 shows that model fit chi-square statistic is zero. This is expected because you are fitting a measurement error model with saturated mean and covariance structures.

Output 27.9.6 Fit Summary of the Saturated Measurement Model with Mean Structures

Fit Summary	
Chi-Square	0.0000
Chi-Square DF	0
Pr > Chi-Square	.

Output 27.9.7 shows the estimates under the measurement model with saturated mean and covariance structures. The effect of Fx on Fy is 1.3028 (standard error=0.1134), which is considerably smaller than the corresponding estimate in the restricted model with zero intercept, as shown in Output 27.9.5. The intercept estimate of Fy is 3.5800 (standard error = 0.7864), with a significant *t* value of 4.55.

Output 27.9.7 Estimates of the Saturated Measurement Model with Mean Structures

PATH List						
-----Path-----			Parameter	Estimate	Standard Error	t Value
x	<===	Fx		1.00000		
Fx	===>	Fy	_Parm1	1.30275	0.11336	11.49241
Fy	===>	y		1.00000		
Variance Parameters

Output 27.9.7 *continued*

Means and Intercepts					
Type	Variable	Parameter	Estimate	Standard Error	t Value
Intercept	x		0		
	y		0		
Mean	Fy	_Parm3	3.57998	0.78641	4.55234
	Fx	_Parm4	6.88865	0.16605	41.48504

In this example, you fit some measurement error models with some parameter constraints that reflect the hypothesized models of interest. You can set equality constraints by simply providing the same parameter names in the PATH model specification of PROC CALIS. You can also fix parameters to constants. In the MEAN statement, you can specify the intercepts and means of the variables in the measurement error models. You can apply all these techniques to more complicated measurement error models with multiple predictors, as shown in [Example 27.10](#), where you also fit measurement error models with correlated errors.

Example 27.10: Measurement Error Models with Multiple Predictors

In [Example 27.8](#) and [Example 27.9](#), you fit various measurement error models with only one predictor. This example illustrates the case in which you have more than one predictor, all measured with errors. The measurement errors might also be correlated.

The data from 37 observations are summarized in a covariance matrix as shown in the following SAS DATA step:

```
data multiple(type=cov);
  input _type_ $ 1-4 _name_ $ 6-8 @10 y x1 x2 x3;
  datalines;
mean      0.93   1.33   1.34   4.11
cov y      1.31   .       .       .
cov x1     1.24   1.42   .       .
cov x2     0.21   0.18   1.15   .
cov x3     3.91   4.21   0.58   14.11
;
```

In this data set, four variables are measured. Variables x1–x3 are predictors of y. Instead of the raw data, you can input the sample covariance matrix in the form of a SAS data set for PROC CALIS to analyze.

You assume all of these variables in the data set are measured with errors. From prior studies, you establish the knowledge about the measurement errors of these variables. You create the true score counterparts for each of these variables in the same manner as you do in [Example 27.8](#) and [Example 27.9](#). The following path diagram represents your measurement error model for the data:

In the path diagram, variables F1–F3 and Fy are latent variables that represent the true score for the measured indicators x1–x3 and y, respectively. All paths from the true scores to the corresponding measured indicators are labeled with the fixed constant 1, as required by the measurement model. Each measured indicator is attached with a double-headed arrow that indicates the error variance. Because you have knowledge about these measurement error variances, you put fixed constant values adjacent to these double-headed arrows. For example, the measurement error variance of y is 0.02 and the measurement error variance of x3 is 0.15. The path diagram also indicates that the paths from F1–F3 to Fy and the error variance for Fy are free parameters to estimate in the model.

Notice that for brevity the variances and covariances among the three exogenous true score variables F1–F3 are not represented in the path diagram. These six variance and covariance parameters could have been represented by double-headed arrows in the path diagram. However, because PROC CALIS always assumes the exogenous variances and covariances as default model parameters, this information is not represented to reduce clutter in the path diagram.

You can transcribe the path diagram easily to the following PATH model specification:

```

proc calis data=multiple nobs=37;
  path
    Fy <=== F1 F2 F3,
    F1 ===> x1 = 1.,
    F2 ===> x2 = 1.,
    F3 ===> x3 = 1.,
    Fy ===> y = 1.;
  pvar
    x1 x2 x3 y = .02 .03 .15 .02,
    Fy;
run;

```

In the first entry of the PATH statement, you specify that F1–F3 predicts Fy. In the next four path entries you specify the measurement model for the true scores and how they are related to the observed variables. In the PVAR statement, you specify all the known measurement error variances for the observed variables. They are all fixed constants in the model. In the last entry in the PVAR statement, you specify the error variance of Fy as a free (unnamed) parameter. You could have omitted this entry because error variances for all endogenous variables in the PATH model are free parameters by default. Setting these default parameters explicitly as free parameters would not affect model fitting.

Output 27.10.1 shows the parameter estimates of the model. The path coefficient or effect from F2 to Fy is not significant, while the other two path coefficients are at least marginally significant.

Output 27.10.1 Parameter Estimates of the Measurement Model with Multiple Predictors

PATH List					
-----Path-----	Parameter	Estimate	Standard Error	t Value	
Fy <=== F1	_Parm1	0.46507	0.22682	2.05035	
Fy <=== F2	_Parm2	0.04123	0.07069	0.58323	
Fy <=== F3	_Parm3	0.13812	0.07175	1.92490	
F1 ===> x1		1.00000			
F2 ===> x2		1.00000			
F3 ===> x3		1.00000			
Fy ===> y		1.00000			

Variance Parameters					
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value
Error	x1		0.02000		
	x2		0.03000		
	x3		0.15000		
	y		0.02000		
	Fy	_Parm4	0.16461	0.04522	3.64028
Exogenous	F1	_Add1	1.40000	0.33470	4.18289
	F2	_Add2	1.12000	0.27106	4.13196
	F3	_Add3	13.96000	3.32576	4.19754

Covariances Among Exogenous Variables					
Var1	Var2	Parameter	Estimate	Standard Error	t Value
F2	F1	_Add4	0.18000	0.21508	0.83688
F3	F1	_Add5	4.21000	1.02416	4.11070
F3	F2	_Add6	0.58000	0.67829	0.85509

The second table of [Output 27.10.1](#) shows the variance estimates. As specified in the model, all measurement error variances for the observed variables are fixed constants. The error variance of Fy is 0.1646 (standard error = 0.0452). Although you do not specify them in the PATH model specification, variances of F1–F3 are free parameters in the model. The second table of [Output 27.10.1](#) shows their estimates. The last table of [Output 27.10.2](#) shows the covariances among the latent true scores. Only the covariance between F3 and F1 is significant.

PROC CALIS not only can handle measurement error variance with multiple true score predictors, but it also can handle correlated errors. Suppose that the measurement errors for variables x1 and x2 are correlated. From prior studies, you determine that their covariance is 0.01. The path diagram with this new piece of information added is shown in the following:

In the path diagram, the double-headed arrow that connects x_1 and x_2 represents the covariance between the error terms for the two variables. The value attached to this double-headed arrow is 0.01, which represents a fixed constant in the model. The PATH model specification is similar to the preceding specification, with one more entry added in the PCOV statement, as shown in the following statements:

```
proc calis data=multiple nob=37;
  path
    Fy <=== F1 F2 F3,
    F1 <==> x1 = 1.,
    F2 <==> x2 = 1.,
    F3 <==> x3 = 1.,
    Fy <==> y = 1.;
  pvar
    x1 x2 x3 y = .02 .03 .15 .02,
    Fy;
  pcov
    x1 x2 = 0.01;
run;
```

Except for the PCOV statement specification, everything else is the same as in the preceding specification. In the PCOV statement, you can specify covariance or error covariances between exogenous or endogenous variables. In the current model, because both x_1 and x_2 are endogenous in the model, the specification is for their error covariance, which is fixed at 0.01 as required.

Output 27.10.2 shows the parameter estimates of the measurement model with correlated errors. The estimates do not change much from the preceding analysis in which correlated errors is not assumed. Perhaps the correlation between the errors in the current model is so small that it is ignorable. The last table in Output 27.10.2 shows the covariance estimates among errors. This table is unique to the current model. It shows that the measurement errors for x_1 and x_2 have a covariance of 0.01, which is treated as a fixed constant in the current model.

Output 27.10.2 Parameter Estimates of the Measurement Model with Multiple Predictors: Correlated Errors

This example shows how you can use PROC CALIS to fit measurement error models with multiple true score predictors. You can also fit models with correlated errors. The model specification tool is the PATH modeling language, which ties closely to the path diagram representations.

However, some researchers might prefer to use linear equations to represent the measurement error models. PROC CALIS provides the LINEQS modeling language for specifying the measurement error models, or

mean and covariance structure models in general. [Example 27.11](#) illustrates the LINEQS model specification of the measurement error models.

Example 27.11: Measurement Error Models Specified As Linear Equations

In [Example 27.8](#), you fit a simple measurement error model with errors in both of the predictor variable x and the outcome variable y . From prior studies, the measurement error variance of x is 0.019 and the measurement error variance of y is 0.022. You use the following path diagram to represent the model:

With this path diagram, you use the PATH modeling language of PROC CALIS to specify the model, as shown in the following:

```

proc calis data=measures;
  path
    x <=== Fx = 1.,
    Fx ==> Fy ,
    Fy ==> y = 1.;
  pvar
    x = 0.019,
    y = 0.022,
    Fx Fy;
run;
  
```

In the path diagram and in the PATH model specification, there are no explicit representations of the error terms in the model. You express the error variances of x , y , and Fy as partial variances of the endogenous variables. In the path diagram, you represent these partial variances by the double-headed arrows. Correspondingly, in the PATH statement of PROC CALIS, you specify these partial variances in the PVAR statement.

In practice, some researchers might prefer to express the error terms in the model explicitly. For example, with the error terms added to the preceding measurement error model, the new path diagram becomes:

In the path diagram, you add paths from error variables $e1$, $e2$, and d to the endogenous variables x , y , and Fy , respectively. All these paths from the error terms have a fixed path coefficient of 1. The error variances are represented by double-headed arrows directly attached to them. For example, the variance of $e1$ is fixed at 0.019, and the variance of $e2$ is fixed at 0.022. The variance of d , which is sometime called

the disturbance, is a free unnamed parameter in the path diagram. Similarly, the variance of Fx is a free unnamed parameter in the model.

Corresponding to this new path diagram, you can use the LINEQS modeling language for specifying your model in PROC CALIS, as shown in the following statements:

```
proc calis data=measures;
  lineqs
    x   = 1. * Fx + e1,
    y   = 1. * Fy + e2,
    Fy  =    * Fx + d;
  variance
    e1  = 0.019,
    e2  = 0.022,
    Fx d;
run;
```

The LINEQS model specification in PROC CALIS emphasizes the linear equation input. In each of the linear equations in the LINEQS statement, you specify an endogenous variable and how it is related to other variables. An endogenous variable in the path diagram is a variable that has at least one single-headed arrow pointing to it. You need to list all endogenous variables on the left-hand side of the linear equations of the LINEQS statement. In the current model, variables x , y , and Fy are endogenous, and therefore you specify three linear equations in the LINEQS statement. The first two equations represent the measurement model for the observed variables, while the third equation represents the structural equation of the model. Notice that in the third equation, you do not specify the path coefficient that is attached to Fx . PROC CALIS treats unspecified path coefficients as free parameters. The effect of Fx on Fy is freely estimated, as required in the path diagram representation.

In the VARIANCE statement, you specify the variances of the exogenous variables in the model. The specifications in the VARIANCE statement of the LINEQS model are very similar to those in the PVAR statement of the PATH model. The main difference is the use of error variable names in the VARIANCE statement. With the LINEQS model specification, you can only specify exogenous variables in the VARIANCE statement. Hence, you must specify the error variables $e1$, $e2$, and d in the VARIANCE statement of the LINEQS model, instead of the corresponding endogenous variables x , y , and Fy in the PVAR statement of the PATH model.

Output 27.11.1 shows the parameter estimates of the LINEQS model.

Output 27.11.1 LINEQS Parameter Estimates of the Measurement Model for the Measures Data

Linear Equations				
x	=	1.0000 Fx	+	1.0000 $e1$

Error	Fy	_Parm3	0.18486	0.06126		3.01755

You can use either the LINEQS or PATH model specification in PROC CALIS for your analysis problems. They give you the same estimation results.

So far the measurement error model is concerned with one predictor. With more predictors in the model, you might also want to model the correlated measurement errors in the x variables. You can analyze this kind of model by using the PATH model specification, as shown in [Example 27.10](#). With measurement error terms explicitly assumed, you can also use the LINEQS model specification. This example illustrates how you can do that by using the same data set and the measurement error model with correlated errors in [Example 27.10](#).

In the data set, you have four observed variables: x1–x3 and y. All are measured with errors, as represented by the following path diagram:

In the path diagram, F1–F3 and Fy represent true scores for the measurement indicators x1–x3 and y, respectively. You predict Fy by F1–F3, which represents the structural relationships in the model. Measurement error variances of the observed variables are treated as known and are represented by the double-headed arrows attached to the observed variables. For example, the error variance of x3 is 0.15. In addition, the error covariance between x1 and x2 is treated as known. The double-headed arrow that connects x1 and x2 represents the error covariance, and this covariance is fixed at 0.01 in the model.

You transcribe this path diagram representation into the following PATH model specification:

```
proc calis data=multiple nob=37;
  path
    Fy <=== F1 F2 F3,
    F1 <==> x1 = 1.,
    F2 <==> x2 = 1.,
    F3 <==> x3 = 1.,
    Fy <==> y = 1.;
  pvar
    x1 x2 x3 y = .02 .03 .15 .02,
    Fy;
  pcov
    x1 x2 = 0.01;
run;
```

To represent the error terms explicitly, you can add the error terms to the path diagram with some modifications, as shown in the following:

In the path diagram, you attach error variables e1–e3, ey, and d to the associated endogenous variables in the model. The error variances and covariances, which are attached to the endogenous variables directly, are now attached to the corresponding error variables. With this new path diagram, you can use the following LINEQS model specification for the model:

```

proc calis data=multiple nobs=37;
  lineqs
    Fy =      * F1 + * F2 + * F3 + d,
    x1 = 1. * F1 + e1,
    x2 = 1. * F2 + e2,
    x3 = 1. * F3 + e3,
    y = 1. * Fy + ey;
  variance
    e1-e3 ey = .02 .03 .15 .02,
    d;
  cov
    e1 e2 = 0.01;
run;

```

Again, in each linear equation of the LINEQS statement, you specify the functional relationship of an endogenous variable with other variables, including the error variable. The first equation is the structural equation in the model. You want to estimate the effects of F1, F2, and F3 on Fy. The error or disturbance variable is d. In the next four equations, you relate the observed variables with their true scores counterparts.

In the VARIANCE statement, you specify the error variances with reference to the error variables in the path diagram. Four of the error variances are fixed constants, as required in the model. The last specification represents a free parameter for the variance of d. The specifications in the VARIANCE statement of the LINEQS model are similar to those in the PVAR statement of the PATH model specification. The difference is that in the PATH model specification the reference variables are the endogenous variables in the PATH model, while in the LINEQS model specification the reference variables are the associated error variables.

In the COV statement, you specify the covariance between the error variables e1 and e2. Again, this is similar to the corresponding specification of the PATH model, where the same error covariance is specified as the partial covariance between x1 and x2 in the PCOV statement.

Output 27.11.3 shows the parameter estimates that result from using the LINEQS model specification. Estimates in the equations, variances, and covariances are shown respectively.

Output 27.11.3 Parameter Estimates of the Measurement Model with Multiple Predictors: LINEQS Model

In this example, you fit measurement error models by using the LINEQS and PATH model specifications of PROC CALIS. The two different model specification languages give you essentially the same estimation results. The measurement models can have multiple true scores predictors and correlated errors. The measurement error models considered so far have only one measured indicator for each true score latent variable. This is usually not the case in many psychometric or sociological applications where latent factors usually have several observed indicators. The confirmatory factor model is a typical example of this kind of applications. See [Example 27.12](#) for an application of PROC CALIS to fit confirmatory factor models. See [Example 27.17](#) for an application of PROC CALIS to fit a general structural equation model where latent variables have more than one measured indicators.

Example 27.12: Confirmatory Factor Models

This example shows how you can fit a confirmatory factor analysis model by the FACTOR modeling language. Thirty-two students take tests of their verbal and math abilities. Six tests are administered separately. Tests x1–x3 test their verbal skills and tests y1–y3 test their math skills.

The data are shown in the following DATA step:

```

data scores;
  input x1 x2 x3 y1 y2 y3;
  datalines;

;

```

Because of the unambiguous nature of the tests, you hypothesize that this is a confirmatory factor model with two factors: one is the verbal ability factor and the other is the math ability factor. You can represent such a confirmatory factor model by the following path diagram:

In the path diagram, there are two clusters of variables. One cluster is for the verbal factor and the other is for the math factor. The single-headed arrows in the path diagram represent functional relationships between factors and the observed variables. The double-headed arrows that point to single variables represent variances of the factors or error variances of the observed variables. The double-headed arrow that connects the two factors represents their covariance. All but two of these arrows are not labeled with numbers. Each of the unlabeled arrows represents a free parameter in the confirmatory factor model. You label the double-headed arrows that attach to the two factors with the constant 1. This means that the variances of the factors are fixed at 1.0 in the model.

You can specify the confirmatory factor model by the FACTOR model language of PROC CALIS, as shown in the following statements:

```
proc calis data=scores;
  factor
    verbal ==> x1-x3,
    math   ==> y1-y3;
  pvar
    verbal = 1.,
    math   = 1.;
run;
```

In each of the entry of the FACTOR statement, you specify a latent factor, followed by a list of observed variables that are functionally related to the latent factor. For example, in the first entry, the verbal factor is related to variables x1–x3, as shown by the single-headed arrows in the path diagram. In fact, all single-headed arrows in the path diagram are specified in the FACTOR statement. Notice that each entry of the FACTOR statement must take the format of

```
factor_name ==> variable_list
```

You cannot reverse the arrow specification as in the following:

```
variable_list <=== factor_name
```

Nor you can have a specification such as the following:

```
variable_list ==> factor_name
```

However, you can specify the functional relationships between factors and variables in different entries. For example, you can specify the same confirmatory factor model by the following statements:

```
title "Basic Confirmatory Factor Model: Separate Path Entries";
title2 "FACTOR Model Specification";
proc calis data=scores;
  factor
    verbal ==> x1,
    verbal ==> x2,
    verbal ==> x3,
    math   ==> y1,
    math   ==> y2,
    math   ==> y3;
  pvar
    verbal = 1.,
    math   = 1.;
  fitindex noindextype on(only)=[chisq df probchi rmsea srmsr bentlercfi];
run;
```

In the PVAR statement, which is for the specification of variances or error variances, you fix the variances of the latent factors to 1. This completes the model specification of the confirmatory factor model, although you do not specify other arrows in the path diagram as free parameters in these statements. The reason is that in the FACTOR modeling language, the variances and covariances among factors and the error variances of the observed variables are default parameters in the confirmatory factor model. It is not necessary to specify these parameters (or the corresponding arrows in the path diagram) explicitly if they are free parameters in the model. You can also specify these free parameters explicitly without affecting the estimation. However, if these parameters (or the corresponding double-headed arrows in the path diagram) are intended to be constrained parameters or fixed values, you must specify them explicitly. For example, in the current confirmatory factor model, you must provide explicit specifications for the variances of the verbal and the math factors because these parameters are fixed at 1.

Output 27.12.1 shows the modeling information and the variables in the confirmatory factor model.

Output 27.12.1 Modeling Information and Variables of the CFA Model: Scores Data

```

Output 27.12.2 *continued*

Initial Error Variances		
Variable	Parameter	Estimate
x1	_Add2	.
x2	_Add3	.
x3	_Add4	.
y1	_Add5	.
y2	_Add6	.
y3	_Add7	.

NOTE: Parameters with prefix '_Add' are added by PROC CALIS.

The first table of [Output 27.12.2](#) shows the pattern of factor loadings of the variables on the two latent factors. As expected, x1–x3 have nonzero loadings only on the verbal factor, while y1–y3 have nonzero loadings on the math factor. PROC CALIS names these free parameters automatically with the “_Parm” prefix and unique numerical suffixes. There are six parameters in the factor loading matrix with six different parameter names.

The next table of [Output 27.12.2](#) shows the covariance matrix of the factors. The variances of the factors are fixed at one, as shown on the diagonal of the covariance matrix. The covariance between the two factors is a free parameter named _Add1. You did not specify this covariance parameter explicitly in the factor model specification. By default, PROC CALIS assumes that latent factors are correlated. Default free parameters added by PROC CALIS have the _Add prefix for their names. If you do not want to assume the covariances among the factors, you must specify zero covariances in the COV statement. For example, the following statement specifies that the math and verbal factors have zero covariance:

```
COV
  math verbal = 0.;
```

The last table of [Output 27.12.2](#) shows the error variance parameters of the observed variables. By default PROC CALIS assumes these error variances are free parameters in the confirmatory factor model. These added parameters are named with the _Add prefix. However, as all other default parameters that are assumed by PROC CALIS, you can overwrite the default by using explicit specifications. You can specify the error variances of a confirmatory factor model explicitly in the PVAR statement. See specifications in [Example 27.13](#).

[Output 27.12.3](#) shows the fit summary of the confirmatory factor model for the scores data.

Output 27.12.3 Fit Summary of the CFA Model: Scores Data

Fit Summary	
Chi-Square	9.8052
Chi-Square DF	8
Pr > Chi-Square	0.2790
Standardized RMR (SRMR)	0.0571
RMSEA Estimate	0.0853
Bentler Comparative Fit Index	0.9887

The model fit chi-square is 9.805 ($df = 8$, $p = 0.279$). This shows that statistically you cannot reject the confirmatory factor model for the test scores. However, the root mean square error of approximation (RMSEA) estimate is 0.0853, which is greater than the conventional 0.05 value for a good model fit. The standardized root mean square residual (SRMR) is 0.0571, which is close to the conventional 0.05 value for a good model fit. Bentler's comparative fit index is 0.9887, which indicates a very good model fit. Overall, the model seems to be quite reasonable for the data.

Output 27.12.4 shows the loading and factor covariance estimates of the confirmatory factor model for the scores data. The first table shows the loading estimates, together with the standard error estimates and the t values. In structural equation modeling, the significance of the parameter estimates is usually inferred by comparing the t values with the critical value of a standardized normal variate (that is, the z -table). Therefore, estimates with associated (absolute) t values greater than 1.96 are significant at $\alpha = .05$. In Output 27.12.4, all the t values for the loading estimates are greater than 2. This indicates that the prescribed relationships between the variables and the factors are significant.

Output 27.12.4 Loading and Factor Covariance Estimates of the CFA Model: Scores Data

Factor Loading Matrix: Estimate/StdErr/t-value		
	verbal	math
x1	5.8406 0.9962 5.8629 [_Parm1]	0
x2	5.8182 0.9537 6.1004 [_Parm2]	0
x3	4.6619 0.7814 5.9662 [_Parm3]	0
y1	0	5.2804 0.6998 7.5455 [_Parm4]
y2	0	4.2003 0.6220 6.7532 [_Parm5]
y3	0	3.7596 0.6341 5.9289 [_Parm6]

Output 27.12.4 *continued*

Factor Covariance Matrix: Estimate/StdErr/t-value		
	verbal	math
verbal	1.0000	0.5175 0.1429 3.6221 [_Add1]
math	0.5175 0.1429 3.6221 [_Add1]	1.0000

The second table of [Output 27.12.4](#) shows the covariance matrix of the verbal and the math factors. Because the factor variances are fixed at one, the covariance estimate is also the correlation between the two factors. [Output 27.12.4](#) shows that the two factors are moderately correlated with a correlation estimate of 0.5175, which is statistically significant.

[Output 27.12.5](#) shows the estimates of the error variances. All but the error variance of y1 are significant. This suggests that y1 might have an almost perfect relationship with the math factor.

Output 27.12.5 Error Variance Estimates of the CFA Model: Scores Data

Error Variances				
Variable	Parameter	Estimate	Standard Error	t Value
x1	_Add2	11.52376	4.26398	2.70259
x2	_Add3	9.14503	3.83219	2.38637
x3	_Add4	6.68169	2.59770	2.57216
y1	_Add5	0.78580	1.29440	0.60708
y2	_Add6	2.88069	1.09395	2.63329
y3	_Add7	5.15573	1.46854	3.51080

[Output 27.12.6](#) echoes this same fact. The R-squares in this table shows the percentages of variance of the variables that are overlapped with the factors. While all these percentages (0.74 – 0.97) are quite high for all variables, the percentage is especially high for y1. It shares 97% of the variance with the math factor. So, it appears that the observed variable y1 is almost a perfect indicator of the math factor.

Output 27.12.6 Squared Multiple Correlations of the CFA Model: Scores Data

Squared Multiple Correlations			
Variable	Error Variance	Total Variance	R-Square
x1	11.52376	45.63609	0.7475
x2	9.14503	42.99597	0.7873
x3	6.68169	28.41532	0.7649
y1	0.78580	28.66835	0.9726
y2	2.88069	20.52319	0.8596
y3	5.15573	19.29032	0.7327

Alternative Identification Constraints

Setting the variances of the latent factors to 1 in the preceding FACTOR model specification makes the model identified. This is necessary because the scales of the latent factors are arbitrary and the constraints imposed on the factor variances fix the scales of the factors.

In practice, there is another way to fix the scales of the factors. For each factor, you can fix the loading of one of its measured indicators to a constant. This fixed loading value is usually set at 1. For example, you can represent the confirmatory factor model for the scores data by the following alternative path diagram:

This path diagram is essentially the same as the preceding one. However, the fixed constants adjacent to the double-headed arrows that attach to the two factors in the preceding path diagram are now moved to two of the single-headed paths in the current path diagram.

You can specify this path diagram by the following FACTOR model specification of PROC CALIS:

```
proc calis data=scores;
  factor
    verbal ==> x1-x3   = 1. ,
    math   ==> y1-y3   = 1. ;
run;
```

In the FACTOR statement, you assign a fixed constant to each of the path entries. In the first entry, the constant 1 is assigned to the loading of x1 on the verbal factor, while all other loadings in this entry are (unnamed) free parameters. Similarly, in the second entry, the fixed constant 1 is assigned to the loading of y1 on the math factor, while all other loadings in this entry are (unnamed) free parameters. This completes the specification of the confirmatory factor model because all the double-headed arrows in the path diagram correspond to default free parameters in the FACTOR modeling language of PROC CALIS.

Output 27.12.7 shows some fit indices for the current confirmatory factor model for the scores data.

Output 27.12.7 Fit Summary of the CFA Model with Alternative Identification Constraints: Scores Data

Fit Summary	
Chi-Square	9.8052
Chi-Square DF	8
Pr > Chi-Square	0.2790
Standardized RMR (SRMR)	0.0571
RMSEA Estimate	0.0853
Bentler Comparative Fit Index	0.9887

The model fit chi-square is 9.805 ($df = 8$, $p = 0.279$). This is the same model fit chi-square as that for the preceding CFA model specification with factor variances constrained to 1. In fact, all fit information in Output 27.12.7 are identical to Output 27.12.3.

Output 27.12.8 shows the parameter estimates under the current model specification. The loading of x1 on the verbal factor is a fixed at 1, as required for the identification of the scale of the verbal factor. Similarly, the loading of y1 on the math factor is a fixed at 1 for the identification of the scale of the math factor. All other loading estimates in Output 27.12.8 are not the same as those in the preceding model specification, as shown in Output 27.12.4. The reason is that the scales of the factors (as measured by the estimated standard deviations of the factors) in the two specifications are not the same. In the current model specification, the verbal factor has an estimated variance of 34.1123 and the math factor has an estimated variance of 27.8825, as shown in the second table of Output 27.12.8. Hence, the estimated standard deviations of these two factors are 5.8406 and 5.2804, respectively. But the standard deviations of the factors in the preceding confirmatory factor model specification are fixed at 1.

Output 27.12.8 Loading and Factor Covariance Estimates of the CFA Model with Alternative Identification Constraints: Scores Data

Factor Loading Matrix: Estimate/StdErr/t-value		
	verbal	math
x1	1.0000	0
x2	0.9962 0.1576 6.3194 [_Parm1]	0
x3	0.7982 0.1286 6.2083 [_Parm2]	0
y1	0	1.0000
y2	0	0.7955 0.0718 11.0820 [_Parm3]
y3	0	0.7120 0.0858 8.3027 [_Parm4]
Factor Covariance Matrix: Estimate/StdErr/t-value		
	verbal	math
verbal	34.1123 11.6366 2.9315 [_Add1]	15.9585 6.7270 2.3723 [_Add3]
math	15.9585 6.7270 2.3723 [_Add3]	27.8825 7.3905 3.7727 [_Add2]

However, if you multiply the loading estimates in [Output 27.12.8](#) by the corresponding estimated factor standard deviation, you get the same set of loading estimates as in [Output 27.12.4](#). For example, the loading of x1 on the verbal factor is 1.0 in [Output 27.12.8](#). Multiplying this loading by the estimated standard deviation 5.8406 of the verbal factor gives you the same corresponding loading as in [Output 27.12.4](#). Another

example is the loading of y3 on the math factor. This loading is 0.7120 in [Output 27.12.8](#). Multiplying this estimate by the estimated standard deviation 5.2804 of the verbal factor gives an estimate of 3.7596, which matches the corresponding loading estimate in [Output 27.12.4](#). Therefore, the discrepancies in the loading estimates are due to different factor scales in the two specifications. The loading estimates in [Output 27.12.8](#) are simply rescaled version of the loading estimates in [Output 27.12.4](#).

However, the scales of the factors do not affect the estimates of the error variances, as shown in [Output 27.12.9](#). These estimates are the same as those for the preceding model specification, as shown in the [Output 27.12.5](#).

Output 27.12.9 Error Variance Estimates of the CFA Model with Alternative Identification Constraints:
Scores Data

Error Variances				
Variable	Parameter	Estimate	Standard Error	t Value
x1	_Add4	11.52376	4.26398	2.70259
x2	_Add5	9.14503	3.83219	2.38637
x3	_Add6	6.68169	2.59770	2.57216
y1	_Add7	0.78580	1.29440	0.60708
y2	_Add8	2.88069	1.09395	2.63329
y3	_Add9	5.15573	1.46854	3.51080

This example shows how you can fit a basic confirmatory factor model by the FACTOR modeling language of PROC CALIS. You can set the identification constraints and get statistically equivalent estimation results in two different ways. By setting up additional parameter constraints, you can also fit some variations of the basic confirmatory factor model. See [Example 27.13](#) for illustrations of some restricted confirmatory factor models for the scores data.

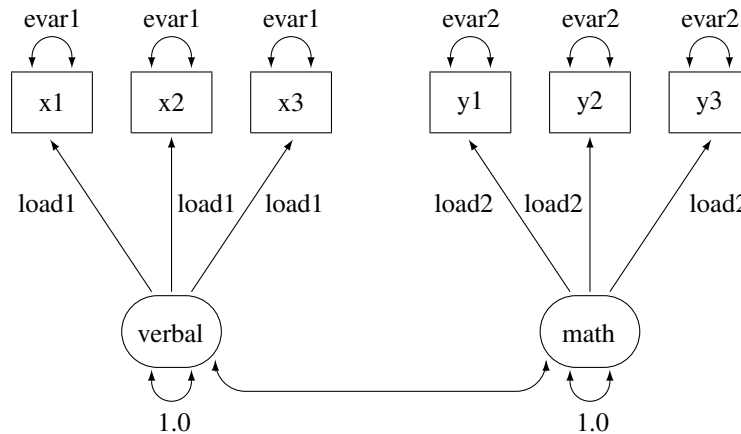

When your data have missing values, with the default ML estimation method PROC CALIS deletes all observations with missing values for the analysis. This might result in a serious loss of information. [Example 27.15](#) considers a hypothetical situation where some observations in the scores data have missing values in the observed variables. Only 16 observations have complete data. By using the full information maximum likelihood (FIML) method for treating the missing data, [Example 27.15](#) shows how you can fully use the information from the scores data set with missing values.

Example 27.13: Confirmatory Factor Models: Some Variations

This example shows how you can fit some variations of the basic confirmatory factor analysis model by the FACTOR modeling language. You apply these models to the scores data set that is described in [Example 27.12](#). The data set contains six test scores of verbal and math abilities. Thirty-two students take the tests. Tests x1–x3 test their verbal skills and tests y1–y3 test their math skills.

The Parallel Tests Model

In classical measurement theory, test items for a latent factor are parallel if they have the same loadings on the factor and the same error variances (or reliability). Suppose for the `scores` data, the items within each of the verbal and the math factors are parallel. You can use the following path diagram to represent such a parallel tests model:

In the path diagram, the variances of the `verbal` and the `math` are both fixed at 1, as indicated by the constants 1.0 adjacent to the double-headed arrows that are attached to factors. You label all the single-headed paths in the path diagram by parameter names. For the three paths (loadings) from the verbal factor, you use the same parameter name `load1`. This means that these loadings are the same parameter. You also label the double-headed arrows that are attached to `x1–x3` by the parameter name `evar1`. This means that the corresponding error variances for these three observed variables are exactly the same. Hence, `x1–x3` are parallel tests for the verbal factor, as required by the current confirmatory factor model.

Similarly, you define parallel tests `y1–y3` for the math factor by using `load2` as the common factor loading parameter and `evar2` as the common error variances for the observed variables.

Corresponding to this path diagram, you can specify the model by the following FACTOR model specification of PROC CALIS:

```

proc calis data=scores;
  factor
    verbal ==> x1-x3   = load1 load1 load1,
    math   ==> y1-y3   = load2 load2 load2;
  pvar
    verbal = 1.,
    math   = 1.,
    x1-x3  = 3*evar1,
    y1-y3  = 3*evar2;
run;

```

In each entry of the **FACTOR** statement, you specify the factor-variables relationships, followed by a list of parameters. For example, the three loading parameters of x_1 – x_3 on the verbal factor are all named **load1**. This effectively constrains the corresponding loading estimates to be the same. Similarly, in the next entry you set equality constraints on the loading estimates y_1 – y_3 on the math factor by using the same parameter name **load2**.

To make the tests parallel, you also need to constrain the error variances for each variable cluster. In the **PVAR** statement, in addition to setting the factor variances to 1 for identification, you set all the error variances of x_1 – x_3 to be the same by using the same parameter name **evar1**. The notation **3*evar1** means that you want to specify **evar1** three times, one time each for the error variances for the three observed variables in the variable list of the entry. Similarly, you set the equality of the error variances of y_1 – y_3 by using the same parameter name **evar2**.

[Output 27.13.1](#) shows some fit indices of the parallel tests model for the scores data. The model fit chi-square is 26.128 ($df = 16$, $p = 0.0522$). The SRMR value is 0.1537 and the RMSEA value is 0.1429. All these indices show that the model does not fit very well. However, Bentler's CFI is 0.9366, which shows a good model fit.

Output 27.13.1 Model Fit of the Parallel Tests Model: Scores Data

Fit Summary	
Chi-Square	26.1283
Chi-Square DF	16
Pr > Chi-Square	0.0522
Standardized RMR (SRMR)	0.1537
RMSEA Estimate	0.1429
Bentler Comparative Fit Index	0.9366

[Output 27.13.2](#) shows the parameter estimates of the parallel tests model. The first table of [Output 27.13.2](#) shows the required factor pattern for parallel tests. Variables x_1 – x_3 all have the same loading estimates on the verbal factor, and variables y_1 – y_3 all have the same loading estimates on the math factor. All loading estimates are statistically significant.

Output 27.13.2 Parameter Estimates of the Parallel Tests Model: Scores Data

Factor Loading Matrix: Estimate/StdErr/t-value		
	verbal	math
x1	5.4226 0.7655 7.0833 [load1]	0
x2	5.4226 0.7655 7.0833 [load1]	0
x3	5.4226 0.7655 7.0833 [load1]	0
y1	0	4.4001 0.5926 7.4246 [load2]
y2	0	4.4001 0.5926 7.4246 [load2]
y3	0	4.4001 0.5926 7.4246 [load2]
Factor Covariance Matrix: Estimate/StdErr/t-value		
	verbal	math
verbal	1.0000	0.5024 0.1497 3.3569 [_Add1]
math	0.5024 0.1497 3.3569 [_Add1]	1.0000

Output 27.13.2 *continued*

Error Variances				
Variable	Parameter	Estimate	Standard Error	t Value
x1	evar1	9.61122	1.72623	5.56776
x2	evar1	9.61122	1.72623	5.56776
x3	evar1	9.61122	1.72623	5.56776
y1	evar2	3.46673	0.62264	5.56776
y2	evar2	3.46673	0.62264	5.56776
y3	evar2	3.46673	0.62264	5.56776

In the second table of [Output 27.13.2](#), the factor covariance (or correlation) estimate is 0.5024, showing moderate relationship between the verbal and the math factors. The last table of [Output 27.13.2](#) shows the error variances of the variables. As required by the parallel tests model, the error variance estimates of x1–x3 are all 9.6112, and the error variance estimates of y1–y3 are all 3.4667.

The Tau-Equivalent Tests Model

Because the parallel tests model does not fit well, you are looking for a less constrained model for the scores data. The tau-equivalent tests model is such a model. It requires only the equality of factor loadings but not the equality of error variances within each factor. The following path diagram represents the tau-equivalent tests model for the scores data:

This path diagram is much the same as that for the parallel tests model except that now you do not use parameter names to label the double-headed arrows that are attached to the observed variables. This means that you allow the corresponding error variances to be free parameters in the tau-equivalent tests model. You can use the following FACTOR model specification of PROC CALIS to specify the tau-equivalent tests model for the scores data:

```

proc calis data=scores;
  factor
    verbal ==> x1-x3   = load1 load1 load1,
    math   ==> y1-y3   = load2 load2 load2;
  pvar
    verbal = 1.,
    math   = 1.;
run;

```

This specification is the same as that for the parallel tests model except that you remove the specifications about the error variances in the PVAR statement in the current tau-equivalent model. This effectively allows the error variances of the observed variables to be (default) free parameters in the model.

Output 27.13.3 shows some model fit indices of the tau-equivalent tests model for the scores data. The chi-square is 22.0468 ($df = 12$, $p = 0.037$). The SRMR is 0.1398 and the RMSEA is 0.1643. The comparative fit index (CFI) is 0.9371. Except for the CFI value, all other values do not support a good model fit. This model has a degrees of freedom of 12, which is less restrictive (has more parameters) than the parallel tests model, which has a degrees of freedom of 16, as shown in Output 27.13.1. However, it seems that the tau-equivalent tests model is still too restrictive for the data.

Output 27.13.3 Model Fit of the Tau-Equivalent Tests Model: Scores Data

Fit Summary	
Chi-Square	22.0468
Chi-Square DF	12
Pr > Chi-Square	0.0370
Standardized RMR (SRMR)	0.1398
RMSEA Estimate	0.1643
Bentler Comparative Fit Index	0.9371

Output 27.13.4 shows the parameter estimates. The first table of Output 27.13.4 shows the required pattern of factor loadings under the tau-equivalent tests model. The third table of Output 27.13.4 shows the error variance estimates. The error variance parameters are no longer constrained under the tau-equivalent tests model. Each has a unique estimate.

Output 27.13.4 Parameter Estimates of the Tau-Equivalent Tests Model: Scores Data

Factor Loading Matrix: Estimate/StdErr/t-value		
	verbal	math

y2	_Add6	1.90435	1.02393	1.85984
y3	_Add7	5.09724	1.61477	3.15663

The Partially Constrained Parallel Tests Model

Because both the parallel tests and tau-equivalent tests models do not fit the data well, you can explore an alternative model for the scores data. Suppose that for each factor only two (but not all) of their measured variables (tests) are parallel. For example, suppose you know that tests x1 and x2 are very similar to each other (for example, both are speeded tests with forced-choice answers), while x3 is a little different in the way it is administered (for example, open-ended questions). Although all tests are designed for measuring the verbal factor, only x1 and x2 are parallel tests while x3 is congenenic to the verbal factor. Similarly, suppose you can argue that y2 and y3 are parallel tests while y1 is only congenenic to the math factor.

The current modeling idea is represented by the following path diagram:

In the path diagram, x1 and x2 have the same parameter load1 for the paths from the verbal factor. Their error variances are also the same, as labeled with the evar1 parameter adjacent to the double-headed arrows that are attached to the variables. The test x3 has distinct parameter names for its associated path and the attached double-headed arrow. The corresponding loading and error variance parameters are alpha and phi, respectively. Similarly, with the use of specific parameter names, you define y2 and y3 as parallel tests for the math factor, while y1 is congenenic to the same factor but with distinct loading and error variance parameters. Lastly, you fix the variances of the factors to 1.0 for identification of the factor scales.

You can specify such a partially constrained parallel tests model by the following FACTOR model specification of PROC CALIS:

```
proc calis data=scores;
  factor
    verbal ==> x1-x3   = load1 load1 alpha,
    math   ==> y1-y3   = beta  load2 load2;
  pvar
    verbal = 1.,
    math   = 1.,
    x1-x3  = evar1  evar1  phi,
    y1-y3  = theta  evar2  evar2;
run;
```

First, in the FACTOR statement, you name the loading parameters that reflect the parallel tests constraints. For example, the loading parameters of x1 and x2 on the verbal factor are both named load1. This means that they are the same. However, the loading parameter of x3 on the verbal factor is named alpha, which means that it is a separate parameter. Similarly, you apply the load2 parameter name to the loading parameters of y2 and y3 on the math factor, but the loading parameter of y1 on the math factor is a distinct parameter named beta.

In the PVAR statement, the two factor variances are set to a constant 1 for the identification of latent factor scales. Next, you use the same naming techniques as in the FACTOR statement to constrain some parts of the error variances. As a result, together with the specifications in the FACTOR statement, x1 and x2 are parallel tests for the verbal factor and y2 and y3 are parallel tests for the math factor, while x3 and y1 are only congeneric tests for their respective factors.

Output 27.13.5 shows some fit indices of the partially constrained parallel tests model. The model fit chi-square is 12.6784 ($df = 12$, $p = 0.3928$). The SRMR is 0.0585 and the RMSEA is close to 0.0427. The comparative fit index (CFI) is 0.9958. All these fit indices point to a quite reasonable model fit for the scores data.

Output 27.13.5 Model Fit of the Partially Constrained Parallel Tests Model: Scores Data

Fit Summary	
Chi-Square	12.6784
Chi-Square DF	12
Pr > Chi-Square	0.3928
Standardized RMR (SRMR)	0.0585
RMSEA Estimate	0.0427
Bentler Comparative Fit Index	0.9958

Notice that the current model actually has the same degrees of freedom as that of the tau-equivalent tests model, as shown in Output 27.13.3. Both models have nine parameters. But the current partially constrained parallel tests model is definitely a better model for the data. This shows that sometimes you do not have to add more parameters to improve the model fit. Structurally different models might explain the data quite differently, even though they might use the same number of parameters.

Output 27.13.6 show the parameter estimates of the partially constrained parallel tests model for the scores data. The estimates in the factor loading matrix and error variances table confirm the prescribed nature of

the tests—that is, x1 and x2 are parallel tests for the verbal factor and y2 and y3 are parallel tests for the math factor.

Output 27.13.6 Parameter Estimates of the Partially Constrained Parallel Tests Model: Scores Data

Factor Loading Matrix: Estimate/StdErr/t-value		
	verbal	math
x1	5.8306 0.8593 6.7853 [load1]	0

Example 27.14: Residual Diagnostics and Robust Estimation

This example illustrates case-level residual diagnostics and robust estimation with PROC CALIS. The data set is available in Mardia, Kent, and Bibby (1979). It contains 88 responses on five subjects: mechanics, vector, algebra, analysis, and statistics. Yuan and Hayashi (2010) use the same data set to illustrate the uses of residual diagnostics in the context of robust estimation. Inspired by their illustrations, this example mirrors their one-factor model, with some modifications.

Case-Level Residual Diagnostics

The following DATA step specifies and inputs five observed variables for the data set mardia:

```
data mardia;
  input mechanics vector algebra analysis statistics;
  datalines;

;
```

You specify a one-factor model for the five variables by using the following statements:

```
ods graphics on;

proc calis data=mardia residual plots=caseresid;
  path
    fact1 ==> mechanics vector algebra analysis statistics = 1. ;
run;

ods graphics off;
```

In the PATH statement, all observed variables are indicators of the latent factor fact1. The first factor loading for mechanics is fixed at 1 for identification of the latent variable scale, while the remaining four loadings are free parameters in the model. The RESIDUAL option that is specified in the PROC CALIS statement requests residual analysis. Because raw data are input, case-level residual analysis is done. To request all the available ODS Graphics output for case-level residual diagnostics, you specify the PLOTS=CASERESID option. To enable ODS Graphics, you specify the ODS GRAPHICS ON statement before running the CALIS procedure.

Output 27.14.1 shows some of the fit statistics of the one-factor model. The model fit chi-square is 8.9782 ($df = 5$, $p = 0.1099$). Therefore, you fail to reject the one-factor model for the data. The SRMR is 0.0411, which shows a good fit. But the RMSEA is 0.0956, which does not show that the one-factor model is a very good approximating model for the data. Output 27.14.2 shows the loading estimates. All are statistically significant.

Output 27.14.1 Model Fit of Mardia Data

Fit Summary	
Chi-Square	8.9782
Chi-Square DF	5
Pr > Chi-Square	0.1099
Standardized RMR (SRMR)	0.0475
RMSEA Estimate	0.0956

Output 27.14.2 Estimates of Loadings

PATH List					
-----Path-----	Parameter	Estimate	Standard Error	t Value	
fact1 ==> mechanics		1.00000			
fact1 ==> vector	_Parm1	0.83770	0.16598	5.04687

fact1 ==> statistics	_Parm4	1.19229	0.22309	5.34440	

Output 27.14.3 shows the classifications of outlier and leverage observations in a two-dimensional space. Four regions are clearly shown.

Output 27.14.3 Outliers and Leverage Observations

The upper and the lower regions are separated by a horizontal line that represents the criterion for outlier detection. This criterion is set by a certain α -level that has a probability meaning. Loosely speaking, if the model is true and the distribution of the residuals is multivariate normal, you would expect that about $\alpha \times 100\%$ of observations will have their residual M-distances above the criterion. The larger the α value, the more liberal the outlier detection criterion. This α -level is set to 0.01 by default. You can change this default by using the `ALPHAOUT=` option.

Notice that all residuals and the criterion are measured in terms of M-distances. Hence, these measures are always positive. [Output 27.14.3](#) classifies observations 81 and 28 as outliers (in the residual dimension). In addition to these two outlying observations, PROC CALIS also labels the next five observations with the largest residual M-distances. [Output 27.14.3](#) shows that observations 33, 54, 56, 61, and 66 are the closest to being labeled as outliers.

The right and left regions are separated by a vertical line that represents the criterion for leverage observations. Again, this criterion is set by a certain α -level that has a probability meaning. If the model is true and the distribution of the predictor variables (in this case, the factor variable `fact1`) is multivariate normal, you would expect that about $\alpha \times 100\%$ of observations will have their leverage M-distances above the criterion. The larger the α value, the more liberal the leverage observation detection criterion. This α -level is also set to 0.01 by default. You can change this default by using the `ALPHALEV=` option.

Output 27.14.3 classifies observations 2, 87, and 88 as leverage points or observations. In addition to these three observations, PROC CALIS also labels the next five observations with the largest leverage M-distances. **Output 27.14.3** shows that observations 1, 3, 6, 8, and 86 are the closest to being labeled as leverage observations.

The lower left region in **Output 27.14.3** contains observations that are neither outliers nor leverage observations. This region contains the majority of the observations. The upper right region in **Output 27.14.3** contains observations that are classified as both outliers and leverage observations. For the current model, no observations are classified as such.

To supplement the graphical depiction of outliers and leverage observations, PROC CALIS shows two tables that contain more numerical information. **Output 27.14.4** shows the seven observations that have the largest residual M-distances. The table reflects the outlier classification in **Output 27.14.3** numerically. Two outliers are flagged in the table. However, none of the seven observations are leverage observations. **Output 27.14.5** shows the eight observations that have the largest leverage M-distances. Again, this table reflects the classification of leverage observations in **Output 27.14.3** numerically. Three leverage observations are flagged, but none of these observations are residual outliers at the same time.

Output 27.14.4 Largest Residual Outliers

Diagnostics of the 7 Largest Case-Level Residuals (alpha=0.01)				
Case Number	Residual (M-Distance)	----Diagnostics-----		
		Outlier	Leverage	
81	4.60511	*		
28	3.69953	*		
54	3.43068			
33	3.17659			
61	3.15104			
56	3.06094			
66	3.03262			

Output 27.14.5 Largest Leverage Observations

Diagnostics of the 8 Largest Case-Level Leverages (alpha=0.01)				
Case Number	Leverage (M-Distance)	----Diagnostics-----		
		Leverage	Outlier	
87	2.96438	*		
88	2.72441	*		
2	2.69293	*		
3	2.15519			
1	2.04014			
6	1.87894			
86	1.72950			
8	1.59242			

Output 27.14.6 shows the histogram and its kernel density function of the residual M-distances. Theoretically, the density should look like a χ^2 -distribution (that is, the distribution of the square root of the corresponding χ^2 variate). While this histogram provides an overall impression of the empirical distribution of the residual M-distances, it is not very useful in diagnosing the observations that do not conform to the theoretical distribution of the residual M-distances. To this end, Output 27.14.7 and Output 27.14.8 are more useful.

Output 27.14.6 Distribution of Case-Level Residuals

Output 27.14.7 shows the so-called Q-Q plot for the residual M-distances. The Y coordinates represent the observed quantiles, and the X coordinates represent the theoretical quantiles. Output 27.14.8 shows the so-called P-P plots for the residual M-distances. The Y coordinates represent the observed percentiles, and the X coordinates represent the theoretical percentiles. If the observed residual M-distances distribute exactly like the theoretical χ^2 -distribution, all observations should lie on the straight lines with a slope of 1 in both plots. In Output 27.14.7 and Output 27.14.8, observations with the largest departures from the straight lines are labeled.

Output 27.14.7 Q-Q Plot of Residual M-Distances

In terms of quantiles, the Q-Q plot in [Output 27.14.7](#) shows that observations 81, 28, and 54 have the largest departures from the theoretical distribution for the residual M-distances. Notice that observations 81 and 28 were also identified as outliers previously.

Output 27.14.8 P-P Plot of Residual M-Distances

In terms of percentiles, the P-P plot in [Output 27.14.8](#) shows that several observations in the middle of the distribution have the largest departures from the theoretical distribution. However, it is not clear from the plot which observations have the largest departures.

To supplement the Q-Q and the P-P plots with numerical information, PROC CALIS outputs the table in [Output 27.14.9](#), which shows the observations with the largest departures from the theoretical residual M-distance distribution in terms of quantiles and percentiles. The observations in the table are arranged by their percentile regions. Approximately 10% of the observations with the largest departures in terms of quantile and in terms of percentile, respectively, are shown in this table. However, the final percentage of observations shown in the table might not add up to 20%, because some observations could have large departures in terms of both quantile and percentile. [Output 27.14.9](#) shows that observations 1, 15, 30, and 72 are this kind of observation. However, none of these are residual outliers.

Output 27.14.9 Largest Departures from the Theoretical Residual Distribution

Largest Departures From the Theoretical Residual Distribution			
Percentile Region	Case Number	Quantile Deviation	Percentile Deviation
(.65, .90)	26		-0.05302
	36		-0.05836
	40		-0.05863
	15	-0.13087	-0.06509
	87		-0.05257
	71		-0.05145
	30	-0.11973	-0.05198
	1	-0.12344	-0.05065
	72	-0.13739	-0.05498
	64	-0.12550	
(.90, .95) > .95	66	0.13803	
	54	0.20039	
	28	0.32398	
	81	0.99843	

Output 27.14.10 shows the residual on fit plot for the variable algebra. Notice that unlike the preceding residual diagnostic plots where the M-distances (nonnegative) for residuals are plotted, the residuals (which can be positive or negative) themselves are plotted against the predicted values for algebra in the current residual on fit (or residual on predicted) plot. If the linear relationship as described by the one-factor model is reasonable, then the residuals should show no systematic trend with the predicted values. That is, the residuals should be randomly scattered around the plot in the range of the predicted values. The pattern of residuals in Output 27.14.10 looks sufficiently “random,” and therefore it gives support to the prescribed linear relationship between the variable algebra and the factor fact1. PROC CALIS also outputs the residual on fit plots for other dependent observed variables. To conserve space, they are not shown here. You can also control the amount of graphical output by specifying the desirable set of dependent observed variables for the residual on fit plots. For example, the following requests the residual on fit plots for the variables mechanics and analysis only, even though there are five dependent observed variables in the model:

```
PLOTS=RESBYPRED (VAR=mechanics analysis)
```

See the **PLOTS=** option for details.

Output 27.14.10 Residual on Fit Plot for the Variable Algebra

Direct Robust Estimation

Usually, the outlier detection process in residual diagnostics implies some treatments after their detections. For example, in the preceding analysis, observations 28 and 81 were detected as outliers. You would naturally think that the next step is to do an additional model fitting with these two outlying observations removed. While this thinking is intuitively appealing, the outlier issues are usually more complicated than can be resolved by such a “pick-and-remove” strategy. One issue is the so-called masking effect of outliers. In the preceding analysis, outliers are detected based on a criterion that is a function of the chosen criterion level (for example, the $\text{ALPHAOUT} =$ value set by the researcher) and the parameter estimates. However, because the outliers have contributed to the estimation of the parameters, you might wonder whether the outlier detection process has been contaminated by the outliers themselves. If such a masking effect is present and an additional analysis is done after employing the pick-and-remove strategy for the outliers, you would be likely to discover more outliers. As a result, you might wonder whether the outlier removal process should be carried out indefinitely.

Robust estimation provides an alternative way to resolve the issue of masking effect. In robust estimation, outlying observations are downweighted simultaneously with the estimation. Iterative steps are used to reweight the observations according to the updated parameter estimates. Hence, with robust estimation you

do not need to make a decision about removing outliers because they are already downweighted during the estimation. The issue of masking effect is avoided.

PROC CALIS provides two major methods of robust estimation—direct and two-stage. This section illustrates the direct robust estimation method, in which the model is estimated simultaneously with the (re)weighting of the observations. The next section illustrates the two-stage estimation method, in which the robust mean and covariance matrices obtained in the first stage are analyzed by the maximum likelihood (ML) estimation in the second stage. Both methods are based on the methodology proposed by Yuan and Zhong (2008) and Yuan and Hayashi (2010).

The following statements request direct robust estimation of the model for the mardia data set:

```
ods graphics on;

proc calis data=mardia residual robust plots=caseresid pcorr;
  path
    fact1 ==> mechanics vector algebra analysis statistics = 1. ;
run;

ods graphics off;
```

The ROBUST option invokes the direct robust estimation method. The direct robust method reweights the observations according to the magnitudes of the residuals during iterative steps. For this reason, you can also specify ROBUST=RES to signify direct robust estimation with residual (M-distance) weighting. Following Yuan and Hayashi (2010), there are two variants of the direct robust estimation. One treats the disturbances (that is, error terms for endogenous latent factors) as factors to estimate (see the ROBUST=RES(F) option), and the other treats the disturbances as true error terms (see the ROBUST=RES(E) option). See the ROBUST= option and the section “Robust Estimation” on page 1315 for details. These variants would not make any difference for the current one-factor model estimation, and the ROBUST option that is used in the specification is the same as ROBUST=RES(E).

You also request case-level residual analysis by using the RESIDUAL option, even though the intention now is to identify rather than to remove the outliers.

Output 27.14.11 shows the fit summary of the direct robust estimation. The model fit chi-square is 6.0031 ($df = 5$, $p = 0.3059$). Again, you fail to reject the one-factor model for the data. Unlike the regular ML estimation in the preceding analysis, both SRMR (0.0321) and RMSEA (0.0480) show good model fit. This result can be attributed to the downweighting of the outlying observations in the direct robust estimation. Output 27.14.12 shows that all loading estimates are statistically significant.

Output 27.14.11 Model Fit of Mardia Data with Direct Robust Estimation

Fit Summary	
Chi-Square	6.0031
Chi-Square DF	5
Pr > Chi-Square	0.3059
Standardized RMR (SRMR)	0.0370
RMSEA Estimate	0.0480
NOTE: Saturated mean structure parameters are excluded from the computations of fit indices.	

Output 27.14.12 Estimates of Loadings with Direct Robust Estimation

PATH List						
-----Path-----			Parameter	Estimate	Standard Error	t Value
fact1	====>	mechanics		1.00000		
fact1	====>	vector	_Parm1	0.83279	0.15680	5.31106
fact1	====>	algebra	_Parm2	0.92854	0.14763	6.28950
fact1	====>	analysis	_Parm3	1.08665	0.18855	5.76317
fact1	====>	statistics	_Parm4	1.18799	0.21487	5.52890

Output 27.14.13 shows the outlier and leverage classifications by the direct robust estimation. This plot has a similar pattern to the one obtained from the preceding regular ML estimation (see Output 27.14.3). Both plots show that observations 28 and 81 are the only outliers. Thus, the results from the direct robust estimation eliminate the concern of the masking effect.

Output 27.14.13 Outliers and Leverage Observations with Direct Robust Estimation

As a by-product of the direct robust estimation, robust (unstructured) covariance and mean matrices are computed with the `PCORR` option. [Output 27.14.14](#) shows the robust covariance and mean matrices obtained for the current direct robust estimation for the `mardia` data set. These matrices are essentially computed by the usual formulas for covariance and mean matrices, but with weights obtained from the final estimates of the direct robust estimation of the model. For the current analysis, outlying observations (28 and 81) receive weights of less than 1 whereas all other observations receive weights of 1 in the computation.

Output 27.14.14 Robust Covariance and Mean Matrices with Direct Robust Estimation

	Robust Covariance Matrix				
	mechanics	vector	algebra	analysis	statistics

Two-Stage Robust Estimation

In addition to the direct robust estimation method, PROC CALIS implements another robust estimation method for structural equation models. The two-stage robust estimation method estimates the robust means and covariance matrices in the first stage. It then fits the model to the robust mean and covariance matrix by using the ML method in the second stage. During the first stage, the robust method downweights the outlying observations in all variable dimensions. The robust properties are then propagated to the second stage of estimation.

In PROC CALIS, you can use the ROBUST=SAT option to invoke the two-stage robust estimation method, as shown in the following statements for fitting the one-factor model to the mardia data set:

```
proc calis data=mardia robust=sat pcorr;
  path
    fact1 ==> mechanics vector algebra analysis statistics = 1. ;
run;
```

With the PCORR option, the (unstructured) robust mean and covariance matrices are displayed in [Output 27.14.15](#). Although the robust covariance and mean matrices obtained here are numerically similar to those obtained from the direct robust estimation (see [Output 27.14.14](#)), they are obtained with totally different methods. The robust mean and covariance matrices in the direct robust estimation are the by-products of the model estimation, while the robust mean and covariance matrices in the two-stage robust estimation are the initial inputs for model estimation.

Output 27.14.15 Robust Covariance and Mean Matrices with Two-Stage Robust Estimation

	Robust Covariance Matrix				
	mechanics	vector	algebra	analysis	statistics

Output 27.14.16 shows the fit summary of the two-stage robust estimation. The model fit chi-square is 7.2941 ($df = 5$, $p = 0.1997$). As in direct robust estimation, you fail to reject the one-factor model for the data. Unlike the case with direct robust estimation, only SRMR (0.0366) shows a good model fit. RMSEA is 0.0726 and is not very close to a good model fit.

Output 27.14.16 Model Fit of Mardia Data with Two-Stage Robust Estimation

Fit Summary	
Chi-Square	7.2941
Chi-Square DF	5
Pr > Chi-Square	0.1997
Standardized RMR (SRMR)	0.0422
RMSEA Estimate	0.0726
NOTE: Saturated mean structure parameters are excluded from the computations of fit indices.	

Output 27.14.16 shows the estimates of loadings with the two-stage robust estimation. All the estimates are statistically significant. All the numerical results are similar to that of the direct robust estimation in Output 27.14.12.

Output 27.14.17 Estimates of Loadings with Two-Stage Robust Estimation

PATH List					
-----Path-----	Parameter	Estimate	Standard Error	t Value	
fact1 ==> mechanics		1.00000			
fact1 ==> vector	_Parm1	0.84322	0.16538	5.09856	
fact1 ==> algebra	_Parm2	0.93683	0.15485	6.04996	
fact1 ==> analysis	_Parm3	1.10397	0.19849	5.56172	
fact1 ==> statistics	_Parm4	1.21080	0.22686	5.33712	

The outlier and leverage observation detection in two-stage robust estimation is essentially the same method as that in direct robust estimation. Therefore, the corresponding results for the two-stage robust estimation are not shown here. See the section “[Residual Diagnostics with Robust Estimation](#)” on page 1342 for details about case-level residual analysis with robust estimation.

Example 27.15: The Full Information Maximum Likelihood Method

This example shows how you can fully utilize all available information from the data when there is a high proportion of observations with random missing value. You use the full information maximum likelihood method for model estimation.

In [Example 27.12](#), 32 students take six tests. These six tests are indicator measures of two ability factors: verbal and math. You conduct a confirmatory factor analysis in [Example 27.12](#) based on a data set without any missing values. The path diagram for the confirmatory factor model is shown the following:

Suppose now due to sickness or unexpected events, some students cannot take part in one of these tests. Now, the data test contains missing values at various locations, as indicated by the following DATA step:

```
data missing;
  input x1 x2 x3 y1 y2 y3;
  datalines;
23 . 16 15 14 16
29 26 23 22 18 19

29 21 22 13 17 .
;
```

This data set is similar to the scores data set used in [Example 27.12](#), except that some values are replaced at random with missing values. You can still fit the same confirmatory factor analysis model described in [Example 27.12](#) to this data set by the default maximum likelihood (ML) method, as shown in the following statement:

```

proc calis data=missing;
  factor
    verbal ==> x1-x3,
    math   ==> y1-y3;
  pvar
    verbal = 1.,
    math   = 1.;
run;

```

The data set, the number of observations, the model type, and analysis type are shown in the first table of [Output 27.15.1](#). Although PROC CALIS reads all 32 records in the data set, only 16 of these records are used. The remaining 16 records contain at least one missing value in the tests. They are discarded from the analysis. Therefore, the maximum likelihood method only uses those 16 observations without missing values.

y3	_Add7	4.59651	1.77777	2.58555

Most of the factor loading estimates shown in [Output 27.15.2](#) are similar to those estimated from the data set without missing values, as shown in [Output 27.12.4](#). The loading estimate of y3 on the math factor shows the largest discrepancy. With only half of the data used in the current estimation, this loading estimate is 2.6338 in the current analysis, while it is 3.7596 if no data were missing, as shown in [Output 27.12.4](#). Another obvious difference between the two sets of results is that the standard error estimates for the loadings are consistently larger in the current analysis than in the analysis in [Example 27.12](#) where there are no missing data. This is expected because you have only half of the data set available in the current analysis.

Similarly, the estimates for the factor covariance and error variances are mostly similar to those in the analysis with complete data, but the standard error estimates in the current analysis are consistently higher.

The maximum likelihood method, as implemented in PROC CALIS, deletes all observations with at least one missing value in the estimation. In a sense, the partially available information of these deleted observations is wasted. This greatly reduces the efficiency of the estimation, which results in higher standard error estimates.

To fully utilize all available information from the data set with the presence of missing values, you can use the full information maximum likelihood (FIML) method in PROC CALIS, as shown in the following statements:

```
proc calis method=fiml data=missing;
  factor
    verbal ==> x1-x3,
    math   ==> y1-y3;
  pvar
    verbal = 1.,
    math   = 1.;
run;
```

In the PROC CALIS statement, you use METHOD=FIML to request the full information maximum likelihood method. Instead of deleting observations with missing values, the full information maximum likelihood method uses all available information in all observations. [Output 27.15.3](#) shows some modeling information of the FIML estimation of the confirmatory factor model on the missing data.

Output 27.15.3 Modeling Information of the CFA Model with FIML: Missing Data

```

Confirmatory Factor Model With Missing Data: FIML
      FACTOR Model Specification

      The CALIS Procedure
Mean and Covariance Structures: Model and Initial Values

      Modeling Information
Full Information Maximum Likelihood Estimation

Data Set           WORK.MISSING
N Records Read      32
N Complete Records  16
N Incomplete Records 16
N Complete Obs      16
N Incomplete Obs    16
Model Type          FACTOR
Analysis            Means and Covariances

```

PROC CALIS shows you that the number of complete observations is 16 and the number of incomplete observations is 16 in the data set. All these observations are included in the estimation. The analysis type is ‘Means and Covariances’ because with full information maximum likelihood, the sample means have to be analyzed during the estimation.

For the full information maximum likelihood estimation, PROC CALIS outputs several tables to summarize the missing data patterns and statistics. [Output 27.15.4](#) shows the proportions of data that are present for the variables, individually or jointly by pairs.

Output 27.15.4 Proportions of Data Present for the Variables: Missing Data

```

Proportions of Data Present for Means (Diagonal) and Covariances (Off-Diagonal)

      x1      x2      x3      y1      y2      y3

x1    0.9375
x2    0.7813    0.8438
x3    0.8125    0.7188    0.8750
y1    0.8750    0.8125    0.8125    0.9375
y2    0.9063    0.8125    0.8438    0.9063    0.9688
y3    0.8125    0.7188    0.7500    0.8125    0.8750    0.8750

Average Proportion Coverage of Means      0.906250
Average Proportion Coverage of Covariances 0.816667

```

The diagonal elements of the table in [Output 27.15.4](#) show the proportions of data coverage by each of the variables. The off-diagonal elements show the proportions of joint data coverage by all possible pairs of variables. For example, the first diagonal element of the table shows that about 94% of the observations have x1 values that are not missing. This percentage value is referred to as the proportion coverage for x1 or the proportion coverage for computing the means of x1. The off-diagonal element for x1 and x2 shows

that about 78% of the observations have nonmissing values for both their x1 and x2 values. This percentage value is referred to as the joint proportion coverage of x1 and x2 or the proportion coverage for computing the covariance between x1 and x2. The larger the coverage proportions this table shows, the more relative information the data contain for estimating the corresponding moments.

To summarize the proportion coverage, [Output 27.15.4](#) shows that on average about 91% of the data are nonmissing for computing the means, and about 82% of the data are nonmissing for computing the covariances.

[Output 27.15.5](#) shows the lowest coverage proportions of the means and the covariances.

Output 27.15.5 Ranking the Lowest Coverage Proportions: Missing Data

Rank Order of the 3 Smallest Variable (Mean) Coverages		
Variable	Coverage	
x2	0.8438	
x3	0.8750	
y3	0.8750	

Rank Order of the 7 Smallest Covariance Coverages		
Var1	Var2	Coverage
x3	x2	0.7188
y3	x2	0.7188
y3	x3	0.7500
x2	x1	0.7813
x3	x1	0.8125
y1	x2	0.8125
y1	x3	0.8125

The first table of [Output 27.15.5](#) shows that x2 has the lowest proportion coverage at about 84%, and x3 and y3 are the next at about 88%. The second table of [Output 27.15.5](#) shows that the joint proportion coverage by the x3–x2 pair and the y3–x2 pair are the lowest at about 72%, followed by the y3–x3 pair at 75%. These two tables are useful to diagnose which variables most lack the information for estimation. For this data set, these tables show that estimation related to the moments of x2, x3, and y3 suffers the missing data problem the most. However, because the worst proportion coverage is still higher than 70%, the missingness problem does not seem to be very serious based on percentage.

In [Output 27.15.6](#), PROC CALIS outputs two tables that show an overall picture of the missing patterns in the data set.

Output 27.15.6 The Most Frequent Missing Patterns and Their Mean Profiles: Missing Data

Rank Order of the 5 Most Frequent Missing Patterns					
Total Number of Distinct Patterns with Missing Values = 7					
	Pattern	NVar Miss	Freq	Proportion	Cumulative
1	x.xxxx	1	4	0.1250	0.1250
2	xx.xxx	1	4	0.1250	0.2500
3	xxxxx.	1	3	0.0938	0.3438
4	.xxxxx	1	2	0.0625	0.4063
5	xxxx..	2	1	0.0313	0.4375

NOTE: Nonmissing Pattern Proportion = 0.5000 (N=16)

Means of the Nonmissing and the Most Frequent Missing Patterns						
		-----Missing Pattern-----				
Variable	Nonmissing (N=16)	1 (N=4)	2 (N=4)	3 (N=3)	4 (N=2)	5 (N=1)
x1	21.75000	18.50000	21.75000	17.66667	.	14.00000
x2	19.37500	.	22.75000	15.66667	9.00000	20.00000
x3	19.31250	17.25000	.	16.66667	16.00000	13.00000
y1	19.00000	18.75000	17.00000	15.00000	9.00000	24.00000
y2	18.12500	18.75000	17.50000	17.33333	10.50000	.
y3	17.75000	19.50000	19.25000	.	10.50000	.

The first table of [Output 27.15.6](#) shows that “x.xxxx” and “xx.xxx” are the two most frequent missing patterns in the data set. Each has a frequency of 4. An “x” in the missing pattern denotes a nonmissing value, while a “.” denotes a missing value. Hence, the first pattern has all missing values for the second variable, and the second pattern has all missing values for the third variable. Each of these two missing patterns accounts for 12.5% of the total observations. Together, the five missing patterns shown in [Output 27.15.6](#) account for about 43.8% of the total observations. The note after this table shows that 50% of the total observations do not have any missing values.

To determine exactly which variables are missing in the missing patterns, it is useful to consult the second table in [Output 27.15.6](#). In this table, the variable means of the most frequent missing patterns are shown, together with the variable means of the nonmissing pattern for comparisons. Missing means in this table show that the corresponding variables are not present in the missing patterns. For example, the column labeled “Nonmissing” is for the group of 16 observations that do not have any missing values. Each of the variable means is computed based on 16 observations. The next column labeled “1” is the first missing pattern that has four observations. The variable mean for x2 is missing for this missing pattern group, while each of the other variable means is computed based on four observations. Comparing these means with those in the nonmissing group, it shows that the means for x1, x3, and y1 in the first missing pattern are smaller than those in the nonmissing group, while the means for y2 and y3 are greater. This comparison does not seem to suggest any systematic bias in the means of the first missing pattern group.

However, the nonmissing means in the third missing pattern (the column labeled “3” do show a consistent downward bias, as compared with the means in the nonmissing group. This might mean that respondents

with low scores in x_1 – x_3 , y_1 , and y_2 tend not to respond to y_3 for some reason. Similarly, the fourth missing pattern shows a consistent downward bias in x_2 , x_3 , and y_1 – y_3 . Whether these patterns suggest a systematic (or nonrandom) pattern of missingness must be judged in the substantive context. Nonetheless, the numerical results in [Output 27.15.6](#) provide some insight on this matter.

The tables shown in [Output 27.15.6](#) do not show all the missing patterns. In general, PROC CALIS shows only the most frequent or dominant missing patterns so that the output results are more focused. By default, if the total number of missing patterns in a data set is below six, then PROC CALIS shows all the missing patterns. If the total number of missing patterns is at least six, PROC CALIS shows up to 10 missing patterns provided that each of these missing patterns accounts for at least 5% of the total observations. The 10 missing patterns is the default maximum number of missing patterns to show, and the 5% is the default proportion threshold for a missing pattern to display. You can override the default maximum number of missing patterns by the `MAXMISSPAT=` option and the proportion threshold by the `TMISSPAT=` option.

[Output 27.15.7](#) shows the parameter estimates by the FIML estimation.

First, you can compare the current FIML results with the results in [Example 27.12](#), where maximum likelihood method is used with the complete data set. Overall, the estimates of loadings, factor covariance, and error variances are similar in the two analyses. Next, you compare the current FIML results with the results in [Output 27.15.2](#), where the default ML method is applied to the same data set with missing values. Except for the standard error estimate of the factor covariance, which are very similar with ML and FIML, the standard error estimates with FIML are consistently smaller than those with ML in [Output 27.15.2](#). This means that with FIML, you improve the estimation efficiency by including the partial information in those observations with missing values.

When you have a data set with no missing values, the ML and FIML methods, as implemented in PROC CALIS, are theoretically the same. Both are equally efficient and produce similar estimates (see [Example 27.16](#)). FIML and ML are the same estimation technique that maximizes the likelihood function under the multivariate normal distribution. However, in PROC CALIS, the distinction between of ML and FIML concerns different treatments of the missing values. With METHOD=ML, all observations with one or more missing values are discarded from the analysis. With METHOD=FIML, all observations with at least one nonmissing value are included in the analysis.

Example 27.16: Comparing the ML and FIML Estimation

This example uses the complete data set from [Example 27.12](#) to illustrate how the maximum likelihood (ML) and full information maximum likelihood (FIML) methods are theoretically equivalent when you apply them to data set without missing values. In [Example 27.15](#), you apply a confirmatory factor model to a data set with missing values. You find that with METHOD=FIML, you can get more stable estimates than with METHOD=ML (which is the default estimation method). Near the end of [Example 27.15](#), you learn that ML and FIML are theoretically equivalent estimation methods when you apply them to data sets *without* missing values.

However, the ML and FIML methods have two major computational differences in their implementations in PROC CALIS. First, with METHOD=FIML the first-order properties (that is, the means of the variables) of the data are automatically included in the analysis. However, by default you analyze only the second-order properties (that is, the covariances of the variables) with METHOD=ML. Second, the biased sample covariance formula (with N as the variance divisor) is used with METHOD=FIML, while the unbiased sample covariance formula (with $DF = N - 1$ as the variance divisor) is used with METHOD=ML. See the section “[Relationships among Estimation Criteria](#)” on page 1318 for more details about the similarities and differences between the ML and FIML methods.

If you take care of these two differences between ML and FIML in PROC CALIS, you can obtain exactly the same results with these two methods when you apply them to data sets without missing values.

For example, with the complete data set scores from [Example 27.12](#), you specify the FIML estimation in the following statements:

```
proc calis method=fiml data=scores;
  factor
    verbal ==> x1-x3,
    math   ==> y1-y3;
  pvar
    verbal = 1.,
    math   = 1.;
run;
```

An equivalent specification with the ML method is shown in the following statements:

```
proc calis method=ml meanstr vardef=n data=scores;
  factor
    verbal ==> x1-x3,
    math   ==> y1-y3;
  pvar
    verbal = 1.,
    math   = 1.;
run;
```

In the PROC CALIS statement, you specify two options to make the ML estimation exactly equivalent to the FIML estimation in PROC CALIS. First, the MEANSTR option requests the first-order properties (the mean structures) to be analyzed with the covariance structures. Second, the VARDEF=N option defines the variance divisor to N, instead of the default DF, which is the same as N-1. These two options make the ML estimation equivalent to the FIML estimation.

Output 27.16.1 and Output 27.16.2 show some fit summary statistics under the FIML and ML methods, respectively.

Output 27.16.1 Model Fitting by the FIML Method: Scores Data

Fit Summary	
Fit Function	31.7837
Chi-Square	10.1215
Chi-Square DF	8
Pr > Chi-Square	0.2566
Standardized RMR (SRMR)	0.0571
RMSEA Estimate	0.0910
Bentler Comparative Fit Index	0.9872
NOTE: Saturated mean structure parameters are excluded from the computations of fit indices.	

Output 27.16.2 Model Fitting by the ML Method: Scores Data

Fit Summary	
Fit Function	0.3163
Chi-Square	10.1215
Chi-Square DF	8
Pr > Chi-Square	0.2566
Standardized RMR (SRMR)	0.0504
RMSEA Estimate	0.0910
Bentler Comparative Fit Index	0.9872

Except for the fit function values, both FIML and ML methods produce the same set of fit statistics. The difference in the fit function values is expected because the FIML function has a constant term which is derived from the likelihood function. This constant term does not depend on the model parameters. Hence, the FIML and ML discrepancy functions that are used in PROC CALIS are equivalent when VARDEF=N is used in the ML method for analyzing mean and covariance structures.

The parameter estimates are shown in Output 27.16.3 and Output 27.16.4 for the FIML and ML methods, respectively. Except for very tiny numerical differences in some estimates, the FIML and ML estimates match.

Output 27.16.3 Parameter Estimates by the FIML Method: Scores Data

The equivalence between METHOD=ML and METHOD=FIML implies that if you do not have any missing data in your data, you can just use METHOD=ML because it is computationally more efficient than the FIML method.

While the equivalence between ML and FIML is established here with the use of the VARDEF= and MEANSTR options (for data without missing values), it is not necessary in practice to use these options with METHOD=ML. The VARDEF= option is used in this example only to demonstrate the theoretical equivalence between METHOD=ML and METHOD=FIML. The VARDEF= option has very little effect if you have at least a moderate sample size (for example, 30 or more observations).

Merely adding the MEANSTR option to an analysis for data without missing values amounts to adding a saturated mean structure to a covariance structure analysis. In this case, the MEANSTR option only gives you more estimates that pertain to the mean structures, but the parameter estimates that pertain to the covariance structures do not change. Therefore, use the MEANSTR option only when you need to estimate certain mean structure parameters or when you fit models with nonsaturated mean structures.

However, use METHOD=FIML when there are missing values in your data and you need to use every bit of information from the incomplete observations with random missing values.

Example 27.17: Path Analysis: Stability of Alienation

The following covariance matrix from Wheaton et al. (1977) has served to illustrate the performance of several implementations for the analysis of structural equation models. Two different models have been analyzed by an early implementation of LISREL and are mentioned in Jöreskog (1978). You can also find a more detailed discussion of these models in the LISREL VI manual (Jöreskog and Sörbom 1985). A slightly modified model for this covariance matrix is included in the EQS 2.0 manual (Bentler 1985, p. 28). However, for the analysis with the EQS implementation, the SEI variable is rescaled by a factor of 0.1 to make the matrix less ill-conditioned. Since the Levenberg-Marquardt or Newton-Raphson optimization techniques are used with PROC CALIS, rescaling the data matrix is not necessary and, therefore, is not done here. The results reported here reflect the estimates based on the original covariance matrix.

The path diagram of this model is displayed in Figure 27.1 and is reproduced in the following:

You use the PATH modeling language of PROC CALIS to specify this path model, as shown in the following statements:

```

title "Stability of Alienation";
title2 "Data Matrix of WHEATON, MUTHEN, ALWIN & SUMMERS (1977)";
data Wheaton(TYPE=COV);
  _type_ = 'cov';
  input _name_ $ 1-11 Anomie67 Powerless67 Anomie71 Powerless71
                    Education SEI;

Since no **METHOD=** option is used in the PROC CALIS statement, maximum likelihood estimates are computed by default.

In the PATH statement, you specify the functional relationships of the variables in the model. These functional relationships are represented as single-headed paths in the path diagram. There are five entries in the PATH statement. You specify the relationships between the latent constructs and the observed variables in the first three path entries. For example, the first entry states that Anomie and Powerless67 are measured indicators of the latent variable Alien67. The path effects or coefficients from the latent factor to these measured indicators are fixed at 1.0 and 0.833, respectively. Similarly, in the next two path entries, you

define the relationships between the latent factors Alien71 and SES and their measured indicators. The last two path entries in the PATH statement represent the functional relationships among the latent variables in the model. SES has effects on Alien67 and Alien71. These effect parameters are labeled or named with gamma1 and gamma2, respectively. Alien67 also has an effect on Alien71, with the effect parameter named beta.

In the PVAR statement, you specify the variance or error variance parameters in the model. These parameters correspond to the double-headed arrows pointing to the individual variables in the path diagram. In the first six entries of the PVAR statement, you specify the error variance parameters of the observed variables. You also give names to these parameters that correspond to the notation in the path diagram. Although you can choose any names for the parameters, it is important to remember that parameters with the same name are identical and will have the same estimates. For example, the error variances of Anomie67 and Anomie71 are the same parameter named theta1. Similarly, you constrain the error variances of Powerless67 and Powerless71. However, the error variance parameters of Education and SEI are unique. They are not constrained with other parameters in the model because they have unique parameter names. Next, you specify the error variance parameters of Alien67 and Alien71. They also have unique parameter names and therefore they are not constrained with any other parameters in the model. Lastly, you specify the variance parameter phi of SES.

In the PCOV statement, you specify the covariances or error covariances among variables in the model. These parameters correspond to the double-headed arrows pointing to distinct pairs of variables in the path diagram. Observed variables Anomie67 and Anomie71 have correlated errors and you specify this error covariance parameter as theta5. Similarly, observed variables Powerless67 and Powerless71 have correlated errors and you also specify this error covariance parameter as theta5. This way, the two error covariances are constrained to be equal.

PROC CALIS can produce a high-quality residual histogram that is useful for showing the distribution of residuals. Before you request the residual histogram, ODS Graphics must be enabled. For example, you can specify the ODS GRAPHICS ON statement, as shown in the preceding statements before the PROC CALIS statement. Then, the residual histogram is requested by the **plots=residuals** option in the PROC CALIS statement.

Output 27.17.1 displays the modeling information and variables in the analysis.

Output 27.17.1 Model Specification and Variables

		Powerless71	SEI		
	Latent	Alien67	Alien71		
Exogenous	Manifest				
	Latent	SES			
Number of Endogenous Variables = 8					
Number of Exogenous Variables = 1					

Output 27.17.1 shows that the data set Wheaton was used with 932 observations. The model is specified with the PATH modeling language. Variables in the model are classified into different categories according to their roles. All manifest variables are endogenous in the model. Also, three latent variables are hypothesized in the model: Alien67, Alien71, and SES. While Alien67 and Alien71 are endogenous, SES is exogenous in the model.

Output 27.17.2 echoes the initial specification of the PATH model.

Output 27.17.2 Initial Estimates

Initial Estimates for PATH List				
-----Path-----		Parameter		Estimate

Initial Estimates for Covariances Among Errors			
Error of	Error of	Parameter	Estimate
Anomie67	Anomie71	theta5	.
Powerless67	Powerless71	theta5	.

In [Output 27.17.2](#), numerical values for estimates are the initial values you input in the model specification. If the associated parameter name for a numerical estimate is blank, it means that the estimate is a fixed value, which would not be changed in the estimation. For example, the first five paths have fixed path coefficients with the fixed values given. For numerical estimates with parameter names given, the numerical values serve as initial values, which would be changed during the estimation. In [Output 27.17.2](#), you actually do not have this kind of specification. All free parameters specified in the model are with missing initial values, denoted by ‘.’. For example, lambda, gamma1, theta1, and psi1, among others, are free parameters without initial values given. PROC CALIS generates the initial values of these parameters automatically.

You can examine this output to ensure that the desired model is being analyzed. PROC CALIS outputs the initial specifications or the estimation results in the order you specify in the model, unless you use reordering options such as [ORDERSPEC](#) and [ORDERALL](#). Therefore, the input order of specifications is important—it determines how your output would look.

Simple descriptive statistics are displayed in [Output 27.17.3](#).

Output 27.17.3 Descriptive Statistics

Simple Statistics			
	Variable	Mean	Std Dev
Anomie67	Anomie (1967)	0	3.44006
Powerless67	Powerlessness (1967)	0	3.06007
Anomie71	Anomie (1971)	0	3.54006
Powerless71	Powerlessness (1971)	0	3.16006
Education	Education	0	3.10000
SEI	Occupational Status Index	0	21.21999

Because the input data set contains only the covariance matrix, the means of the manifest variables are assumed to be zero. Note that this has no impact on the estimation, unless a mean structure model is being analyzed.

Initial estimates are necessary in all kinds of optimization problems. You can provide these initial estimates or let PROC CALIS to generate them automatically. As shown in [Output 27.17.2](#), you did not provide any initial estimates for the parameters. PROC CALIS uses a combination of well-behaved mathematical methods to complete the initial estimation. The initial estimation methods for the current analysis are shown in [Output 27.17.4](#).

Output 27.17.4 Optimization Starting Point

Initial Estimation Methods			
1	Instrumental Variables Method		
2	McDonald Method		
3	Two-Stage Least Squares		
Optimization Start Parameter Estimates

Lambda			0	Actual Over Pred Change			1.0060912391	
Radius			0.001390392					
Convergence criterion (ABSGCONV=0.00001) satisfied.								

The convergence status is important for the validity of your solution. In most cases, you should interpret your results only when the solution is converged. In this example, you obtain a converged solution, as shown in the message at the bottom of the table. The final objective function value is 0.01448, which is the minimized function value during the optimization. If problematic solutions such as nonconvergence are encountered, PROC CALIS issues an error message.

The fit summary statistics are displayed in [Output 27.17.6](#). By default, PROC CALIS displays all available fit indices and modeling information.

Output 27.17.6 Fit Summary

Fit Summary

	Bollen Normed Index Rho1	0.9895
	Bollen Non-normed Index Delta2	0.9979
	James et al. Parsimonious NFI	0.5962

First, the fit summary table starts with some basic modeling information, as shown in [Output 27.17.6](#). You can check the number of observations, number of variables, number of moments being fitted, number of parameters, number of active constraints in the solution, and the independent model chi-square and its degrees of freedom in this modeling information category. Next, three types of fit indices are shown: absolute, parsimony, and incremental.

The absolute indices are fit measures that you interpret them without referring to any baseline model. These indices do not adjust for model parsimony. They always favor models with a large number of parameters. The chi-square test statistic is the best-known absolute index in this category. In this example, the p -value of the chi-square is 0.1419, which is greater than the conventional 0.05 value. From the statistical hypothesis testing point of view, you cannot reject this model. The Z-test of Wilson and Hilferty is also insignificant at $\alpha = .05$, which echoes the result of the chi-square test. You can consult other absolute indices as

well. Although it seems that there are no clear conventional levels for these absolute indices to indicate an acceptable model fit, you can always use these indices to compare the relative fit among competing models.

Next, the parsimony fit indices take the model parsimony into account. These indices adjust the model fit by the degrees of freedom (or the number of the parameters) of the model in certain ways. The advantage of these indices is that merely increasing the number of parameters in the model might not necessarily lead better model fit measures. These fit indices penalize models with large numbers of parameters. There is no universal way to interpret all these indices. However, for the relatively well-known RMSEA estimate, by convention values under 0.05 indicate good model fit. The RMSEA value for this example is 0.0231, and so this is a very good model fit. For interpretations of other parsimony indices, you can consult the original articles for these indices.

Last, the incremental fit indices are computed based on comparing the target model fit against the fit of a baseline model, which is usually the so-called uncorrelatedness model where all manifest variables are assumed to be uncorrelated. This is the baseline model that PROC CALIS uses. The baseline model fit statistic is shown under the 'Modeling Info' category of the same fit summary table. In this example, the model fit chi-square of the baseline model is 2131.43, with 15 degrees of freedom. The incremental indices show how well the hypothesized model improves over the baseline model for the data. Various incremental fit indices have been proposed. In the fit summary table, there are six of such fit indices. Large values for these indices are desired. It has been suggested that values greater than .9 for these indices indicate acceptable model fit. In this example, all incremental indices but James et al. parsimonious NFI show that the hypothesized model fits well.

There is no consensus as to which fit index is the best to judge model fit. Probably, with artificial data and model, all fit indices can be shown defective in some aspects of measuring model fit. Conventional wisdom is to look at all fit indices and determine whether the majority of them are close to the desirable ranges of values. In this example, almost all fit indices are good, and so it is safe to conclude that the model fits well.

Nowadays, most researchers pay less attention to the model fit chi-square statistic because it tends to reject all meaningful models with minimum departures from the truth. Although the model fit chi-square test statistic is an impeccable statistical inference tool when the underlying statistical assumptions are satisfied, for practical purposes it is just too powerful to accept any useful and reasonable models with only tiny imperfections. Some fit indices are more popular than others. Standardized RMR, RMSEA estimate, adjusted AGFI, and Bentler's comparative fit index are frequently reported in empirical research for judging model fit. In this example, all these measures show good model fit of the hypothesized model. While there are certainly legitimate reasons why these fit indices are more popular than others, they are out of the current scope of discussion.

PROC CALIS can perform a detailed residual analysis. Large residuals might indicate misspecification of the model. In [Output 27.17.7](#), raw residuals are reported and ranked.

Output 27.17.7 Raw Residuals and Ranking

Raw Residual Matrix				
		Anomie67	Powerless67	Anomie71

Powerless71	Powerless71	0.58521
Powerless67	Anomie67	0.52686
SEI	Powerless71	-0.49608
SEI	Anomie67	0.46484

The model performs the poorest concerning the covariances of Education with all measures of Powerless and Anomie. This might suggest a misspecification of the functional relationships of Education with other variables in the model. However, because the model fit is quite good, such a possible misspecification should not be a serious concern in the analysis.

The histogram of the asymptotically standardized residuals is displayed in [Output 27.17.9](#), which also shows the normal and kernel approximations.

Output 27.17.9 Distribution of Asymptotically Standardized Residuals

The residual distribution looks quite symmetrical. It shows a small to medium departure from the normal distribution, as evidenced by the discrepancies between the kernel and the normal distribution curves.

Output 27.17.10 shows the estimation results.

Output 27.17.10 Estimation Results

PATH List

Covariances Among Errors					
Error of	Error of	Parameter	Estimate	Standard Error	t Value
Anomie67	Anomie71	theta5	0.90580	0.12167	7.44472
Powerless67	Powerless71	theta5	0.90580	0.12167	7.44472

The paths, variances and partial (or error) variances, and covariances and partial covariances are shown. When you have fixed parameters such as the first five path coefficients in the output, the standard errors and t values are all blanks. For free or constrained estimates, standard errors and t values are computed. Researchers in structural equation modeling usually use the value 2 as an approximate critical value for the observed t values. The reason is that the estimates are asymptotically normal, and so the two-sided critical point with $\alpha = 0.05$ is 1.96, which is close to 2. Using this criterion, all estimates shown in [Output 27.17.10](#) are significantly different from zero, supporting the presence of these parameters in the model.

Squared multiple correlations are shown in [Output 27.17.11](#).

Output 27.17.11 Squared Multiple Correlations

Squared Multiple Correlations			
Variable	Error Variance	Total Variance	R-Square

Anomie71	3.60796	12.61581	0.7140
Education	2.99366	9.61000	0.6885
Powerless67	3.59488	9.35139	0.6156
Powerless71	3.59488	9.84533	0.6349
SEI	259.57639	450.28798	0.4235
Alien67	5.67046	8.29601	0.3165
Alien71	4.51479	9.00786	0.4988

For each endogenous variable in the model, the corresponding squared multiple correlation is computed by:

$$1 - \frac{\text{error variance}}{\text{total variance}}$$

In regression analysis, this is the percentage of explained variance of the endogenous variable by the predictors. However, this interpretation is complicated or even uninterpretable when your structural equation model has correlated errors or reciprocal casual relations. In these situations, it is not uncommon to see negative R-squares. Negative R-squares do not necessarily mean that your model is wrong or the model prediction is weak. Rather, the R-square interpretation is questionable in these situations.

When your variables are measured on different scales, comparison of path coefficients cannot be made directly. For example, in [Output 27.17.10](#), the path coefficient for path Education <== SES is fixed at one, while the path coefficient for path SEI <== SES is 5.369. It would be simple-minded to conclude that the effect of SES on SEI is greater than that SES on Education. Because SEI and Education are measured on different scales, direct comparison of the corresponding path coefficients is simply inappropriate.

In alleviating this problem, some might resort to the standardized solution for a better comparison. In a standardized solution, because the variances of manifest variables and systematic predictors are all standardized to ones, you hope the path coefficients are more comparable. In this example, PROC CALIS standardizes your results in [Output 27.17.12](#).

Output 27.17.12 Standardized Results

Standardized Results for PATH List					
-----Path-----	Parameter	Estimate	Standard Error	t Value	
Anomie67 <== Alien67		0.83481	0.01093	76.35313	
Powerless67 <== Alien67		0.78459	0.01163	67.47756	
Anomie71 <== Alien71		0.84499	0.01031	81.97956	
Powerless71 <== Alien71		0.79678	0.01107	71.96263	
Education <== SES		0.82975	0.03172	26.15990	
SEI <== SES	lambda	0.65079	0.03019	21.55331	
Alien67 <== SES	gamma1	-0.56257	0.03456	-16.27961	
Alien71 <== SES	gamma2	-0.20642	0.04483	-4.60430	
Alien71 <== Alien67	beta	0.56920	0.04066	14.00001	
Standardized Results for Variance Parameters					
Variance Type	Variable	Parameter	Estimate	Standard Error	t Value
Error	Anomie67	theta1	0.30309	0.01825	16.60309
	Powerless67	theta2	0.38442	0.01825	21.06948
	Anomie71	theta1	0.28599	0.01742	16.41782
	Powerless71	theta2	0.36514	0.01764	20.69424
	Education	theta3	0.31152	0.05264	5.91822
	SEI	theta4	0.57647	0.03930	14.66804
	Alien67	psi1	0.68352	0.03888	17.57968
	Alien71	psi2	0.50121	0.03321	15.08974
Exogenous	SES	phi	1.00000		

Output 27.17.12 *continued*

Standardized Results for Covariances Among Errors					
Error of	Error of	Parameter	Estimate	Standard Error	t Value
Anomie67	Anomie71	theta5	0.07391	0.01013	7.29574
Powerless67	Powerless71	theta5	0.09440	0.01274	7.40922

Now, the standardized path coefficient for path Education <== SES is 0.830, while the standardized path coefficient for path SEI <== SES is 0.651. So the standardized effect of SES on SEI is actually smaller than that of SES on Education.

Furthermore, in PROC CALIS the standardized estimates are computed with standard error estimates and *t* values so that you can make statistical inferences on the standardized estimates as well.

PROC CALIS might differ from other software in its standardization scheme. Unlike other software that might standardize the path coefficients that attach to the error terms (unsystematic sources), PROC CALIS keeps these path coefficients at ones (not shown in the output). Unlike other software that might also standardize the corresponding error variances to ones, the error variances in the standardized solution of PROC CALIS are rescaled so as to keep the mathematical consistency of the model.

Essentially, in PROC CALIS only variances of manifest and non-error-type latent variables are standardized to ones. The error variances are rescaled, but not standardized. For example, in the standardized solution shown in [Output 27.17.12](#), the error variances for all endogenous variables are not ones (see the middle portion of the output). Only the variance for the latent variable SES is standardized to one. See the section “[Standardized Solutions](#)” on page 1345 for the logic of the standardization scheme adopted by PROC CALIS.

In appearance, the standardized solution is like a correlational analysis on the standardized manifest variables with standardized exogenous latent factors. Unfortunately, this statement is over-simplified, if not totally inappropriate. In standardizing a solution, the implicit equality constraints are likely destroyed. In this example, the unstandardized error variances for Anomie67 and Anomie71 are both 3.608, represented by a common parameter theta1. However, after standardization, these error variances have different values at 0.303 and 0.286, respectively. In addition, fixed parameter values are no longer fixed in a standardized solution (for example, the first five paths in the current example). The issue of standardization is common to all other SEM software and beyond the current discussion. PROC CALIS provides the standardized solution so that users can interpret the standardized estimates whenever they find them appropriate.

Example 27.18: Simultaneous Equations with Mean Structures and Reciprocal Paths

The supply-and-demand food example of Kmenta (1971, pp. 565, 582) is used to illustrate PROC CALIS for the estimation of intercepts and coefficients of simultaneous equations in econometrics. The model is specified by two simultaneous equations containing two endogenous variables Q and P , and three exogenous variables D , F , and Y :

$$Q_t(\text{demand}) = \alpha_1 + \beta_1 P_t + \gamma_1 D_t$$

$$Q_t(\text{supply}) = \alpha_2 + \beta_2 P_t + \gamma_2 F_t + \gamma_3 Y_t$$

for $t = 1, \dots, 20$.

To analyze this model in PROC CALIS, the second equation needs to be written in another form. For instance, in the LINEQS model each endogenous variable must appear on the left-hand side of exactly one equation. To satisfy this requirement, you can rewrite the second equation as an equation for P_t as:

$$P_t = -\frac{\alpha_2}{\beta_2} + \frac{1}{\beta_2} Q_t - \frac{\gamma_2}{\beta_2} F_t - \frac{\gamma_3}{\beta_2} Y_t$$

or, equivalently reparameterized as:

$$P_t = \theta_1 + \theta_2 Q_t + \theta_3 F_t + \theta_4 Y_t$$

where

$$\theta_1 = -\frac{\alpha_2}{\beta_2}, \quad \theta_2 = \frac{1}{\beta_2}, \quad \theta_3 = -\frac{\gamma_2}{\beta_2}, \quad \theta_4 = -\frac{\gamma_3}{\beta_2}$$

This new equation for P_t together with the first equation for Q_t suggest the following LINEQS model specification in PROC CALIS:

```

  bounds
    eps1-eps2 >= 0. ;
run;

```

The LINEQS modeling language is used in this example because its specification is similar to the original equations. In the **LINEQS** statement, you essentially input the two model equations for Q and P. Parameters for intercepts and regression coefficients are also specified in the equations. Note that Intercept in the two equations is treated as a special variable that contains ones for all observations. Intercept is not a variable in the data set, nor do you need to create such a variable in your data set. Hence, the variable Intercept does not represent the intercept parameter itself. Instead, the intercept parameters for the two equations are the coefficients attached to Intercept. In this example, the intercept parameters are alpha1 and theta1, respectively, in the two equations. As required, error terms E1 and E2 are added to complete the equation specification.

In the **VARIANCE** statement, you specify eps1 and eps2, respectively, for the variance parameters of the error terms. In the **COV**, you specify eps3 for the covariance parameter between the error terms. In the **BOUNDS** statement, you set lower bounds for the error variances so that estimates of eps1 and eps2 would be nonnegative.

In this example, the **PSHORT** and the **NOSTAND** options are used in the PROC CALIS statement. The **PSHORT** option suppresses a large amount of the output. For example, initial estimates are not printed and simple descriptive statistics and standard errors are not computed. The **NOSTAND** option suppresses the printing of the standardized results. Because the default printing in PROC CALIS might produce a large amount of output, using these printing options make your output more concise and readable. Whenever appropriate, you may consider using these printing options.

The estimated equations are shown in [Output 27.18.1](#).

Output 27.18.1 Linear Equations

Linear Equations				
Q	=	93.6193*Intercept	+ -0.2295*P	+ 0.3100*D
Std Err		7.5748 alpha1	0.0923 beta1	0.0448 gamma1
t Value		12.3592	-2.4856	6.9186
		+ 1.0000 E1		

Linear Equations				
P	=	-218.9*Intercept	+ 4.2140*Q	+ -0.9305*F
Std Err		137.7 theta1	1.7540 theta2	0.3960 theta3
t Value		-1.5897	2.4025	-2.3500
		+ -1.5579*Y	+ 1.0000 E2	
		0.6650 theta4		
		-2.3429		

The estimates of intercepts and regression coefficients are shown directly in the equations. Any number in an equation followed by an asterisk is an estimate. For the estimates in equations, the parameter names are shown underneath the associated variables. Any number in an equation not followed by an asterisk is a fixed value. For example, the value 1.0000 attached to the error term in each of the output equation is fixed. Also, for fixed coefficients there are no parameter names underneath the associated variables.

All but the intercept estimates in the equation for predicting P are statistically significant at $\alpha = 0.05$ (when using an approximate critical value of 2). The t ratio for theta1 is -1.590 , which implies that this intercept might have been zero in the population. However, because you have reparameterized the original model to use the LINEQS model specification, transformed parameters like theta1 in this model might not be of primary interest. Therefore, you might not need to pay any attention to the significance of the theta1 estimate. There is a way to use the original econometric parameters to specify the LINEQS model. It is discussed in the later part of this example.

Estimates for variance, covariance, and mean parameters are shown in [Output 27.18.2](#).

Output 27.18.2 Variance, Covariance, and Mean Parameters

Estimates for Variances of Exogenous Variables					
Variable Type	Variable	Parameter	Estimate	Standard Error	t Value
Error	E1	eps1	3.51274	1.20204	2.92233
	E2	eps2	105.06749	83.89446	1.25238
Observed	D	_Add1	139.96029	45.40911	3.08221
	F	_Add2	161.51355	52.40192	3.08221
	Y	_Add3	35.00000	11.35550	3.08221

Output 27.18.2 *continued*

Covariances Among Exogenous Variables					
Var1	Var2	Parameter	Estimate	Standard Error	t Value
E1	E2	eps3	-18.87270	8.77951	-2.14963
F	D	_Add4	74.02539	38.44699	1.92539
Y	D	_Add5	22.99211	16.90102	1.36040
Y	F	_Add6	-21.58158	17.94544	-1.20262

Mean Parameters					
Variable Type	Variable	Parameter	Estimate	Standard Error	t Value
Observed	D	_Add7	97.53500	2.71410	35.93643
	F	_Add8	96.62500	2.91560	33.14071
	Y	_Add9	10.50000	1.35724	7.73628

Parameters with a name prefix `_Add` are added automatically by PROC CALIS. These parameters are added as free parameters to complete the model specification. In PROC CALIS, variances and covariances among the set of exogenous manifest variables must be parameters. You either specify them explicitly or let the CALIS procedure to add them. If you need to constrain or to fix these parameters, then you must specify them explicitly. When your model also fits the mean structures, the same principle applies to the means of the exogenous manifest variables. In this example, because variables D, F, and Y are all exogenous manifest variables, their associated means, variances and covariances must be parameters in the model.

The squared multiple correlations for the equations are shown in [Output 27.18.3](#).

Output 27.18.3 Squared Multiple Correlations

Squared Multiple Correlations			
Variable	Error Variance	Total Variance	R-Square
Q	3.51274	14.11128	0.7511
P	105.06749	35.11850	-1.9918

For endogenous variable P, the R-square is -1.9918, which is obviously an invalid value. In fact, because there are correlated errors (between E1 and E2) and reciprocal paths (paths to and from Q and P), the model departs from the regular assumptions of multiple regression analysis. As a result, you should not interpret the R-squares for this example.

Specifying the LINEQS with the Original Econometric Parameters

If you are interested in estimating the parameters in the original econometric model (that is, α_2 , β_2 , γ_2 , and γ_3), the previous reparameterized LINEQS model does not serve your purpose well enough. However, using the relations between these original parameters with the θ parameters in the reparameterized LINEQS model, you can set up some “super-parameters” in the LINEQS model, as shown in the following statements:

```
proc calis data=Food pshort nostand;
  lineqs
    Q = alpha1 * Intercept + beta1 * P + gamma1 * D + E1,
    P = theta1 * Intercept + theta2 * Q + theta3 * F + theta4 * Y + E2;
  variance
    E1-E2 = eps1-eps2;
  cov
    E1-E2 = eps3;
  bounds
    eps1-eps2 >= 0. ;
  parameters alpha2 (50.) beta2 gamma2 gamma3 (3*.25);
    theta1 = -alpha2 / beta2;
    theta2 = 1 / beta2;
    theta3 = -gamma2 / beta2;
    theta4 = -gamma3 / beta2;
run;
```

In this new specification, only the **PARAMETERS** statement and the **SAS programming statements** following it are new. In the **PARAMETERS** statement, you define super-parameters alpha2, beta2, gamma2, and gamma3, and put initial values for them in parentheses. These parameters are the original econometric parameters of interest. The **SAS programming statements** that follow the **PARAMETERS** statement are used to define the functional relationships of the super-parameters with the parameters in the LINEQS model. Consequently, in this new specification, theta1, theta2, theta3, and theta4 are no longer independent parameters in the model, as they are in the previous reparameterized model. Instead, alpha2, beta2, gamma2, and gamma3 are independent parameters in this new specification. By fitting this new model, you get the same set of estimates as those in the previous LINEQS model. In addition, you get estimates of the super-parameters, as shown in [Output 27.18.4](#).

Output 27.18.4 Additional Parameters

Additional Parameters				
Type	Parameter	Estimate	Standard Error	t Value
Independent	alpha2	51.94452	11.70002	4.43969
	beta2	0.23731	0.09877	2.40262
	gamma2	0.22082	0.04161	5.30695
	gamma3	0.36971	0.07060	5.23649

You can now interpret the results in terms of the original econometric parameterization. As shown in [Output 27.18.4](#), all these estimates are significant, despite the fact that one of the transformed parameter estimates in the linear equations of the LINEQS model is not. You can obtain almost equivalent results by applying the SAS/ETS procedure SYSLIN on this problem.

Alternative Ways to Specify Your LINEQS Model

In specifying the linear equations in the LINEQS model, it might become cumbersome when you need to name a lot of parameters into the equations. If the parameters in your model are unconstrained, you need to be very careful to use unique parameter names to distinguish the free parameters because parameters with the same name are identical and will have the same estimate. To make model specification easier and to avoid accidental constraints, PROC CALIS provides an efficient way to specify these free parameters. That is, you can simply omit the parameter names in the specification. For example, in the first specification of the current example, except for the boundary constraints on the error variance parameters, all other parameters in the model are not constrained, as shown in the following statements:

```
proc calis data=food pshort nostand;
  lineqs
    Q = alpha1 * Intercept + beta1 * P + gamma1 * D + E1,
    P = theta1 * Intercept + theta2 * Q + theta3 * F + theta4 * Y + E2;
  variance
    E1-E2 = eps1-eps2;
  cov
    E1-E2 = eps3;
  bounds
    eps1-eps2 >= 0. ;
run;
```

Parameters such as alpha1, beta1, and so on are unique parameter names in the specific locations of the model. They are free parameters. Hence, you can use the following equivalent specification:

```
proc calis data=food pshort nostand;
  lineqs
    Q = * Intercept + * P + * D + E1,
    P = * Intercept + * Q + * F + * Y + E2;
  variance
    E1-E2 = eps1-eps2;
  cov
    E1 E2;
  bounds
    eps1-eps2 >= 0. ;
run;
```

Only the parameters eps1 and eps2 remain in this equivalent specification. You omit the specification of all other parameter names. But the estimation results are the same, as shown in [Output 27.18.5](#).

Output 27.18.5 Estimation Results With Generated Parameter Names

Linear Equations					
Q	=	93.6193*Intercept	+ -0.2295*P	+ 0.3100*D	
Std Err		7.5748 _Parm1	0.0923 _Parm2	0.0448 _Parm3

		+ 1.0000 E1			
Linear Equations					
P	=	-218.9*Intercept	+ 4.2140*Q	+ -0.9305*F	
Std Err		137.7 _Parm4	1.7540 _Parm5	0.3960 _Parm6	
t Value		-1.5897	2.4025	-2.3500	
		+ -1.5579*Y + 1.0000 E2			
		0.6650 _Parm7			
		-2.3429			
Estimates for Variances of Exogenous Variables					
Variable Type	Variable	Parameter	Estimate	Standard Error	t Value
Error	E1	eps1	3.51274	1.20204	2.92233
	E2	eps2	105.06749	83.89446	1.25238
Observed	D	_Add1	139.96029	45.40911	3.08221
	F	_Add2	161.51355	52.40192	3.08221
	Y	_Add3	35.00000	11.35550	3.08221
Covariances Among Exogenous Variables					
Var1	Var2	Parameter	Estimate	Standard Error	t Value
E1	E2	_Parm8	-18.87270	8.77951	-2.14963
F	D	_Add4	74.02539	38.44699	1.92539
Y	D	_Add5	22.99211	16.90102	1.36040
Y	F	_Add6	-21.58158	17.94544	-1.20262
Mean Parameters					
Variable Type	Variable	Parameter	Estimate	Standard Error	t Value
Observed	D	_Add7	97.53500	2.71410	35.93643
	F	_Add8	96.62500	2.91560	33.14071
	Y	_Add9	10.50000	1.35724	7.73628

The estimation results in [Output 27.18.5](#) are the same as those in [Output 27.18.2](#) and [Output 27.18.3](#) with the original LINEQS model specification, only now PROC CALIS generates the parameter names with the `_Parm` in the results, as shown in [Output 27.18.5](#). Note that you retain the parameter names `eps1` and `eps2` because you need to refer to them in the `BOUNDS` statement.

Example 27.19: Fitting Direct Covariance Structures

In the section “[Direct Covariance Structures Analysis](#)” on page 1075, the MSTRUCT modeling language is used to specify a model with direct covariance structures. In the model, four variables from the data set of Wheaton et al. (1977) are used. The analysis is carried out in this example to investigate the tenability of the hypothesized covariance structures.

The four variables used are: `Anomie67`, `Powerless67`, `Anomie71`, and `Powerless71`. The hypothesized covariance matrix is structured as:

$$\Sigma = \begin{pmatrix} \phi_1 & \theta_1 & \theta_2 & \theta_1 \\ \theta_1 & \phi_2 & \theta_1 & \theta_3 \\ \theta_2 & \theta_1 & \phi_1 & \theta_1 \\ \theta_1 & \theta_3 & \theta_1 & \phi_2 \end{pmatrix}$$

where:

- ϕ_1 : variance of anomie
- ϕ_2 : variance of powerlessness
- θ_1 : covariance between anomie and powerlessness
- θ_2 : covariance between anomie measures
- θ_3 : covariance between powerlessness measures

In this example, you hypothesize the covariance structures directly, as opposed to those models with implied covariance structures from path models (see [Example 27.17](#)), structural equations (see [Example 27.18](#)), or other types of models. The basic assumption of the direct covariance structures in this example is that `Anomie` and `Powerless` were invariant over the measurement periods employed. This implies that the time of measurement did not change the variances and covariances of the measures. Therefore, both `Anomie67` and `Anomie71` have the same variance parameter ϕ_1 , and both `Powerless67` and `Powerless71` have the same variance parameter ϕ_2 . These two parameters, ϕ_1 and ϕ_2 , are hypothesized on the diagonal of the covariance matrix Σ . In the same structured covariance matrix, θ_1 represents the covariance between `Anomie` and `Powerless`, without regard to the time of measurement. The θ_2 parameter represents the covariance between the `Anomie` measures, or the reliability of the `Anomie` measure. Similarly, the θ_3 parameter represents the covariance between the `Powerless` measures, or the reliability of the `Anomie` measure.

As explained in the section “[Direct Covariance Structures Analysis](#)” on page 1075, you can use the MSTRUCT modeling language to specify the hypothesized covariance structures directly, as shown in the following statements:

```

proc calis nobs=932 data=Wheaton psummary;
  fitindex on(only)=[chisq df probchi] outfit=savefit;
  mstruct
    var = Anomie67 Powerless67 Anomie71 Powerless71;
  matrix _COV_ [1,1] = phi1,
                [2,2] = phi2,
                [3,3] = phi1,
                [4,4] = phi2,
                [2,1] = theta1,
                [3,1] = theta2,
                [3,2] = theta1,
                [4,1] = theta1,
                [4,2] = theta3,
                [4,3] = theta1;
run;

```

In the **MSTRUCT** statement you specify the variables in the **VAR=** list. The order of variables in this **VAR=** list is assumed to be the same as that in the row and column of the hypothesized covariance matrix. Next, in the **MATRIX** statement you specify parameters as entries in the hypothesized covariance matrix **_COV_**. Only the lower diagonal elements need to be specified because covariance matrices, by nature, are symmetric. Redundant specification of the upper triangular elements are unnecessary as PROC CALIS has the information accounted for. You can also set initial estimates by putting parenthesized numbers after the parameter names. But in this example you let PROC CALIS determine all the initial estimates.

In the PROC CALIS statement, the **PSUMMARY** option is used. As a **global display option**, this option suppresses a lot of displayed output and requests only the fit summary table be printed. This way you can eliminate quite a lot of displayed output that is not of your primary interest. In this example, the specification of the covariance structures is straightforward, and you do not need any output regarding the initial estimation or standardized solution. Suppose that you are not even concerned with the estimates of the parameters because you are not yet sure if this model is good enough for the data. All you want to know at this stage is whether the hypothesized covariance structures fit the data well. Therefore, the **PSUMMARY** option would serve your purpose well in this example.

In fact, even the fit summary table can be trimmed down quite a bit if you only want to look at certain specific fit indices. In the **FITINDEX** statement of this example, the **ON(ONLY)=** option turns on the printing of the model fit chi-square, its *df*, and *p*-value only. This does not mean that you must lose the information of all other fit indices. In addition to the printed output, you can save all fit indices in an output data set. To this end, you can use the **OUTFIT=** option in the **FITINDEX** statement. In this example, you save the results of all fit indices in a SAS data set called **savefit**.

Output 27.19.1 shows the entire printed output.

Output 27.19.1 Testing Direct Covariance Structures

Fit Summary	
Chi-Square	221.5798
Chi-Square DF	5
Pr > Chi-Square	<.0001

The displayed output is very concise. It contains only a fit summary table with three statistics. The *p*-value for the model fit chi-square test indicates that the hypothesized structures should be rejected at $\alpha = 0.05$.

Therefore, this rather restrictive direct covariance structure model does not fit the data well. A less restrictive covariance structure model is needed to explain the variances and covariances.

All fit indices are saved in the savefit data set. To view it, you can use the following statement:

```
proc print data=savefit;
run;
```

Output 27.19.2 shows all indices, their types and values of all fit indices and information.

Output 27.19.2 Saved Fit Indices

The results of various fit indices from this output data set confirm that the hypothesized model does not fit the data well.

As an aside, it is noted with some shorthand notation, the specification of the MSTRUCT model parameters that use the **MATRIX** statements can be made a little more precise for the current example. This is shown as follows:

```
proc calis nob=932 data=Wheaton psummary;
  mstruct
    var = Anomie67 Powerless67 Anomie71 Powerless71;
  matrix _COV_ [1,1] = phi1 phi2 phi1 phi2,
               [2, ] = theta1,
               [3, ] = theta2 theta1,
               [4, ] = theta1 theta3 theta1;
  fitindex on(only)=[chisq df probchi] outfit=savefit;
run;
```

In the first entry of the **MATRIX** statement, the notation [1,1] represents that the parameter list specified after the equal sign starts with the [1,1] element of the **_COV_** matrix and proceeds down the diagonal. In the next three entries, the notations [2,], [3,], and [4,] represent that parameter lists start with the first elements of the second, third, and fourth rows, respectively, and proceed to the next (right) elements on the same rows. See the syntax of the **MATRIX** statement on page 1175 for more details about this kind of shorthand notation.

This example shows how you can use the MSTRUCT modeling language to test specific covariance patterns. You need to define the parameters of the covariance patterns explicitly by the **MATRIX** statements. See [Example 27.4](#) and [Example 27.21](#) for more applications.

However, some commonly-used covariance and mean patterns are built into PROC CALIS. For these covariance and mean patterns, you can simply use the **COVPATTERN=** and the **MEANPATTERN=** options without the need to specify the parameters in the **MATRIX** statements. See the **COVPATTERN=** and the **MEANPATTERN=** options for the supported covariance and mean patterns. See [Example 27.5](#) and [Example 27.22](#) for applications.

Example 27.20: Confirmatory Factor Analysis: Cognitive Abilities

In this example, cognitive abilities of 64 students from a middle school were measured. The fictitious data contain nine cognitive test scores. Three of the scores were for reading skills, three others were for math skills, and the remaining three were for writing skills. The covariance matrix for the nine variables was obtained. A confirmatory factor analysis with three factors was conducted. The following is the input data set:

```
title "Confirmatory Factor Analysis Using the FACTOR Modeling Language";
title2 "Cognitive Data";
data cognitivel(type=cov);
  _type_='cov';

;

```

Confirmatory Factor Model with Uncorrelated Factors

You first fit a confirmatory factor model with uncorrelated factors to the data, as shown in the following statements:

```

proc calis data=cognitive1 nobs=64 modification;
  factor
    Read_Factor  ===> reading1-reading3 ,
    Math_Factor  ===> math1-math3      ,
    Write_Factor ===> writing1-writing3 ;
  pvar
    Read_Factor Math_Factor Write_Factor = 3 * 1.;
  cov
    Read_Factor Math_Factor Write_Factor = 3 * 0.;
run;

```

In the PROC CALIS statement, the number of observations is specified with the **NOBS=** option. With the **MODIFICATION** in the PROC CALIS statement, LM (Lagrange Multiplier) tests are conducted. The results of LM tests can suggest the inclusion of additional parameters for a better model fit.

The FACTOR modeling language is most handy when you specify confirmatory factor models. You use the **FACTOR** statement to invoke the FACTOR modeling language. Entries in the **FACTOR** statement are for specifying factor-variables relationships and are separated by commas. In each entry, you first specify a latent factor, followed by the right arrow sign **===>** (you can use **>**, **=>**, **==>**, or **===>**). Then you specify the observed variables that have nonzero loadings on the factor. For example, in the first entry of FACTOR statement, you specify that latent factor **Read_Factor** has nonzero loadings (free parameters) on variables **reading1-reading3**. Optionally, you can specify the parameter list after you specify the factor-variable relationships. For example, you can name the loading parameters as in the following specification:

```

factor
  Read_Factor  ===> reading1-reading3    = load1-load3;

```

This way, you name the factor loadings with parameter names **load1**, **load2**, and **load3**, respectively. However, in the current example, because the loading parameters are all unconstrained, you can just let PROC CALIS to generate the parameter names for you. In this example, there are three factors: **Read_Factor**, **Math_Factor**, and **Write_Factor**. These factors have simple cluster structures with the nine observed variables. Each observed variable has only one loading on exactly one factor.

In the **PVAR** statement, you can specify the variances of the factors and the error variances of the observed variables. The factor variances in this model are all fixed at 1.0 for identification purposes. You do not need to specify the error variances of the observed variables in the current model because PROC CALIS assumes these are free parameters by default.

In the COV statement, you specify that the covariances among the factors are fixed zeros. There are three covariances among the three latent factors and therefore you put $3 \times 0.$ for their fixed values. This means that the factors in the current model are uncorrelated. Note that you must specify uncorrelated factors explicitly in the COV statement because all latent factors are correlated by default.

In [Output 27.20.1](#), the initial model specification is echoed in matrix form. The observed variables and factors are also displayed.

Output 27.20.1 Uncorrelated Factor Model Specification

NOTE: Parameters with prefix '_Add' are added by PROC CALIS.

In the table for initial factor loading matrix, the nine loading parameters are shown to have simple cluster relations with the factors. In the table for initial factor covariance matrix, the diagonal matrix shows that the factors are not correlated. The diagonal elements are fixed at ones so that this matrix is also a correlation matrix for the factors. In the table for initial error variances, the nine variance parameters are shown. As described previously, these error variances are generated by PROC CALIS as default parameters.

In [Output 27.20.2](#), initial estimates are generated by the instrumental variable method and the McDonald method.

The fit summary is shown in [Output 27.20.4](#).

Output 27.20.4 Fit of the Uncorrelated Factor Model

Fit Summary		
Modeling Info	Number of Observations	64
	Number of Variables	9
	Number of Moments	45
	Number of Parameters	18
	Number of Active Constraints	0
	Baseline Model Function Value	4.3182
	Baseline Model Chi-Square	272.0467
	Baseline Model Chi-Square DF	36
Absolute Index	Pr > Baseline Model Chi-Square	<.0001
	Fit Function	0.7837
	Chi-Square	49.3752
	Chi-Square DF	27
	Pr > Chi-Square	0.0054
	Z-Test of Wilson & Hilferty	2.5474
	Hoelter Critical N	52
	Root Mean Square Residual (RMR)	19.5739
Parsimony Index	Standardized RMR (SRMR)	0.2098
	Goodness of Fit Index (GFI)	0.8555
	Adjusted GFI (AGFI)	0.7592
	Parsimonious GFI	0.6416
	RMSEA Estimate	0.1147
	RMSEA Lower 90% Confidence Limit	0.0617
	RMSEA Upper 90% Confidence Limit	0.1646
	Probability of Close Fit	0.0271
Incremental Index	ECVI Estimate	1.4630
	ECVI Lower 90% Confidence Limit	1.2069
	ECVI Upper 90% Confidence Limit	1.8687
	Akaike Information Criterion	85.3752
	Bozdogan CAIC	142.2351
	Schwarz Bayesian Criterion	124.2351
	McDonald Centrality	0.8396
	Bentler Comparative Fit Index	0.9052
	Bentler-Bonett NFI	0.8185
	Bentler-Bonett Non-normed Index	0.8736
	Bollen Normed Index Rho1	0.7580
	Bollen Non-normed Index Delta2	0.9087
	James et al. Parsimonious NFI	0.6139

Using the chi-square model test criterion, the uncorrelated factor model should be rejected at $\alpha = 0.05$. The RMSEA estimate is 0.1147, which is not indicative of a good fit according to Browne and Cudeck (1993). Other indices might suggest only a marginal good fit. For example, Bentler's comparative fit index and Bollen nonnormed index delta2 are both above 0.90. However, many other do not attain this 0.90 level. For example, adjusted GFI is only 0.759. It is thus safe to conclude that there could be some improvements on the model fit.

The **MODIFICATION** option in the PROC CALIS statement has been used to request for computing the LM test indices for model modifications. The results are shown in [Output 27.20.5](#).

Output 27.20.5 Lagrange Multiplier Tests

Rank Order of the 10 Largest LM Stat for Factor Loadings

Rank Order of the 3 Largest LM Stat for Covariances of Factors				
Var1	Var2	LM Stat	Pr > ChiSq	Parm Change
Write_Factor	Read_Factor	8.95268	0.0028	0.44165
Write_Factor	Math_Factor	7.07904	0.0078	0.40132
Math_Factor	Read_Factor	4.61896	0.0316	0.30411

Rank Order of the 10 Largest LM Stat for Error Variances and Covariances				
Error of	Error of	LM Stat	Pr > ChiSq	Parm Change
writing1	math2	5.45986	0.0195	-13.16822
writing1	math1	5.05573	0.0245	12.32431
writing3	math3	3.93014	0.0474	13.59149
writing3	math1	2.83209	0.0924	-9.86342
writing2	reading1	2.56677	0.1091	10.15901
writing2	math2	1.94879	0.1627	8.40273
writing2	reading3	1.75181	0.1856	-7.82777
writing3	reading1	1.57978	0.2088	-7.97915
writing1	reading2	1.34894	0.2455	7.77158
writing2	math3	1.11704	0.2906	-7.23762

Three different tables for ranking the LM test results are shown. In the first table, the new loading parameters that would improve the model fit the most are shown first. For example, in the first row a new factor loading of writing1 on the Read_Factor is suggested to improve the model fit the most. The 'LM Stat' value is 9.77. This is an approximation of the chi-square drop if this parameter was included in the model. The 'Pr > ChiSq' value of 0.0018 indicates a significant improvement of model fit at $\alpha = 0.05$. Nine more new loading parameters are suggested in the table, with less and less statistical significance in the change of model fit chi-square. Note that these approximate chi-squares are one-at-a-time chi-square changes. That means that the overall chi-square drop is not a simple sum of individual chi-square changes when you include two or more new parameters in the modified model.

The other two tables in [Output 27.20.5](#) shows the new parameters in factor covariances, error variances, or error covariances that would result in a better model fit. The table for the new parameters of the factor covariance matrix indicates that adding each of the covariances among factors might lead to a statistically significant improvement in model fit. The largest ‘LM Stat’ value in this table is 8.95, which is smaller than that of the largest ‘LM Stat’ for the factor loading parameters. Despite this, it is more reasonable to add the covariance parameters among factors first to determine whether that improves the model fit.

Confirmatory Factor Model with Correlated Factors

To fit the corresponding confirmatory factor model with correlated factors, you can remove the fixed zeros from the COV statement in the preceding specification, as shown in the following statements:

```
proc calis data=cognitive1 nobs=64 modification;
  factor
    Read_Factor    ==> reading1-reading3 ,
    Math_Factor    ==> math1-math3      ,
    Write_Factor   ==> writing1-writing3 ;
  pvar
    Read_Factor Math_Factor Write_Factor = 3 * 1.;
  cov
    Read_Factor Math_Factor Write_Factor /* = 3 * 0. */;
run;
```

In the COV statement, you comment out the fixed zeros so that the covariances among the latent factors are now free parameters. An alternative way is to delete the entire COV statement so that the covariances among factors are free parameters by the FACTOR model default.

The fit summary of the correlated factor model is shown in [Output 27.20.6](#).

Output 27.20.6 Fit of the Correlated Factor Model

	Bentler-Bonett Non-normed Index	0.9653
	Bollen Normed Index Rho1	0.8375
	Bollen Non-normed Index Delta2	0.9780
	James et al. Parsimonious NFI	0.5945

The model fit chi-square value is 29.47, which is about 20 less than the model with uncorrelated factors. The p -value is 0.20, indicating a satisfactory model fit. The RMSEA value is 0.06, which is close to 0.05, a value recommended as an indication of good model fit by Browne and Cudeck (1993). More fit indices that do not attain the 0.9 level with the uncorrelated factor model now have values close to or above 0.9. These include the goodness-of-fit index (GFI), McDonald centrality, Bentler-Bonnet NFI, and Bentler-Bonnet nonnormed index. By all counts, the correlated factor model is a much better fit than the uncorrelated factor model.

In [Output 27.20.7](#), the estimation results for factor loadings are shown. All these loadings are statistically significant, indicating non-chance relationships with the factors.

Output 27.20.7 Estimation of the Factor Loading Matrix

writing2	_Add8	49.28881	11.39812	4.32429
writing3	_Add9	48.10684	11.48868	4.18733

All t values except the one for reading3 are greater than 2, a value close to a critical t value at $\alpha = 0.05$. This means that the error variance for reading3 could have been zero in the population, or it could have been nonzero but the current sample just has this insignificant value by chance (that is, a Type 2 error). Further research is needed to confirm either way.

In addition to the parameter estimation results, PROC CALIS also outputs supplementary results that could be useful for interpretations. In [Output 27.20.10](#), the squared multiple correlations and the factor scores regression coefficients are shown.

Output 27.20.10 Supplementary Estimation Results

Squared Multiple Correlations

The percentages of variance for the observed variables that can be explained by the factors are shown in the 'R-Square' column of the table for squared multiple correlations (R-squares). These R-squares can be interpreted meaningfully because there is no reciprocal relationships among variables or correlated errors in the model. All estimates of R-squares are bounded between 0 and 1.

In the table for factor scores regression coefficients, entries are coefficients for the variables you can use to create the factor scores. The larger the coefficient, the more influence of the corresponding variable for creating the factor scores. It makes intuitive sense to see the cluster pattern of these coefficients—the reading measures are more important to create the latent variable scores of `Read_Factor` and so on.

Example 27.21: Testing Equality of Two Covariance Matrices Using a Multiple-Group Analysis

You can use PROC CALIS to do multiple-group or multiple-sample analysis. The groups in the analysis must be independent. In this example, a relatively simple multiple-group analysis is carried out. The covariance matrices of two independent groups are tested for equality. Hence, individual covariance matrices are actually not structured. Rather, they are constrained to be the same under the null hypothesis. That is, you want to test the following null hypothesis:

$$H_0 : \Sigma_1 = \Sigma_2$$

where Σ_1 and Σ_2 represent the population covariance matrices of the two independent groups in question.

In PROC CALIS, you can use two different approaches to test the equality of covariance matrices. The first approach is to define an MSTRUCT model explicitly and to fit this model to the independent groups. The second approach is to use the [COVPATTERN=](#) option to invoke the required covariance structure model for the independent groups. Some standard covariance structures or patterns with the MSTRUCT modeling language are built into PROC CALIS internally. With appropriate keywords for the COVPATTERN= option, you can invoke the target built-in covariance patterns without defining the MSTRUCT model explicitly. This example considers these two approaches successively.

This example is concerned with a reaction time experiment that was conducted on two groups of individuals. One group ($N = 20$) was considered to be an expert group with prior training related to the tasks of the experiment. Another group ($N = 18$) was a control group without prior training. Three tasks of dexterity were administered to all individuals. These tasks differed by their required complexity levels of body skills. They were labeled as high, medium, and low complexities.

Apparently, the differential performance of the two groups under different task complexities was the primary research objective. In this example, however, you are interested in testing whether the groups have the same covariance matrix for the tasks. Equality of covariance matrices might be an essential assumption in some statistical tests for comparing group means. In this example, the sample covariance matrices for the two groups are stored in the data sets Expert and Novice, as shown in the following:

```
data expert(type=cov);
  input _type_ $ _name_ $ high medium low;
  datalines;
COV  high    5.88      .      .
COV  medium  2.88      7.16    .
COV  low     3.12      4.44    8.14
;

data novice(type=cov);
  input _type_ $ _name_ $ high medium low;
  datalines;
COV  high    6.42      .      .
COV  medium  1.24      8.25    .
COV  low     4.26      2.75    7.99
;
```

These data sets are read into the analysis through the [GROUP](#) statements in the following PROC CALIS specification:

```

proc calis;
  group 1 / data=expert nobs=20 label="Expert";
  group 2 / data=novice nobs=18 label="Novice";
  model 1 / groups=1,2;
    mstruct
      var=high medium low;
  fitindex NoIndexType On(only)=[chisq df probchi]
    chicorrect=eqcovmat;
  ods select ModelingInfo MSTRUCTVariables MSTRUCTCovInit Fit;
run;

```

The first **GROUP** statement defines **group 1** for the expert group. The second **GROUP** statement defines **group 2** for the novice group. You use the **NOBS=** option in both statements to provide the number of observations of these groups. You use the **LABEL=** option in these statements to provide meaningful group labels.

The **MODEL** statement defines **MODEL 1**. In the analysis, this model fits to both groups 1 and 2, as indicated by the **GROUPS=** option of the statement. This is done to test the null hypothesis of equality of covariance matrices in the two groups. An **MSTRUCT** model for **MODEL 1** is defined immediately afterward. Three variables, high, medium, and low, are specified in the **VAR=** option of the **MSTRUCT** statement.

Without further specification about the **MSTRUCT** model, PROC CALIS assumes all non redundant elements in the covariance matrix are free parameters. This is what is required under the null hypothesis of the equality of covariance matrices in the two groups—the groups have the same covariance matrix, but the covariance matrix itself is unconstrained. Your model under the null hypothesis is now well-defined and ready to run. In addition, you use **FITINDEX** and **ODS SELECT** statements to customize or fine tune the analysis.

By using the options in the **FITINDEX** statement, you can customize the fit summary table and control some analytic options. In the current example, you use the **NOINDEXTYPE** option to suppress the printing of the index types in the fit summary table. Then, you use the **ON(ONLY)=** option to specify the fit indices printed in the fit summary table. In this example, you request only the model fit chi-square statistic, degrees of freedom, and the probability value of the chi-square be printed. Finally, you use the **CHICORRECT=EQCOVMAT** option to request a chi-square correction for the test of equality of covariance matrices. This correction is due to Box (1949) and is implemented in PROC CALIS as a built-in chi-square correction option.

In addition, because you are not interested in all displayed output for the current hypothesized model, you use the **ODS SELECT** statement to display only those output (or ODS tables) of interest. In this example, you request only the modeling information, the variables involved, the initial covariance matrix specification, and the fit summary table be printed. All output in PROC CALIS are named as an ODS table. To locate a particular output in PROC CALIS, you must know the corresponding ODS table name. See the section “**ODS Table Names**” on page 1368 for a listing of ODS tables produced by PROC CALIS.

Output 27.21.1 displays some information regarding the basic model setup.

Output 27.21.1 Modeling Information and Initial Specification

Modeling Information Maximum Likelihood Estimation						
Group	Label	Data Set	N Obs	Model	Type	Analysis
1	Expert	WORK.EXPERT	20	Model 1	MSTRUCT	Covariances
2	Novice	WORK.NOVICE	18	Model 1	MSTRUCT	Covariances
Model 1. Variables in the Model						
high medium low						
Number of Variables = 3						
Model 1. Initial MSTRUCT _COV_ Matrix						
		high	medium	low		
high		.	.	.		
		[_Add1]	[_Add2]	[_Add4]		
medium		.	.	.		
		[_Add2]	[_Add3]	[_Add5]		
low		.	.	.		
		[_Add4]	[_Add5]	[_Add6]		

The modeling information table summarizes some basic information about the two groups. Both of them are fitted by Model 1. The next table shows the variables involved: high, medium, and low. The order of variables in this table is the same as that of the row and column variables of the covariance model matrix, which is shown next in [Output 27.21.1](#). The parameters for the entries in the covariance matrix are shown. The names of parameters are displayed in parentheses. All these parameters are set by default and their names have the prefix `_Add`. No initial estimates are given as input, as indicated by the missing value ‘.’.

[Output 27.21.2](#) shows the customized fit summary table, which has been much simplified for the current example due to the uses of some options in the `FITINDEX` statement.

Output 27.21.2 Model Fit

Fit Summary	
Chi-Square	2.4924
Chi-Square DF	6
Pr > Chi-Square	0.8693

As shown in [Output 27.21.2](#), the chi-square test statistic is 2.4924. With six degrees of freedom, the test statistic is not significant at $\alpha = 0.01$. Therefore, the hypothesized model is supported, which means that the equality of the covariance matrices of the groups is supported.

Instead of using the MSTRUCT modeling language explicitly for defining the hypothesized covariance patterns (or structures), you can also invoke the same covariance patterns by using the **COVPATTERN=** option, as shown in the following statements:

```
proc calis covpattern=eqcovmat;
  var high medium low;
  group 1 / data=expert nobs=20 label="Expert";
  group 2 / data=novice nobs=18 label="Novice";
  fitindex NoIndexType On(only)=[chisq df probchi];
run;
```

The COVPATTERN=EQCOVMAT option in the PROC CALIS statement hypothesizes that the two population covariance matrices for the groups are the same. Next, you specify the set of variables in the covariance matrices in the VAR statement, followed by the specification of the data for the two groups. You use the FITINDEX statement to select a subset of fit indices to display in the output.

Output 27.21.3 shows the data sets and the corresponding MSTRUCT models that are generated by the COVPATTERN=EQCOVMAT option.

Output 27.21.3 Modeling Information with the COVPATTERN=EQCOVMAT Option

Modeling Information Maximum Likelihood Estimation						
Group	Label	Data Set	N Obs	Model	Type	Analysis
1	Expert	WORK.EXPERT	20	Model 1	MSTRUCT	Covariances
2	Novice	WORK.NOVICE	18	Model 2	MSTRUCT	Covariances

PROC CALIS generates Model 1 for the expert group and Model 2 for the novice group. Output 27.21.4 and Output 27.21.5 show the covariance matrices of these two models.

Output 27.21.4 Initial Specification of Model 1 for the Expert Group

Model 1. Variables in the Model			
	high	medium	low
Number of Variables = 3			
Model 1. Initial MSTRUCT _COV_ Matrix			
	high	medium	low
high	.	.	.
	[_cov_1_1]	[_cov_2_1]	[_cov_3_1]
medium	.	.	.
	[_cov_2_1]	[_cov_2_2]	[_cov_3_2]
low	.	.	.
	[_cov_3_1]	[_cov_3_2]	[_cov_3_3]

Output 27.21.5 Initial Specification of Model 2 for the Novice Group

```

Model 2. Variables in the Model

      high  medium  low

Number of Variables = 3

Model 2. Initial MSTRUCT _COV_ Matrix

           high           medium           low

high      .             .             .
      [_cov_1_1]      [_cov_2_1]      [_cov_3_1]

medium    .             .             .
      [_cov_2_1]      [_cov_2_2]      [_cov_3_2]

low       .             .             .
      [_cov_3_1]      [_cov_3_2]      [_cov_3_3]

```

In [Output 27.21.4](#), the covariance matrix for the expert group has three variables: high, medium, and low. The second table of [Output 27.21.4](#) shows the parameters for the corresponding covariance matrix. PROC CALIS generates the parameter names for the elements in this covariance matrix: `_cov_1_1`, `_cov_2_1`, ..., `_cov_3_3`. In [Output 27.21.5](#), the covariance matrix for the novice group has exactly the same set of three variables: high, medium, and low. The second table of [Output 27.21.5](#) shows the parameters for the corresponding covariance matrix. These variance and covariance parameters are exactly the same as those in [Output 27.21.4](#), as required by the testing of equality of covariance matrices.

[Output 27.21.6](#) shows the fit summary of the test. The test results are exactly the same as those in [Output 27.21.2](#), as expected. The chi-square value is 2.4924. With six degrees of freedom, the test statistic is not significant at $\alpha = 0.01$. The hypothesis about the equality of the covariance matrices between the groups is supported.

Output 27.21.6 Model Fit with the COVPATTERN=EQCOVMAT Option

Fit Summary	
Chi-Square	2.4924
Chi-Square DF	6
Pr > Chi-Square	0.8693

One advantage of using the built-in covariance patterns such as the current COVPATTERN=EQCOVMAT option is that it is more efficient and less error-prone than if you specify the covariance patterns manually by using the MSTRUCT and MATRIX statements. With the COVPATTERN= option, PROC CALIS generates the correct model specification internally. Another advantage is that when applicable, PROC CALIS applies the appropriate chi-square correction to the chi-square test statistic. For the current example, PROC CALIS displays the following message in the output:

NOTE: The chi-square correction due to Box for testing equality of covariance matrices was applied. Use the CHICORRECT=0 option if this correction is not desirable.

This shows that when you use the COVPATTERN=EQCOVMAT option, an appropriate chi-square correction is applied automatically to the chi-square test statistic. To turn off this automatic chi-square, you can use the CHICORRECT=0 in the PROC CALIS statement (although this should be a rare practice with the COVPATTERN= options).

To extend the test of the equality of covariance matrices to the test of the equality of mean vectors, see [Example 27.4](#). To extend the multiple-group analysis of covariance patterns to the multiple-group analysis of a general structural equation model, see [Example 27.28](#).

Example 27.22: Testing Equality of Covariance and Mean Matrices between Independent Groups

To make the specification of some standard MSTRUCT models for covariance and mean patterns more efficient, PROC CALIS defines these standard models internally. You can use two options to invoke these built-in covariance and mean patterns easily. For example, with the COVPATTERN= option, you can define the compound symmetry (COMPSYM) pattern for the covariance matrix or the equality of covariance matrices between groups (EQCOVMAT). With the MEANPATTERN= option, you can define uniform means (UNIFORM) for the mean vector or the equality of mean vectors between groups (EQMEANVEC). See the COVPATTERN= and the MEANPATTERN= options for details about the supported built-in covariance and mean patterns.

In [Example 27.21](#), you test of the equality of covariance matrices between two groups. This example extends the application to the test of equality of mean vectors between three independent groups by using the COVPATTERN= and MEANPATTERN= options together. The “best” fit model for the data is explored. The following DATA steps define the covariance and mean matrices for the three independent groups, respectively:

```

```

Each of these data sets contains the information about the correlations, means, standard deviations, and sample sizes. Even though these data sets contain correlations, by default PROC CALIS analyzes the covariances and means.

The first hypothesis to test is the equality of covariance matrices and mean vectors:

$$H_0 : \Sigma_1 = \Sigma_2 = \Sigma_3 \text{ and } \mu_1 = \mu_2 = \mu_3$$

where Σ_1 , Σ_2 , and Σ_3 are the population covariance matrices for the three independent groups, respectively, and μ_1 , μ_2 , and μ_3 are the population mean vectors for the three independent groups, respectively.

The following statements specify this test:

```

proc calis covpattern=eqcovmat meanpattern=eqmeanvec;
  var x1-x9;
  group 1 / data=g1;
  group 2 / data=g2;
  group 3 / data=g3;
  fitindex NoIndexType On(only)=[chisq df probchi rmsea aic caic sbc];
run;

```

In the PROC CALIS statement, the COVPATTERN=EQCOVMAT option specifies the same covariance matrix for the three groups and the MEANPATTERN=EQMEANVEC option specifies the same mean vector for the three groups. The VAR statement specifies that x1–9 are the variables in the hypothesis test. Next, the GROUP statements specify the data sets for the three independent groups. You use the FITINDEX statement to limit the amount of output fit statistics to the quantities specified: the chi-square test (CHISQ), the degrees of freedom (DF), the significance value of the test statistic (PROBCHI), the root mean square error approximation (RMSEA), Akaike's information criterion (AIC), consistent Akaike's information criterion (CAIC), and Schwarz's Bayesian criterion (SBC). The first three quantities are useful for the chi-square model fit test, while the rest of the fit indices are useful for comparing competing models for the data. Because there are not many quantities in this customized fit summary table, the NOINDEXTYPE option is used to suppress the printing of the fit index types.

Output 27.22.1 shows the general modeling information, including the sample sizes, the models for the groups, the model types, and the analysis types.

Output 27.22.1 Modeling Information for Testing Equality of Covariance and Mean Matrices

Modeling Information Maximum Likelihood Estimation					
Group	Data Set	N Obs	Model	Type	Analysis
1	WORK.G1	21	Model 1	MSTRUCT	Means and Covariances
2	WORK.G2	22	Model 2	MSTRUCT	Means and Covariances
3	WORK.G3	20	Model 3	MSTRUCT	Means and Covariances

Output 27.22.2 shows the initial mean vector and the initial covariance matrix specifications for Model 1, which fits to Group 1. PROC CALIS generates the mean parameter names _mean_1, _mean_2, ..., and _mean_9 for the nine elements in the mean vector. It also generates the covariance parameter names _cov_1_1, _cov_2_1, ..., and _cov_9_9 for the 45 nonredundant elements in the covariance matrix.

Output 27.22.2 Initial Mean Vector and Covariance Matrix for Model 1

Model 1. Initial MSTRUCT _MEAN_ Vector

Although not shown here, the initial mean vector and covariance matrices for Models 2 and 3 are exactly the same as those shown in [Output 27.22.2](#), as required by the equality of covariance and mean matrices in the null hypothesis H_0 .

[Output 27.22.3](#) shows the customized fit summary table. The chi-square test statistic is 203.2605. The degrees of freedom is 108 and the p -value is less than 0.0001. Therefore, the hypothesis H_0 of equality in covariance and mean matrices is rejected for the three independent groups. The RMSEA index is much greater than 0.05, which does not indicate a good model fit. Other fit indices such as AIC, CAIC, and SBC are not interpreted for the fit of the model itself, but are useful for comparing competing models in the later discussion.

Output 27.22.3 Fit Summary for Testing H_0 : Equality of Covariance and Mean Matrices

Fit Summary	
Chi-Square	203.2605
Chi-Square DF	108
Pr > Chi-Square	<.0001
RMSEA Estimate	0.2100
Akaike Information Criterion	311.2605
Bozdogan CAIC	480.9897
Schwarz Bayesian Criterion	426.9897

A less restrictive hypothesis is now considered. This hypothesis states the equality of covariance matrices only:

$$H_1 : \Sigma_1 = \Sigma_2 = \Sigma_3 (\mu_1, \mu_2, \text{ and } \mu_3 \text{ unconstrained})$$

H_1 differs from H_0 in that the population means in H_1 are not constrained. To test this hypothesis, you need to change the MEANPATTERN= option to use the SATURATED keyword, as shown in the following statements:

```
proc calis covpattern=eqcovmat meanpattern=saturated;
  var x1-x9;
  group 1 / data=g1;
  group 2 / data=g2;
  group 3 / data=g3;
  fitindex NoIndexType On(only)=[chisq df probchi rmsea aic caic sbc];
run;
```

[Output 27.22.4](#) shows the results of the testing H_1 .

Output 27.22.4 Fit Summary for Testing H_1 : Equality of Covariance Matrices but Unconstrained Means

Fit Summary	
Chi-Square	26.7897
Chi-Square DF	90
Pr > Chi-Square	1.0000
RMSEA Estimate	0.0000
Akaike Information Criterion	170.7897
Bozdogan CAIC	397.0954
Schwarz Bayesian Criterion	325.0954

The chi-square test statistic is 26.7897 ($df = 90$, $p = 1.000$). You cannot reject this null hypothesis about the equality of the population covariance matrices. The RMSEA value is virtually zero, which indicates a perfect fit. Comparing the models under H_0 and H_1 , it is clear that the three groups are significantly different with regard to their mean vectors. By relaxing all the equality constraints on the means in H_0 , H_1 is derived and is supported by the chi-square test. In addition, the RMSEA value for the model under H_1 is perfect. Because lower values of AIC, CAIC, and SBC values indicate better model fit (with the model complexity taken into account), these indices in [Output 27.22.3](#) and [Output 27.22.4](#) support that the model under H_1 is better than H_0 .

However, in getting a superior model fit, H_1 might have relaxed more constraints than absolutely necessary for an optimal fit. That is, it might be possible to impose equality constraints on only some (but not all, as in H_1) of the means to reach the same or even better model fit (by the RMSEA, AIC, CAIC, or SBC criterion) than the model under H_1 . But how can you determine this set of constrained means?

To answer this question, you conduct an exploratory analysis of the data by using some model modification techniques. Models established from exploratory analysis should be validated by external data in the future. However, this example demonstrates the exploratory part only.

Beginning with the model under H_0 , you can manually take away some particular constraints on the means and explore whether the revised model improves the fit. If the revised model fits better, you can repeat the process until you cannot improve more. Ultimately, you might be able to find the “best” model between the models specified under H_0 and H_1 . Such an exploratory analysis is laborious, considering the vast possibilities of constraints on the nine variable means in three independent groups that you could attempt to release. Fortunately, PROC CALIS provides some model modification statistics, called the LM (Lagrange multiplier) statistics, to assist this kind of exploratory analysis.

The following statements specify the model under H_0 , but now with the **MODIFICATION** option added to the PROC CALIS statement:

```
proc calis covpattern=eqcovmat meanpattern=eqmeanvec modification;
  var x1-x9;
  group 1 / data=g1;
  group 2 / data=g2;
  group 3 / data=g3;
  fitindex NoIndexType On(only)=[chisq df probchi rmsea aic caic sbc];
run;
```

The MODIFICATION option requests the so-called LM (Lagrange multiplier) statistics for releasing the parameter constraints. These constraints include the cross-group or within-group constraints and the fixed values in the model. For the model under H_0 , the covariances and the means are all constrained across groups.

These are the equality constraints that you would like to release to obtain a better model fit. [Output 27.22.5](#) shows the results of the LM statistics for releasing these equality constraints in variances, covariances, and means.

Output 27.22.5 Lagrange Multiplier Statistics for Releasing the Equality Constraints

To use the results of this table, you look for parameters that have large LM statistics (in the LM Stat column). Equivalently, you can look for parameters that have small p -values (in the Pr > ChiSq column). Loosely speaking, an LM statistic estimates the reduction of model fit chi-square statistic if you release the constraint on the corresponding parameter. The p -value indicates whether the improvement would be significant. Therefore, releasing those parameters with a high LM statistic and small p -value would be the key to model improvements. Bear in mind that the LM statistics are linear approximations and they might not be very accurate as estimates of the actual model improvement, which could only be accessed when you refit the model with the particular constraint released. Nonetheless, the LM statistics could still be very useful because they show which constraints could potentially improve the model the most.

Output 27.22.5 shows the results from releasing the constraints on the variances and covariances first. Each constrained element of the covariance matrix has three rows, respectively, for the three models (or groups). For example, the first parameter is `_cov_1_1`, which is the same variance parameter for `x1` in the three models. The first row shows that if you release the variance of `x1` in Model 1 from the constraint (while keeping the variances of `x1` being constrained between Models 2 and 3), the LM statistic is 0.01127, and the corresponding p -value is 0.9155. This means that the model fit improvement would be very small and so you do not expect a significant model fit improvement by releasing this constraint. The columns entitled

“Changes” show the estimated parameter changes in the original parameters (that is, `_cov_1_1` for Models 2 and 3) and in the released parameter (that is, the new parameter for the variance of `x1` in Model 1) if you release the corresponding equality constraint. These two “Changes” columns are not very useful for the present purpose.

Looking through the results for the variance and covariance constraints, you can see that almost all the associated *p*-values are large (that is, as compared with the conventional 0.05 level for significance). Therefore, all these constraints on variances and covariances would not improve the model fit significantly. In contrast, the constraints on the means show that several of them could be released for a sizable model fit improvement. The largest LM statistic in the table is the one for `_mean_3` in Model 3. The LM statistic is 22.27678 and its corresponding *p*-value is less than 0.0001. This means that if the mean of `x3` in Model 3 were not constrained with the means of `x3` in Models 1 and 2, you would have expected a reduction in the model fit chi-square statistic that is estimated at 22.27678. Other notable LM statistics are those for `_mean_1` in Model 1, `_mean_2` in Model 1 or 2, and `_mean_6` in Model 2.

Two important points are noted about the use of the LM statistics. First, the LM statistics are not additive. You cannot expect that the total reduction in model fit chi-square for releasing a particular set of parameter constraints is the sum of the corresponding LM statistics. Second, once you release a particular constraint and refit the model, the LM statistics in the revised model might not follow the same pattern as those LM statistics in the original model. Basically, these are due to the nonlinearity of the fit function and the dependence of the parameter estimates. Therefore, in order to find the best model for the data, it would be more sensible to adopt a one-at-a-time approach to release the constraints. That is, you release one constraint at a time and refit the model to see if you can release more constraints to improve the model fit.

According to the results of LM statistics in [Output 27.22.5](#), you first release the constraint on the `_mean_3` parameter, which is for the mean of `x3` in Model 3. The following statements fit such a model:

```
proc calis modification;
  var x1-x9;
  group 1 / data=g1;
  group 2 / data=g2;
  group 3 / data=g3;
  model 1 / group = 1;
    mstruct;
    matrix _cov_ = cov01-cov45;
    matrix _mean_ = mean1-mean9;
  model 2 / group = 2;
    refmodel 1;
  model 3 / group = 3;
    refmodel 1;
    renameparm mean3=mean3_md13;
  fitindex NoIndexType On(only)=[chisq df probchi rmsea aic caic sbc];
run;
```

Because the revised model is no longer a supported built-in MSTRUCT model, you cannot use the `MEANPATTERN=` or the `COVPATTERN=` options any more. Instead, you now use the MSTRUCT modeling language to specify the covariance and mean patterns. Model 1, which fits to Group 1, is an MSTRUCT model with variance and covariance parameters `cov01–cov45` and mean parameters `mean1–mean9`. Model 2, which fits to Group 2, refers to the specifications of Model 1, as indicated in a `REFMODEL` statement. Hence, Model 1 and Model 2 are completely constrained in variances, covariances, and means. Model 3, which fits to Group 3, also refers to the specifications of Model 1, as indicated in another `REFMODEL` statement. However, the `RENAMEPARM` statement renames the parameter `mean3` in the reference model

(that is, Model 1) to a new name mean3_md13. As a results, all variance, covariance, and mean parameters except one in Model 3 are constrained to be the same as those in Model 1. The mean of x3 in Model 3 is the only parameter that is not constrained with any other parameters. This forms the first revised model from H_0 . The MODIFICATION option is specified again to determine whether a further model fit improvement is possible.

Output 27.22.6 shows the modeling information of the first revised model. It shows that Models 2 and 3 make references to Model 1. Therefore, parameters between models are constrained by referencing.

Output 27.22.6 Modeling Information for The First Revised Model

Output 27.22.8 shows the initial specifications of the means in Model 2. The mean parameters in Model 2 are exactly the same as those in Model 1, as shown in Output 27.22.7. The variance and covariance parameters in Model 2 are also exactly the same as those in Model 1, but are not shown here to conserve space.

Output 27.22.8 Initial Mean Vector for Model 2 in the First Revised Model

Model 2. Initial MSTRUCT _MEAN_ Vector		
Variable	Parameter	Estimate
x1	mean1	.
x2	mean2	.
x3	mean3	.
x4	mean4	.
x5	mean5	.
x6	mean6	.
x7	mean7	.
x8	mean8	.
x9	mean9	.

Output 27.22.9 shows the initial specifications of the means in Model 3. All but one mean parameter in Model 3 are exactly the same as those in Models 1 and 2, as shown in Output 27.22.7 and Output 27.22.8, respectively. The mean for x3 in Model 3 is mean3_md13, which is now a distinct parameter, and therefore it is not constrained with any other parameters in the first or the second models for Groups 1 or 2. However, the variance and covariance parameters in Model 3 are exactly the same as those in Model 1. They are not shown here to conserve space.

Output 27.22.9 Initial Mean Vector for Model 3 in the First Revised Model

Model 3. Initial MSTRUCT _MEAN_ Vector		
Variable	Parameter	Estimate
x1	mean1	.
x2	mean2	.
x3	mean3_md13	.
x4	mean4	.
x5	mean5	.
x6	mean6	.
x7	mean7	.
x8	mean8	.
x9	mean9	.

Output 27.22.10 shows the fit summary of the first revised model. The model fit chi-square is 148.8865, which drops quite a bit from the original model under H_0 . The p -value of the model fit chi-square is 0.0046, which is statistically significant. The RMSEA value is 0.1399, which is also a sizable improvement. All the AIC, CAIC, and SBC values are reduced, indicating better model fit than the model under H_0 .

Output 27.22.10 Fit Summary for the First Revised Model

Fit Summary	
Chi-Square	148.8865
Chi-Square DF	107
Pr > Chi-Square	0.0046
RMSEA Estimate	0.1399
Akaike Information Criterion	258.8865
Bozdogan CAIC	431.7589
Schwarz Bayesian Criterion	376.7589

Output 27.22.11 shows the LM statistics for releasing the equality constraints in the first revised model. Almost all of the results for the variance and covariance constraints are omitted because their LM statistics are not significant. However, Output 27.22.11 shows all the LM statistics for releasing the constraints in means. The mean of x2 in Model 2 has the largest LM statistic at 26.25044.

Output 27.22.11 LM Statistics for Releasing the Equality Constraints in the First Revised Model

You now modify the preceding statements to specify the second revised model, as shown in the following statements:

```
proc calis modification;
  var x1-x9;
  group 1 / data=g1;
  group 2 / data=g2;
  group 3 / data=g3;
  model 1 / group = 1;
    mstruct;
    matrix _cov_ = cov01-cov45;
    matrix _mean_ = mean1-mean9;
  model 2 / group = 2;
    refmodel 1;
    renameparm mean2=mean2_new;      /* constraint a */
  model 3 / group = 3;
    refmodel 1;
    renameparm mean2=mean2_new,      /* constraint a */
              mean3=mean3_md13;
  fitindex NoIndexType On(only)=[chisq df probchi rmsea aic caic sbc];
run;
```

This second revised model must not constrain the mean of x_2 in Model 1 with any parameters. A straightforward way to do this is to rename the `mean2` parameter to a unique name in Model 1. However, for the current specification it is more convenient to rename the `mean2` parameter in Models 2 and 3 to another name. In the specification of the second revised model, Models 2 and 3 still make references to Model 1. However, in the respective `RENAMEPARM` statements, both Model 2 and 3 rename the `mean2` parameter that is referenced from Model 1 to the new name `mean2_new`. This way the mean for x_2 in Model 1 is not constrained with the means of x_2 in Models 2 and 3. But the means for x_2 in Models 2 and 3 are still constrained to be equal by the same parameter `mean2_new`. [Output 27.22.12](#) shows the fit summary of the second revised model.

Output 27.22.12 Fit Summary for the Second Revised Model

Fit Summary	
Chi-Square	86.3927
Chi-Square DF	106
Pr > Chi-Square	0.9183
RMSEA Estimate	0.0000
Akaike Information Criterion	198.3927
Bozdogan CAIC	374.4083
Schwarz Bayesian Criterion	318.4083

Again, a sizable improvement over the first revised model is shown in the second revised model. The model fit chi-square statistic is no longer significant ($p = 0.9183$), and the RMSEA value is perfect at 0. Large drops in the AIC, CAIC, and SBC values are also observed.

Output 27.22.13 suggests that the mean of x6 in Model 2 (which has the largest LM statistic at 11.41243) could be released from the equality constraints to achieve the largest model improvement over the current model.

Output 27.22.13 LM Statistics for Releasing the Equality Constraints in the Second Revised Model

The process of model refitting should now become familiar. You modify the previous model to release the constraint on the mean of x6 in Model 2. As a result, the third revised model is specified by the following statements:

```
proc calis modification;
  var x1-x9;
  group 1 / data=g1;
  group 2 / data=g2;
  group 3 / data=g3;
  model 1 / group = 1;
    mstruct;
    matrix _cov_ = cov01-cov45;
    matrix _mean_ = mean1-mean9;
  model 2 / group = 2;
    refmodel 1;
    renameparm mean2=mean2_new,      /* constraint a */
               mean6=mean6_md12;
  model 3 / group = 3;
    refmodel 1;
    renameparm mean2=mean2_new,      /* constraint a */
               mean3=mean3_md13;
  fitindex NoIndexType On(only)=[chisq df probchi rmsea aic caic sbc];
run;
```

The only modification from the previous specification is to rename mean6 to mean6_md12 in the RENAMEPARM statement of Model 2. [Output 27.22.14](#) shows the model fit summary of the third revised model.

Output 27.22.14 Fit Summary for the Third Revised Model

Fit Summary	
Chi-Square	68.7869
Chi-Square DF	105
Pr > Chi-Square	0.9976
RMSEA Estimate	0.0000
Akaike Information Criterion	182.7869
Bozdogan CAIC	361.9456
Schwarz Bayesian Criterion	304.9456

The model improvement over the second revised model is still notable in the third revised model. The chi-square value drops about 20 points in the third revised model. The AIC, CAIC, and the SBC values are reduced notably, though not as impressively as with the previous improvements.

Output 27.22.15 suggests that the mean of x4 in Model 1 (which has the largest LM statistic at 7.01946) could be released from the equality constraint to improve model fit further.

Output 27.22.15 LM Statistics for Releasing the Equality Constraints in the Third Revised Model

	3	MEAN	x2		3.21203	0.0731	-0.2280	0.2484

To make the mean parameter for x4 in Model 1 unique, the mean parameters for x4 in Models 2 and 3 are renamed from mean4 to mean4_new, as shown in the following statements:

```
proc calis modification;
  var x1-x9;
  group 1 / data=g1;
  group 2 / data=g2;
  group 3 / data=g3;
  model 1 / group = 1;
    mstruct;
    matrix _cov_ = cov01-cov45;
    matrix _mean_ = mean1-mean9;
  model 2 / group = 2;
    refmodel 1;
    renameparm mean2=mean2_new,      /* constraint a */
               mean4=mean4_new,      /* constraint b */
               mean6=mean6_md12;
  model 3 / group = 3;
    refmodel 1;
    renameparm mean2=mean2_new,      /* constraint a */
               mean3=mean3_md13,
               mean4=mean4_new;      /* constraint b */
  fitindex NoIndexType On(only)=[chisq df probchi rmsea aic caic sbc];
run;
```

This forms the fourth revised model. [Output 27.22.16](#) shows the fit summary of this revised model. Again, the chi-square, AIC, CAIC, and SBC values all show improvements, as compared with the third revised model. However, the improvements do seem to slow down. For example, the CAIC value drops from 361.95 to the current value at 358.43—a mere 3 points reduction. The SBC value drops from 304.95 to the current value at 300.43—a mere 4 points reduction. These small reductions indicate that you might soon reach the point that no more model fit improvement would be possible with additional release of parameter constraints.

Output 27.22.16 Fit Summary for the Fourth Revised Model

Fit Summary	
Chi-Square	60.1265
Chi-Square DF	104
Pr > Chi-Square	0.9998
RMSEA Estimate	0.0000
Akaike Information Criterion	176.1265

	3	MEAN	x4		1.81983	0.1773	-0.2003	0.2306

To make the mean parameter for x1 in Model 1 unique, the mean parameters for x1 in Models 2 and 3 are renamed from mean1 to mean1_new, as shown in the following statements:

```
proc calis modification;
  var x1-x9;
  group 1 / data=g1;
  group 2 / data=g2;
  group 3 / data=g3;
  model 1 / group = 1;
    mstruct;
    matrix _cov_ = cov01-cov45;
    matrix _mean_ = mean1-mean9;
  model 2 / group = 2;
    refmodel 1;
    renameparm mean1=mean1_new,      /* constraint c */
               mean2=mean2_new,      /* constraint a */
               mean4=mean4_new,      /* constraint b */
               mean6=mean6_md12;
  model 3 / group = 3;
    refmodel 1;
    renameparm mean1=mean1_new,      /* constraint c */
               mean2=mean2_new,      /* constraint a */
               mean3=mean3_md13,
               mean4=mean4_new;      /* constraint b */
  fitindex NoIndexType On(only)=[chisq df probchi rmsea aic caic sbc];
run;
```

This forms the fifth revised model. [Output 27.22.18](#) shows the fit summary of the fifth revised model. Again, the chi-square, AIC, CAIC, and SBC values all show improvements, as compared with the fourth revised model. However, the improvements slow down even more. For example, the CAIC value drops from 358.43 to the current value at 356.32. The SBC value drops from 300.43 to the current value at 297.32. Because the model fit does not improve much, this is the point where you would cease to release more equality constraints for improving the model fit.

Output 27.22.18 Fit Summary for the Fifth Revised Model

Fit Summary	
Chi-Square	52.8821
Chi-Square DF	103
Pr > Chi-Square	1.0000
RMSEA Estimate	0.0000
Akaike Information Criterion	170.8821
Bozdogan CAIC	356.3270
Schwarz Bayesian Criterion	297.3270

Output 27.22.19 does not suggest the release of any equality constraints on the means, because all the p -values for the LM statistics are not significant (that is, all are greater than 0.05). Therefore, the same suggestion from examining the model fit improvements of the fifth revised model echoes here: this is the point that the “best” model for the data is found.

Output 27.22.19 LM Statistics for Releasing the Equality Constraints in the Fifth Revised Model

	3	MEAN	x4		2.25832	0.1329	-0.2253	0.2558

To see where the fifth revised model (equality in the covariance matrix and partial equality in the means) stands between the models under H_0 (equality in the covariance and mean matrices) and H_1 (equality in the covariance matrix only), the following table shows the fit statistics of these three models:

	H_0	“Fifth”	H_1
Chi-square	203.2605	52.8821	26.7897
Chi-square DF	108	103	90
Pr > chi-square	<0.0001	1.0000	1.0000
RMSEA estimate	0.2100	0.0000	0.0000
Akaike information criterion	311.2605	170.8821	170.7897
Bozdogan CAIC	480.9898	356.3270	397.0954
Schwarz Bayesian criterion	426.9898	297.3270	325.0954

The fifth revised model is labeled “Fifth” in the table. Compared with the model under H_0 , the fifth revised model is clearly superior. It uses only five more parameters (or five fewer degrees of freedom), but the improvement in the model fit chi-square and the RMSEA value are huge. The AIC, CAIC, and SBC are also much better.

Compared with the model under H_1 , the fifth revised model appears to be inferior in only the chi-square model fit statistic, although both models already have the highest possible p -value at 1.000 and smallest possible RMSEA value at 0. However, the model under H_1 uses 13 more parameters (or it has 13 fewer degrees of freedom), and hence it is more complex. In fact, because the model fit chi-square value does not take model complexity into account, it is often criticized as the basis for choosing competing models for the data. In contrast, the AIC, CAIC, and SBC measures take model complexity into account, and they are more reasonable as the basis for choosing competing models. Although the AIC values for the fifth revised model and the model under H_1 are very close, the CAIC and SBC values clearly favor the fifth revised model. Therefore, according to the CAIC and SBC criteria, the fifth revised model, which is a model with partial equality constraints on the means, is actually better than the model with all the means being unconstrained (that is, under H_1) for the current data with three independent groups.

Example 27.23: Illustrating Various General Modeling Languages

In PROC CALIS, you can use many different modeling languages to specify the same model. The choice of modeling language depends on personal preferences and the purposes of the analysis. See the section “Which Modeling Language?” on page 1077 for guidance. In this example, the data and the model in Example 27.17 are used to illustrate how a particular model can be specified by various general modeling languages.

RAM Model Specification

In Example 27.17, you use the PATH modeling language to specify the model because of its close resemblance to the path diagram. In this example, you consider another modeling language of PROC CALIS that is also closely related to the path diagram representation of structural equation models. The so-called RAM model language has syntax that represents the single- and double-headed paths (or arrows) in the path diagram. However, unlike the PATH modeling language, the RAM modeling language is matrix-based. The following statements show how you can specify the same path model with the RAM model specification for the data in Example 27.17:

```
proc calis nob=932 data=Wheaton;
  ram
    var = Anomie67      /* 1 */
          Powerless67   /* 2 */
          Anomie71      /* 3 */
          Powerless71   /* 4 */
          Education     /* 5 */
          SEI           /* 6 */
          Alien67       /* 7 */
          Alien71       /* 8 */
          SES,          /* 9 */
    _A_ 1 7 1.0,
    _A_ 2 7 0.833,
    _A_ 3 8 1.0,
    _A_ 4 8 0.833,
    _A_ 5 9 1.0,
    _A_ 6 9 lambda,
    _A_ 7 9 gamma1,
    _A_ 8 9 gamma2,
    _A_ 8 7 beta,
    _P_ 1 1 theta1,
    _P_ 2 2 theta2,
    _P_ 3 3 theta1,
    _P_ 4 4 theta2,
    _P_ 5 5 theta3,
    _P_ 6 6 theta4,
    _P_ 7 7 psi1,
    _P_ 8 8 psi2,
    _P_ 9 9 phi,
    _P_ 1 3 theta5,
    _P_ 2 4 theta5;
run;
```

In the RAM model for covariance structure analysis, you have two important matrices to specify. The first one is the `_A_` matrix, which is for the specification of the single-headed paths (arrows) in the path diagram. The second one is the `_P_` matrix, which is for the specification of the double-headed paths (arrows) in the path diagram. Hence, to specify the RAM model is much like mapping the path diagram arrows into the parameter of the RAM model matrices.

In the RAM statement, you can specify the variables in the model in the `VAR=` option. The `VAR=` list contains all observed and latent variables in your path diagram (without the use of error terms). Although you can specify the variables in the `VAR=` list in any order you like, the variable order in the list is also the order of variables in the RAM model matrices. In `VAR=` list of the RAM statement, you put comments to note the order of the variables.

After you specify the variable list, you can specify the model parameter locations in the RAM statement entries. In the first nine entries, you specify the single-headed paths by mapping them into the elements of the `_A_` matrix of the RAM model. For example, the first entry represents the single-headed path of variable 1 (Anomie67) from variable 7 (Alien67). The corresponding path effect or coefficient is fixed at 1, which is also the value for `_A_[1,7]`. Another example is the ninth path entry. You specify a single-headed path of variable 8 (Alien71) from variable 7 (Alien67). The corresponding path effect or coefficient is a free parameter named `beta`, which is also the parameter for `_A_[8,7]`. Hence, you can specify all single-headed paths in the path diagram as elements in the `_A_` matrix of the RAM model.

To facilitate the comparisons between the RAN and PATH modeling languages, the PATH model specification in [Example 27.17](#) for the same data is reproduced in the following:

```
proc calis nobs=932 data=Wheaton plots=residuals;
  path
    Anomie67    Powerless67 <==== Alien67    = 1.0  0.833,
    Anomie71    Powerless71 <==== Alien71    = 1.0  0.833,
    Education   SEI         <==== SES        = 1.0  lambda,
    Alien67     Alien71     <==== SES        = gamma1 gamma2,
    Alien71     <==== Alien67    = beta;
  pvar
    Anomie67    = theta1,
    Powerless67 = theta2,
    Anomie71    = theta1,
    Powerless71 = theta2,
    Education   = theta3,
    SEI         = theta4,
    Alien67     = psi1,
    Alien71     = psi2,
    SES         = phi;
  pcov
    Anomie67    Anomie71    = theta5,
    Powerless67 Powerless71 = theta5;
run;
```

It is clear that each of the path entries specified in the PATH statement corresponds to an matrix element entry of the `_A_` matrix in the RAM statement. How about the specifications of the double-headed arrows in the path diagram? Do the RAM and PATH model specifications correspond to each other?

The answer is yes. In the PATH modeling language, you specify all double-headed arrows in the path diagram as entries either in the PVAR or PCOV statement. In the RAM modeling language, you specify the corresponding entries as matrix element entries of the `_P_` matrix in the RAM statement. For example, the error variance of `Anomie67` is a parameter called `_Variabletheta1` in the PVAR statement of the PATH model. You specify the same parameter for the `_P_[1,1]` element in an entry of the RAM statement. Another example is the error covariance between `Powerless67` and `Powerless71`. You specify this a parameter called `theta5` in the last entry of the PCOV statement in the PATH model. You specify the same parameter for the `_P_[2,4]` element in the last entry of the RAM statement. Therefore, it is not difficult to find that the specifications in the PATH and the RAM model have some kind of one-to-one correspondence.

[Output 27.23.1](#) shows the RAM model estimates for the Wheaton data. These RAM model estimates match the set of estimates using the PATH model specification, as shown in [Output 27.17.10](#).

Output 27.23.1 RAM Model Estimates

LINEQS Model Specification

Another way to specify the model in [Example 27.17](#) is to use the LINEQS modeling language, which is shown in the following:

```

proc calis nob=932 data=Wheaton;
  lineqs
    Anomie67      = 1.0      * f_Alien67 + e1,
    Powerless67   = 0.833    * f_Alien67 + e2,
    Anomie71      = 1.0      * f_Alien71 + e3,
    Powerless71   = 0.833    * f_Alien71 + e4,
    Education     = 1.0      * f_SES      + e5,
    SEI           = lambda   * f_SES      + e6,
    f_Alien67     = gamma1   * f_SES      + d1,
    f_Alien71     = gamma2   * f_SES      + beta * f_Alien67 + d2;
  variance
    E1            = theta1,
    E2            = theta2,
    E3            = theta1,
    E4            = theta2,
    E5            = theta3,
    E6            = theta4,
    D1            = psi1,
    D2            = psi2,
    f_SES         = phi;
  cov
    E1 E3        = theta5,
    E2 E4        = theta5;
run;

```

As compared with the PATH and RAM modeling languages, the most distinct feature of the LINEQS modeling language is the explicit use of error terms in equation specifications. In the LINEQS statement, you specify exactly one equation for each endogenous variable. In each equation, you list an endogenous variable on the left-hand-side of the equation and all its predictors on the right-hand-side of the equation. You must also include an error term in each equation. Because each endogenous variable in the LINEQS statement can only be specified in exactly one equation, the number of equations in the LINEQS model and the number of paths in the corresponding path diagram do not match necessarily. In this example, there are eight equations in the **LINEQS** statement, but there are nine paths in the corresponding path diagram.

In addition, in the LINEQS model, you need to follow a convention of naming latent variables. For latent variables that are neither errors nor disturbances, you must use either the ‘F’ or ‘f’ prefix. For error terms, you must use either the ‘E’ or ‘e’ prefix. For disturbances, you must use either the ‘D’ or ‘d’ prefix. However, in the PATH or RAM model specification, no such convention is imposed. For example, `f_Alien67`, `f_Alien71`, and `f_SES` are latent factors in the LINEQS model. They are not error terms, and so they must start with the ‘f’ prefix. However, this prefix is not needed in the PATH or RAM model. Furthermore, there are no explicit error terms that need to be specified in the PATH or RAM model, let alone specific prefixes for the error terms.

The **PVAR** statement in the PATH model is replaced with the **VARIANCE** statement in the LINEQS model, and the **PCOV** statement with the **COV** statement. The **PVAR** and **PCOV** statements in the PATH model are for the partial variance and partial covariance specifications. The partial variance or covariance concepts are used in the PATH or RAM model specification because error terms are not named explicitly. Specification of error variances in the PATH and RAM model is conceptualized as the specification of the partial variances of the corresponding variables. But in the LINEQS model, because errors or disturbances are named explicitly as *exogenous* variables, the partial variance or covariance concepts are no longer necessary. Instead, you specify the variances of the error terms directly, which reflects the conceptualization behind the **VARIANCE**

statement of the LINEQS modeling language. Similarly, you use the COV, but not PCOV, statement in the LINEQS modeling language because you can specify the covariances among variables or error terms without using the partial covariance conceptualization.

In this example, the variances of the errors (“E”-variables) and disturbances (“D”-variables) specified in the **VARIANCE** statement of the LINEQS model correspond to the partial variances of the endogenous variables specified in the **PVAR** statement of the PATH model. Similarly, covariances of errors specified in the **COV** statement of the LINEQS model correspond to the partial covariances of endogenous variables specified in the **PCOV** statement of the PATH model. The estimation results of the LINEQS model are shown in **Output 27.23.2**. Again, they are essentially the same estimates obtained from the PATH model specified in **Example 27.17**, as shown in **Output 27.17.10**.

Output 27.23.2 LINEQS Model Estimates

LISMOD Specification

You can also specify general structural models by using the LISMOD modeling language. See the section “[The LISMOD Model and Submodels](#)” on page 1277 for details.

To use the LISMOD modeling language, you must recognize four types of variables in the model. The η -variables (eta-variables) are latent factors that are endogenous, or predicted by other latent factors. The ξ -variables (xi-variables) are exogenous latent variables that are not predicted by any other variables. The y-variables are manifest variables that are indicators of the η -variables, and the x-variables are manifest variables that are indicators of the ξ -variables. In this example, Alien67 and Alien71 are the η -variables, and SES is the ξ -variable in the model. Manifest indicators for Alien67 and Alien71 include Anomie67, Powerless67, Anomie71, and Powerless71, which are the y-variables. Manifest indicators for SES include Education and SEI, which are the x-variables.

After defining these four types of variables, the parameters of the model are defined as entries in the model matrices. The `_LAMBDAY_`, `_LAMBDAX_`, `_GAMMA_`, and `_BETA_` are matrices for the path coefficients or effects. The `_THETAY_`, `_THETAX_`, `_PSI_`, and `_PHI_` are matrices for the variances and covariances.

The following is the LISMOD specification for the model in [Example 27.17](#):

```
proc calis nob=932 data=Wheaton;
  lismod
    yvar   = Anomie67 Powerless67 Anomie71 Powerless71,
    xvar   = Education SEI,
    etavar = Alien67 Alien71,
    xivar  = SES;
  matrix _LAMBDAY_
    [1,1] = 1,
    [2,1] = 0.833,
    [3,2] = 1,
    [4,2] = 0.833;
  matrix _LAMBDAX_
    [1,1] = 1,
    [2,1] = lambda;
  matrix _GAMMA_
    [1,1] = gamma1,
    [2,1] = gamma2;
  matrix _BETA_
    [2,1] = beta;
  matrix _THETAY_
    [1,1] = theta1-theta2 theta1-theta2,
    [3,1] = theta5,
    [4,2] = theta5;
  matrix _THETAX_
    [1,1] = theta3-theta4;
  matrix _PSI_
    [1,1] = psi1-psi2;
  matrix _PHI_
    [1,1] = phi;
run;
```

In the **LISMOD** statement, you specify the four lists of variables in the model. The orders of the variables in these lists define the order of the row and column variables in the model matrices, of which the parameter locations are specified in the **MATRIX** statements.

The estimated model is divided into three conceptual parts. The first part is the measurement model that relates the η -variables with the y -variables, as shown in [Output 27.23.3](#):

Output 27.23.3 LISMOD Model Measurement Model for the η -Variables

<u>_LAMBDAY_ Matrix: Estimate/StdErr/t-value</u>		
	Alien67	Alien71
Anomie67	1.0000	0
Powerless67	0.8330	0
Anomie71	0	1.0000
Powerless71	0	0.8330

<u>_THETAY_ Matrix: Estimate/StdErr/t-value</u>				
	Anomie67	Powerless67	Anomie71	Powerless71
Anomie67	3.6080 0.2009 17.9572 [theta1]	0	0.9058 0.1217 7.4447 [theta5]	0
Powerless67	0	3.5949 0.1645 21.8556 [theta2]	0	0.9058 0.1217 7.4447 [theta5]
Anomie71	0.9058 0.1217 7.4447 [theta5]	0	3.6080 0.2009 17.9572 [theta1]	0
Powerless71	0	0.9058 0.1217 7.4447 [theta5]	0	3.5949 0.1645 21.8556 [theta2]

The `_LAMBDAY_` matrix contains the coefficients or effects of the η -variables on the y -variables. All these estimates are fixed constants as specified. The `_THETAY_` matrix contains the error variances and covariances for the y -variables. Three free parameters are located in this matrix: `theta1`, `theta2`, and `theta5`.

The second part of the estimated model is the measurement model that relates the ξ -variable with the x -variables, as shown in [Output 27.23.4](#):

Output 27.23.4 LISMOD Model Measurement Model for the ξ -Variables

<code>_LAMBDAX_</code> Matrix: Estimate/StdErr/t-value		
		SES
Education	1.0000	
SEI	5.3688	
	0.4337	
	12.3788	
	[lambda]	
<code>_THETAX_</code> Matrix: Estimate/StdErr/t-value		
	Education	SEI
Education	2.9937	0
	0.4986	
	6.0040	
	[theta3]	
SEI	0	259.5764
		18.3115
		14.1756
		[theta4]

The `_LAMBDAX_` matrix contains the coefficients or effects of the ξ -variable SES on the x -variables. The effect of SES on Education is fixed at one. The effect of SES on SEI is represented by the free parameter `lambda`, which is estimated at 5.3688. The `_THETAX_` matrix contains the error variances and covariances for the x -variables. Two free parameters are located in this matrix: `theta3` and `theta4`.

The last part of the estimated model is the structural model that relates the latent variables η and ξ , as shown in [Output 27.23.5](#):

Output 27.23.5 LISMOD Structural Model for the Latent Variables

<u>_BETA_</u> Matrix: Estimate/StdErr/t-value		
	Alien67	Alien71
Alien67	0	0
Alien71	0.5931 0.0468 12.6788 [beta]	0
<u>_GAMMA_</u> Matrix: Estimate/StdErr/t-value		
	SES	
Alien67	-0.6299 0.0563 -11.1809 [gamma1]	
Alien71	-0.2409 0.0549 -4.3884 [gamma2]	
<u>_PSI_</u> Matrix: Estimate/StdErr/t-value		
	Alien67	Alien71
Alien67	5.6705 0.4230 13.4050 [psi1]	0
Alien71	0	4.5148 0.3353 13.4639 [psi2]

Output 27.23.5 *continued*

PHI Matrix: Estimate/StdErr/t-value	
	SES
SES	6.6163
	0.6391
	10.3519
	[phi]

The **_BETA_** matrix contains effects of η -variables on themselves. In the current example, there is only one such effect. The effect of Alien67 on Alien71 is represented by the free parameter beta. The **_GAMMA_** matrix contains effects of the ξ -variable, which is SES in this example, on the η -variables Alien67 on Alien71. These effects are represented by the free parameters gamma1 and gamma2. The **_PSI_** matrix contains the error variances and covariances in the structural model. In this example, psi1 and psi2 are two free parameters for the error variances. Finally, the **_PHI_** matrix is the covariance matrix for the ξ -variables. In this example, there is only one ξ -variable so that this matrix contains only the estimated variance of SES. This variance is represented by the parameter phi.

The estimates obtained from fitting the LISMOD model are the same as those from fitting the equivalent PATH, RAM, or LINEQS model. To some researchers the LISMOD modeling language might be more familiar, while for others modeling languages such as PATH, RAM, or LINEQS are more convenient to use.

Example 27.24: Testing Competing Path Models for the Career Aspiration Data

This example uses some well-known data from Haller and Butterworth (1960). The section “[A Combined Measurement-Structural Model](#)” on page 320 analyzes some models for these data. Inspired by the examples given in Loehlin (1987), this example shows additional applications to the same data set, but with a focus on testing nested models. By manipulating the **OUTMODEL=** data set, this example shows how you can specify new models in an efficient way. Various models and analyses of these data are also given by Duncan, Haller, and Portes (1968), Jöreskog and Sörbom (1988), and Loehlin (1987).

The study is concerned with the career aspirations of high school students and how these aspirations are affected by close friends. The data are collected from 442 seventeen-year-old boys in Michigan. There are 329 boys in the sample who named another boy in the sample as a best friend. The data from these 329 boys paired with the data from their best friends are analyzed.

Because of the dependency of the data, the effective sample size assumed in the example is 329, which you can specify in the **NOBS=** option in the PROC CALIS statements. See the section “[A Combined Measurement-Structural Model](#)” on page 320 for the justification of the use of this effective sample size.

The correlation matrix, taken from Jöreskog and Sörbom (1988), is shown in the following DATA step:

```

title 'Peer Influences on Aspiration: Haller & Butterworth (1960)';
data aspire(type=corr);
  _type_='corr';
  input _name_ $ riq rpa rses roa rea fiq fpa fses foa fea;
  label riq='Respondent: Intelligence'
        rpa='Respondent: Parental Aspiration'
        rses='Respondent: Family SES'
        roa='Respondent: Occupational Aspiration'

;

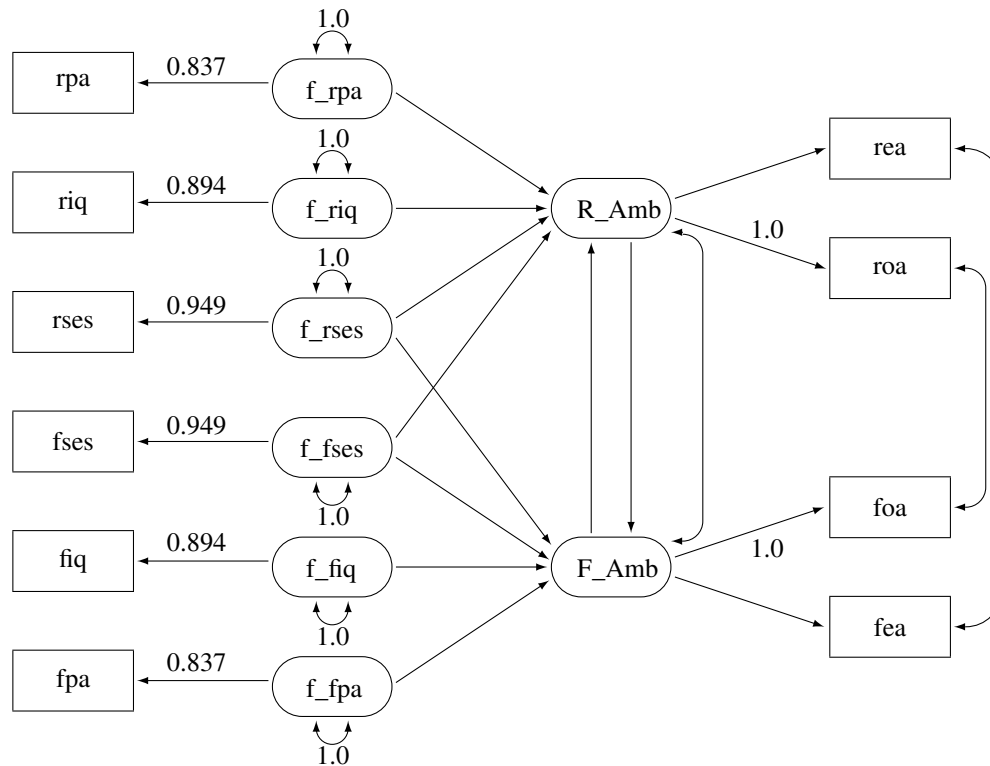

```

For illustration purposes, this correlation matrix is treated here as if it were a covariance matrix for PROC CALIS to analyze. The reason is that the chi-square tests shown in this example are valid only with covariance structure analysis. See [Example 27.27](#) for an illustration of covariance structure analysis on correlations.

Model 1: The Full Model

Loehlin (1987) analyzes the following path model for the data:

Figure 27.4 Path Diagram for Career Aspiration: Model 1

In Figure 27.4, the observed variables *rpa*, *riq*, *rses*, *fses*, *fiq*, and *fpa* are measured with errors. Their true scores counterparts *f_rpa*, *f_riq*, *f_rses*, *f_fses*, *f_fiq*, and *f_fpa* are latent variables in the model. Path coefficients from these latent variables to the observed variables are fixed coefficients, indicating the square roots of the theoretical reliabilities in the model. These latent variables, rather than the observed counterparts, serve as predictors of the ambition factors *R_Amb* and *F_Amb*. The error terms for these two latent factors are correlated, as indicated by a double-headed path (arrow) that connects the two factors. Correlated errors for the occupational aspiration variables (*roa* and *foa*) and the educational aspiration variables (*rea* and *fea*) are also shown in Figure 27.4. These correlated errors are also represented by two double-headed paths (arrows) in the path diagram.

Notice that the covariances among the six exogenous latent variables (*f_rpa*, *f_riq*, *f_rses*, *f_fses*, *f_fiq*, and *f_fpa*) are not represented in the path diagram for two reasons. First, there are 15 of these covariances and hence you need 15 double-headed arrows to represent them in the path diagram. Apparently, because of the space limitations, it would be difficult to put all these double-headed arrows in the path diagram without cluttering it. Second, covariances among exogenous latent variables are free parameters by default in PROC CALIS, and therefore omitting these double-headed arrows in the path diagram is compatible with the default model specification in PROC CALIS. Similarly, double-headed arrows for the error variances of the endogenous variables (*rpa*, *riq*, *rses*, *fses*, *fiq*, *fpa*, *R_Amb*, and *F_Amb*) in the path diagram are omitted because they are unconstrained free parameters and are set automatically by default in PROC CALIS.

The model represented by the path diagram in [Figure 27.4](#) is considered to be the full model for the data, in the sense that it has the largest number of parameters among the competing models considered this example. The same model is analyzed in the section “[A Combined Measurement-Structural Model](#)” on page 320 with the following specification:

```
proc calis data=aspire nobs=329;
  path
    /* measurement model for intelligence and environment */
    rpa      <=== f_rpa      = 0.837,
    riq      <=== f_riq      = 0.894,
    rses     <=== f_rses     = 0.949,
    fses     <=== f_fses     = 0.949,
    fiq      <=== f_fiq      = 0.894,
    fpa      <=== f_fpa      = 0.837,

    /* structural model of influences: 5 equality constraints */
    f_rpa    <==> R_Amb ,
    f_riq    <==> R_Amb ,
    f_rses   <==> R_Amb ,
    f_fses   <==> R_Amb ,
    f_rses   <==> F_Amb ,
    f_fses   <==> F_Amb ,
    f_fiq    <==> F_Amb ,
    f_fpa    <==> F_Amb ,
    F_Amb    <==> R_Amb ,
    R_Amb    <==> F_Amb ,

    /* measurement model for aspiration: 1 equality constraint */
    R_Amb    <==> rea ,
    R_Amb    <==> roa      = 1.,
    F_Amb    <==> foa      = 1.,
    F_Amb    <==> fea ;

  pvar
    f_rpa f_riq f_rses f_fpa f_fiq f_fses = 6 * 1.0;
  pcov
    R_Amb F_Amb      ,
    rea fea          ,
    roa foa          ;
run;
```

The PATH model specification represents each arrow (single-headed and double-headed) in the path diagram. You transcribe each arrow in [Figure 27.4](#) into an entry in the PATH model. The PATH statement specifies all the single-headed arrows in the path diagram. The PVAR statement specifies all the double-headed arrows that point to individual variables (that is, the fixed error variances of the exogenous latent variables) in the path diagram. The PCOV statement specifies all the double-headed arrows that connect paired variables (that is, the error covariances) in the path diagram.

Output 27.24.1 shows the fit summary of Model 1.

Output 27.24.1 Career Aspiration Data: Fit Summary of Model 1

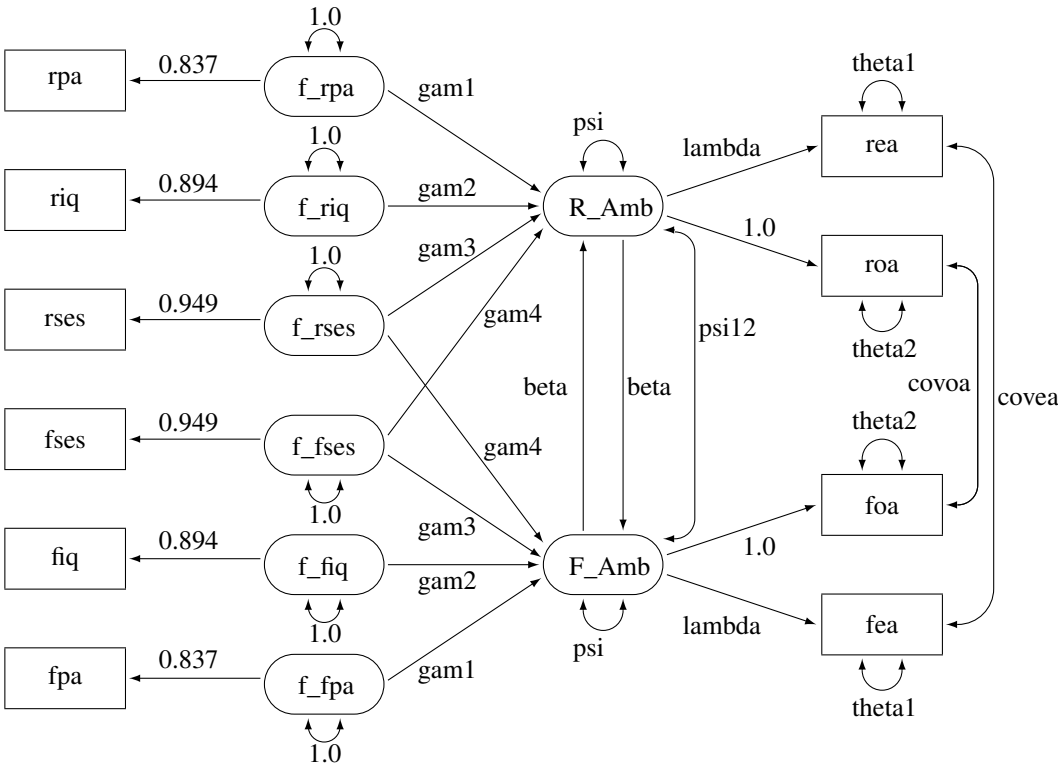

Fit Summary	
Chi-Square	12.0132
Chi-Square DF	13
Pr > Chi-Square	0.5266
Standardized RMR (SRMR)	0.0149
RMSEA Estimate	0.0000
Akaike Information Criterion	96.0132
Bozdogan CAIC	297.4476
Schwarz Bayesian Criterion	255.4476

Since the p -value for the chi-square test is 0.5266, this model clearly cannot be rejected. Both standardized RMR and RMSEA are very small. All these point to an excellent model fit. Three information-theoretic fit indices are also shown: Akaike's information criterion (AIC), Bozdogan's CAIC, and Schwarz's Bayesian Criterion (SBC). These indices are useful when you need to compare competing models for the data.

Model 2: The Model with Equality Constraints

You now consider a much more restrictive model with equality constraints in the model. The path diagram for this constrained model is shown in Figure 27.5.

Figure 27.5 Path Diagram for Career Aspiration: Model 2

The main idea about setting the equality constraints in this model is that there is some symmetry in the model components that correspond to the respondent and his friend. In particular, the corresponding coefficients or parameters should be equal. For example, the path $f_rpa \Rightarrow R_Amb$ for the respondent has the same effect as that of $f_fpa \Rightarrow F_Amb$. In the path diagram, they are both labeled by the same parameter γ_{am1} . Generalizing the same idea to other pairs of paths, [Output 27.5](#) shows nine pairs of these equality constraints, which are all represented by the same parameter names for distinct (single-headed or double-headed) paths.

However, because of the space limitation, there are six more equality constraints that are not shown in the path diagram. These six constraints concern the covariance structures of the exogenous latent factors f_rpa , f_riq , f_rses , f_fpa , f_fiq , and f_fses . The first three factors are for the respondent, and the last three are for his friend. Using the same symmetry argument, the covariance structures imposed on these exogenous latent factors are shown in the following:

	f_rpa	f_riq	f_rses	f_fpa	f_fiq	f_fses
f_rpa	1.					
f_riq	$c1$	1.				
f_rses	$c2$	$c3$	1.			
f_fpa	$c4$	$c5$	$c6$	1.		
f_fiq	$c5$	$c7$	$c8$	$c1$	1.	
f_fses	$c6$	$c8$	$c9$	$c2$	$c3$	1.

In this pattern of covariance structures, the covariance matrix (upper left portion) for the latent factors of the respondent is the same as that (lower right portion) for the latent factors of his friend. The cross-covariances among the factors between the friends (lower left portion) also display a symmetry pattern. There are six pairs of equality constraints in the covariance structures. Imposing these six pairs of equality constraints and the nine pairs of equality constraints in the path diagram lead to Model 2 of Loehlin (1987).

You can specify the current constrained model by the following PATH modeling language of PROC CALIS:

```
proc calis data=aspire nobs=329 outmodel=model2;
  path
    /* measurement model for intelligence and environment */
    rpa      <=== f_rpa      = 0.837,
    riq      <=== f_riq      = 0.894,
    rses     <=== f_rses     = 0.949,
    fses     <=== f_fses     = 0.949,
    fiq      <=== f_fiq      = 0.894,
    fpa      <=== f_fpa      = 0.837,

    /* structural model of influences: 5 equality constraints */
    f_rpa    ==> R_Amb      = gam1,
    f_riq    ==> R_Amb      = gam2,
    f_rses   ==> R_Amb      = gam3,
    f_fses   ==> R_Amb      = gam4,
    f_rses   ==> F_Amb      = gam4,
    f_fses   ==> F_Amb      = gam3,
    f_fiq    ==> F_Amb      = gam2,
    f_fpa    ==> F_Amb      = gam1,
    F_Amb    ==> R_Amb      = beta,
    R_Amb    ==> F_Amb      = beta,

    /* measurement model for aspiration: 1 equality constraint */
    R_Amb    ==> rea        = lambda,
    R_Amb    ==> roa        = 1.,
    F_Amb    ==> foa        = 1.,
    F_Amb    ==> fea        = lambda;
  pvar
    f_rpa f_riq f_rses f_fpa f_fiq f_fses = 6 * 1.0,
    R_Amb F_Amb                        = 2 * psi,          /* 1 ec */
    rea fea                            = 2 * theta1,       /* 1 ec */
    roa foa                            = 2 * theta2;       /* 1 ec */
  pcov
    R_Amb F_Amb                        = psi12,
    rea fea                            = covea,
    roa foa                            = covoa,
    f_rpa f_riq f_rses                 = cov1-cov3,        /* 3 ec */
    f_fpa f_fiq f_fses                 = cov1-cov3,
    f_rpa f_riq f_rses * f_fpa f_fiq f_fses = /* 3 ec */
    cov4 cov5 cov6 cov5 cov7 cov8 cov6 cov8 cov9;
run;
```

In the current PATH model specification, you specify the same set of paths as in Model 1. In addition, to set the required constraints in this path model, you use parameter names to label the related paths, variances, or covariances. Same parameter names mean equality constraints. The 15 equality constraints are labeled with comments in the specification. In the PROC CALIS statement, you use the OUTMODEL= option to output the model estimation results into the output data set model2, which is used for subsequent hypotheses tests.

Output 27.24.2 shows the fit summary of Model 2.

Output 27.24.2 Career Aspiration Data: Fit Summary of Model 2 in Loehlin (1987)

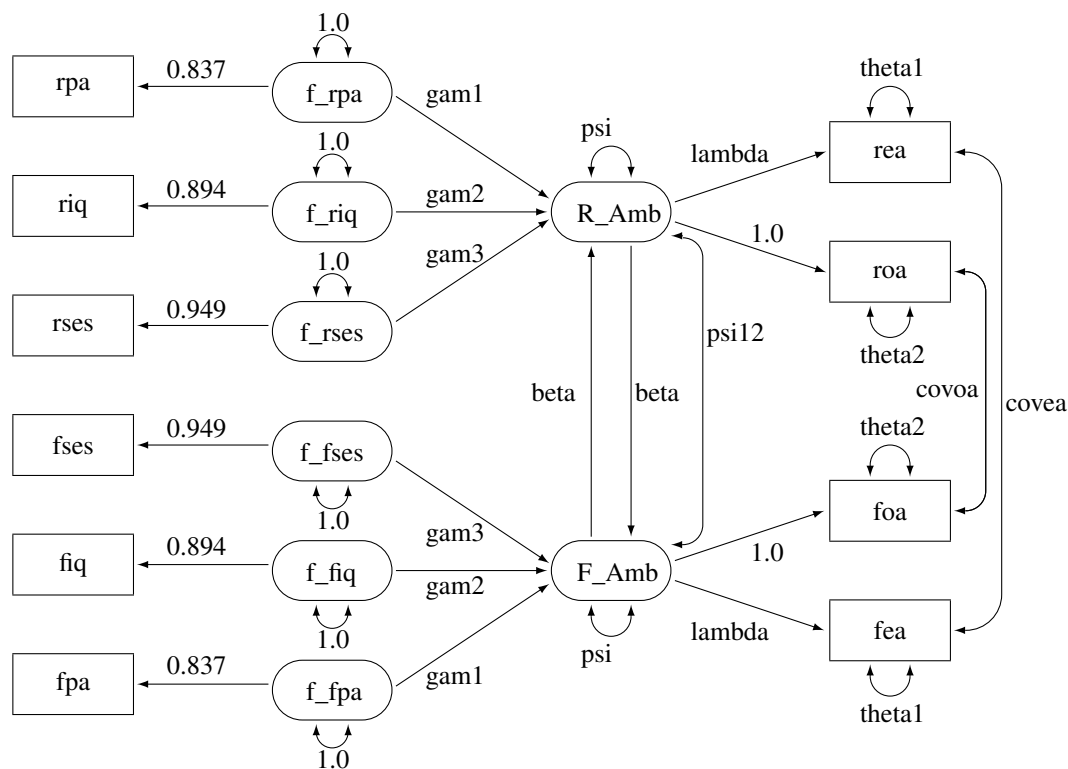

Fit Summary	
Chi-Square	19.0697
Chi-Square DF	28
Pr > Chi-Square	0.8960
Standardized RMR (SRMR)	0.0276
RMSEA Estimate	0.0000
Akaike Information Criterion	73.0697
Bozdogan CAIC	202.5632
Schwarz Bayesian Criterion	175.5632

The test of Model 2 against Model 1 (Loehlin 1987) yields a chi-square of $19.0697 - 12.0132 = 7.0565$ with 15 degrees of freedom, which is clearly not significant. This indicates that the restricted Model 2 fits at least as well as Model 1. Schwarz's Bayesian criterion (SBC) is also much lower for Model 2 (175.5623) than for Model 1 (255.4476). Hence, Model 2 seems preferable on both substantive and statistical grounds.

Model 3: No SES Paths

A question of substantive interest is whether the friend's socioeconomic status (SES) has a significant direct influence on a boy's ambition. This can be addressed by omitting the paths from `f_ses` to `R_Amb` and from `f_rses` to `F_Amb` designated by the parameter name `gam4`, yielding Model 3 of Loehlin (1987). The corresponding path diagram is shown in Figure 27.6.

Figure 27.6 Path Diagram for Career Aspiration: Model 3

In Figure 27.6, you drop the paths `f_rses====>F_Amb` and `f_fses====>R_Amb` from the previous model. Using the path diagram in Figure 27.6, you can specify the current model the same way you do for Model 2. However, because you have the estimation results from Model 2 in the SAS data set `model2`, you can modify this SAS data set to reflect the current model specification and then input the modified SAS data set as an `INMODEL=` file for PROC CALIS to analyze.

First, you create a new SAS data set model3 by the following DATA step:

```
data model3(type=calismdl);
  set model2;
  if _name_='gam4' then
    do;
      _name_=' ';
      _estim_=0;
    end;
run;
```

Essentially, by blanking out the parameter name for the target paths, you are stating that these paths are no longer associated with the free parameter gam4 in the new model. Instead, you put a fixed zero to these paths. This way you eliminate the paths `f_rses==>F_Amb` and `f_fses==>R_Amb` for Model 3, of which the model specification is now saved in the model3 data set.

Next, you input model3 as the INMODEL= data set for PROC CALIS to analyze, as shown in the following statements:

```
proc calis data=aspire nobs=329 inmodel=model3;
run;
```

PROC CALIS can now use the previous estimation results for fitting the required model. [Output 27.24.3](#) shows the fit summary of Model 3.

Output 27.24.3 Career Aspiration Data: Fit Summary of Model 3 in Loehlin (1987)

Fit Summary	
Chi-Square	23.0365
Chi-Square DF	29
Pr > Chi-Square	0.7749
Standardized RMR (SRMR)	0.0304
RMSEA Estimate	0.0000
Akaike Information Criterion	75.0365
Bozdogan CAIC	199.7340
Schwarz Bayesian Criterion	173.7340

The chi-square value for testing Model 3 versus Model 2 is $23.0365 - 19.0697 = 3.9668$ with one degree of freedom and a p -value of 0.0464. The chi-square test shows a marginal significance, which means that the paths might be needed in the model. However, the SBC (173.7340) indicates that Model 3 is slightly preferable to Model 2, which has an SBC value of 175.5632.

Model 4: No Reciprocal Influence between the Ambition Factors

Another important question is whether the reciprocal influences between the respondent's and friend's ambitions are needed in the model. To test whether these paths are zero, you can set the parameter `beta` for the paths linking `R_Amb` and `F_Amb` to zero to obtain Model 4 of Loehlin (1987).

Similar to Model 3, you can modify the `model2` data set to form the new model data set `model4` for PROC CALIS to analyze, as shown in the following statements:

```
data model4(type=calismdl);
  set model2;
  if _name_='beta' then
    do;
      _name_=' ';
      _estim_=0;
    end;
run;

proc calis data=aspire nobs=329 inmodel=model4;
run;
```

Output 27.24.4 shows the fit summary of Model 4.

Output 27.24.4 Career Aspiration Data: Fit Summary of Model 4 in Loehlin (1987)

Fit Summary	
Chi-Square	20.9981
Chi-Square DF	29
Pr > Chi-Square	0.8592
Standardized RMR (SRMR)	0.0304
RMSEA Estimate	0.0000
Akaike Information Criterion	72.9981
Bozdogan CAIC	197.6956
Schwarz Bayesian Criterion	171.6956

The chi-square value for testing Model 4 versus Model 2 is $20.9981 - 19.0697 = 1.9284$ with one degree of freedom and a p -value of 0.1649. Hence, there is little evidence of reciprocal influence.

Model 5: No Disturbance Correlation between the Ambition Factors

Model 2 of Loehlin (1987) has the direct paths connecting the latent ambition factors R_Amb and F_Amb and a covariance between the disturbance or error terms (that is, a double-headed arrow connecting the two factors in the path diagram shown in [Figure 27.5](#)). The presence of this disturbance correlation serves as a “wastebasket” that enables other omitted variables to have joint influences on the respondent’s and his friend’s ambition factors. To test the hypothesis that this disturbance correlation is zero, you use the following statements to set the parameter psi12 to zero in the model5 data set and fit the new model by PROC CALIS:

```
data model5(type=calismdl);
  set model2;
  if _name_='psi12' then
    do;
      _name_=' ';
      _estim_=0;
    end;
run;

proc calis data=aspire nobs=329 inmodel=model5;
run;
```

[Output 27.24.5](#) displays the fit summary of Model 5.

Output 27.24.5 Career Aspiration Data: Fit Summary of Model 5 in Loehlin (1987)

Fit Summary	
Chi-Square	19.0745
Chi-Square DF	29
Pr > Chi-Square	0.9194
Standardized RMR (SRMR)	0.0276
RMSEA Estimate	0.0000
Akaike Information Criterion	71.0745
Bozdogan CAIC	195.7721
Schwarz Bayesian Criterion	169.7721

The chi-square value for testing Model 5 versus Model 2 is $19.0745 - 19.0697 = 0.0048$ with one degree of freedom. This test statistic is insignificant. Therefore, omitting the covariance between the disturbance terms causes hardly any deterioration in the fit of the model.

Model 7: No Reciprocal Influence and No Disturbance Correlation between the Ambition Factors

The test in Model 4 fails to provide evidence of a direct reciprocal influence between the respondent's and friend's ambitions, and the test in Model 5 fails to provide evidence of a covariance or correlation between the disturbance terms for the ambition factors. Because you consider these two tests separately, you cannot establish evidence to eliminate the reciprocal influence and the disturbance correlation jointly. Instead, to make such a joint inference, it is important to test both hypotheses together by setting both beta and psi12 to zero as in Model 7 of Loehlin (1987). The following statements show how you can do that by modifying the model2 data set to form a new INMODEL= data set model7 for PROC CALIS to analyze:

```
data model7(type=calismdl);
  set model2;
  if _name_='psi12'|_name_='beta' then
    do;
      _name_=' ';
      _estim_=0;
    end;
run;

proc calis data=aspire nobs=329 inmodel=model7;
run;
```

Output 27.24.6 shows the fit summary of Model 7.

Output 27.24.6 Career Aspiration Data: Fit Summary of Model 7 in Loehlin (1987)

Fit Summary	
Chi-Square	25.3466
Chi-Square DF	30
Pr > Chi-Square	0.7080
Standardized RMR (SRMR)	0.0363
RMSEA Estimate	0.0000
Akaike Information Criterion	75.3466
Bozdogan CAIC	195.2480
Schwarz Bayesian Criterion	170.2480

When Model 7 is tested against Models 2, 4, and 5, the p -values are respectively 0.0433, 0.0370, and 0.0123, indicating that the combined effect of the reciprocal influence and the covariance of the disturbance terms is statistically significant. Thus, the hypothesis tests indicate that it is acceptable to omit either the reciprocal influences or the covariance of the disturbances, but not both.

Model 6: No Error Correlations between the Friend's Educational and Occupational Aspiration

It is also of interest to test the covariances (covea and covoa) between the error terms for educational aspiration (that is, between rea and fea) and occupational aspiration (that is, between roa and foa), because these terms are omitted from Jöreskog and Sörbom (1988) models. Constraining covea and covoa to zero produces Model 6 of Loehlin (1987). You can use the following statements to fit this model:

```
data model6(type=calismdl);
  set model2;
  if _name_='covea' | _name_='cova' then
    do;
      _name_=' ';
      _estim_=0;
    end;
run;

proc calis data=aspire nobs=329 inmodel=model6;
run;
```

Output 27.24.7 shows the fit summary of Model 6.

Output 27.24.7 Career Aspiration Data: Model 6 of Loehlin (1987)

Fit Summary	
Chi-Square	33.4475
Chi-Square DF	30
Pr > Chi-Square	0.3035
Standardized RMR (SRMR)	0.0306
RMSEA Estimate	0.0187
Akaike Information Criterion	83.4475
Bozdogan CAIC	203.3489
Schwarz Bayesian Criterion	178.3489

The chi-square value for testing Model 6 versus Model 2 is $33.4476 - 19.0697 = 14.3779$ with two degrees of freedom and a p -value of 0.0008, indicating that there is considerable evidence of correlation between the error terms.

Summary of Competing Models

The following table summarizes the results from the seven models described in Loehlin (1987).

Model	χ^2	df	p-value	SBC
1. Full model	12.0132	13	0.5266	255.4476
2. Equality constraints	19.0697	28	0.8960	175.5632
3. No SES path	23.0365	29	0.7749	173.7340
4. No reciprocal influence	20.9981	29	0.8592	171.6956
5. No disturbance correlation	19.0745	29	0.9194	169.7721
6. No error correlation	33.4475	30	0.3035	178.3489
7. Constraints from both 4 and 5	25.3466	30	0.7080	170.2480

For comparing models, you can use a DATA step to compute the differences of the chi-square statistics and *p*-values, as shown in the following statements:

```
data _null_;
  array achisq[7] _temporary_
    (12.0132 19.0697 23.0365 20.9981 19.0745 33.4475 25.3466);
  array adf[7] _temporary_
    (13 28 29 29 29 30 30);
  retain indent 16;
  file print;
  input ho ha @@;
  chisq = achisq[ho] - achisq[ha];
  df = adf[ho] - adf[ha];
  p = 1 - probchi( chisq, df);
  if _n_ = 1 then put
    / +indent 'model comparison    chi**2    df    p-value'
    / +indent '-----';
  put +indent +3 ho ' versus ' ha @18 +indent chisq 8.4 df 5. p 9.4;
  datalines;
2 1      3 2      4 2      5 2      7 2      7 4      7 5      6 2
;
```

The DATA step displays the table in [Output 27.24.8](#).

Output 27.24.8 Career Aspiration Data: Model Comparisons

Peer Influences on Aspiration: Haller & Butterworth (1960)				
model	comparison	chi**2	df	p-value

2	versus 1	7.0565	15	0.9561
3	versus 2	3.9668	1	0.0464
4	versus 2	1.9284	1	0.1649
5	versus 2	0.0048	1	0.9448
7	versus 2	6.2769	2	0.0433
7	versus 4	4.3485	1	0.0370
7	versus 5	6.2721	1	0.0123
6	versus 2	14.3778	2	0.0008

Although none of the seven models can be rejected when tested against the alternative of an unrestricted covariance matrix, the model comparisons make it clear that there are important differences among the models. Schwarz's Bayesian criterion indicates Model 5 as the model of choice. The constraints added to Model 5 in Model 7 can be rejected ($p = 0.0123$), while Model 5 cannot be rejected when tested against the less constrained Model 2 ($p = 0.9448$). Hence, among the small number of models considered, Model 5 has strong statistical support. However, as Loehlin (1987, p. 106) points out, many other models for these data could be constructed. Further analysis should consider, in addition to simple modifications of the models, the possibility that more than one friend could influence a boy's aspirations, and that a boy's ambition might have some effect on his choice of friends. Pursuing such theories would be statistically challenging.

Example 27.25: Fitting a Latent Growth Curve Model

Latent factors in structural equation modeling are constructed to represent important unobserved hypothetical constructs. However, with some manipulations latent factors can also represent random effects in models. In this example, a simple latent growth curve model is considered. You use latent factors to represent the random intercepts and slopes in the latent growth curve model.

Sixteen individuals were invited to a training program that was designed to boost self-confidence. During the training, the individuals' confidence levels were measured at five time points: initially and four more times separated by equal intervals. The data are stored in the following SAS data set:

```
data growth;
  input y1 y2 y3 y4 y5;
  datalines;
17.6 21.4 25.6 32.1 37.7
13.2 14.3 18.9 20.3 25.4
11.6 13.5 17.4 22.1 39.6

14.6 19.3 21.7 28.5 32.0
11.7 15.2 19.1 23.7 28.7
;
```

First, consider a simple linear regression model for the confidence levels at time t due to training. That is,

$$y_t = \alpha + \beta T_t + e_t$$

where y_t represents the confidence level at time t ($t = 1, 2, \dots, 5$), α represents the intercept, β represents the slope or the effect of training, T_t represents the fixed time point at t ($T_1 = 0$ and $T_i = T_{i-1} + 1$), and e_t is the error term at time t .

This simple linear regression assumes that the effect of training (slope) and the intercept are constants for the individuals. However, individual differences are rules rather than exceptions. It is thus more reasonable to argue that an index i for individuals should be added to the intercept and slope in the model. As a result, the following individualized regression model is derived:

$$y_{it} = \alpha_i + \beta_i T_t + e_t$$

where $i = 1, 2, \dots, 16$. In this model, individuals are assumed to have different intercepts and slopes (regression coefficients). Note that theoretically e_t could also be “individualized” as e_{ti} in the model. But this is not done because such a model would be unnecessarily complicated without gaining additional insights in return.

Unfortunately, this individualized model with individual intercepts and slopes cannot be estimated directly. If you treat each α_i and β_i as fixed parameters, you are going to have too many parameters for the model to be identified or estimable. A workable solution is to treat α and β in the original linear regression model as random variables instead. That is, the latent growth curve model of interest is as follows:

$$y_t = \alpha + \beta T_t + e_t$$

where (α, β) is bivariate normal with unknown means, variances, and covariance. Therefore, instead of having 16 intercepts and 16 slopes to estimate in the individualized regression model, the final latent growth curve model has to estimate only two means, two variances and one covariance in the bivariate distribution of (α, β) .

To use PROC CALIS to fit this latent growth curve model, the random intercept and effect are treated as if they were covarying latent factors. To make them stand out more as latent variables, the random intercept and slope are renamed as f_α and f_β in the following structural equation:

$$y_t = f_\alpha + T_t f_\beta + e_t$$

where f_α and f_β are bivariate-normal latent variables. This model assumes that the error distribution is time dependent (with the index t). A simpler version is to make this error term invariant over time, which is then represented by the following model with constrained error variances:

$$y_t = f_\alpha + T_t f_\beta + e$$

This constrained model is considered first. The LINEQS modeling language is used to specify this constrained model, as shown in the following statements.

```
proc calis method=ml data=growth nostand noparmname;
  lineqs
    y1 = 0. * Intercept + f_alpha + e1,
    y2 = 0. * Intercept + f_alpha + 1 * f_beta + e2,
    y3 = 0. * Intercept + f_alpha + 2 * f_beta + e3,
    y4 = 0. * Intercept + f_alpha + 3 * f_beta + e4,
    y5 = 0. * Intercept + f_alpha + 4 * f_beta + e5;
  variance
    f_alpha f_beta,
    e1-e5 = 5 * evar;
  mean
    f_alpha f_beta;
  cov
    f_alpha f_beta;
  fitindex on(only)=[chisq df probchi];
run;
```

In the LINEQS model specification, `f_alpha` and `f_beta` are treated as latent factors representing the random intercept and random slope, respectively. The `f_` prefix for latent factors is required as a convention in the LINEQS modeling language. See the sections “[Naming Variables in the LINEQS Model](#)” on page 1272 and “[Naming Variables and Parameters](#)” on page 1302 for details.

Notice that you need to set the ordinary (non-random) intercepts for endogenous variables to zero by the `0.*Intercept` specification because non-random intercepts for observed endogenous variables are default parameters in the LINEQS model. Because you have already used `f_alpha` as the random intercept, you must turn off the default non-random intercept term for the observed endogenous variables `y1–y5`. Otherwise, your latent growth curve model might be over-parameterized.

At $T_1 = 0$, y_1 represents the initial confidence measurement so that it is not subject to the random effect `f_beta`. The next four measurements y_2 , y_3 , y_4 , and y_5 are measured at time points T_2 , T_3 , T_4 , and T_5 , respectively. These are fixed time points with constant values 1, 2, 3, and 4, respectively, in the equations of the LINEQS statement.

The means, variances and covariances of `f_alpha` and `f_beta` are parameters in the model. The variances of these two latent variables are specified in the [VARIANCE](#) statement, while their covariance is specified in the [COV](#) statement. The means of `f_alpha` and `f_beta` are specified in the [MEAN](#) statement. Unlike the specification for the variances of `e1–e5`. All these parameters for the latent factors are unnamed because you do not need to constrain them by references.

The error variances for `e1–e5` are also specified in the [VARIANCE](#) statement. Using the shorthand notation `5 * evar`, the parameter name `evar` is repeated five times for the five error variances. This constrains the error variances for `e1–e5` to be equal.

You also use some special printing options in this example. In the PROC CALIS statement, the [NOSTAND](#) option is specified because standardized solution is not of interest. The reason is that $y_1–y_5$ were already measured on comparable scales, making standardization unnecessary for interpretations. Another printing option specified is the [NOPARMNAME](#) option in the PROC CALIS statement. This option suppresses the printing of parameter names in the output for estimation. This makes the output look more concise when you do not need to make references to the parameter names. Still another printing option used is

the ON(ONLY)= option of the **FITINDEX** statement. This option trims down the display of fit indices to include only those listed in the option. See the **FITINDEX** statement on page 1148 for details.

Output 27.25.1 shows the fit summary table.

Output 27.25.1 Random Intercepts and Effects with Constrained Error Variances: Model Fit

Fit Summary	
Chi-Square	31.4310
Chi-Square DF	14
Pr > Chi-Square	0.0048

In Output 27.25.1, the chi-square value in the fit summary table is 31.431 ($df = 14$, $p < 0.01$), which is a statistically significant result that might indicate a poor model fit. Despite that, it is illustrative to continue to look at the main estimation results, which are shown in the following table.

Output 27.25.2 Estimation of Random Intercepts and Effects with Constrained Error Variances

Estimates for Variances of Exogenous Variables				
Variable Type	Variable	Estimate	Standard Error	t Value
Latent	f_alpha	13.89140	5.81540	2.38873
	f_beta	0.80742	0.42198	1.91342
Error	e1	3.32185	0.70031	4.74342
	e2	3.32185	0.70031	4.74342
	e3	3.32185	0.70031	4.74342
	e4	3.32185	0.70031	4.74342
	e5	3.32185	0.70031	4.74342
Covariances Among Exogenous Variables				
Var1	Var2	Estimate	Standard Error	t Value
f_alpha	f_beta	-0.35281	1.13815	-0.30998
Mean Parameters				
Variable Type	Variable	Estimate	Standard Error	t Value
Latent	f_alpha	14.15875	1.02906	13.75890
	f_beta	4.04813	0.27563	14.68665

In [Output 27.25.2](#), the estimated variance of the random intercept α , which is represented by the variance estimate of the latent factor `f_alpha`, is 13.891 ($t = 2.389$). In the next row of the same table, the variance estimate of the random effect β , which is represented by the variance estimate of the latent factor `f_beta`, is 0.807 ($t = 1.913$).

The covariance of the random intercept and the random effect is shown in the next table for “Covariances Among Exogenous Variables.” A negative estimate of -0.353 is shown. This means that the initial self-confidence level and the boosting effect of training are negatively correlated. The higher the initial self-confidence level, the smaller the training effect.

In the last table for the “Mean Parameters,” the estimated mean of the random intercept is 14.159, which is an estimate of the averaged initial self-confidence level. The estimated mean of random effect is 4.048, which is an estimate of the averaged training effect. They are both significantly different from zero.

Given that the model does not fit that well, perhaps you should not take the interpretations of these estimates so seriously. Knowing that the distribution of the errors might have been time-dependent, you now try to improve the fit of the model by relaxing the constraint about common error variances. You can use the following specifications:

```
proc calis method=ml data=growth nostand noparmname;
  lineqs
    y1 = 0. * Intercept + f_alpha + e1,
    y2 = 0. * Intercept + f_alpha + 1 * f_beta + e2,
    y3 = 0. * Intercept + f_alpha + 2 * f_beta + e3,
    y4 = 0. * Intercept + f_alpha + 3 * f_beta + e4,
    y5 = 0. * Intercept + f_alpha + 4 * f_beta + e5;
  variance
    f_alpha f_beta,
    e1-e5;
  mean
    f_alpha f_beta;
  cov
    f_alpha f_beta;
  fitindex on(only)=[chisq df probchi];
run;
```

In this new specification, there is only one change in the **VARIANCE** statement from the previous specification. That is, you now specify only the error variables without putting parameter names for them. This makes the variances of `e1–e5` free (unconstrained) parameters in the model.

[Output 27.25.3](#) shows the model fit summary.

Output 27.25.3 Random Intercepts and Effects with Unconstrained Error Variances: Model Fit

Fit Summary	
Chi-Square	11.6250
Chi-Square DF	10
Pr > Chi-Square	0.3109

The chi-square for the unconstrained model is 11.625 ($df = 10$, $p > .10$). This indicates an acceptable model fit. The chi-square difference test can also be conducted for testing the previous constrained model

against this new model. The chi-square difference is $19.81 = 31.431 - 11.625$. With $df = 4$, this chi-square difference value is statistically significant at $\alpha=0.01$, indicating a significant improvement of model fit by using the unconstrained model.

Output 27.25.4 shows the estimation results.

Output 27.25.4 Estimation of Random Intercepts and Effects with Unconstrained Error Variances

Estimates for Variances of Exogenous Variables				
Variable Type	Variable	Estimate	Standard Error	t Value
Latent	f_alpha	14.70071	5.66943	2.59298
	f_beta	0.45059	0.29867	1.50867

	e3	1.94429	0.86824	2.23935
	e4	1.88569	1.21306	1.55448
	e5	14.65193	5.99354	2.44462
Covariances Among Exogenous Variables				
Var1	Var2	Estimate	Standard Error	t Value
f_alpha	f_beta	0.35291	0.90366	0.39054
Mean Parameters				
Variable Type	Variable	Estimate	Standard Error	t Value
Latent	f_alpha	14.03046	1.01534	13.81851
	f_beta	3.96793	0.22612	17.54781

The estimation results for the unconstrained model present a slightly different picture than the constrained model. While the estimates for the means and variances of the random intercept and the random training effect look similar in both models, estimates of the covariance between the random intercept and the random training effect are quite different in the two models. The covariance estimate is negative (-0.353) in the constrained model, but it is positive (0.353) in the unconstrained model. However, because the covariance estimates are not statistically significant in both models ($t = -0.310$ and 0.391 , respectively), you wonder whether the current data are showing strong evidence that supports one way or another. To get a clearer picture, perhaps you need to collect more data and fit the models again to examine the significance of the covariance between the random intercept and slope.

Example 27.26: Higher-Order and Hierarchical Factor Models

In this example, confirmatory higher-order and hierarchical factor models are fitted by PROC CALIS.

In higher-order factor models, factors are at different levels. The higher-order factors explain the relationships among factors at the next lower level, in the same way that the first-order factors explain the relationships among manifest variables. For example, in a two-level higher order factor model you have nine manifest variables V1–V9 with three first-order factors F1–F3. The first-order factor pattern of the model might appear like the following:

	F1	F2	F3
V1	x		
V2	x		
V3	x		
V4		x	
V5		x	
V6		x	
V7			x
V8			x
V9			x

where each “x” marks a nonzero factor loading and all other unmarked entries are fixed zeros in the model. To explain the correlations among the first-order factors, a second-order factor F4 is hypothesized with the following second-order factor pattern:

	F4
F1	x
F2	x
F3	x

If substantiated by your theory, you might have higher-order factor models with more than two levels.

In hierarchical factor models, all factors are at the same (first-order) level but are different in their clusters of manifest variables related. Using the terminology of Yung, Thissen, and McLeod (1999), factors in hierarchical factor models are classified into “layers.” The factors in the first layer partition the manifest variables into clusters so that each factor has a distinct cluster of related manifest variables. This part of the factor pattern of the hierarchical factor model is similar to that of the first-order factor model for manifest variables. The next layer of factors in the hierarchical factor model again partitions the manifest variables into clusters. However, this time each cluster contains at least two clusters of manifest variables that are formed in the previous layer. For example, the following is a factor pattern of a confirmatory hierarchical factor model with two layers:

	First Layer				Second Layer
	F1	F2	F3		F4
V1	x				x
V2	x				x
V3	x				x
V4		x			x
V5		x			x
V6		x			x
V7			x		x
V8			x		x
V9			x		x

F1–F3 are first-layer factors and F4 is the only second-layer factor. This special kind of two-layer hierarchical pattern is also known as the bifactor solution. In a bifactor solution, there are two classes of factors—group factors and a general factor. For example, in the preceding hierarchical factor pattern F1–F3 are group factors for different abilities and F4 is a general factor such as “intelligence” (see, for example, Holzinger and Swineford 1937). See Mulaik and Quartetti (1997) for more examples and distinctions among various types of hierarchical factor models. Certainly, if substantiated by your theory, hierarchical factor models with more than two layers are possible.

In this example, you use PROC CALIS to fit these two types of confirmatory factor models. First, you fit a second-order factor model to a real data set. Then you fit a bifactor model to the same data set. In the final section of this example, an informal account of the relationship between the higher-order and hierarchical factor models is attempted. Techniques for constraining parameters using PROC CALIS are also shown. This final section might be too technical in the first reading. Interested readers are referred to articles by Mulaik and Quartetti (1997), Schmid and Leiman (1957), and Yung, Thissen, and McLeod (1999) for more details.

A Second-Order Factor Analysis Model

In this section, a second-order confirmatory factor analysis model is applied to a correlation matrix of Thurstone reported by McDonald (1985). The correlation matrix is read into a SAS data set in the following statements:

```
data Thurst(type=corr);
title "Example of THURSTONE resp. McDONALD (1985, p.57, p.105)";
_type_ = 'corr'; input _name_ $ V1-V9;
label V1='Sentences' V2='Vocabulary' V3='Sentence Completion'
      V4='First Letters' V5='Four-letter Words' V6='Suffices'
      V7='Letter series' V8='Pedigrees' V9='Letter Grouping';
datalines;
V1 1. . . . . . . . .
V2 .828 1. . . . . . . .
V3 .776 .779 1. . . . . . .
V4 .439 .493 .460 1. . . . .
V5 .432 .464 .425 .674 1. . . .
V6 .447 .489 .443 .590 .541 1. . .
V7 .447 .432 .401 .381 .402 .288 1. .
V8 .541 .537 .534 .350 .367 .320 .555 1. .
V9 .380 .358 .359 .424 .446 .325 .598 .452 1.
;
```

Variables in this data set are measures of cognitive abilities. Three factors are assumed for these nine variables V1–V9. These three factors are the first-order factors in the analysis. A second-order factor is also assumed to explain the correlations among the three first-order factors.

The following statements define a second-order factor model by using the **LINEQS** modeling language.

```
proc calis corr data=Thurst method=max nobs=213 nose nostand;
  lineqs
    V1      = X11 * Factor1                      + E1,
    V2      = X21 * Factor1                      + E2,
    V3      = X31 * Factor1                      + E3,
    V4      =           X42 * Factor2              + E4,
    V5      =           X52 * Factor2              + E5,
    V6      =           X62 * Factor2              + E6,
    V7      =           X73 * Factor3              + E7,
    V8      =           X83 * Factor3              + E8,
    V9      =           X93 * Factor3              + E9,
    Factor1 = L1g * FactorG + E10,
    Factor2 = L2g * FactorG + E11,
    Factor3 = L3g * FactorG + E12;
  variance
    FactorG = 1. ,
    E1-E12 = U1-U9 W1-W3;
  bounds
    0. <= U1-U9;
  fitindex ON(ONLY)=[chisq df probchi];
  /* SAS Programming Statements: Dependent parameter definitions */
    W1 = 1. - L1g * L1g;
    W2 = 1. - L2g * L2g;
    W3 = 1. - L3g * L3g;
run;
```

In the first nine equations of the **LINEQS** statement, variables V1–V3 are manifest indicators of latent factor Factor1, variables V4–V6 are manifest indicators of latent factor Factor2, and variables V7–V9 are manifest indicators of latent factor Factor3. In the last three equations of the **LINEQS** statement, the three first-order factors Factor1–Factor3 are explained by a common source: FactorG. Hence, Factor1–Factor3 are correlated due to the common source FactorG in the model.

An error term is added to each equation in the **LINEQS** statement. These error terms E1–E12 are needed because the factors are not assumed to be perfect predictors of the corresponding outcome variables.

In the **VARIANCE** statement, you specify variance parameters for all independent or exogenous variables in the model: FactorG, and E1–E12. The variance of FactorG is fixed at one for identification. Variances for E1–E9 are given parameter names U1–U9, respectively. Variances for E10–E12 are given parameter names W1–W3, respectively. Note that for model identification purposes, W1–W3 are defined as dependent parameters in the **SAS programming statements**. That is,

$$W_i = 1. - L_{ig}^2 \quad (i = 1, 2, 3)$$

These dependent parameter definitions ensure that the variances for Factor1–Factor3 are fixed at ones for identification.

In the **BOUNDS** statement, you specify that variance parameters U1–U9 must be positive in the solution.

In addition to the statements for model specification, you specify some output control options in the PROC CALIS statement. You use the **NOSE** and **NOSTAND** options suppress the display of standard errors and standardized results. In the **FITINDEX** statement, the **ON(ONLY)=** option requests only the model fit chi-square and its associated degrees of freedom and *p*-value be shown in the fit summary table. Using printing options in PROC CALIS to reduce the amount of printout is a good practice. It makes your output more focused, as you output only what you need in a particular situation.

In **Output 27.26.1**, parameters and their initial values, gradients, and bounds are shown.

First, there are 21 independent parameters in the optimization by using 45 “Functions (Observations).” The so-called functions refer to the moments in the model that are structured with parameters. Nine lower bounds, which are specified for the error variance parameters, are specified in the optimization. The next table for iteration history shows that the optimization stops in 11 iterations. The notes at the bottom of table show that the solution converges without problems.

Output 27.26.3 shows the fit summary table. The chi-square model fit value is 38.196, with $df = 24$, and $p = 0.033$. This indicates a satisfactory model fit.

Output 27.26.3 Fit Summary

Fit Summary		
Chi-Square		38.1963
Chi-Square DF		24
Pr > Chi-Square		0.0331

Output 27.26.4 shows the fitted equations with final estimates. Interpretations of these loadings are not done here. The last table in this output shows various variance estimates. These estimates are classified by whether they are for the latent variables, error variables, or disturbance variables.

Estimates for Variances of Exogenous Variables			
Variable Type	Variable	Parameter	Estimate
Latent	FactorG		1.00000
Error	E1	U1	0.18150
	E2	U2	0.16493
	E3	U3	0.26713
	E4	U4	0.30150
	E5	U5	0.36450
	E6	U6	0.50642
	E7	U7	0.39033
	E8	U8	0.48137
	E9	U9	0.50510
Disturbance	E10	W1	0.32420
	E11	W2	0.38879
	E12	W3	0.33576

For illustration purposes, you might check whether the model constraints put on the variances of Factor1–Factor3 are honored (although this should have been taken care of in the optimization). For example, the variance of Factor1 should be:

$$1 = (\text{Loading on FactorG})^2 + \text{Variance of E10}$$

Extracting the estimates from the output, you indeed verify the required equality, as shown in the following:

$$1.0000 = (0.8221)^2 + 0.32420$$

A Bifactor Model

A bifactor model (or a hierarchical factor model with two layers) for the same data set is now considered. In this model, the same set of factors as in the preceding higher-order factor model are used. The most notable difference is that the second-order factor FactorG in the higher-order factor model is no longer a factor of the first-order factors Factor1–Factor3. Instead, FactorG, like Factor1–Factor3, now also serves as a factor of the observed variable V1–V9. Unlike Factor1–Factor3, FactorG is considered to be a *general* factor in the sense that *all* observed variables have direct functional relationships with it. In contrast, Factor1–Factor3 are *group* factors in the sense that each of them has a direct functional relationship with only one group of *observed* variables. Because of the coexistence of a general factor and group factors at the same factor level, such a hierarchical model is also called a bifactor model.

The bifactor model is specified in the following statements:

```

proc calis corr data=Thurst method=max nobs=213 nose nostand;
  lineqs
    V1 = X11 * Factor1                                + X1g * FactorG + E1,
    V2 = X21 * Factor1                                + X2g * FactorG + E2,
    V3 = X31 * Factor1                                + X3g * FactorG + E3,
    V4 =                X42 * Factor2                    + X4g * FactorG + E4,
    V5 =                X52 * Factor2                    + X5g * FactorG + E5,
    V6 =                X62 * Factor2                    + X6g * FactorG + E6,
    V7 =                X73 * Factor3 + X7g * FactorG + E7,
    V8 =                X83 * Factor3 + X8g * FactorG + E8,
    V9 =                X93 * Factor3 + X9g * FactorG + E9;
  variance
    Factor1-Factor3 = 3 * 1.,
    FactorG          = 1. ,
    E1-E9           = U1-U9;
  cov
    Factor1-Factor3 FactorG = 6 * 0.;
  bounds
    0. <= U1-U9;
  fitindex ON(ONLY)=[chisq df probchi];
run;

```

In the **LINEQS** statement, there are only nine equations for the manifest variables in the model. Unlike the second-order factor model fitted previously, Factor1–Factor3 are no longer functionally related to FactorG and therefore there are no equations with Factor1–Factor3 as outcome variables.

The factor variances are all fixed at 1 in the **VARIANCE** statement. The variance parameters for E1–E9 are named U1–U9, respectively. The **BOUNDS** statement, again, is specified so that only positive estimates are accepted for error variance estimates.

All factors in the bifactor model are uncorrelated. In the **COV** statement, you specify that the six covariances among Factor1–Factor3 and FactorG are all zero. This specification is necessary because by default exogenous variables (excluding error terms) in the **LINEQS** model are correlated.

Like the previous PROC CALIS run, options are specified in the PROC CALIS and the **FITINDEX** statements to reduce the amount of default output.

There are more parameters in this model than in the preceding higher-order factor model, as shown in [Output 27.26.5](#), which shows the optimization information.

One might ask whether this bifactor (hierarchical) model provides a significantly better fit than the previous second-order model. Can one use a chi-square difference test for nested models to answer this question? The answer is yes.

Although it is not obvious that the previous second-order factor model is nested within the current bifactor model, a general nested relationship between the higher-order factor and the hierarchical factor model is formally proved by Yung, Thissen, and McLeod (1999). Therefore, a chi-square difference test can be conducted using the following DATA step:

```

data _null_;
  df0 = 24; chi0 = 38.1963;
  df1 = 18; chi1 = 24.2163;
  diff = chi0-chi1;
  p = 1.-probbchi(chi0-chi1,df0-df1);
  put 'Chi-square difference = ' diff;
  put 'p-value = ' p;
run;

```

The results are shown in the following:

Output 27.26.8 Chi-square Difference Test

```

Chi-square difference = 13.98
p-value = 0.0298603746

```

The chi-square difference is 13.98, with $df = 6$ and $p = 0.02986$. If α -level is set at 0.05, the bifactor model indicates a significantly better fit. But if α -level is set at 0.01, statistically the two models fit equally well to the data.

In the next section, it is demonstrated that the second-order factor model is indeed nested within the bifactor model, and hence the chi-square test conducted in the previous section is justified. In addition, through the demonstration of the nested relationship between the two classes of models, you can see how some parameter constraints in structural equation model can be set up in PROC CALIS.

For some practical researchers, the technical details involved in the next section might not be of interest and therefore could be skipped.

A Constrained Bifactor Model and Its Equivalence to the Second-Order Factor Model

To demonstrate that the second-order factor model is indeed nested within the bifactor model, a constrained bifactor model is fitted in this section. This constrained bifactor model is essentially the same as the preceding bifactor model, but with additional constraints on the factor loadings. Hence, the constrained bifactor model is nested within the unconstrained bifactor model.

Furthermore, if it can be shown that the constrained bifactor model is equivalent to the previous second-order factor, then the second-order factor model must also be nested within the unconstrained bifactor model. As a result, it justifies the chi-square difference test conducted in the previous section.

The construction of such a constrained bifactor model is based on Yung, Thissen, and McLeod (1999). In the following statements, a constrained bifactor model is specified.

```

proc calis corr data=Thurst method=max nobs=213 nose nostand;
  lineqs
    V1 = X11 * Factor1                                + X1g * FactorG + E1,
    V2 = X21 * Factor1                                + X2g * FactorG + E2,
    V3 = X31 * Factor1                                + X3g * FactorG + E3,
    V4 =                X42 * Factor2                    + X4g * FactorG + E4,
    V5 =                X52 * Factor2                    + X5g * FactorG + E5,
    V6 =                X62 * Factor2                    + X6g * FactorG + E6,
    V7 =                X73 * Factor3 + X7g * FactorG + E7,
    V8 =                X83 * Factor3 + X8g * FactorG + E8,
    V9 =                X93 * Factor3 + X9g * FactorG + E9;
  variance
    Factor1-Factor3 = 3 * 1.,
    FactorG          = 1. ,
    E1-E9           = U1-U9;
  cov
    Factor1-Factor3 FactorG = 6 * 0.;
  bounds
    0. <= U1-U9;

  parameters p1 (.5) p2 (.5) p3 (.5);
  /* Proportionality constraints */
  X1g = p1 * X11;
  X2g = p1 * X21;
  X3g = p1 * X31;
  X4g = p2 * X42;
  X5g = p2 * X52;
  X6g = p2 * X62;
  X7g = p3 * X73;
  X8g = p3 * X83;
  X9g = p3 * X93;
run;

```

In this constrained model, you add a **PARAMETERS** statement and nine **SAS programming statements** to the previous bifactor model. In the **PARAMETERS** statement, three new independent parameters are added: *p1*, *p2*, and *p3*. These parameters represent the proportions that constrain the factor loadings of the observed variables on the group factors Factor1–Factor3 and the general factor FactorG. They are all free parameters and have initial values at 0.5. The next nine **SAS programming statements** represent the proportionality constraints imposed. For example, *X1g*–*X3g* are now dependent parameters expressed as functions of *p1*, *X11*, *X21*, and *X31*. Adding three new parameters (in the **PARAMETERS** statement) and redefining nine original parameters as dependent (in the **SAS programming statements**) is equivalent to adding six (=9–3) constraints to the original bifactor model. Mathematically, the additional statements in specifying the constrained bifactor model realizes the following six constraints:

$$\frac{X1g}{X11} = \frac{X2g}{X21} = \frac{X3g}{X31}$$

$$\frac{X4g}{X42} = \frac{X5g}{X52} = \frac{X6g}{X62}$$

$$\frac{X7g}{X73} = \frac{X8g}{X83} = \frac{X9g}{X93}$$

As shown [Output 27.26.9](#), there are 21 independent parameters in the constrained bifactor model for the 45 “Functions (Observations).” These numbers match those of the second-order factor model exactly. The optimization shows some problems in initial iterations. The iteration numbers with asterisks indicate that the Hessian matrix is not positive definite in those iterations. But as long as the final converged iteration is not marked with an asterisk, the problems exhibited in early iterations do not raise any concern, as in the current case. Next, the fit summary is shown in [Output 27.26.10](#).

Output 27.26.10 Model Fit

Fit Summary	
Chi-Square	38.1963
Chi-Square DF	24
Pr > Chi-Square	0.0331

In [Output 27.26.10](#), the chi-square value in the fit summary table is 38.196, with $df = 24$, and $p = 0.033$. Again, these numbers match those of the second-order factor model exactly. These matches (same model fit with the same number of parameters) are necessary (but not sufficient) to show that the constrained bifactor model is equivalent to the second-order model. Stronger evidence is now presented.

In [Output 27.26.11](#), estimation results of the constrained bifactor model are shown.

	Factor3		1.00000
	FactorG		1.00000
Error	E1	U1	0.18150
	E2	U2	0.16493
	E3	U3	0.26713
	E4	U4	0.30150
	E5	U5	0.36450
	E6	U6	0.50641
	E7	U7	0.39034
	E8	U8	0.48136
	E9	U9	0.50511

According to Yung, Thissen, and McLeod (1999), two models are equivalent if there is a one-to-one correspondence of the parameters in the models. This fact is illustrated for the constrained bifactor model and the second-order factor model.

First, the error variances for E1–E9 in the second-order factor model are transformed directly (using an identity map) to that of the bifactor models. The nine error variances in [Output 27.26.4](#) for the second-order factor model match those of the constrained bifactor model exactly in [Output 27.26.11](#). In addition, the variances of factors are fixed at one in both models. The error variances and the factor loadings at both factor levels in [Output 27.26.4](#) for the second-order factor model are now transformed to yield the loading estimates in the constrained bifactor model.

Denote \mathbf{P}_1 as the first-order factor loading matrix, \mathbf{P}_2 as the second-order factor loading matrix, and \mathbf{U}_1^2 be the matrix of variances for disturbances. That is, for the second-order factor model,

$$\mathbf{P}_1 = \begin{pmatrix} 0.9047 & 0 & 0 \\ 0.9138 & 0 & 0 \\ 0.8561 & 0 & 0 \\ 0 & 0.8358 & 0 \\ 0 & 0.7972 & 0 \\ 0 & 0.7026 & 0 \\ 0 & 0 & 0.7808 \\ 0 & 0 & 0.7202 \\ 0 & 0 & 0.7035 \end{pmatrix}$$

$$\mathbf{P}_2 = \begin{pmatrix} 0.8221 \\ 0.7818 \\ 0.8150 \end{pmatrix}$$

$$\mathbf{U}_1^2 = \begin{pmatrix} 0.3242 & 0 & 0 \\ 0 & 0.3888 & 0 \\ 0 & 0 & 0.3358 \end{pmatrix}$$

According to Yung, Thissen, and McLeod (1999), the transformation to obtain the estimates in the equivalent constrained bifactor model is:

$$\mathbf{L}_1 = \mathbf{P}_1 \mathbf{U}_1$$

$$\mathbf{L}_2 = \mathbf{P}_1 \mathbf{P}_2$$

where \mathbf{L}_1 is the matrix of the first-layer factor loadings (that is, loadings on group factors Factor1–Factor3), and \mathbf{L}_2 is the matrix of the second-layer factor loadings (that is, loadings on FactorG) in the constrained bifactor model. Carrying out the matrix calculations for \mathbf{L}_1 and \mathbf{L}_2 shows that:

$$\mathbf{L}_1 = \begin{pmatrix} 0.5151 & 0 & 0 \\ 0.5203 & 0 & 0 \\ 0.4875 & 0 & 0 \\ 0 & 0.5212 & 0 \\ 0 & 0.4971 & 0 \\ 0 & 0.4381 & 0 \\ 0 & 0 & 0.4525 \\ 0 & 0 & 0.4173 \\ 0 & 0 & 0.4077 \end{pmatrix}$$

$$\mathbf{L}_2 = \begin{pmatrix} 0.7438 \\ 0.7512 \\ 0.7038 \\ 0.6534 \\ 0.6232 \\ 0.5493 \\ 0.6364 \\ 0.5870 \\ 0.5734 \end{pmatrix}$$

With very minor numerical differences and ignorable sign changes, these transformation results match the estimated loadings observed in [Output 27.26.11](#) for the constrained bifactor model. Therefore, the second-order factor model is shown to be equivalent to the constrained bifactor model, and hence is nested within the unconstrained bifactor model.

Example 27.27: Linear Relations among Factor Loadings

In this example, you use the FACTOR modeling language of PROC CALIS to specify a confirmatory factor analysis model with linear constraints on loadings. You use [SAS programming statements](#) to set the constraints. This example also discusses the differences between fitting covariance structures and correlation structures in the current modeling context.

The correlation matrix of six variables from Kinzer and Kinzer (N=326) is used by Guttman (1957) as an example that yields an approximate simplex. McDonald (1980) uses this data set as an example of factor analysis where he assumes that the loadings on the second factor are linear functions of the loadings on the first factor. Let \mathbf{B} be the factor loading matrix containing the two factors and six variables so that:

$$\mathbf{B} = \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \\ b_{31} & b_{32} \\ b_{41} & b_{42} \\ b_{51} & b_{52} \\ b_{61} & b_{62} \end{pmatrix}$$

and

$$b_{j2} = \alpha + \beta b_{j1}, \quad j = 1, \dots, 6$$

The correlation structures are represented by:

$$\mathbf{P} = \mathbf{B}\mathbf{B}' + \mathbf{\Psi}$$

where $\mathbf{\Psi} = \text{diag}(\psi_{11}, \psi_{22}, \psi_{33}, \psi_{44}, \psi_{55}, \psi_{66})$ represents the diagonal matrix of unique variances for the variables.

With parameters α and β being unconstrained, McDonald (1980) has fitted an underidentified model with seven degrees of freedom. Browne (1982) imposes the following identification condition:

$$\beta = -1$$

In this example, Browne's identification condition is imposed. The following is the specification of the confirmatory factor model using the FACTOR modeling language.

```
data kinzer(type=corr);
title "Data Matrix of Kinzer & Kinzer, see GUTTMAN (1957)";

run;

```

In the **FACTOR** statement, you specify two factors, named `factor1` and `factor2`, for the variables. In this model, all manifest variables have nonzero loadings on the two factors. These loading parameters are specified after the equal signs and are named with the prefix ‘b.’ You specify the initial estimates in the parentheses for the parameters in the first entry of the **FACTOR** statement. The loadings in the first entry are all free parameters with initial estimates of .6. In the second entry of the **FACTOR** statement, you specify the Loadings of `var1–var6` on `factor2`. However, these parameters are dependent, as shown in the [SAS programming statements](#). Initial values for these dependent parameters are thus unnecessary.

In the **PVAR** statement, the factor variances are fixed at ones, while the error variances of the variables are free parameters named `psi1–psi6`. Again, you provide initial estimates for these error variance parameters. All have the initial value of 0.3.

An additional parameter `alpha` is specified in the **PARAMETERS** statement with an initial value of 1. Then, you use six [SAS programming statements](#) to define the loadings on the second factor as functions of the loadings on the first factor. Lastly, the **FITINDEX** statement is used to trim the results in the fit summary table.

In the specification, there are twelve loadings in the **FACTOR** statement and six error variances in the **PVAR** statement. Adding the parameter `alpha` in the list, there are 19 parameters in total. However, the loading parameters are not all independent of each other. As defined in the [SAS programming statements](#), six loadings are dependent. This reduces the number of free parameters to 13. Hence the degrees of freedom for the model is $8 = 21 - 13$. Notice that the factor variances are fixed at 1, as specified in the **PVAR** statement, and covariance among the two factors is fixed at zero, as specified in the **COV** statement.

[Output 27.27.1](#) shows a concise fit summary table. The chi-square test statistic of model fit is 10.337 with $df = 8$ ($p = 0.242$). This indicates a good model fit.

Output 27.27.1 Fit of the Correlation Structures

Fit Summary		
Chi-Square	10.3374	
Chi-Square DF	8	
Pr > Chi-Square	0.2421	

The estimated factor loading matrix is presented in [Output 27.27.2](#), and the estimated error variances and the estimate for alpha are presented in [Output 27.27.3](#).

Output 27.27.2 Loading Estimates

Factor Loading Matrix		
	factor1	factor2
var1	0.3609 [b11]	0.6174 [b12]
var2	0.3212 [b21]	0.6571 [b22]
var3	0.4859 [b31]	0.4923 [b32]
var4	0.5745 [b41]	0.4038 [b42]
var5	0.7985 [b51]	0.1797 [b52]
var6	0.6736 [b61]	0.3046 [b62]

Output 27.27.3 Unique Variances and the Additional Parameter

Error Variances		
Variable	Parameter	Estimate
var1	psi1	0.53036
var2	psi2	0.44986
var3	psi3	0.48756
var4	psi4	0.47278
var5	psi5	0.31125
var6	psi6	0.53815

Output 27.27.3 *continued*

Additional Parameters		
Type	Parameter	Estimate
Independent	alpha	0.97825

All these estimates are essentially the same as those reported in Browne (1982). Notice that there are no standard error estimates in the output, as requested by the **NOSE** option in the PROC CALIS statement. Standard error estimates are not of interest in this example.

In fitting the preceding factor model, wrong covariance structures rather than the intended correlation structures have been specified. As pointed out by Browne (1982), fitting such covariance structures directly is not entirely appropriate for analyzing correlations. For example, when fitting the correlation structures, the diagonal elements of **P** must always be fixed ones. This fact has never been enforced in the preceding specification. A simple check of the estimates will illustrate the problem. In [Output 27.27.2](#), the loading estimates of VAR1 on the two factors are 0.3609 and 0.6174, respectively. In [Output 27.27.3](#), the error variance estimate for VAR1 is 0.53036. The fitted variance of VAR1 can therefore be computed by the following equation:

$$\text{fitted variance} = 0.3609^2 + 0.6174^2 + 0.53036 = 1.0418$$

This fitted value is quite a bit off from 1.00, as required for the standardized variance of VAR1.

Fortunately, even though the wrong covariance structure model has been analyzed, the preceding analysis is not completely useless. For the current confirmatory factor model, according to Browne (1982) the estimates obtained from fitting the wrong covariance structure model are still consistent (as if they were estimating the population parameters in the correlation structures). However, the chi-square test statistic as reported previously is not correct.

Note that using the **CORR** option in the PROC CALIS statement will not solve the problem. By specifying the **CORR** option you merely request PROC CALIS to use the correlation matrix directly as a covariance matrix in the objective function for model fitting. It still would not constrain the fitting of the diagonal elements to 1 during estimation.

In the next section, a solution to the correlation analysis problem is suggested. It is not claimed that this is the only solution or the best solution. Alternative treatments of the problem are possible.

Fitting the Correct Correlation Structures

This main idea of this solution is to embed the intended correlation structures (with correct constraints on the diagonal elements of the correlation matrix) into a covariance structure model so that the estimation methods of PROC CALIS can be applied legitimately to the specially constructed covariance structures.

First, the issue of the fixed ones on the diagonal of the correlation structure model is addressed. That is, the diagonal elements of the correlation structures represented by $(\mathbf{B}\mathbf{B}' + \mathbf{\Psi})$ must be fitted by ones. This can be accomplished by constraining the error variances as dependent parameters of the loadings, as shown in the following:

$$\Psi_{jj} = 1. - b_{j1}^2 - b_{j2}^2, \quad j = 1, \dots, 6$$

Other constraints might also serve the purpose, but the proposed constraints here are the most convenient and intuitive.

Now, due to the fact that discrepancy functions used in PROC CALIS are derived for covariance matrices rather than correlation matrices, PROC CALIS is essentially set up for analyzing covariance structures (with or without mean structures), but not correlation structures. Hence, the statistical theory behind PROC CALIS applies to covariance structure analysis, but it might not generalize to correlation structure analysis in all situations. Despite that, with some manipulations PROC CALIS can fit the correct correlation structures to the current data without compromising the statistical theory. These manipulations are now discussed. Recall that the correlation structures are represented by:

$$\mathbf{P} = \mathbf{B}\mathbf{B}' + \mathbf{\Psi}$$

As before, in the \mathbf{B} matrix, there are six linear constraints on the factor loadings. In addition, the diagonal elements of $(\mathbf{B}\mathbf{B}' + \mathbf{\Psi})$ are constrained to ones, as done by defining the error variances as dependent parameters of the loadings in the preceding equation. To analyze the correlation structures by using PROC CALIS, a covariance structure model with such correlation structures embedded is now specified. That is, the covariance structure to be fitted by PROC CALIS is as follows:

$$\mathbf{\Sigma} = \mathbf{D}\mathbf{P}\mathbf{D}' = \mathbf{D}(\mathbf{B}\mathbf{B}' + \mathbf{\Psi})\mathbf{D}'$$

where \mathbf{D} is a 6 x 6 diagonal matrix containing the population standard deviations for the manifest variables. Theoretically, it is legitimate that you analyze this covariance structure model for studying the embedded correlation structures. In addition, it does not matter whether your input matrix is a correlation or covariance matrix, or any rescaled covariance matrix (by multiplying any variables by any positive constants). You would get correct results if you could somehow specify these covariance structures correctly in PROC CALIS. However, there seems to be nowhere in PROC CALIS that you can specify the diagonal matrix \mathbf{D} for the population standard deviations. So what can one do with this formulation? The answer is to rewrite the covariance structure model in a form similar to the usual confirmatory factor model, as presented in the following.

Let $\mathbf{T} = \mathbf{D}\mathbf{B}$ and $\mathbf{K} = \mathbf{D}\mathbf{\Psi}\mathbf{D}'$. The covariance structure model of interest can now be rewritten as:

$$\mathbf{\Sigma} = \mathbf{T}\mathbf{T}' + \mathbf{K}$$

This form of covariance structures implies a confirmatory factor model with factor loading matrix \mathbf{T} and error covariance matrix \mathbf{K} . This confirmatory factor model can certainly be specified using the FACTOR modeling language, in much the same way you specify a confirmatory factor model in the preceding section. However, because you are actually more interested in estimating the basic set of parameters in matrices \mathbf{B} and $\mathbf{\Psi}$ of the embedded correlation structures, you would define the model parameters as functions of this basic set of parameters of interest. This can be accomplished by using the [PARAMETERS](#) and the [SAS programming statements](#).

All in all, you can use the following statements to set up such a confirmatory factor model with the desired correlation structures embedded.

```
proc calis data=Kinzer nobs=326 nose;
  factor
    factor1 ==> var1-var6    = t11 t21 t31 t41 t51 t61,
    factor2 ==> var1-var6    = t12 t22 t32 t42 t52 t62;
  pvar
    factor1-factor2 = 2 * 1.,
    var1-var6       = k1-k6;
  cov
    factor1 factor2 = 0.;
  parameters alpha (1.) d1-d6 (6 * 1.)
    b11 b21 b31 b41 b51 b61 (6 *.6),
    b12 b22 b32 b42 b52 b62
    psi1-psi6;
  /* SAS Programming Statements */
  /* 12 Constraints on Correlation structures */
  b12 = alpha - b11;
  b22 = alpha - b21;
  b32 = alpha - b31;
  b42 = alpha - b41;
  b52 = alpha - b51;
  b62 = alpha - b61;
  psi1 = 1. - b11 * b11 - b12 * b12;
  psi2 = 1. - b21 * b21 - b22 * b22;
  psi3 = 1. - b31 * b31 - b32 * b32;
  psi4 = 1. - b41 * b41 - b42 * b42;
  psi5 = 1. - b51 * b51 - b52 * b52;
  psi6 = 1. - b61 * b61 - b62 * b62;
  /* Defining Covariance Structure Parameters */
  t11 = d1 * b11;
  t21 = d2 * b21;
  t31 = d3 * b31;
  t41 = d4 * b41;
  t51 = d5 * b51;
  t61 = d6 * b61;
  t12 = d1 * b12;
  t22 = d2 * b22;
  t32 = d3 * b32;
  t42 = d4 * b42;
  t52 = d5 * b52;
  t62 = d6 * b62;
  k1 = d1 * d1 * psi1;
  k2 = d2 * d2 * psi2;
  k3 = d3 * d3 * psi3;
  k4 = d4 * d4 * psi4;
  k5 = d5 * d5 * psi5;
  k6 = d6 * d6 * psi6;
  fitindex on(only)=[chisq df probchi];
run;
```

First, you notice that specifications in the **FACTOR** and the **PVAR** statements are essentially unchanged from the previous specification, except that the parameters are named differently here to reflect different model matrices. In the current specification, the factor loading parameters in matrix **T** are named with prefix 't,' and the error variance parameters in matrix **K** are named with prefix 'k.' Specification of these parameters reflects the covariance structures. As you see in the last block of the **SAS programming statements**, all these parameters are functions of the correlation structure parameters in **B**, **Ψ**, and **D**.

Next, in the **PARAMETERS** statement, all correlation structure parameters are defined with initial values provided. These are the parameters of interest: alpha is used to define dependencies among loadings, d's are the population standard deviations, b's are the loading parameters, and psi's are the error variance parameters. There are 25 parameters specified in this statement, but not all of them are free or independent.

In the first block of **SAS programming statements**, parameter dependencies or constraints on the correlation structures are specified. The first six statements realize the required linear relations among the factor loadings:

$$b_{j2} = \alpha - b_{j1}, \quad j = 1, \dots, 6$$

The next six statements constrain the error variances so as to ensure that an embedded correlation structure model is being fitted. That is, each error variance is dependent on the corresponding loadings, as prescribed by the following equation:

$$\Psi_{jj} = 1. - b_{j1}^2 - b_{j2}^2, \quad j = 1, \dots, 6$$

These twelve constraints reduce the number of independent parameters to 13, as expected.

The next block of **SAS programming statements** are essentially for relating the correlation structure parameters to the covariance structures that are specified in the **FACTOR** and the **PVAR** statements. These **SAS programming statements** realize the required relations: **T** = **DB** and **K** = **DΨD'**, but in non-matrix forms:

$$t_{ji} = d_j b_{ji} \quad (j = 1, \dots, 6; \quad i = 1, 2)$$

$$k_{jj} = d_j d_j \Psi_{jj} \quad (j = 1, \dots, 6)$$

where d_j denotes the j th diagonal element of **D**.

The fit summary is presented in **Output 27.27.4**. The chi-square test statistic is 14.63 with $df = 8$ ($p = 0.067$). This shows that the previous chi-square test based on fitting a wrong covariance structure model is indeed questionable.

Output 27.27.4 Model Fit of the Correlation Structures

Fit Summary	
Chi-Square	14.6269
Chi-Square DF	8
Pr > Chi-Square	0.0668

Estimates of the loadings and error variances are presented in [Output 27.27.5](#). These estimates are for the covariance structure model with loading matrix **T** and error covariance matrix **K**. They are rescaled versions of the correlation structure parameters and are not of primary interest themselves.

Output 27.27.5 Estimates of Loadings and Error Variances

Factor Loading Matrix		
	factor1	factor2
var1	0.3448 [t11]	0.6367 [t12]

	psi4	0.50998
	psi5	0.35762
	psi6	0.46116

Except for the population standard deviation parameter d's, all other parameters estimated in the current model can be compared with those from the previous fitting of an incorrect covariance structure model. Although estimates in the current model do not differ very much from those in the previous specification, it is at least reassuring that they are obtained from fitting a correctly specified covariance structure model with the intended correlation structures embedded.

Example 27.28: Multiple-Group Model for Purchasing Behavior

In this example, data were collected from customers who made purchases from a retail company during years 2002 and 2003. A two-group structural equation model is fitted to the data.

The variables are:

Spend02:	total purchase amount in 2002
Spend03:	total purchase amount in 2003
Courtesy:	rating of the courtesy of the customer service
Responsive:	rating of the responsiveness of the customer service
Helpful:	rating of the helpfulness of the customer service
Delivery:	rating of the timeliness of the delivery
Pricing:	rating of the product pricing
Availability:	rating of the product availability
Quality:	rating of the product quality

For the ratings scales, nine-point scales were used. Customers could respond 1 to 9 on these scales, with 1 representing “extremely unsatisfied” and 9 representing “extremely satisfied.” Data were collected from two different regions, which are labeled as Region 1 ($N = 378$) and Region 2 ($N = 423$), respectively. The ratings were collected at the end of year 2002 so that they represent customers’ purchasing experience in year 2002.

The central questions of the study are:

- How does the overall customer service affect the current purchases and predict future purchases?
- How does the overall product quality affect the current purchases and predict future purchases?
- Do current purchases predict future purchases?
- Do the two regions have different structural models for predicting the purchases?

In stating these research questions, you use several constructs that might or might not correspond to objective measurements. Current and future purchases are certainly measurable directly by the spending of the customers. That is, because customer service and product satisfaction and quality were surveyed between 2002 and 2003, Spend02 represents current purchases and Spend03 represents future purchases in the study. Both variables Spend02 and Spend03 are objective measurements without measurement errors. All you need to do is to extract the information from the transaction records. But how about hypothetical constructs such as customer service quality and product quality? How would you measure them in the model?

In measuring these hypothetical constructs, you might ask customers' perception about the service or product quality directly in a single question. A simple survey with two questions about the customer service and product qualities could then be what you need. These questions are called indicators (or indicator variables) of the underlying constructs. However, using just one indicator (question) for each of these hypothetical constructs would be quite unreliable—that is, measurement errors might dominate in the data collection process. Therefore, multiple indicators are usually recommended for measuring such hypothetical constructs.

There are two main advantages of using multiple indicators for hypothetical constructs. The first one is conceptual and the other is statistical and mathematical.

First, hypothetical constructs might conceptually be multifaceted themselves. Measuring a hypothetical construct by a single indicator does not capture the full meaning of the construct. For example, the product quality might refer to the durability of the product, the outlook of the product, the pricing of the product, and the availability of product, among others. The customer service quality might refer to the politeness of the customer service, the timeliness of the delivery, and the responsiveness of customer services, among others. Therefore, multiple indicators for a single hypothetical construct might be necessary if you want to cover the multifaceted aspects of a given hypothetical construct.

Second, from a statistical point of view, the reliability would be higher if you combine correlated indicators for a construct than if you use a single indicator only. Therefore, combining correlated indicators would lead to more accurate and reliable results.

One way to combine correlated indicators is to use a simple sum of them to represent the underlying hypothetical construct. However, a better way is to use the structural equation modeling technique that represents each indicator (variable) as a function of the underlying hypothetical construct plus an error term. In structural equation modeling, hypothetical constructs are constructed as latent factors, which are unobserved systematic (that is, non-error) variables. Theoretically, latent factors are free from measurement errors, and so the estimation through the structural equation modeling technique is more accurate than if you just use simple sums of indicators to represent hypothetical constructs. Therefore, a structural equation modeling approach is the method of the choice in the current analysis.

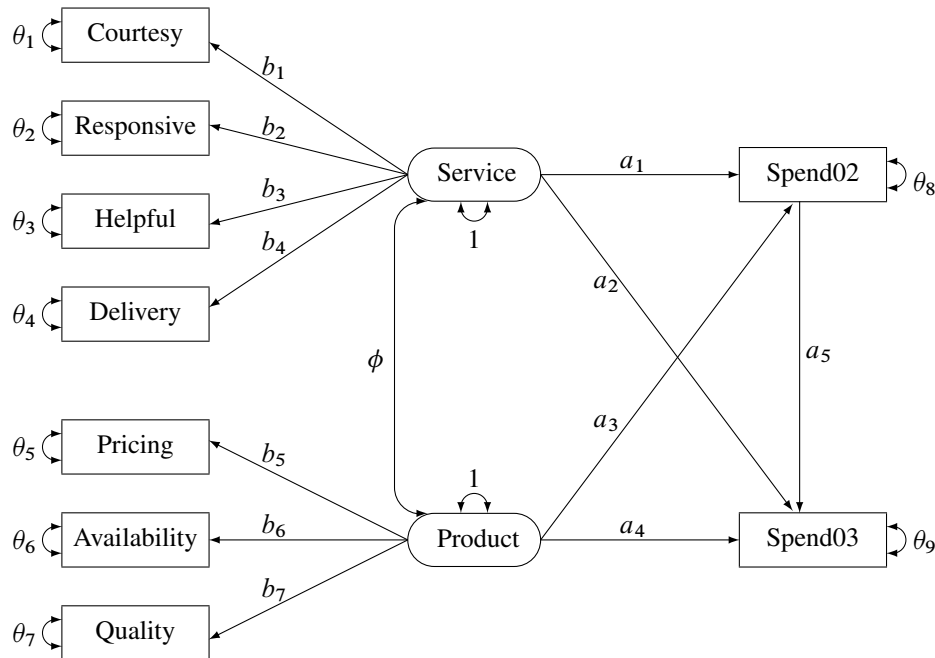

In practice, you must also make sure that there are enough indicators for the identification of the underlying latent factor, and hence the identification of the entire model. Necessary and sufficient rules for identification are very complicated to describe and are out of the scope of the current discussion (however, see Bollen 1989b for discussions of identification rules for various classes of structural equation models). Some simple rules of thumb might be useful as a guidance. For example, for unconstrained situations, you should at least have three indicators (variables) measured for a latent factor. Unfortunately, these rules of thumb do not guarantee identification in every case.

In this example, Service and Product are latent factors in the structural equation model which represent service and product qualities, respectively. In the model, these two latent factors are reflected by the ratings of the customers. Ratings on the Courtesy, Responsive, Helpful, and Delivery scales are indicators of Service. Ratings on the Pricing, Availability, and Quality scales are indicators of Product (that is, product quality).

A Path Diagram

A path diagram shown in Figure 27.7 represents the structural equation model for the purchase behavior. Observed or manifest variables are represented by rectangles, and latent variables are represented by ovals. As mentioned, two latent variables (factors), Service and Product, are created as overall measures of customer service and product qualities, respectively.

Figure 27.7 Path Diagram of Purchasing Behavior

The left part of the diagram represents the measurement model of the latent variables. The Service factor has four indicators: Courtesy, Responsive, Helpful, and Delivery. The path coefficients to these observed variables from the Service factor are b_1 , b_2 , b_3 , and b_4 , respectively. Similarly, the Product variable has three indicators: Pricing, Availability, and Quality, with path coefficients b_5 , b_6 , and b_7 , respectively.

The two latent factors are predictors of the purchase amounts Spend02 and Spend03. In addition, Spend02 also serves as a predictor of Spend03. Path coefficients (effects) for this part of functional relationships are represented by a_1 – a_5 in the diagram.

Each variable in the path diagram has a variance parameter. For endogenous or dependent variables, which serve as outcome variables in the model, the variance parameters are the error variances that are not accounted for by the predictors. For example, in the current model all observed variables are endogenous variables. The double-headed arrows that are attached to these variables represent error variances. In the diagram, θ_1 to θ_9 are the names of these error variance parameters. For exogenous or independent variables, which never serve as outcome variables in the model, the variance parameters are the (total) variances of these variables. For example, in the diagram the double-headed arrows that are attached to Service and Product represent the variances of these two latent variables. In the current model, both of these variances are fixed at one.

When the double-headed arrows point to two variables, they represent covariances in the path diagram. For example, in [Figure 27.7](#) the covariance between Service and Product is represented by the parameter ϕ .

The Basic Path Model Specification

For the moment, it is hypothesized that both ‘Region 1’ and ‘Region 2’ data are fitted by the same model as shown in [Figure 27.7](#). Once the path diagram is drawn, it is readily translated into the PATH modeling language. See the [PATH statement](#) on page 1202 for details about how to use the PATH modeling language to specify structural equation models.

To represent all the features in the path diagram in the PATH model language, you can use the following specification:

```
path
  Service ==> Spend02      = a1,
  Service ==> Spend03      = a1,
  Product ==> Spend02      = a3,
  Product ==> Spend03      = a4,
  Spend02 ==> Spend03      = a5,
  Service ==> Courtesy     = b1,
  Service ==> Responsive   = b2,

  Service Product = phi;
```

The [PATH](#) statement captures all the path coefficient specifications and the direction of the paths (single-headed arrows) in the path diagram. The first five paths define how Spend02 and Spend03 are predicted from the latent variables Service, Product, and Spend02. The next seven paths define the measurement model, which shows how the latent variables in the model relate to the observed indicator variables.

The [PVAR](#) statement captures the specification of the error variances and the variances of exogenous variables (that is, the double-headed arrows in the path diagram). The [PCOV](#) statement captures the specification of covariance between the two latent variables in the model (which is represented by the double-headed arrow that connects Service and Product in the path diagram).

You can also use the following simpler version of the PATH model specification for the path diagram:

```
path
  Service ==> Spend02 Spend03      ,
  Product ==> Spend02 Spend03      ,
  Spend02 ==> Spend03              ,
  Service ==> Courtesy Responsive
                Helpful Delivery    ,
  Product ==> Pricing Availability
                Quality              ;
pvar
  Courtesy Responsive Helpful Delivery Pricing
  Availability Quality Spend02 Spend03,
  Service Product = 2 * 1.;
pcov
  Service Product;
```

There are two simplifications in this PATH model specification. First, you do not need to specify the parameter names if they are unconstrained in the model. For example, parameter `a1` in the model is unique to the path effect from `Service` to `Spend02`. You do not need to name this effect because it is not constrained to be the same as any other parameter in the model. Similar, all the path coefficients (effects), error variances, and covariances in the path diagram are not constrained. Therefore, you can omit all the corresponding parameter name specifications in the PATH model specification. The only exceptions are the variances of `Service` and `Product`. Both are fixed constants 1 in the path diagram, and so you must specify them explicitly in the PVAR statement.

Second, you use a condensed way to specify the paths. In the first three path entries of the PATH statement, you specify how `Spend02` and `Spend03` are predicted from the latent variables `Service`, `Product`, and `Spend02`. Notice that in each path entry, you can define more than one path (single-headed arrow relationship). For example, in the first path entry, you specify two paths: one is `Service==>Spend02` and the other is `Service==>Spend03`. In the last two path entries of the PATH statement, you define the relationships between the two latent constructs `Spend` and `Service` and their measured indicators. Each of these path entries specifies multiple paths (single-headed arrow relationships).

You use this simplified PATH specifications in the subsequent analysis.

A Restrictive Model with Invariant Mean and Covariance Structures

In this section, you fit a mean and covariance structure model to the data from two regions, as shows in the following DATA steps:

```

```

To include the analysis of the mean structures, you need to introduce the mean and intercept parameters in the model. Although various researchers propose some representation schemes that include the mean parameters in the path diagram, the mean parameters are not depicted in [Figure 27.7](#). The reason is that representing the mean and intercept parameters in the path diagram would usually obscure the “causal” paths, which are of primary interest. In addition, it is a simple matter to specify the mean and intercept parameters in the [MEAN](#) statement without the help of a path diagram when you follow these principles:

- Each variable in the path diagram has a mean parameter that can be specified in the [MEAN](#) statement. For an exogenous variable, the mean parameter refers to the variable mean. For an endogenous variable, the mean parameter refers to the intercept of the variable.
- The means of exogenous observed variables are free parameters by default. The means of exogenous latent variables are fixed zeros by default.

- The intercepts of endogenous observed variables are free parameters by default. The intercepts of endogenous latent variables are fixed zeros by default.
- The total number of mean parameters should not exceed the number of observed variables.

Because all nine observed variables are endogenous (each has at least one single-headed arrow pointing to it) in the path diagram, you can specify these nine intercepts in the MEAN statement, as shown in the following specification:

```
mean
  Courtesy Responsive Helpful Delivery Pricing
  Availability Quality Spend02 Spend03;
```

However, the intercepts of endogenous observed variables are already free parameters by default and this MEAN statement specification is not necessary for the current situation. For the means of the latent variables Service and Product, you do not have any theoretical reasons to set them other than the default fixed zero. Hence, you do not need to set these mean parameters explicitly either. Consequently, to include the analysis of the mean structures with these default mean parameters, all you need to specify the MEANSTR option in the PROC CALIS statement, as shown in the following specification of the fitting of a constrained two-group model for the purchase data:

```
proc calis meanstr;
  group 1 / data=region1 label="Region 1" nobs=378;
  group 2 / data=region2 label="Region 2" nobs=423;
  model 1 / group=1,2;
    path
      Service ==> Spend02 Spend03      ,
      Product  ==> Spend02 Spend03      ,
      Spend02  ==> Spend03              ,
      Service  ==> Courtesy Responsive
                  Helpful Delivery      ,
      Product  ==> Pricing Availability
                  Quality                ;
    pvar
      Courtesy Responsive Helpful Delivery Pricing
      Availability Quality Spend02 Spend03,
      Service Product = 2 * 1.;
    pcov
      Service Product;
run;
```

The optimization converges. The fit summary table is presented in [Output 27.28.2](#).

Output 27.28.2 Fit Summary

	Bozdogan CAIC	3058.5121
	Schwarz Bayesian Criterion	3027.5121
	McDonald Centrality	0.1804
	Bentler Comparative Fit Index	0.0000
	Bentler-Bonett NFI	-6.0551
	Bentler-Bonett Non-normed Index	-6.8265
	Bollen Normed Index Rho1	-5.5970
	Bollen Non-normed Index Delta2	-7.4997
	James et al. Parsimonious NFI	-6.4756

The model chi-square statistic is 2820.25. With $df = 77$ and $p < .0001$, the null hypothesis for the mean and covariance structures is rejected. All incremental fit indices are negative. These negative indices indicate a bad model fit, as compared with the independence model. The same fact can be deduced by comparing the chi-square values of the baseline model and the fitted model. The baseline model has five degrees of freedom less (five parameters more) than the structural model but the chi-square value is only 399.747, much less than the model fit chi-square value of 2820.25. Because variables in social and behavioral sciences are almost always expected to correlate with each other, a structural model that explains relationships even worse than the baseline model is deemed inappropriate for the data. The RMSEA for the structural model is 0.2986, which also indicates a bad model fit. However, the GFI, AGFI, and parsimonious GFI indicate good model fit, which is a little surprising given the fact that all other indices indicate the opposite and the overall model is pretty restrictive in the first place.

There are some warnings in the output:

WARNING: Model 1. The estimated error variance for variable Spend02 is negative.

WARNING: Model 1. Although all predicted variances for the observed and latent variables are positive, the corresponding predicted covariance matrix is not positive definite. It has one negative eigenvalue.

PROC CALIS routinely checks the properties of the estimated variances and the predicted covariance matrix. It issues warnings when there are problems. In this case, the error variance estimate of Spend02 is negative, and the predicted covariance matrix for the observed and latent variables is not positive definite and has one negative eigenvalue. You can inspect [Output 27.28.3](#), which shows the variance parameter estimates of the variables.

Output 27.28.3 Variance Estimates

	Spend03	_Parm21	22.79309	5.75120	3.96319
Exogenous	Service		1.00000		
	Product		1.00000		

The error variance estimate for Spend02 is –14.40, which is negative and might have led to the negative eigenvalue problem in the predicted covariance matrix for the observed and latent variables.

A Model with Unconstrained Parameters for the Two Regions

With all the bad model fit indications and the problematic predicted covariance matrix for the latent variables, you might conclude that an overly restricted model has been fit. Region 1 and Region 2 might not share exactly the same set of parameters. How about fitting a model at the other extreme with all parameters unconstrained for the two groups (regions)? Such a model can be easily specified, as shown in the following statements:

```
proc calis meanstr;
  group 1 / data=region1 label="Region 1" nobs=378;
  group 2 / data=region2 label="Region 2" nobs=423;
  model 1 / group=1;
    path
      Service ==> Spend02 Spend03 ,
      Product ==> Spend02 Spend03 ,
      Spend02 ==> Spend03 ,
      Service ==> Courtesy Responsive Helpful Delivery ,
      Product ==> Pricing Availability Quality ;
    pvar
      Courtesy Responsive Helpful Delivery Pricing
      Availability Quality Spend02 Spend03,
      Service Product = 2 * 1.;
    pcov
      Service Product;
  model 2 / group=2;
    refmodel 1/ allnewparms;
run;
```

Unlike the previous specification, in the current specification Group 2 is now fitted by a new model labeled as Model 2. This model is based on Model 1, as specified in [REFMODEL](#) statement. The [ALLNEWPARMS](#) option in the [REFMODEL](#) statement request that all parameters specified in Model 1 be renamed so that they become new parameters in Model 2. As a result, this specification gives different sets of estimates for Model 1 and Model 2, although both models have the same path structures and a comparable set of parameters.

The optimization converges without problems. The fit summary table is displayed in [Output 27.28.4](#). The chi-square statistic is 29.613 ($df = 46, p = .97$). The theoretical model is not rejected. Many other measures of fit also indicate very good model fit. For example, the GFI, AGFI, Bentler CFI, Bentler-Bonett NFI, and Bollen nonnormed index delta2 are all close to one, and the RMSEA is close to zero.

Output 27.28.4 Fit Summary

Fit Summary		
Modeling Info	Number of Observations	801
	Number of Variables	9
	Number of Moments	108
	Number of Parameters	62
	Number of Active Constraints	0
	Baseline Model Function Value	0.5003

	Bozdogan CAIC	506.1365
	Schwarz Bayesian Criterion	444.1365
	McDonald Centrality	1.0103
	Bentler Comparative Fit Index	1.0000
	Bentler-Bonett NFI	0.9259
	Bentler-Bonett Non-normed Index	1.0783
	Bollen Normed Index Rho1	0.8840
	Bollen Non-normed Index Delta2	1.0463
	James et al. Parsimonious NFI	0.5916

Notice that because there are no constraints between the two models for the groups, you might have fit the two sets of data by the respective models separately and gotten exactly the same results as in the current analysis. For example, you get two model fit chi-square values from separate analyses. Adding up these two chi-squares gives you the same overall chi-square as in [Output 27.28.4](#).

PROC CALIS also provides a table for comparing the relative model fit of the groups. In [Output 27.28.5](#), basic modeling information and some measures of fit for the two groups are shown along with the corresponding overall measures.

Output 27.28.5 Fit Comparison among Groups

Fit Comparison Among Groups			
		Overall	Region 1

	Bentler-Bonett NFI	0.8730	

When you examine the results of this table, the first thing you have to realize is that in general the group statistics are not independent. For example, although the overall chi-square statistic can be written as the weighted sum of fit functions of the groups, in general it does not imply that the individual terms are statistically independent. In the current two-group analysis, the overall chi-square is written as

$$T = (N_1 - 1)f_1 + (N_2 - 1)f_2$$

where N_1 and N_2 are sample sizes for the groups and f_1 and f_2 are the discrepancy functions for the groups. Even though T is chi-square distributed under the null hypothesis, in general the individual terms $(N_1 - 1)f_1$ and $(N_2 - 1)f_2$ are not chi-square distributed under the same null hypothesis. So when you compare the group fits by using the statistics in [Output 27.28.5](#), you should treat those as descriptive measures only.

The current model is a special case where f_1 and f_2 are actually independent of each other. The reason is that there are no constrained parameters for the models fitted to the two groups. This would imply that the individual terms $(N_1 - 1)f_1$ and $(N_2 - 1)f_2$ are chi-square distributed under the null hypothesis. Nonetheless, this fact is not important to the group comparison of the descriptive statistics in [Output 27.28.5](#). The values of f_1 and f_2 are shown in the row labeled “Fit Function.” Group 1 (Region 1) is fitted better by its model ($f_1 = 0.0023$) than is Group 2 (Region 2) by its model ($f_2 = 0.0681$). Next, the percentage contributions to the overall chi-square statistic for the two groups are shown. Group 1 contributes only 3% ($= (N_1 - 1)f_1 / T \times 100\%$) while Group 2 contributes 97%. Other measures like RMR, SRMR, and Bentler-Bonett NFI show that Group 1 data are fitted better. The GFI’s show equal fits for the two groups, however.

Despite a very good fit, the current model is not intended to be the final model. It was fitted mainly for illustration purposes. The next section considers a partially constrained model for the two groups of data.

A Model with Partially Constrained Parameters for the Two Regions

For multiple-group analysis, cross-group constraints are of primary interest and should be explored whenever appropriate. The first fitting with all model parameters constrained for the groups has been shown to be too restrictive, while the current model with no cross-group constraints fits very well—so well that it might have overfit unnecessarily. A multiple-group model between these extremes is now explored. The following statements specify such a partially constrained model:

```

proc calis meanstr modification;
  group 1 / data=region1 label="Region 1" nobs=378;

      QualityDiff     = G2_intercept07 - G1_intercept07;
run;

```

In this specification, you use a special model definition. Model 3 serves as a reference model. You are not going to fit this model directly to any data set, but the specifications of other two models makes reference to it. Model 3 is no different from the basic path model specification used in preceding examples. The PATH model specification reflects the path diagram in [Figure 27.7](#).

Region 1 is fitted by Model 1, which makes reference to Model 3 by using the [REFMODEL](#) statement. In addition, you add the MEAN statement specification. You now specify the intercept parameters explicitly by using the parameter names G1_intercept01–G1_intercept07, G1_InterSpend02, and G1_InterSpend03. In previous examples, these intercept parameters are set by default by PROC CALIS. This explicit parameter naming serves the purpose of distinguishing these parameters from those for Model 2.

Region 2 is fitted by Model 2, which also refers to Model 3 by using the [REFMODEL](#) statement. You also specify a MEAN statement for this model with explicit specifications of the intercept parameters. You name these intercepts G2_intercept01–G2_intercept07, G2_InterSpend02, and G2_InterSpend03. The G2 prefix distinguishes these parameters from the corresponding intercept parameters in the parent model. All in all, this means that both Models 1 and 2 refers to Model 3, except that Model 2 uses a different set of intercept parameters. In other words, in this multiple-group model the covariance structures for the two regions are constrained to be the same, while the means structures are allowed to be unconstrained.

You request additional statistics or tests in the current PROC CALIS analysis. The [MODIFICATION](#) option in the PROC CALIS statement requests that the Lagrange multiplier tests and Wald tests be conducted. The Lagrange multiplier tests provide information about which constrained or fixed parameters could be freed or added so as to improve the overall model fit. The Wald tests provide information about which existing parameters could be fixed at zeros (eliminated) without significantly affecting the overall model fit. These tests are discussed in more detail when the results are presented.

In the [SIMTESTS](#) statement, two simultaneous tests are requested. The first simultaneous test is named SpendDiff, which includes two parametric functions Spend02Diff and Spend03Diff. The second simultaneous test is named MeasurementDiff, which includes seven parametric functions: CourtesyDiff, ResponsiveDiff, HelpfulDiff, DeliveryDiff, PricingDiff, AvailabilityDiff, and QualityDiff. The null hypothesis of these simultaneous tests is of the form

$$H_0 : t_i = 0 \quad (i = 1 \dots k)$$

where k is the number of parametric functions within the simultaneous test. In the current analysis, the component parametric functions are defined in the [SAS programming statements](#), which are shown in the last block of the specification. Essentially, all these parametric functions represent the differences of the mean or intercept parameters between the two models for groups. The first simultaneous test is intended to test whether the mean or intercept parameters in the structural models are the same, while the second simultaneous test is intended to test whether the mean parameters in the measurement models are the same.

The fit summary table is shown in [Output 27.28.6](#).

Output 27.28.6 Fit Summary

Fit Summary		
Modeling Info	Number of Observations	801
	Number of Variables	9
	Number of Moments	108
	Number of Parameters	40
	Number of Active Constraints	0
	Baseline Model Function Value	0.5003
	Baseline Model Chi-Square	399.7468
	Baseline Model Chi-Square DF	72
Absolute Index	Pr > Baseline Model Chi-Square	<.0001
	Fit Function	0.1346
	Chi-Square	107.5461
	Chi-Square DF	68
	Pr > Chi-Square	0.0016
	Z-Test of Wilson & Hilferty	2.9452
	Hoelter Critical N	657
	Root Mean Square Residual (RMR)	0.1577
Parsimony Index	Standardized RMR (SRMR)	0.0678
	Goodness of Fit Index (GFI)	1.0000
	Adjusted GFI (AGFI)	0.9999
	Parsimonious GFI	0.9444
	RMSEA Estimate	0.0382
	RMSEA Lower 90% Confidence Limit	0.0237
	RMSEA Upper 90% Confidence Limit	0.0514
	Probability of Close Fit	0.9275
Incremental Index	Akaike Information Criterion	187.5461
	Bozdogan CAIC	414.9806
	Schwarz Bayesian Criterion	374.9806
	McDonald Centrality	0.9756
	Bentler Comparative Fit Index	0.8793
	Bentler-Bonett NFI	0.7310
	Bentler-Bonett Non-normed Index	0.8722
	Bollen Normed Index Rho1	0.7151
	Bollen Non-normed Index Delta2	0.8808
	James et al. Parsimonious NFI	0.6904

The chi-square value is 107.55 ($df = 68$, $p = 0.0016$), which is statistically significant. The null hypothesis of the mean and covariance structures is rejected if an α -level at 0.01 or larger is chosen. However, in practical structural equation modeling, the chi-square test is not the only criterion, or even an important criterion, for evaluating model fit. The RMSEA estimate for the current model is 0.0382, which indicates a good fit. The probability level of close fit is 0.9275, indicating that a good population fit hypothesis (that is, population RMSEA < 0.05) cannot be rejected. The GFI, AGFI, and parsimonious GFI all indicate good fit. However, the incremental indices show only a respectable model fit.

Comparison of the model fit to the groups is shown in [Output 27.28.7](#).

Output 27.28.7 Fit Comparison among Groups

Fit Comparison Among Groups			
		Overall	Region 1
Modeling Info	Number of Observations	801	378

	Baseline Model Chi-Square DF	36	
Fit Index	Fit Function	0.1422	
	Percent Contribution to Chi-Square	56	
	Root Mean Square Residual (RMR)	0.1599	
	Standardized RMR (SRMR)	0.0557	
	Goodness of Fit Index (GFI)	1.0000	
	Bentler-Bonett NFI	0.7348	

Looking at the percentage contribution to the chi-square, the Region 2 fitting shows a worse fit. However, this might be due to the larger sample size in Region 2. When comparing the fit of the two regions by using RMR, which does not take the sample size into account, the fitting of two groups are about the same. The standardized RMR even shows that Region 2 is fitted better. So, it seems to be safe to conclude that the models fit almost equally well (or badly) for the two regions.

The constrained parameter estimates for the two regions are shown in [Output 27.28.8](#).

Output 27.28.8 Estimates of Path Coefficients and Other Covariance Parameters

All parameter estimates but one are statistically significant at $\alpha = 0.05$. The parameter `_Parm01`, which represents the path coefficient from `Service` to `Spend02`, has a t value of 1.76. This is only marginally significant. Although all these results bear the title of Model 1, these estimates are the same for Model 2, of which the corresponding results are not shown here.

The mean and intercept parameters for the two models (regions) are shown in [Output 27.28.9](#).

Output 27.28.9 Estimates of Means and Intercepts

Model 1. Means and Intercepts

All the mean and intercept estimates are statistically significant at $\alpha = 0.01$. Except for the fixed zero means for `Service` and `Product`, a quick glimpse of these mean and intercepts estimates shows a quite different pattern for the two models. Do these estimates truly differ beyond chance? The simultaneous tests of these parameter estimates shown in [Output 27.28.10](#) can confirm this.

Output 27.28.10 shows two simultaneous tests, as requested in the original statements.

Output 27.28.10 Simultaneous Tests

Simultaneous Tests					
Simultaneous Test	Parametric Function	Function Value	DF	Chi-Square	p Value
SpendDiff			2	10458	<.0001
	Spend02Diff	-27.25000	1	10225	<.0001
	Spend03Diff	14.18831	1	185.86725	<.0001
MeasurementDiff			7	1610	<.0001
	CourtesyDiff	-1.90000	1	286.58605	<.0001
	ResponsiveDiff	-1.99700	1	279.63659	<.0001
	HelpfulDiff	1.30300	1	141.59942	<.0001
	DeliveryDiff	2.01900	1	239.35318	<.0001
	PricingDiff	1.00300	1	85.52567	<.0001
	AvailabilityDiff	-1.76100	1	278.09360	<.0001
	QualityDiff	-0.85200	1	53.06240	<.0001

The first one is SpendDiff, which tests simultaneously the following hypotheses:

$$H_0 : G2_InterSpend02 - G1_InterSpend02 = 0$$

$$H_0 : G2_InterSpend03 - G1_InterSpend03 = 0$$

The exceedingly large chi-square value 10,460 suggests the composite null hypothesis is false. Individual tests for these hypotheses suggest that each of these hypotheses should be rejected. The chi-square values for individual tests are 10,227 and 185.84, respectively.

Similarly, the simultaneous and individual tests of the intercepts in the measurement model suggest that the two models (groups) differ significantly in the means of the measured variables. Region 2 has significantly higher means in variables Helpful, Delivery, and Pricing, but significantly lower means in variables Courtesy, Responsive, Availability, and Quality.

Now you are ready to answer the main research questions. The overall customer service (Service) does affect the future purchase (Spend03), but not the current purchase (Spend02), because the corresponding path coefficient (_Parm01) is only marginally significant. Perhaps this is an artifact because the rating was done after the purchases in 2002. That is, purchases in 2002 had been done before the impression about customer service was fully formed. However, this argument cannot explain why overall customer service (Service) also shows a strong and significant relationship with purchases in 2002 (Spend02). Nonetheless, customer service and product quality do affect the future purchases (Spend03) in an expected way, even after partialling out the effect of the previous purchase amount (Spend02). Apart from the mean differences of the variables, the common measurement and prediction (or structural) models fit the two regions very well.

Because the current model fits well and most parts of fitting meet your expectations, you might accept this model without looking for further improvement. Nonetheless, for illustration purposes, it would be useful to consider the LM test results. In [Output 27.28.11](#), ranked LM statistics for the path coefficients in Model 1 and Model 2 are shown.

Output 27.28.11 LM Tests for Path Coefficients

Path coefficients that lead to better improvement (larger chi-square decrease) are shown first in the tables. For example, the first path coefficient that is suggested to be freed in Model 1 is the Service <==== Courtesy path. The associated p -value is 0.0008 and the estimated change of parameter value is -0.171. The second path coefficient is for the Service <==== Helpful path, but it is not significant at the 0.05 level. So, is it good to add the Service <==== Courtesy path to Model 1, based on the LM test results? The answer is that it depends on your application and the theoretical and practical implications. For example, the Service <====> Courtesy path, which is a part of the measurement model, is already specified in Model 1. Even though the LM test statistic shows a significant decrease of model fit chi-square, adding the Service <==== Courtesy path might destroy the measurement model and lead to problematic interpretations. In this case, it is wise not to add the Service <==== Courtesy path, which is suggested by the LM test results.

LM tests for the path coefficients in Model 2 are shown at the bottom of [Output 27.28.11](#). Quite a few of these tests suggest significant improvements in model fit. Again, you are cautioned against adding these paths blindly.

LM tests for the error variances and covariances are shown in [Output 27.28.12](#).

Output 27.28.12 LM Tests for Error Covariances

Model 1. Rank Order of the 10 Largest LM Stat for Error Variances and Covariances

Responsive	Quality	1.88736	0.1695	-0.16963

Using $\alpha = 0.05$, you might consider adding two pairs of correlated errors in Model 2. The first pair is for Delivery and Courtesy, which has a p -value less than 0.0001. The second pair is Pricing and Responsive, which has a p -value of 0.027. Again, adding correlated errors (in the PCOV statement) should not be a pure statistical consideration. You should also consider theoretical and practical implications.

LM tests for other subsets of parameters are also conducted. Some subsets do not have parameters that can be freed, and so they are not shown here. Other subsets are not shown here simply for conserving space.

PROC CALIS ranks and outputs the LM test results for some default subsets of parameters. You have seen the subsets for path coefficients and correlated errors in the two previous outputs. Some other LM test results are not shown. With this kind of default LM output, there could be a huge amount of modification indices to look at. Fortunately, you can limit the LM test results to any subsets of potential parameters that you might be interested in. With your substantive knowledge, you can define such meaningful subsets of potential parameters by using the LMTESTS statement. The LM test indices and rankings are then done for each predefined subset of potential parameters. With these customized LM results, you can limit your attention to consider only those meaningful parameters to be added. See the LMTESTS statement on page 1166 for details.

The next group of LM tests is for releasing implicit equality constraints in your model, as shown in Output 27.28.13.

Output 27.28.13 LM Tests for Equality Constraints

Recall that the measurement and the prediction models for the two regions are constrained to be the same by model referencing (that is, the **REFMODEL** statement). **Output 27.28.13** shows you which parameter can be unconstrained so that your overall model fit might improve. For example, if you unconstrain the

first parameter `_Parm01`, which is for the path effect of `Spend02 <=== Service`, for the two models, the expected chi-square decrease (LM Stat) is about 0.0158, which is not significant ($p = .9001$). The associated parameter changes are small too. However, if you consider unconstraining parameter `_Parm06`, which is for the path effect of `Courtesy <=== Service`, the expected decrease of chi-square is 19.22 ($p < 0.0001$). There are two rows for this parameter. Each row represents a parameter location to be released from the equality constraint. Consider the first row first. If you rename the coefficient for the `Courtesy <=== Service` path in Model 1 to a new parameter, say “new” (while keeping `_Parm06` as the parameter for the `Courtesy <=== Service` path in Model 2) and fit the model again, the new estimate of `_Parm06` is 0.2852 greater than the previous `_Parm06` estimate. The estimate of “new” is 0.3196 less than the previous `_Parm06` estimate. The second row for the `_Parm06` parameter shows similar but reflected results. It is for renaming the parameter location in Model 2. For this example each equality constraint has exactly two locations, one for Model 1 and one for Model 2. That is the reason why you always observe reflected results for freeing the locations successively. Reflected results are not the case if you have equality constraints with more than two parameter locations.

Another example of a large expected improvement of model fit is the result of freeing the constrained variances of `Courtesy` among the two models. The corresponding row to look at is the row with parameter `_Parm13`, where the parameter type is labeled “COVERR” and the values for `Var1` and `Var2` are both “`Courtesy`.” The LM statistic is 45.255, which is a significant chi-square decrease if you free either parameter location. If you choose to rename the error variance for `Courtesy` in Model 1, the new `_Parm13` estimate is 0.8052 smaller than the original `_Parm13` estimate. The new estimate of the error variance for `Courtesy` in Model 2 is 0.7211 greater than the previous `_Parm13` estimate. Finally, the constrained parameter `_Parm15`, which is the error variance parameter for `Helpful` in both models, is also a potential constraint that can be released with a significant model fit improvement.

In addition to the LM statistics for suggesting ways to improve model fit, PROC CALIS also computes the Wald tests to show which parameters can be constrained to zero without jeopardizing the model fit significantly. The Wald test results are shown in [Output 27.28.14](#).

Output 27.28.14 Wald Tests

Stepwise Multivariate Wald Test					
Parm	-----Cumulative Statistics-----			--Univariate Increment--	
	Chi-Square	DF	Pr > ChiSq	Chi-Square	Pr > ChiSq
<code>_Parm01</code>	3.09039	1	0.0788	3.09039	0.0788

In [Output 27.28.14](#), you see that `_Parm01`, which is for the path effect of `Spend02 <=== Service`, is suggested to be a fixed zero parameter (eliminated from the model) by the Wald test. Fixing this parameter to zero (or dropping the `Spend02 <=== Service` path from the model) is expected to increase the model fit chi-square by 3.085 ($p = .079$), which is only marginally significant at $\alpha = 0.05$.

As is the case for the LM test statistics, you should not automatically adhere to the suggestions by the Wald statistics. Substantive and theoretical considerations should always be considered when determining whether a parameter should be added or dropped.

Example 27.29: Fitting the RAM and EQS Models by the COSAN Modeling Language

The COSAN modeling language in PROC CALIS enables you to specify the direct or implied mean and covariance structures for the data in terms of matrix formulas. It is a very general modeling language, and all other modeling languages in PROC CALIS are special cases of the COSAN modeling language. This example shows how you can apply the COSAN modeling language to situations where you might usually use the “easier” modeling languages. Therefore, the purpose of this example is not to recommend the use of the COSAN modeling specification to the specific application. Rather, through its connections with other more well-known model types, this example intends to help you understand the basics of the COSAN modeling language.

In [Example 27.17](#), you fit a path model to the Wheaton data (Wheaton et al. 1977) by using the PATH modeling language. The mathematical basis of the PATH modeling language is the RAM model. In [Example 27.23](#), you use the RAM and LINEQS statements to specify the same path model. In all these different types of specifications, you specify the functional relationships of the variables and the variance and covariance parameters in the model. PROC CALIS then generates the implied covariance structures for analysis internally. The COSAN modeling language is quite different. In the COSAN statement, you specify the covariance structures directly as a matrix formula. This example shows how you can do that in two different ways. One specification emulates the RAM model (McDonald 1978, 1980) covariance structures and the other emulates the EQS model (Bentler 1995) covariance structures.

Emulating the RAM model by the COSAN Modeling Language

In the RAM model, you specify all information regarding the path effects or coefficients (that is, single-headed arrows in the path diagram) in the so-called **A** (**_A_**) matrix. You specify all the information regarding the variances and covariances (that is, the double-headed arrows in the path diagram) in the **P** (**_P_**) matrix. See the section “[The RAM Model](#)” on page 1294 for more details about the mathematical model for RAM. Once you define these two matrices, the implied covariance structures for the observed variables are derived by the formula

$$\Sigma = \mathbf{J} * (\mathbf{I} - \mathbf{A})^{-1} * \mathbf{P} * (\mathbf{I} - \mathbf{A})^{-1'} * \mathbf{J}'$$

where **I** is an identity matrix and **J** is a selection matrix that contains 0 or 1 as its elements for selecting the covariance structures elements for the observed variables.

For example, in the RAM model specification in [Example 27.23](#), you essentially use the following RAM model specification:

```

proc calis nob=932 data=Wheaton primat nose;
  ram
    var =  Anomie67      /* 1 */
           Powerless67   /* 2 */
           Anomie71      /* 3 */
           Powerless71   /* 4 */
           Education     /* 5 */
           SEI           /* 6 */
           Alien67       /* 7 */
           Alien71       /* 8 */
           SES,          /* 9 */
    _A_   1  7  1.0,
    _A_   2  7  0.833,
    _A_   3  8  1.0,
    _A_   4  8  0.833,
    _A_   5  9  1.0,
    _A_   6  9  lambda,
    _A_   7  9  gamma1,
    _A_   8  9  gamma2,
    _A_   8  7  beta,
    _P_   1  1  theta1,
    _P_   2  2  theta2,
    _P_   3  3  theta1,
    _P_   4  4  theta2,
    _P_   5  5  theta3,
    _P_   6  6  theta4,
    _P_   7  7  psi1,
    _P_   8  8  psi2,
    _P_   9  9  phi,
    _P_   1  3  theta5,
    _P_   2  4  theta5;
run;

```

In the RAM statement, you specify all the parameters in the `_A_` and `_P_` matrices, and PROC CALIS generates the corresponding covariance structures for analysis. However, with the COSAN modeling language, in addition to the parameter in the model matrices, you need to supply the matrix formula for the covariance structures, as shown in the preceding formula for Σ .

Before discussing how you can specify the COSAN model that corresponds to this RAM model specification, it is useful to look at the initial model matrices that are generated by the preceding RAM model specification. To do this, you use the `PRIMAT` option in the PROC CALIS statement.

Output 27.29.1 and Output 27.29.2 show the initial $_A_$ and $_P_$ matrices, respectively, for the RAM model.

Essentially, to specify the same model by the COSAN modeling language, you need to provide the same information in these two initial model matrices and the covariance structure formula for Σ in the COSAN model specification, which is shown in the following statements:

```

proc calis data=Wheaton nobs=932 nose;
  cosan
    var= Anomie67 Powerless67 Anomie71 Powerless71 Education SEI,
    J(9, IDE) * A(9, GEN, IMI) * P(9, SYM);
  matrix A
    [1 2 8 , 7] = 1.0 0.833 beta,
    [3 4 , 8] = 1.0 0.833 ,
    [5 6 7 8 , 9] = 1. lambda gamma1 gamma2;
  matrix P
    [1,1] = theta1-theta2 theta1-theta4 ,
    [7,7] = psi1 psi2 phi,
    [3,1] = theta5 ,
    [4,2] = theta5 ;
  vnames
    J = [Anomie67 Powerless67 Anomie71 Powerless71
        Education SEI Alien67 Alien71 SES],
    A = J,
    P = A;
run;

```

In the PROC CALIS statement, you provide the data set in the DATA= option and the number of observations in the NOBS= option. You use the NOSE option to turn off the computation of the standard error estimates.

In the VAR= option of the COSAN statement, you provide the list of observed variables for the analysis. You do not specify the latent variables in the VAR= option in the COSAN statement as you do in the VAR= option in the RAM statement. Then, you specify the formula for the covariance structures for the set of variables in the VAR= list. Because the covariance structure formula is symmetric, you only need to specify “half” of it. That is, the specification $J(9, IDE) * A(9, GEN, IMI) * P(9, SYM)$ in the COSAN statement automatically expands to

$$J * (I - A)^{-1} * P * (I - A)^{-1'} * J'$$

which is the required covariance structures. The arguments in the matrices represent the number of columns, the matrix type, and the transformation type (optional), respectively. For example, the notation $A(9, GEN, IMI)$ means that matrix A has nine columns and it is a general (GEN) rectangular or square matrix. You do not specify the number of rows for matrix A explicitly, but PROC CALIS can deduce that because matrix A follows matrix J in the multiplication. To make matrix multiplication conformable, the number of rows for matrix A must be the same as the number of columns for matrix J , which is nine. The IMI notation means the identity-minus-inverse transformation, which results in putting $(I - A)^{-1}$ in the expression. Matrix P in the covariance structure formula is a 9×9 symmetric matrix. It does not have any transformation in the formula. Matrix J in the covariance structure formula is a so-called generalized identity matrix (IDE), which has six rows and nine columns. Basically, you use this matrix to select the observed variables in the covariance structure formula. The exact form of this matrix will become clear when the PROC CALIS output is shown.

Next, you use two MATRIX statements to specify the parameters in the model matrices A and P , for RAM model matrices $_A_$ and $_P_$, respectively. For example, in the first entry of the MATRIX statement for the A matrix, you specify the elements $[1, 7]$, $[2, 7]$, and $[8, 7]$ by 1.0, 0.833, and beta, respectively. The first two elements are fixed constants, while the last one is a free parameter named beta. Similarly, you specify all the fixed or free parameters in matrix A , which reflects the same pattern you specify for the $_A_$ matrix of the RAM model, as shown in [Output 27.29.1](#).

For the **P** matrix, you specify the parameters in the same fashion. Because **P** is defined as a symmetric matrix, you need to specify only the lower triangular elements. In the first entry of the **MATRIX** statement for the **P** matrix, you specify the **[1,1]** element, but the trailing parameter list has six parameters. The **[1,1]** notation here is interpreted as the starting location of the matrix. It proceeds to **[2,2]**, **[3,3]**, **[4,4]** and so on. The length of the trailing parameter list determines the number of elements being specified. Therefore, the last parameter in this entry is for **P[6,6]**, which is a free parameter **theta4**. Similarly, you define all other parameters in the **P** matrix, which reflects the same pattern you specify for the **_P_** matrix of the RAM model, as shown in [Output 27.29.2](#).

In the **VNAMES** statement, you can specify the column variable names for the model matrices. You provide a set of nine variable names for the column of matrix **J** in the pairs of brackets. The first six names are those of the observed variables in the COSAN model, while the last six names are for latent factors. How about the row variable names for matrix **J**? Because matrix **J** is the first matrix in the covariance structure formula, its row names are automatically the same as the names of the observed variables in the **VAR=** list of the COSAN statement. Next, you specify the column variable names of matrix **A**. You equate that to matrix **J**, meaning that the column variable names in matrix **A** are the same those for matrix **J**. How about the row variable names for matrix **A**? Because matrix **A** follows matrix **J** in the covariance structure formula, its row names are automatically same as the column names for matrix **J**. Lastly, you define that the column names for matrix **P** are the same as those for matrix **A**.

Notice that column names serve only as labels. PROC CALIS does not know the identities of the row and column variables. For example, the first column of matrix **A** is **Anomie67**, which is also a name for an observed variable in the COSAN model. Keeping other specifications intact, you could name this column by any other name without affecting the model estimation. It is recommended that you use sensible names that help you remember the identities of the row and column variables, such as this example shows.

[Output 27.29.3](#) shows the modeling information and the observed variables in the COSAN model. PROC CALIS analyzed the covariance structures of the six observed variables listed in [Output 27.29.3](#).

Output 27.29.3 Modeling Information of the COSAN Model for the Wheaton Data: RAM Emulation

Modeling Information					
Maximum Likelihood Estimation					
Data Set	WORK.WHEATON				
N Obs	932				
Model Type	COSAN				
Analysis	Covariances				
Observed Variables (N = 6) in the Model					
Anomie67	Powerless67	Anomie71	Powerless71	Education	SEI

[Output 27.29.4](#) shows the covariance structures and some properties of the model matrices. The covariance structure formula for Sigma is defined as required. You can also check the matrix properties in this output to see if they are what you intend them to be.

Output 27.29.4 The Covariance Structures and Model Matrices of the COSAN Model for the Wheaton Data: RAM Emulation

COSAN Model Structures			
Sigma = J*inv(_I_-A)*P*(inv(_I_-A))`*J`			
Summary of Model Matrices			
Matrix	N Row	N Col	Matrix Type
A	9	9	GEN: Square
J	6	9	IDE: (I 0)
P	9	9	SYM: Symmetric

Output 27.29.4 shows that **J** is a 6×9 “identity” matrix ($I||0$). Essentially, **J** is a selection matrix that contains either 0 or 1 as its elements. The role of matrix **J** in the covariance structure formula is to extract first six rows and columns in the inner covariance structures $(\mathbf{I} - \mathbf{A})^{-1} * \mathbf{P} * (\mathbf{I} - \mathbf{A})^{-1'}$ (which is 9×9) to form the covariance structures only for the observed variables (which is 6×6). But how can this identity matrix have more columns (9) than rows (6)? In common mathematical notation, an identity matrix must always be a square matrix. However, for convenience in notation, PROC CALIS generalizes it to the IDE type. An IDE matrix that has the same numbers of columns and rows is a square identity matrix. If an IDE matrix has more columns than rows, it denotes an identity matrix concatenated (to the right) by a null matrix (that is, the $(I||0)$ notation). If an IDE matrix has more rows than columns, it denotes an identity matrix appended (to the bottom) by a null matrix (that is, the $(I//0)$ notation). The generalized definition for the IDE matrix offers an efficient way to define selection matrix, such as the **J** matrix shown in this example.

Output 27.29.5 shows the model fit chi-square of the COSAN model. This is the same model fit as in Output 27.17.6 of Example 27.17, as expected.

Output 27.29.5 Model Fit of the COSAN Model for the Wheaton Data: RAM Emulation

Emulating the EQS model by the COSAN Modeling Language

The LINEQS modeling language in PROC CALIS enables you to specify the functional relationships among variables by using the equation input, much the same way that you can do with the EQS software (Bentler 1995). The covariance structure formula for the observed variables in the EQS model is

$$\Sigma = J * (I - \text{Beta})^{-1} * \text{Gamma} * \text{Phi} * \text{Gamma}' * (I - \text{Beta})^{-1'} * J'$$

where **I** is an identity matrix, **J** is a selection matrix that contains 0 or 1 as its elements for selecting the covariance structures elements for the observed variables, **Beta** is a square matrix for specifying relationships among the endogenous variables, **Gamma** is a matrix for specifying relationships between the endogenous variables and the exogenous variables, and **Phi** is a matrix for specifying the variances and covariances of the exogenous variables. Notice that in the EQS model, error or disturbance variables are counted as exogenous variables in the model.

In [Example 27.23](#), you use the following LINEQS specification for the Wheaton data:

```
proc calis nobobs=932 data=Wheaton primat nose;
  lineqs
    Anomie67      = 1.0      * f_Alien67 + e1,
    Powerless67   = 0.833    * f_Alien67 + e2,
    Anomie71      = 1.0      * f_Alien71 + e3,
    Powerless71   = 0.833    * f_Alien71 + e4,
    Education     = 1.0      * f_SES      + e5,
    SEI           = lambda   * f_SES      + e6,
    f_Alien67     = gamma1   * f_SES      + d1,
    f_Alien71     = gamma2   * f_SES      + beta * f_Alien67 + d2;
  variance
    E1            = theta1,
    E2            = theta2,
    E3            = theta1,
    E4            = theta2,
    E5            = theta3,
    E6            = theta4,
    D1            = psi1,
    D2            = psi2,
    f_SES         = phi;
  cov
    E1 E3         = theta5,
    E2 E4         = theta5;
run;
```

In the LINEQS statement, you specify all the functional relationships among variables. In the VARIANCE and COV statements, you specify all the variance and covariance parameters in the model. None of the parameters is specified as a matrix element in the LINEQS model. The default output by PROC CALIS does not print the EQS model matrices. To print these model matrices, you use the PRIMAT option in the PROC CALIS statement. [Output 27.29.10](#), [Output 27.29.11](#), and [Output 27.29.12](#) show the initial specification of these model matrices:

				[psi2]

In the COSAN modeling language, you need to provide the three initial model matrices and the covariance structure formula for Σ , which is shown in the following statements:

```
proc calis cov data=Wheaton nobs=932 nose;
  cosan
    var = Anomie67 Anomie71 Education Powerless67 Powerless71 SEI,
        J(8, IDE) * Beta(8, GEN, IMI) * Gamma(9, GEN) * Phi(9, SYM);
  matrix Beta
    [1 4 8 , 7] = 1.0 0.833 beta,
    [2 5 , 8] = 1.0 0.833 ;
  matrix Gamma
    [3 6 7 8 , 1] = 1.0 lambda gamma1 gamma2,
    [1,2] = 8 * 1.0;
  matrix Phi
    [1,1] = phi 2*theta1 theta3 2*theta2 theta4 psi1 psi2,
    [3,2] = theta5 ,
    [6,5] = theta5 ;
  vnames J = [Anomie67 Anomie71 Education Powerless67 Powerless71 SEI
              f_Alien67 f_Alien71],
    Beta = J,
    Gamma = [f_SES e1 e3 e5 e2 e4 e6 d1 d2],
    Phi = Gamma;
run;
```

In the PROC CALIS statement, you provide the data set in the DATA= option and the number of observations in the NOBS= option. You use the NOSE option to turn off the computation of the standard error estimates.

In the VAR= option of the COSAN statement, you provide the list of observed variables for the analysis. You arrange the observed variables in such a way that they are in the same order as in [Output 27.29.10](#), [Output 27.29.10](#), and [Output 27.29.12](#). This is useful for comparing the results from the LINEQS and COSAN model specifications. After the specification of the observed variables, you specify the covariance structure model in the COSAN statement. Again, you only need to specify “half” of it. That is, the specification $J(8, IDE) * Beta(8, GEN, IMI) * Gamma(9, GEN) * Phi(9, SYM)$ in the COSAN statement automatically expands to

$$\Sigma = J * (I - Beta)^{-1} * Gamma * Phi * Gamma' * (I - Beta)^{-1'} * J'$$

which is the required covariance structures. Matrix properties and transformation types are defined in the arguments for the matrices.

Next, you use three matrix statements to specify the parameters in the matrix elements. The specifications here reflect exactly the initial specifications for the LINEQS model matrices as shown in [Output 27.29.10](#), [Output 27.29.10](#), and [Output 27.29.12](#).

In the VNAMES statement, you specify the column variable names for the matrices. The column variable names of the J matrix include all the observed variable names and the names of the intended endogenous latent factors f_Alien67 and f_Alien71. The column variable names for the Beta matrix are the same as those for matrix J. The column variables for the Gamma matrix include the intended latent factor f_SES and error variable names e1–e6 and d1–d2, which are arranged in such a way that they match the order of the error variables in the LINEQS output shown in [Output 27.29.12](#).

[Output 27.29.13](#) shows the covariance structures and some properties of the model matrices. The covariance structure formula for Σ is defined as required. You can also check the matrix properties in this output to see if they are what you intend them to be.

Output 27.29.13 The Covariance Structures and Model Matrices of the COSAN Model for the Wheaton Data: EQS Emulation

COSAN Model Structures			
Sigma = J*inv(_I_-Beta)*Gamma*Phi*Gamma`*(inv(_I_-Beta))`*J`			
Summary of Model Matrices			
Matrix	N Row	N Col	Matrix Type

Example 27.30: Second-Order Confirmatory Factor Analysis

A second-order confirmatory factor analysis model is applied to a correlation matrix of Thurstone reported by McDonald (1985). The data set is shown in the following DATA step:

```
data Thurst (TYPE=CORR);
title "Example of THURSTONE resp. McDONALD (1985, p.57, p.105)";
  _TYPE_ = 'CORR'; Input _NAME_ $ Obs1-Obs9;
  label obs1='Sentences' obs2='Vocabulary' obs3='Sentence Completion'
        obs4='First Letters' obs5='Four-letter Words' obs6='Suffices'
        obs7='Letter series' obs8='Pedigrees' obs9='Letter Grouping';
  datalines;
obs1  1.      .      .      .      .      .      .      .      .
obs2  .828    1.      .      .      .      .      .      .      .
obs3  .776    .779    1.      .      .      .      .      .      .
obs4  .439    .493    .460    1.      .      .      .      .      .
obs5  .432    .464    .425    .674    1.      .      .      .      .
obs6  .447    .489    .443    .590    .541    1.      .      .      .
obs7  .447    .432    .401    .381    .402    .288    1.      .      .
obs8  .541    .537    .534    .350    .367    .320    .555    1.      .
obs9  .380    .358    .359    .424    .446    .325    .598    .452    1.
;
```

Using the LINEQS modeling language, you specify the three-term second-order factor analysis model in the following statements:

```
proc calis data=Thurst nobs=213 corr nose;
lineqs
  obs1 = x1 * f1 + e1,
  obs2 = x2 * f1 + e2,
  obs3 = x3 * f1 + e3,
  obs4 = x4 * f2 + e4,
  obs5 = x5 * f2 + e5,
  obs6 = x6 * f2 + e6,
  obs7 = x7 * f3 + e7,
  obs8 = x8 * f3 + e8,
  obs9 = x9 * f3 + e9,
  f1   = x10 * f4 + e10,
  f2   = x11 * f4 + e11,
  f3   = x12 * f4 + e12;
variance
  f4    = 1.,
  e1-e9 = u1-u9,
  e10-e12 = 3 * 1.;
bounds
  0. <= u1-u9;
run;
```

In the PROC CALIS statement, you specify the data set in the DATA= option and the number of observations in the NOBS= option. With the CORR option, you request the correlations be analyzed. You use the NOSE option to suppress the computation of standard error estimates.

In the LINEQS statement, the first-order loadings for the three factors, f1, f2, and f3, each refer to three variables, X1–X3, X4–X6, and X7–X9, respectively. One second-order factor, f4, reflects the correlations among the three first-order factors, f1, f2, and f3.

In the VARIANCE statement, you fix the variance of f4 to 1.0 for identification. The variances of error terms e1–e9 are free parameters u1–u9. The error variances for the three first-order factors are also fixed at 1.0 for identification purposes.

You also specify the boundary constraints for the error variance parameters u1–u9. You require them to be positive in the estimation.

Output 27.30.1 shows the estimation results.

Output 27.30.1 Estimation Results of the Second-Order Factor Model for Thurstone Data: LINEQS Model

	x12		

Output 27.30.1 *continued*

Estimates for Variances of Exogenous Variables			
Variable Type	Variable	Parameter	Estimate
Latent	f4		1.00000
Error	e1	u1	0.18150
	e2	u2	0.16493
	e3	u3	0.26713
	e4	u4	0.30150
	e5	u5	0.36450
	e6	u6	0.50642
	e7	u7	0.39033
	e8	u8	0.48138
	e9	u9	0.50509
Disturbance	e10		1.00000
	e11		1.00000
	e12		1.00000

Alternatively, you can use the COSAN model specification for analyzing the same data set. First, under the second-order factor model, the covariance structures of the observed variables can be derived as

$$\Sigma = \mathbf{F1} * \mathbf{F2} * \mathbf{P} * \mathbf{F2}' * \mathbf{F1}' + \mathbf{F1} * \mathbf{U2} * \mathbf{F1}' + \mathbf{U1}$$

where $\mathbf{F1}$ is the 9×3 first-order loading matrix for the observed variables, $\mathbf{F2}$ is the 3×1 second-order loading matrix for the first-order factors, \mathbf{P} is the 1×1 covariance matrix for the second-order factor f4, $\mathbf{U2}$ is the 3×3 error covariance matrix of the first-order factors f1–f3 (or the covariance matrix of the error terms e10–12), and $\mathbf{U1}$ is the 9×9 error covariance matrix for the observed variables (or the covariance matrix of the error terms e1–9).

Matrix $\mathbf{F1}$ contains the loading parameters x1–x9 and matrix $\mathbf{F2}$ contains the loading parameters x10–x12. Because there is only one second-order factor f4 in the model, matrix \mathbf{P} is a scalar, which is a fixed constant 1 in the LINEQS model. Matrix $\mathbf{U2}$ is an identity matrix because all error variances are fixed at 1 and they are not correlated. Matrix $\mathbf{U2}$ is a diagonal matrix that contains the parameters u1–u9. Given this information, you can use the following statements to specify the second-order factor model as a COSAN model:

```

proc calis data=Thurst nobs=213 corr nose;
  cosan
    var = obs1-obs9,
    F1(3) * F2(1) * P(1,IDE) + F1(3) * U2(3,IDE) + U1(9,DIA);
  matrix F1
    [1 , @1] = x1-x3,
    [4 , @2] = x4-x6,
    [7 , @3] = x7-x9;
  matrix F2
    [ ,1] = x10-x12;
  matrix U1
    [1,1] = u1-u9;
  bounds
    0. <= u1-u9;
  vnames
    F1 = [f1 f2 f3],
    F2 = [f4],
    U1 = [e1-e9];
run;

```

In the PROC CALIS statement, you specify the observed variables in the VAR= option and the covariance structures for the observed variables. In the terms of the covariance structure formula, you need to specify the expressions only up to the central symmetric matrices. The latter parts of these expressions are redundant and can be generated automatically by PROC CALIS, as shown in [Output 27.30.2](#).

Output 27.30.2 The Covariance Structures and Model Matrices of the Second-Order Factor Model: COSAN Model

COSAN Model Structures				
Sigma = F1*F2*P*F2`*F1` + F1*U2*F1` + U1				
Summary of Model Matrices				
Matrix	N Row	N Col	Matrix Type	
F1	9	3	GEN: Rectangular	
F2	3	1	GEN: Vector	
P	1	1	IDE: Identity	
U1	9	9	DIA: Diagonal	
U2	3	3	IDE: Identity	

[Output 27.30.2](#) shows that the intended covariance structures for the observed variables are being analyzed. The matrix types are shown next. Matrix **F1** is a rectangular matrix and matrix **F2** is a vector, although they have the default general (GEN) matrix type. Matrices **P** and **U2** are fixed identity (IDE) matrices in the model. For these two matrices, you do not need to specify any of their elements by using the MATRIX statement because they are already well-defined with the IDE type. Lastly, matrix **U1** is a diagonal (DIA) matrix in the model.

Output 27.30.3 shows the estimates of the first-order factor loading matrix **F1**.

Output 27.30.3 Estimation of the **F1** Matrix of the Second-Order Factor Model: COSAN Model

Model Matrix F1 (9 x 3 General Rectangular Matrix)			
	f1	f2	f3
Obs1	0.5151	0	0
	[x1]		
Obs2	0.5203	0	0
	[x2]		
Obs3	0.4874	0	0
	[x3]		
Obs4	0	0.5211	0
		[x4]	
Obs5	0	0.4971	0
		[x5]	
Obs6	0	0.4381	0
		[x6]	
Obs7	0	0	0.4524
			[x7]
Obs8	0	0	0.4173
			[x8]
Obs9	0	0	0.4076
			[x9]

In the **MATRIX** statement for **F1**, you specify the pattern of the loadings. In the first entry of the **MATRIX** statement, you specify the loadings in the following elements: [1,1], [2,1], and [3,1]. They are free parameters x1–x3, respectively. Notice that the @ sign is necessary in the first entry because the elements being defined would have been [1,1], [2,2], and [3,3] otherwise. The @ sign fixes the column number to 1. See the **MATRIX** statement for more details about the notation. Similarly, you define the other clusters of loading in the second and third entries in the **MATRIX** statement for **F1**. This explains the pattern of factor loadings in Output 27.30.3. These loading estimates x1–x9 match those by the LINEQS model specification, as shown in Output 27.30.1.

Output 27.30.3 shows the estimates of the second-order factor loading matrix **F2**.

Output 27.30.4 Estimation of the **F2** Matrix of the Second-Order Factor Model: COSAN Model

Model Matrix F2 (3 x 1 Column Vector)	
	f4
f1	1.4438 [x10]
f2	1.2538 [x11]
f3	1.4066 [x12]

In the MATRIX statement for **F2**, you do not specify the row numbers in the [, 1] specification. PROC CALIS interprets this as stating that all the valid elements in the first column are being specified in the parameter list. In the current example, this means that elements **F2**[1, 1], **F2**[2, 1], and **F2**[3, 1] are filled with the free parameters x10, x11, and x12, respectively. Output 27.30.3 shows these specification and the corresponding estimates, which match those of the LINEQS model specification, as shown in Output 27.30.1.

Output 27.30.5 shows the estimates of the error covariance matrix $U1$.

Output 27.30.5 Estimation of the $U1$ Matrix of the Second-Order Factor Model: COSAN Model

Model Matrix U1 (9 x 9 Diagonal Matrix)					
	e1	e2	e3	e4	e5
e1	0.1815 [u1]	0	0	0	0
e2	0	0.1649 [u2]	0	0	0
e3	0	0	0.2671 [u3]	0	0
e4	0	0	0	0.3015 [u4]	0
e5	0	0	0	0	0.3645 [u5]
e6	0	0	0	0	0
e7	0	0	0	0	0
e8	0	0	0	0	0
e9	0	0	0	0	0

Output 27.30.5 *continued*

Model Matrix U1 (9 x 9 Diagonal Matrix)				
	e6	e7	e8	e9
e1	0	0	0	0
e2	0	0	0	0
e3	0	0	0	0
e4	0	0	0	0
e5	0	0	0	0
e6	0.5064 [u6]	0	0	0
e7	0	0.3903 [u7]	0	0
e8	0	0	0.4814 [u8]	0
e9	0	0	0	0.5051 [u9]

In the MATRIX statement for U1, you specify the diagonal elements of the matrix by using the starting element at [1,1]. The parameter assignment proceeds to [2,2], [3,3] and so on such that all the trailing parameters u1–u9 are filled. This means that the last element U1[9,9] is a free parameter named u9. [Output 27.30.5](#) confirms this intended pattern. Again, all these error variance estimates match those by the LINEQS model specification, as shown in [Output 27.30.1](#).

Example 27.31: Linear Relations among Factor Loadings: COSAN Model Specification

This example reanalyzes the models in [Example 27.27](#) by using the COSAN modeling language. The correlation matrix of six variables from Kinzer and Kinzer (N=326) is used (see Guttman 1957). McDonald (1980) uses this data set to demonstrate the fitting of a factor analysis model with linear constraints on factor loadings. Two factors are assumed for the data. The factor loading matrix \mathbf{B} is shown in the following:

$$\mathbf{B} = \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \\ b_{31} & b_{32} \\ b_{41} & b_{42} \\ b_{51} & b_{52} \\ b_{61} & b_{62} \end{pmatrix}$$

The loadings on the second factor are linearly related to the loadings on the first factor, as described by the following formula:

$$b_{j2} = \alpha - b_{j1}, \quad j = 1, \dots, 6$$

The correlation structures are represented by

$$\mathbf{P} = \mathbf{B}\mathbf{B}' + \mathbf{\Psi}$$

where $\mathbf{\Psi} = \text{diag}(\psi_{11}, \psi_{22}, \psi_{33}, \psi_{44}, \psi_{55}, \psi_{66})$ represents the diagonal matrix of unique variances for the variables. Because matrix \mathbf{P} is a correlation matrix, its diagonal elements are fixed constants 1. This means that the diagonal elements of the correlation structures must also satisfy the following condition:

$$\Psi_{jj} = 1 - b_{j1}^2 - b_{j2}^2, \quad j = 1, \dots, 6$$

To analyze the correlation structures by using PROC CALIS, you formulate a covariance structure model with such correlation structures embedded in the model. That is, you want to fit the following covariance structure model to the Kinzer data:

$$\mathbf{\Sigma} = \mathbf{D}\mathbf{P}\mathbf{D}' = \mathbf{D}(\mathbf{B}\mathbf{B}' + \mathbf{\Psi})\mathbf{D}' = \mathbf{D}\mathbf{B}\mathbf{B}'\mathbf{D}' + \mathbf{D}\mathbf{\Psi}\mathbf{D}'$$

where \mathbf{D} is a 6 x 6 diagonal matrix that contains the population standard deviations of the observed variables.

The following statements use the COSAN modeling language to specify this covariance structure model:

```
proc calis data=Kinzer nobs=326 nose;
  cosan
    var= var1-var6,
    D(6,DIA) * B(2,GEN) + D(6,DIA) * Psi(6,DIA);
  matrix B
    [ ,1] = b11 b21 b31 b41 b51 b61,
    [ ,2] = b12 b22 b32 b42 b52 b62;
  matrix Psi
    [1,1] = psi1-psi6;
  matrix D
    [1,1] = d1-d6;
  parameters alpha (1.);

  /* SAS Programming Statements to Define Dependent Parameters*/
  /* 6 constraints on the factor loadings */
  b12 = alpha - b11;
  b22 = alpha - b21;
  b32 = alpha - b31;
  b42 = alpha - b41;
  b52 = alpha - b51;
  b62 = alpha - b61;

  /* 6 Constraints on Correlation structures */
  psi1 = 1. - b11 * b11 - b12 * b12;
  psi2 = 1. - b21 * b21 - b22 * b22;
  psi3 = 1. - b31 * b31 - b32 * b32;
  psi4 = 1. - b41 * b41 - b42 * b42;
  psi5 = 1. - b51 * b51 - b52 * b52;
  psi6 = 1. - b61 * b61 - b62 * b62;
  vnames
    D = [var1-var6],
    B = [factor1 factor2],
    Psi = D;
run;
```

In the PROC CALIS statement, you specify the data set by the DATA= option and the number of observations by the NOBS= option. You also use the NOSE option to suppress the printing of the standard error estimates.

In the COSAN statement, you specify the variables for the covariance structure analysis in the VAR= option. Next, you specify the covariance structure formula for the variables. When generating the covariance structure expressions for the terms, PROC CALIS examines the matrix type of the last matrix in each term to determine how the expression is generated. If the last matrix in a term is not a symmetric matrix (including diagonal or identity matrix), the transpose of the last matrix would be included in the expression. This ensures that a symmetric matrix expression is formed for the covariance structures. For example, the first term in the current covariance structure formula is $D(6, DIA) * B(2, GEN)$. Because **B** is not a symmetric matrix, the expression generated by PROC CALIS is

$$D * B * B' * D'$$

However, for the second term $D(6, DIA) * Psi(6, DIA)$, matrix **Psi** is a symmetric matrix so that the expression generated by PROC CALIS is

$$D * Psi * D'$$

Output 27.31.1 shows the covariance structure model and the model matrices. With **Psi** representing the unique variance matrix Ψ , the printed covariance structure formula for **Sigma** is clearly what you intend to specify.

Output 27.31.1 The Covariance Structures and Model Matrices: Linearly Constrained Loadings

COSAN Model Structures			
Sigma = D*B*B`*D` + D*Psi*D`			
Summary of Model Matrices			
Matrix	N Row	N Col	Matrix Type
B	6	2	GEN: Rectangular
D	6	6	DIA: Diagonal
Psi	6	6	DIA: Diagonal

In the MATRIX statements, you specify the parameters in the model matrices. You use parameters with the **b** prefix to name the two columns of loadings of the factor matrix **B**. You use free parameters **psi1–psi6** for the diagonal elements of the **Psi** matrix, and free parameters **d1–d6** for the diagonal elements of the **D** matrix. Next, you use a PARAMETERS statement to define an independent parameter **alpha** in the model. This parameter takes an initial value of 1.0. Using this independent parameter and six SAS programming statements, you define the loadings in the second column of matrix **B** as functions of the loadings in the first column of the same matrix.

You use six more SAS programming statements to define the unique variance parameters **psi1–psi6** as dependent parameters of the factor loadings. These constraints ensure that the embedded correlation structures have diagonal elements fixed at 1.0.

Lastly, you use the VNAMEs statement to label the column names of the model matrices. The column names of the diagonal matrix **D** are the same as the observed variables. The column names of matrix **B** are for the factor names.

As compared with the covariance structure specification (that is, the second specification) by the LINEQS model in Example 27.27, the current COSAN specification seems to be more direct and concise in specifying the parameter constraints. Because of the direct references to the matrix elements in the COSAN modeling language, you can set the required 12 constraints in a very straightforward way as the 12 SAS programming statements in the preceding specification. However, with the LINEQS model specification language in Example 27.27, you need 18 more SAS programming statements to define the correct constraints for the same covariance structure model.

Output 27.31.2 shows the fit summary table. The chi-square test statistic is 14.63 with $df = 8$ ($p = 0.067$). These are the same model fitting results as using the LINEQS model specification, as shown in Output 27.27.4 of Example 27.27.

Output 27.31.2 Model Fit: Linearly Constrained Loadings with Embedded Correlation Structures

Fit Summary	
Chi-Square	14.6269
Chi-Square DF	8
Pr > Chi-Square	0.0668

Output 27.31.3 shows the estimation of the loading matrix **B**. These estimates of factor loadings are essentially the same as those obtained from the LINEQS model specification, as shown in Output 27.27.6, except that the two columns of the loading matrix **B** are switched. The column switching is not a concern because the factor labels are arbitrary.

Output 27.31.3 Estimation of the B Matrix by the COSAN Model Specification

Model Matrix B (6 x 2 General Rectangular Matrix)		
	factor1	factor2
var1	0.6318 [b11]	0.3422 [b12]
var2	0.6531 [b21]	0.3210 [b22]
var3	0.4822 [b31]	0.4918 [b32]
var4	0.3985 [b41]	0.5755 [b42]
var5	0.1971 [b51]	0.7769 [b52]
var6	0.3074 [b61]	0.6666 [b62]

Output 27.31.4 shows the estimation of the scaling matrix **D**. All these standard deviation estimates for the observed variables match those obtained from the LINEQS model specification, as shown in Output 27.27.6.

Output 27.31.4 Estimation of the D Matrix by the COSAN Model Specification

Model Matrix D (6 x 6 Diagonal Matrix)						
	var1	var2	var3	var4	var5	var6
var1	1.0077 [d1]	0	0	0	0	0
var2	0	0.9971 [d2]	0	0	0	0
var3	0	0	0.9908 [d3]	0	0	0
var4	0	0	0	0.9909 [d4]	0	0
var5	0	0	0	0	0.9964 [d5]	0
var6	0	0	0	0	0	1.0169 [d6]

Output 27.31.5 shows the estimation of the unique covariance matrix **Psi**. All these unique variance parameter estimates match those obtained from the LINEQS model specification, as shown in Output 27.27.6.

Output 27.31.5 Estimation of the Psi Matrix by the COSAN Model Specification

Model Matrix Psi (6 x 6 Diagonal Matrix)						
	var1	var2	var3	var4	var5	var6
var1	0.4837 [psi1]	0	0	0	0	0
var2	0	0.4705 [psi2]	0	0	0	0
var3	0	0	0.5256 [psi3]	0	0	0
var4	0	0	0	0.5100 [psi4]	0	0
var5	0	0	0	0	0.3576 [psi5]	0
var6	0	0	0	0	0	0.4612 [psi6]

Finally, Output 27.31.6 shows the estimation of the independent parameter **alpha**. The same estimate of **alpha** is shown in Output 27.27.6.

Output 27.31.6 Estimation of the Independent Parameter **alpha** by the COSAN Model Specification

Additional Parameters		
Type	Parameter	Estimate
Independent	alpha	0.97400

Example 27.32: Ordinal Relations among Factor Loadings

The same data set as in [Example 27.31](#) is used in McDonald (1980) for analysis with ordinally constrained factor loadings. In [Example 27.27](#), the results of the linearly constrained factor analysis show that the loadings of the two factors are ordered as 2, 1, 3, 4, 6, 5. McDonald (1980) then tests the hypothesis that the factor loadings are all nonnegative and can be ordered in the following manner:

$$b_{11} \geq b_{21} \geq b_{31} \geq b_{41} \geq b_{51} \geq b_{61}$$

$$b_{12} \leq b_{22} \leq b_{32} \leq b_{42} \leq b_{52} \leq b_{62}$$

In this example, you implement these ordinal relationships by using the LINCON statement in the following COSAN model specification:

```
proc calis data=Kinzer nobs=326 nose;
  cosan
    var= var1-var6,
    D(6,DIA) * B(2,GEN) + D(6,DIA) * Psi(6,DIA);
  matrix B
    [ ,1]= b11 b21 b31 b41 b51 b61,
    [ ,2]= 0. b22 b32 b42 b52 b62;
  matrix Psi
    [1,1]= psi1-psi6;
  matrix D
    [1,1]= d1-d6 ;
  lincon
    b61 <= b51,
    b51 <= b41,
    b41 <= b31,
    b31 <= b21,
    b21 <= b11,
    0. <= b22,
    b22 <= b32,
    b32 <= b42,
    b42 <= b52,
    b52 <= b62;

  /* SAS Programming Statements */
  /* 6 Constraints on Correlation structures */
  psi1 = 1. - b11 * b11;
  psi2 = 1. - b21 * b21 - b22 * b22;
  psi3 = 1. - b31 * b31 - b32 * b32;
  psi4 = 1. - b41 * b41 - b42 * b42;
  psi5 = 1. - b51 * b51 - b52 * b52;
  psi6 = 1. - b61 * b61 - b62 * b62;
  vnames
    B = [factor1 factor2],
    Psi = [var1-var6],
    D = Psi;
run;
```

As in [Example 27.31](#), correlation structures are analyzed in the current example so that the unique variance parameters psi1–psi6 are defined as functions of the loadings in the SAS programming statements. However,

the loading parameters are no longer not constrained in the current model. Instead, you impose ordinal constraints on the loading parameters. First, b21 is fixed at 0 for identification purposes. Then, you use the LINCON statement to specify the ordinal relations of the factor loadings.

As shown in [Output 27.32.1](#), the solution converges in 12 iterations. In the fit summary table, the chi-square test statistic is 8.48 ($df = 6$, $p = 0.20$). This indicates a good fit. However, in the model there are 11 loading parameters (the b's) and 6 population standard deviation parameters (the d's). The degrees of freedom should have been $4 = 21 - 11 - 6$, but why is this number 6 in the fit summary table?

Output 27.32.1 Final Iteration Status and Fit

Optimization Results			
Iterations	12	Function Calls	29
Jacobian Calls	14	Active Constraints	2
Objective Function	0.0260990149	Max Abs Gradient Element	2.7626747E-6
Lambda	0	Actual Over Pred Change	1.1572072766
Radius	0.0000851592		
Convergence criterion (ABSGCONV=0.00001) satisfied.			
Fit Summary			
Chi-Square	8.4822		
Chi-Square DF	6		
Pr > Chi-Square	0.2049		

The reason is that there are two active constraints in the solution, resulting in two free parameters fewer in the final solution than originally specified. Active constraints are those inequality constraints that are fulfilled on the boundary equalities. As shown in the “Optimization Results” table, the number of active constraints for the current fitting is two. The default treatment in PROC CALIS is to treat these active constraints as if they were going to happen for all possible repeated sampling. This might as well be seen as fitting the active equality constraints on every possible repeated sample. This results in an increase of the degrees of freedom for model fit, as adjusted in the current fit summary table in [Output 27.32.1](#). To warn you about the degrees-of-freedom adjustment, the following messages are also printed with the output:

WARNING: There are 2 active boundary or linear inequality constraints at the solution. The standard errors and chi-square test statistic assume that the solution is located in the interior of the parameter space; hence, they do not apply if it is likely that some different set of inequality a constraints could be active.

NOTE: The degrees of freedom are increased by the number of active constraints. The number of parameters in calculating fit indices is decreased by the number of active constraints. To turn off the adjustment, use the NOADJDF option.

When active constraints are encountered, you need to be cautious about two implications. First, the estimates fall on the boundary of the parameter space originally specified. As shown in [Output 27.32.2](#), estimates for b_{11} and b_{21} are the same, and so are the pair of estimates for b_{52} and b_{62} . These pairs of parameters were originally constrained by inequalities in the model. For example, b_{62} was constrained to be at least as large as b_{52} . The fact that this constraint is honored only on the bound means that a better model fit might exist with b_{62} being smaller than b_{52} . Similarly, a better model fit might result without requiring b_{11} to be at least as large as b_{21} . Therefore, solutions with active boundary constraints might imply that the original strict inequality constraints are not appropriate for the data.

Output 27.32.2 Estimation of the Factor Loading Matrix B

Model Matrix B (6 x 2 General Rectangular Matrix)		
	factor1	factor2
var1	0.7100 [b11]	0
var2	0.7100 [b21]	0.0393 [b22]
var3	0.6799 [b31]	0.2463 [b32]
var4	0.6561 [b41]	0.3295 [b42]
var5	0.5541 [b51]	0.5432 [b52]
var6	0.4733 [b61]	0.5432 [b62]

Output 27.32.3 Estimation of the Scaling Matrix D and Unique Covariance Matrix Psi

Model Matrix D (6 x 6 Diagonal Matrix)						
	var1	var2	var3	var4	var5	var6
var1	1.0022 [d1]	0	0	0	0	0
var2	0	0.9985 [d2]	0	0	0	0
var3	0	0	1.0004 [d3]	0	0	0
var4	0	0	0	1.0004 [d4]	0	0
var5	0	0	0	0	0.9990 [d5]	0
var6	0	0	0	0	0	1.0021 [d6]
Model Matrix Psi (6 x 6 Diagonal Matrix)						
	var1	var2	var3	var4	var5	var6
var1	0.4959 [psi1]	0	0	0	0	0
var2	0	0.4944 [psi2]	0	0	0	0
var3	0	0	0.4771 [psi3]	0	0	0
var4	0	0	0	0.4610 [psi4]	0	0
var5	0	0	0	0	0.3979 [psi5]	0
var6	0	0	0	0	0	0.4809 [psi6]

The second implication for the presence of active constraints is that the chi-square test statistic and the standard error estimates are computed as if repeated samples were fitted by the model with the presence of the active equality constraints. The degrees-of-freedom adjustment by PROC CALIS is based on this assumption. However, if the particular active constraints reflect only a rare sampling event, the degrees-of-freedom adjustment (or even the computation of the chi-square statistic and standard error estimates) might not be justified. Unfortunately, whether the active constraints are reflecting the truth of the model or pure sampling fluctuation is usually difficult to determine.

Example 27.33: Longitudinal Factor Analysis

The following example (McDonald 1980) illustrates both the ability of PROC CALIS to formulate complex covariance structure analysis problems by the generalized COSAN matrix model and the use of programming statements to impose nonlinear constraints on the parameters. The example is a longitudinal factor analysis that uses the Swaminathan (1974) model. For $m = 3$ tests, $k = 3$ occasions, and $r = 2$ factors, the covariance structure model is formulated as follows:

$$\Sigma = \mathbf{F}_1 \mathbf{F}_2 \mathbf{F}_3 \mathbf{L} \mathbf{F}_3^{-1} \mathbf{F}_2^{-1} \mathbf{P} (\mathbf{F}_2^{-1})' (\mathbf{F}_3^{-1})' \mathbf{L}' \mathbf{F}_3' \mathbf{F}_2' \mathbf{F}_1' + \mathbf{U}^2$$

$$\mathbf{F}_1 = \begin{pmatrix} \mathbf{B}_1 & & \\ & \mathbf{B}_2 & \\ & & \mathbf{B}_3 \end{pmatrix}, \quad \mathbf{F}_2 = \begin{pmatrix} \mathbf{I}_2 & & \\ & \mathbf{D}_2 & \\ & & \mathbf{D}_2 \end{pmatrix}, \quad \mathbf{F}_3 = \begin{pmatrix} \mathbf{I}_2 & & \\ & \mathbf{I}_2 & \\ & & \mathbf{D}_3 \end{pmatrix}$$

$$\mathbf{L} = \begin{pmatrix} \mathbf{I}_2 & 0 & 0 \\ \mathbf{I}_2 & \mathbf{I}_2 & 0 \\ \mathbf{I}_2 & \mathbf{I}_2 & \mathbf{I}_2 \end{pmatrix}, \quad \mathbf{P} = \begin{pmatrix} \mathbf{I}_2 & & \\ & \mathbf{S}_2 & \\ & & \mathbf{S}_3 \end{pmatrix}, \quad \mathbf{U} = \begin{pmatrix} \mathbf{U}_{11} & \mathbf{U}_{12} & \mathbf{U}_{13} \\ \mathbf{U}_{21} & \mathbf{U}_{22} & \mathbf{U}_{23} \\ \mathbf{U}_{31} & \mathbf{U}_{32} & \mathbf{U}_{33} \end{pmatrix}$$

$$\mathbf{S}_2 = \mathbf{I}_2 - \mathbf{D}_2^2, \quad \mathbf{S}_3 = \mathbf{I}_2 - \mathbf{D}_3^2$$

The Swaminathan longitudinal factor model assumes that the factor scores for each (m) common factor change from occasion to occasion (k) according to a first-order autoregressive scheme. The matrix \mathbf{F}_1 contains the k factor loading matrices \mathbf{B}_1 , \mathbf{B}_2 , and \mathbf{B}_3 (each is $n \times m$). The matrices \mathbf{D}_2 , \mathbf{D}_3 , \mathbf{S}_2 , \mathbf{S}_3 and \mathbf{U}_{ij} , $i, j = 1, \dots, k$, are diagonal, and the matrices \mathbf{D}_i and \mathbf{S}_i , $i = 2, \dots, k$, are subjected to the constraint

$$\mathbf{S}_i + \mathbf{D}_i^2 = \mathbf{I}$$

Although the covariance structure model looks pretty complicated, it poses no problem for the COSAN model specifications. Since the constructed correlation matrix given by McDonald (1980) is singular, only unweighted least squares (METHOD=LS) estimates can be computed. The following statements specify the COSAN model for the correlation structures.

```

In the PROC CALIS statement, you use the NOBS= option to specify the number of observations. The CORR option requests the analysis of the correlation matrix.

In the COSAN statement, you list the observed variables for the analysis in the VAR= option. Then you specify the formula for the covariance structures. Notice that in the covariance structure formula, some matrices are specified twice. That is, matrix **F2** and **F3** appear in two different places. Matrices with the same name means that they are identical—which certainly makes sense. In addition, you can apply different transformations to the same matrix in different locations of the matrix formula. For example, you do not transform matrix **F2** in the first location, but the same matrix is inverted (INV) later in the expression. Similarly for matrix **F3**.

Next, you define the parameters in the six distinct model matrices by six **MATRIX** statements. Each matrix has some specific patterns under the covariance structure model. For the **F1** matrix, it has the following pattern for the free parameters in the model:

	col1	col2	col3	col4	col5	col6
row1	x					
row2	x	x				
row3	x	x				
row4			x			
row5			x	x		
row6			x	x		
row7					x	
row8					x	x
row9					x	x

To specify these parameters, you can use some shorthand notation in the **MATRIX** statement. For example, in the first entry of the **MATRIX** statement for matrix **F1**, you use the notation **[1,@1]**. This means that the parameter specification starts with the **[1,1]** element and proceeds to the next element while fixing the column number at 1. Hence, parameters **x1–x3** are specified for the **F1[1,1]**, **F1[2,1]**, and **F1[3,1]** elements, respectively. Similarly, you specify other parameters in the **F1** matrix in a column by column fashion.

If you do not use the **@** sign in the specification, the parameters are assigned differently. For example, in the specification of the **L** matrix, the first entry in the corresponding **MATRIX** statement also starts with the **[1,1]** element. But it proceeds down to **[2,2]**, **[3,3]**, and so on because the **@** sign is not used to fix any column or row number. As a result, the **MATRIX** statement for **L** specifies the following pattern:

	col1	col2	col3	col4	col5	col6
row1	1					
row2		1				
row3	1		1			
row4		1		1		
row5	1		1		1	
row6		1		1		1

The unspecified elements are fixed zeros in the model.

Similarly, you specify the diagonal matrices **F2**, **F3**, and **P**, and the symmetric matrix **U**.

You also set bounds for some parameters in the **BOUNDS** statement and some dependent parameters in the SAS programming statements.

[Output 27.33.1](#) shows the correlation structures and the model matrices in the analysis. All appear to be intended.

Output 27.33.1 The Correlation Structures and Model Matrices of the Longitudinal Factor Model

COSAN Model Structures	
Sigma =	F1*F2*F3*L*inv(F3)*inv(F2)*P*(inv(F2))`*(inv(F3))`*L`*F3`*F2`*F1` + U

Output 27.33.1 *continued*

Row6	0	0	0	0	0	0 [x23]

In fact, PROC CALIS routinely checks for zero values for the estimates on the diagonal of the central symmetric matrices. In this case, you get the following messages regarding the estimation of matrix **P**:

WARNING: Although all predicted variances for the observed variables are positive, the corresponding predicted covariance matrix is not positive definite. It has one negative eigenvalue.

WARNING: The estimated variance of variable 6 is essentially zero in the central matrix P of term 1 of the COSAN model.

WARNING: The central matrix P of term 1 of the COSAN model is not positive definite. It has one zero eigenvalue.

Output 27.33.7 shows the estimation results of the U matrix. Parameter estimates x28 and x32 fall on the lower boundary at zero. PROC CALIS issues the following messages regarding the estimation of matrix U:

WARNING: The estimated variance of obs5 is essentially zero in the central matrix U of term 2 of the COSAN model.

WARNING: The estimated variance of obs9 is essentially zero in the central matrix U of term 2 of the COSAN model.

WARNING: The central matrix U of term 2 of the COSAN model is not positive definite. It has 3 negative eigenvalues.

Output 27.33.7 Estimation of the U Matrix of the Longitudinal Factor Model

Because this formulation of Swaminathan's model in general leads to an unidentified problem, the results given here are different from those reported by McDonald (1980). The displayed output of PROC CALIS also indicates that the fitted central model matrices **P** and **U** are not positive-definite. The BOUNDS statement constrains the diagonals of the matrices **P** and **U** to be nonnegative, but this cannot prevent **U** from having three negative eigenvalues. The fact that many of the published results for more complex models in covariance structure analysis are connected to unidentified problems implies that more theoretical work should be done to study the general features of such models.

Overview: CANCORR Procedure

The CANCORR procedure performs canonical correlation, partial canonical correlation, and canonical redundancy analysis.

Canonical correlation is a generalization of multiple correlation for analyzing the relationship between two sets of variables. In multiple correlation, you examine the relationship between a linear combination of a set of explanatory variables, **X**, and a *single* response variable, **Y**. In canonical correlation, you examine the relationship between linear combinations of the set of **X** variables and linear combinations of a *set* of **Y** variables. These linear combinations are called *canonical variables* or *canonical variates*. Either set of variables can be considered explanatory or response variables, since the statistical model is symmetric in the two sets of variables. Simple and multiple correlation are special cases of canonical correlation in which one or both sets contain a single variable.

The CANCELL procedure tests a series of hypotheses that each canonical correlation and all smaller canonical correlations are zero in the population. PROC CANCELL uses an F approximation (Rao 1973; Kshirsagar 1972) that gives better small sample results than the usual χ^2 approximation. At least one of the two sets of variables should have an approximate multivariate normal distribution in order for the probability levels to be valid.

Both standardized and unstandardized canonical coefficients are computed, as well as the four *canonical structure* matrices showing correlations between the two sets of canonical variables and the two sets of original variables. A canonical redundancy analysis (Stewart and Love 1968; Cooley and Lohnes 1971) can also be done. PROC CANCELL provides multiple regression analysis options to aid in interpreting the canonical correlation analysis. You can examine the linear regression of each variable on the opposite set of variables.

PROC CANCELL can produce a data set containing the scores of each observation on each canonical variable, and you can use the PRINT procedure to list these values. A plot of each canonical variable against its counterpart in the other group is often useful, and you can use PROC SGLOT with the output data set to produce these plots. A second output data set contains the canonical correlations, coefficients, and most other statistics computed by the procedure.

Background

Canonical correlation was developed by Hotelling (1935, 1936).

The application of canonical correlation is discussed by Cooley and Lohnes (1971); Tatsuoka (1971); Mar-dia, Kent, and Bibby (1979). One of the best theoretical treatments is given by Kshirsagar (1972).

Given a set of p X variables and q Y variables, the CANCELL procedure finds the linear combinations

$$\begin{aligned}w_1 &= a_{11}x_1 + a_{21}x_2 + \cdots + a_{p1}x_p \\v_1 &= b_{11}y_1 + b_{21}y_2 + \cdots + b_{q1}y_q\end{aligned}$$

such that the two canonical variables, w_1 and v_1 , have the largest possible correlation. This maximized correlation between the two canonical variables is the first canonical correlation. The coefficients of the linear combinations are canonical coefficients or canonical weights. It is customary to normalize the canonical coefficients so that each canonical variable has a variance of 1.

PROC CANCELL continues by finding a second set of canonical variables, uncorrelated with the first pair, that produces the second-highest correlation coefficient. That is, the second pair of canonical variables is

$$\begin{aligned}w_2 &= a_{12}x_1 + a_{22}x_2 + \cdots + a_{p2}x_p \\v_2 &= b_{12}y_1 + b_{22}y_2 + \cdots + b_{q2}y_q\end{aligned}$$

such that w_2 is uncorrelated with w_1 and v_1 , v_2 is uncorrelated with w_1 and v_1 , and w_2 and v_2 have the largest possible correlation subject to these constraints. The process of constructing canonical variables continues until the number of pairs of canonical variables is $\min(p, q)$, the number of variables in the smaller group.

Each canonical variable is uncorrelated with all the other canonical variables of either set except for the one corresponding canonical variable in the opposite set. The canonical coefficients are not generally orthogonal, however, so the canonical variables do not represent jointly perpendicular directions through the space of the original variables.

The first canonical correlation is at least as large as the multiple correlation between any variable and the opposite set of variables. It is possible for the first canonical correlation to be very large while all the multiple correlations for predicting one of the original variables from the opposite set of canonical variables are small. Canonical redundancy analysis (Stewart and Love 1968; Cooley and Lohnes 1971; van den Wollenberg 1977) examines how well the original variables can be predicted from the canonical variables.

PROC CANCERR can also perform partial canonical correlation, which is a multivariate generalization of ordinary partial correlation (Cooley and Lohnes 1971; Timm 1975). Most commonly used parametric statistical methods, ranging from t tests to multivariate analysis of covariance, are special cases of partial canonical correlation.

Getting Started: CANCERR Procedure

The following example demonstrates how you can use the CANCERR procedure to calculate and test canonical correlations between two sets of variables.

Suppose you want to determine the degree of correspondence between a set of job characteristics and measures of employee satisfaction. Using a survey instrument for employees, you calculate three measures of job satisfaction. With another instrument designed for supervisors, you calculate the corresponding job characteristics profile.

Your three variables associated with job satisfaction are as follows:

- career track satisfaction: employee satisfaction with career direction and the possibility of future advancement, expressed as a percent
- management and supervisor satisfaction: employee satisfaction with supervisor's communication and management style, expressed as a percent
- financial satisfaction: employee satisfaction with salary and other benefits, using a scale measurement from 1 to 10 (1=unsatisfied, 10=satisfied)

The three variables associated with job characteristics are as follows:

- task variety: degree of variety involved in tasks, expressed as a percent
- feedback: degree of feedback required in job tasks, expressed as a percent
- autonomy: degree of autonomy required in job tasks, expressed as a percent

The following statements create the SAS data set Jobs and request a canonical correlation analysis:

```
data Jobs;
  input Career Supervisor Finance Variety Feedback Autonomy;
  label Career      ='Career Satisfaction' Variety ='Task Variety'
        Supervisor='Supervisor Satisfaction' Feedback='Amount of Feedback'
        Finance     ='Financial Satisfaction' Autonomy='Degree of Autonomy';
  datalines;
72 26 9          10 11 70
63 76 7          85 22 93
96 31 7          83 63 73
96 98 6          82 75 97
84 94 6          36 77 97
66 10 5          28 24 75
31 40 9          64 23 75
45 14 2          19 15 50
42 18 6          33 13 70
79 74 4          23 14 90
39 12 2          37 13 70
54 35 3          23 74 53
60 75 5          45 58 83
63 45 5          22 67 53
;

proc cancorr data=Jobs
  vprefix=Satisfaction wprefix=Characteristics
  vname='Satisfaction Areas' wname='Job Characteristics';
  var Career Supervisor Finance;
  with Variety Feedback Autonomy;
run;
```

The DATA= option in the PROC CANCELL statement specifies Jobs as the SAS data set to be analyzed. The VPREFIX and WPREFIX options specify the prefixes for naming the canonical variables from the VAR statement and the WITH statement, respectively. The VNAME option specifies 'Satisfaction Areas' to refer to the set of variables from the VAR statement. Similarly, the WNAME option specifies 'Job Characteristics' to refer to the set of variables from the WITH statement.

The VAR statement defines the first of the two sets of variables to be analyzed as Career, Supervisor, and Finance. The WITH statement defines the second set of variables to be Variety, Feedback, and Autonomy. The results of this analysis are displayed in Figure 28.1 to Figure 28.4.

Figure 28.1 displays the canonical correlation, adjusted canonical correlation, approximate standard error, and squared canonical correlation for each pair of canonical variables. The first canonical correlation (the correlation between the first pair of canonical variables) is 0.9194. This value represents the highest possible correlation between any linear combination of the job satisfaction variables and any linear combination of the job characteristics variables.

Figure 28.1 also lists the likelihood ratio and associated statistics for testing the hypothesis that the canonical correlations in the current row and all that follow are zero.

Figure 28.1 Canonical Correlations, Eigenvalues, and Likelihood Tests

The CANCORR Procedure					
Canonical Correlation Analysis					
	Canonical Correlation	Adjusted Canonical Correlation	Approximate Standard Error	Squared Canonical Correlation	
1	0.919412	0.898444	0.042901	0.845318	
2	0.418649	0.276633	0.228740	0.175267	
3	0.113366	.	0.273786	0.012852	
Eigenvalues of Inv(E)*H = CanRsqr/(1-CanRsqr)					
	Eigenvalue	Difference	Proportion	Cumulative	
1	5.4649	5.2524	0.9604	0.9604	
2	0.2125	0.1995	0.0373	0.9977	
3	0.0130		0.0023	1.0000	
Test of H0: The canonical correlations in the current row and all that follow are zero					
	Likelihood Ratio	Approximate F Value	Num DF	Den DF	Pr > F
1	0.12593148	2.93	9	19.621	0.0223
2	0.81413359	0.49	4	18	0.7450
3	0.98714819	0.13	1	10	0.7257

The first approximate F value of 2.93 corresponds to the test that all three canonical correlations are zero. Since the p -value is small (0.0223), you would reject the null hypothesis at the 0.05 level. The second approximate F value of 0.49 corresponds to the test that both the second and the third canonical correlations are zero. Since the p -value is large (0.7450), you would fail to reject the hypothesis and conclude that only the first canonical correlation is significant.

Figure 28.2 lists several multivariate statistics and tests that use approximations based on the F distribution for the null hypothesis that all canonical correlations are zero. Alternatively, you can specify `MSTAT=EXACT` to compute exact p -values for three of the four tests (Wilks' Lambda, the Hotelling-Lawley Trace, and Roy's greatest root) and an improved F approximation for the fourth (Pillai's Trace). These statistics are described in the section “[Multivariate Tests](#)” on page 92 in Chapter 4, “[Introduction to Regression Procedures](#).”

Figure 28.2 Multivariate Statistics and *F* Approximations

Multivariate Statistics and F Approximations					
	S=3	M=-0.5	N=3		
Statistic	Value	F Value	Num DF	Den DF	Pr > F
Wilks' Lambda	0.12593148	2.93	9	19.621	0.0223
Pillai's Trace	1.03343732	1.75	9	30	0.1204
Hotelling-Lawley Trace	5.69042615	4.76	9	9.8113	0.0119
Roy's Greatest Root	5.46489324	18.22	3	10	0.0002
NOTE: F Statistic for Roy's Greatest Root is an upper bound.					

The small *p*-values for these tests (< 0.05), except for Pillai's trace, suggest rejecting the null hypothesis that all canonical correlations are zero in the population, confirming the results of the preceding likelihood ratio test (Figure 28.1). With only one of the tests resulting in a *p*-value larger than 0.05, you can assume that the first canonical correlation is significant. The next step is to interpret or identify the two canonical variables corresponding to this significant correlation.

Even though canonical variables are artificial, they can often be "identified" in terms of the original variables. This is done primarily by inspecting the standardized coefficients of the canonical variables and the correlations between the canonical variables and their original variables. Since only the first canonical correlation is significant, only the first pair of canonical variables (Satisfaction1 and Characteristics1) need to be identified.

PROC CANCORR calculates and displays the raw canonical coefficients for the job satisfaction variables and the job characteristic variables. However, since the original variables do not necessarily have equal variance and are not measured in the same units, the raw coefficients must be standardized to allow interpretation. The coefficients are standardized by multiplying the raw coefficients with the standard deviation of the associated variable.

The standardized canonical coefficients in Figure 28.3 show that the first canonical variable for the Satisfaction group is a weighted sum of the variables Supervisor (0.7854) and Career (0.3028), with the emphasis on Supervisor. The coefficient for the variable Finance is near 0. Thus, a person satisfied with his or her supervisor and with a large degree of career satisfaction would score high on the canonical variable Satisfaction1.

Figure 28.3 Standardized Canonical Coefficients from the CANCORR Procedure

Standardized Canonical Coefficients for the Satisfaction Areas				
		Satisfaction1	Satisfaction2	Satisfaction3
Career	Career Satisfaction	0.3028	-0.5416	1.0408
Supervisor	Supervisor Satisfaction	0.7854	0.1305	-0.9085
Finance	Financial Satisfaction	0.0538	0.9754	0.3329

Figure 28.3 continued

Standardized Canonical Coefficients for the Job Characteristics				
		Characteristics1	Characteristics2	
Variety	Task Variety	-0.1108	0.8095	
Feedback	Amount of Feedback	0.5520	-0.7722	
Autonomy	Degree of Autonomy	0.8403	0.1020	
Standardized Canonical Coefficients for the Job Characteristics				
		Characteristics3		
Variety	Task Variety	0.9071		
Feedback	Amount of Feedback	0.4194		
Autonomy	Degree of Autonomy	-0.8297		

The coefficients for the job characteristics variables show that degree of autonomy (Autonomy) and amount of feedback (Feedback) contribute heavily to the Characteristics1 canonical variable (0.8403 and 0.5520, respectively).

Figure 28.4 shows the table of correlations between the canonical variables and the original variables.

Figure 28.4 Canonical Structure Correlations from the CANCERR Procedure

The CANCORR Procedure				
Canonical Structure				
Correlations Between the Satisfaction Areas and Their Canonical Variables				
		Satisfaction1	Satisfaction2	Satisfaction3
Career	Career Satisfaction	0.7499	-0.2503	0.6123
Supervisor	Supervisor Satisfaction	0.9644	0.0362	-0.2618
Finance	Financial Satisfaction	0.2873	0.8814	0.3750
Correlations Between the Job Characteristics and Their Canonical Variables				
		Characteristics1	Characteristics2	
Variety	Task Variety	0.4863		0.6592
Feedback	Amount of Feedback	0.6216		-0.5452
Autonomy	Degree of Autonomy	0.8459		0.4451
Correlations Between the Job Characteristics and Their Canonical Variables				
		Characteristics3		
Variety	Task Variety		0.5736	
Feedback	Amount of Feedback		0.5625	
Autonomy	Degree of Autonomy		-0.2938	

Figure 28.4 *continued*

Correlations Between the Satisfaction Areas and the Canonical Variables of the Job Characteristics				
		Characteristics1	Characteristics2	
Career	Career Satisfaction	0.6895	-0.1048	
Supervisor	Supervisor Satisfaction	0.8867	0.0152	
Finance	Financial Satisfaction	0.2642	0.3690	
Correlations Between the Satisfaction Areas and the Canonical Variables of the Job Characteristics				
		Characteristics3		
Career	Career Satisfaction	0.0694		
Supervisor	Supervisor Satisfaction	-0.0297		
Finance	Financial Satisfaction	0.0425		
Correlations Between the Job Characteristics and the Canonical Variables of the Satisfaction Areas				
		Satisfaction1	Satisfaction2	Satisfaction3
Variety	Task Variety	0.4471	0.2760	0.0650
Feedback	Amount of Feedback	0.5715	-0.2283	0.0638
Autonomy	Degree of Autonomy	0.7777	0.1863	-0.0333

Although these univariate correlations must be interpreted with caution since they do not indicate how the original variables contribute *jointly* to the canonical analysis, they are often useful in the identification of the canonical variables.

Figure 28.4 shows that the supervisor satisfaction variable Supervisor is strongly associated with the Satisfaction1 canonical variable, with a correlation of 0.9644. Slightly less influential is the variable Career, which has a correlation with the canonical variable of 0.7499. Thus, the canonical variable Satisfaction1 seems to represent satisfaction with supervisor and career track.

The correlations for the job characteristics variables show that the canonical variable Characteristics1 seems to represent all three measured variables, with degree of autonomy variable (Autonomy) being the most influential (0.8459).

Hence, you can interpret these results to mean that job characteristics and job satisfaction are related—jobs that possess a high degree of autonomy and level of feedback are associated with workers who are more satisfied with their supervisor and their career. While financial satisfaction is a factor in job satisfaction, it is not as important as the other measured satisfaction-related variables.

Syntax: CANCERR Procedure

The following statements are available in the CANCERR procedure:

```
PROC CANCERR < options > ;
    WITH variables ;
    BY variables ;
    FREQ variable ;
    PARTIAL variables ;
    VAR variables ;
    WEIGHT variable ;
```

The PROC CANCERR statement and the WITH statement are required. The rest of this section provides detailed syntax information for each of the preceding statements, beginning with the PROC CANCERR statement. The remaining statements are covered in alphabetical order.

PROC CANCERR Statement

```
PROC CANCERR < options > ;
```

The PROC CANCERR statement invokes the CANCERR procedure. Optionally, it also identifies input and output data sets, specifies the analyses performed, and controls displayed output. [Table 28.1](#) summarizes the options available in the PROC CANCERR statement.

Table 28.1 Summary of PROC CANCERR Statement Options

Option	Description
Specify computational details	
EDF=	Specifies error degrees of freedom if input observations are regression residuals
MSTAT=	Specifies the method of evaluating the multivariate test statistics
NOINT	Omits intercept from canonical correlation and regression models
RDF=	Specifies regression degrees of freedom if input observations are regression residuals
SINGULAR=	Specifies the singularity criterion
Specify input and output data sets	
DATA=	Specifies input data set name
OUT=	Specifies output data set name
OUTSTAT=	Specifies output data set name containing various statistics
Specify labeling options	
PARPREFIX=	Specifies a prefix for naming residual variables
VNAME=	Specifies a name to refer to VAR statement variables
VPREFIX=	Specifies a prefix for naming VAR statement canonical variables
WNAME=	Specifies a name to refer to WITH statement variables
WPREFIX=	Specifies a prefix for naming WITH statement canonical variables

Table 28.1 *continued*

Option	Description
Control amount of output	
ALL	Produces simple statistics, input variable correlations, and canonical redundancy analysis
CORR	Produces input variable correlations
NCAN=	Specifies number of canonical variables for which full output is desired
NOPRINT	Suppresses all displayed output
REDUNDANCY	Produces canonical redundancy analysis
SHORT	Suppresses default output from canonical analysis
SIMPLE	Produces means and standard deviations
Request regression analyses	
VDEP	Requests multiple regression analyses with the VAR variables as dependents and the WITH variables as regressors
VREG	Requests multiple regression analyses with the VAR variables as regressors and the WITH variables as dependents
WDEP	Same as VREG
WREG	Same as VDEP
Specify regression statistics	
ALL	Produces all regression statistics and includes these statistics in the OUTSTAT= data set
B	Produces raw regression coefficients
CLB	Produces 95% confidence interval limits for the regression coefficients
CORRB	Produces correlations among regression coefficients
INT	Requests statistics for the intercept when you specify the B, CLB, SEB, T, or PROBT option
PCORR	Displays partial correlations between regressors and dependents
PROBT	Displays probability levels for <i>t</i> statistics
SEB	Displays standard errors of regression coefficients
SMC	Displays squared multiple correlations and <i>F</i> tests
SPCORR	Displays semipartial correlations between regressors and dependents
SQPCORR	Displays squared partial correlations between regressors and dependents
SQSPCORR	Displays squared semipartial correlations between regressors and dependents
STB	Displays standardized regression coefficients
T	Displays <i>t</i> statistics for regression coefficients

Following are explanations of the options that can be used in the PROC CANCELL statement (in alphabetic order).

ALL

displays simple statistics, correlations among the input variables, the confidence limits for the regression coefficients, and the canonical redundancy analysis. If you specify the VDEP or WDEP option, the ALL option displays all related regression statistics (unless the NOPRINT option is specified) and includes these statistics in the OUTSTAT= data set.

B

produces raw regression coefficients from the regression analyses.

CLB

produces the 95% confidence limits for the regression coefficients from the regression analyses.

CORR**C**

produces correlations among the original variables. If you include a PARTIAL statement, the CORR option produces a correlation matrix for all variables in the analysis, the regression statistics (R square, RMSE), the standardized regression coefficients for both the VAR and WITH variables as predicted from the PARTIAL statement variables, and partial correlation matrices.

CORRB

produces correlations among the regression coefficient estimates.

DATA=SAS-data-set

names the SAS data set to be analyzed by PROC CANCORR. It can be an ordinary SAS data set or a TYPE=CORR, COV, FACTOR, SSCP, UCORR, or UCOV data set. By default, the procedure uses the most recently created SAS data set.

EDF=error-df

specifies the error degrees of freedom if the input observations are residuals from a regression analysis. The effective number of observations is the EDF= value plus one. If you have 100 observations, then specifying EDF=99 has the same effect as omitting the EDF= option.

INT

requests that statistics for the intercept be included when B, CLB, SEB, T, or PROBT is specified for the regression analyses.

MSTAT=FAPPROX | EXACT

specifies the method of evaluating the multivariate test statistics. The default is MSTAT=FAPPROX, which specifies that the multivariate tests are evaluated using the usual approximations based on the F distribution, as discussed in the section “[Multivariate Tests](#)” on page 92 in Chapter 4, “[Introduction to Regression Procedures](#).” Alternatively, you can specify MSTAT=EXACT to compute exact p -values for three of the four tests (Wilks’ lambda, the Hotelling-Lawley trace, and Roy’s greatest root) and an improved F approximation for the fourth (Pillai’s trace). While MSTAT=EXACT provides better control of the significance probability for the tests, especially for Roy’s greatest root, computations for the exact p -values can be appreciably more demanding, and are in fact infeasible for large problems (many dependent variables). Thus, although MSTAT=EXACT is more accurate for most data, it is not the default method.

NCAN=number

specifies the number of canonical variables for which full output is desired. The *number* must be less than or equal to the number of canonical variables in the analysis.

The value of the NCAN= option specifies the number of canonical variables for which canonical coefficients and canonical redundancy statistics are displayed, and the number of variables shown in the canonical structure matrices. The NCAN= option does not affect the number of displayed canonical correlations.

If an OUTSTAT= data set is requested, the NCAN= option controls the number of canonical variables for which statistics are output. If an OUT= data set is requested, the NCAN= option controls the number of canonical variables for which scores are output.

NOINT

omits the intercept from the canonical correlation and regression models. Standard deviations, variances, covariances, and correlations are not corrected for the mean. If you use a TYPE=SSCP data set as input to the CANCELL procedure and list the variable Intercept in the VAR or WITH statement, the procedure runs as if you also specified the NOINT option. If you use NOINT and also create an OUTSTAT= data set, the data set is TYPE=UCORR.

NOPRINT

suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, “Using the Output Delivery System.”

OUT=SAS-data-set

creates an output SAS data set to contain all the original data plus scores on the canonical variables. The OUT= option cannot be used when the DATA= data set is TYPE=CORR, COV, FACTOR, SSCP, UCORR, or UCOV. For details about OUT= data sets, see the section “Output Data Sets” on page 1729. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

OUTSTAT=SAS-data-set

creates an output SAS data set containing various statistics, including the canonical correlations and coefficients and the multiple regression statistics you request. For details about OUTSTAT= data sets, see the section “Output Data Sets” on page 1729. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

PCORR

produces partial correlations between regressors and dependent variables, removing from each dependent variable and regressor the effects of all other regressors.

PROBT

produces probability levels for the t statistics in the regression analyses.

RDF=regression-df

specifies the regression degrees of freedom if the input observations are residuals from a regression analysis. The effective number of observations is the actual number minus the RDF= value. The degrees of freedom for the intercept should not be included in the RDF= option.

REDUNDANCY

RED

produces canonical redundancy statistics.

PARPREFIX=*name*

PPREFIX=*name*

specifies a prefix for naming the residual variables in the OUT= data set and the OUTSTAT= data set. By default, the prefix is R_. The number of characters in the prefix plus the maximum length of the variable names should not exceed the current name length defined by the VALIDVARNAME= system option.

SEB

produces standard errors of the regression coefficients.

SHORT

suppresses all default output from the canonical analysis except the tables of canonical correlations and multivariate statistics.

SIMPLE

S

produces means and standard deviations.

SINGULAR=*p*

SING=*p*

specifies the singularity criterion, where $0 < p < 1$. If a variable in the PARTIAL statement has an R square as large as $1 - p$ (where p is the value of the SINGULAR= option) when predicted from the variables listed before it in the statement, the variable is assigned a standardized regression coefficient of 0, and the SAS log generates a linear dependency warning message. By default, SINGULAR=1E-8.

SMC

produces squared multiple correlations and F tests for the regression analyses.

SPCORR

produces semipartial correlations between regressors and dependent variables, removing from each regressor the effects of all other regressors.

SQPCORR

produces squared partial correlations between regressors and dependent variables, removing from each dependent variable and regressor the effects of all other regressors.

SQSPCORR

produces squared semipartial correlations between regressors and dependent variables, removing from each regressor the effects of all other regressors.

STB

produces standardized regression coefficients.

T

produces t statistics for the regression coefficients.

VDEP**WREG**

requests multiple regression analyses with the VAR variables as dependent variables and the WITH Variables as regressors.

VNAME=*label*

VN=*label*

specifies a character constant to refer to variables from the VAR statement in the output. Enclose the constant in single or double quotes. If you omit the VNAME= option, these variables are referred to as the VAR variables. The number of characters in the label should not exceed the label length defined by the VALIDVARNAME= system option. For more information about the VALIDVARNAME= system option, see *SAS System Options: Reference*.

VPREFIX=*name*

VP=*name*

specifies a prefix for naming canonical variables from the VAR statement. By default, these canonical variables are given the names V1, V2, and so on. If you specify VPREFIX=ABC, the names are ABC1, ABC2, and so on. The number of characters in the prefix plus the number of digits required to designate the variables should not exceed the name length defined by the VALIDVARNAME= system option. For more information about the VALIDVARNAME= system option, see *SAS System Options: Reference*.

WDEP**VREG**

requests multiple regression analyses with the WITH variables as dependent variables and the VAR variables as regressors.

WNAME=*label*

WN=*label*

specifies a character constant to refer to variables in the WITH statement in the output. Enclose the constant in single or double quotes. If you omit the WNAME= option, these variables are referred to as the WITH variables. The number of characters in the label should not exceed the label length defined by the VALIDVARNAME= system option. For more information about the VALIDVARNAME= system option, see *SAS System Options: Reference*.

WPREFIX=*name*

WP=*name*

specifies a prefix for naming canonical variables from the WITH statement. By default, these canonical variables are given the names W1, W2, and so on. If you specify WPREFIX=XYZ, the names are XYZ1, XYZ2, and so on. The number of characters in the prefix plus the number of digits required to designate the variables should not exceed the label length defined by the VALIDVARNAME= system option. For more information about the VALIDVARNAME= system option, see *SAS System Options: Reference*.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC CANCORR to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the CANCORR procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FREQ Statement

FREQ *variable* ;

If one variable in your input data set represents the frequency of occurrence for other values in the observation, specify the variable's name in a FREQ statement. PROC CANCORR then treats the data set as if each observation appeared n times, where n is the value of the FREQ variable for the observation. If the value of the FREQ variable is less than one, the observation is not used in the analysis. Only the integer portion of the value is used. The total number of observations is considered to be equal to the sum of the FREQ variable when PROC CANCORR calculates significance probabilities.

PARTIAL Statement

PARTIAL *variables* ;

You can use the PARTIAL statement to base the canonical analysis on partial correlations. The variables in the PARTIAL statement are partialled out of the VAR and WITH variables. If you request an OUT= or OUTSTAT= data set, the residual variables are named by prefixing the characters R_ by default or the string specified in the RPREFIX= option to the VAR variables.

VAR Statement

VAR *variables* ;

The VAR statement lists the variables in the first of the two sets of variables to be analyzed. The variables must be numeric. If you omit the VAR statement, all numeric variables not mentioned in other statements make up the first set of variables. If, however, the DATA= data set is TYPE=SSCP, the default set of variables used as VAR variables does not include the variable Intercept.

WEIGHT Statement

WEIGHT *variable* ;

If you want to compute weighted product-moment correlation coefficients, specify the name of the weighting variable in a WEIGHT statement. The WEIGHT and FREQ statements have a similar effect, except the WEIGHT statement does not alter the degrees of freedom or number of observations. An observation is used in the analysis only if the WEIGHT variable is greater than zero.

WITH Statement

WITH *variables* ;

The WITH statement lists the variables in the second set of variables to be analyzed. The variables must be numeric. The WITH statement is required.

Details: CANCORR Procedure

Missing Values

If an observation has a missing value for any of the variables in the analysis, that observation is omitted from the analysis.

Formulas

Assume without loss of generality that the two sets of variables, \mathbf{X} with p variables and \mathbf{Y} with q variables, have means of zero. Let n be the number of observations, and let m be $n - 1$.

Note that the scales of eigenvectors and canonical coefficients are arbitrary. PROC CANCORR follows the usual procedure of rescaling the canonical coefficients so that each canonical variable has a variance of one.

There are several different sets of formulas that can be used to compute the canonical correlations, ρ_i , $i = 1, \dots, \min(p, q)$, and unscaled canonical coefficients:

1. Let $S_{XX} = X'X/m$ be the covariance matrix of X , $S_{YY} = Y'Y/m$ be the covariance matrix of Y , and $S_{XY} = X'Y/m$ be the covariance matrix between X and Y . Then the eigenvalues of $S_{YY}^{-1}S_{XY}'S_{XX}^{-1}S_{XY}$ are the squared canonical correlations, and the right eigenvectors are raw canonical coefficients for the Y variables. The eigenvalues of $S_{XX}^{-1}S_{XY}S_{YY}^{-1}S_{XY}'$ are the squared canonical correlations, and the right eigenvectors are raw canonical coefficients for the X variables.
2. Let $T = Y'Y$ and $H = Y'X(X'X)^{-1}X'Y$. The eigenvalues ξ_i of $T^{-1}H$ are the squared canonical correlations, ρ_i^2 , and the right eigenvectors are raw canonical coefficients for the Y variables. Interchange X and Y in the preceding formulas, and the eigenvalues remain the same, but the right eigenvectors are raw canonical coefficients for the X variables.
3. Let $E = T - H$. The eigenvalues of $E^{-1}H$ are $\lambda_i = \rho_i^2/(1 - \rho_i^2)$. The right eigenvectors of $E^{-1}H$ are the same as the right eigenvectors of $T^{-1}H$.
4. Canonical correlation can be viewed as a principal component analysis of the predicted values of one set of variables from a regression on the other set of variables, in the metric of the error covariance matrix. For example, regress the Y variables on the X variables. Call the predicted values $P = X(X'X)^{-1}X'Y$ and the residuals $R = Y - P = (I - X(X'X)^{-1}X')Y$. The error covariance matrix is $R'R/m$. Choose a transformation Q that converts the error covariance matrix to an identity—that is, $(RQ)'(RQ) = Q'R'RQ = mI$. Apply the same transformation to the predicted values to yield, say, $Z = PQ$. Now do a principal component analysis on the covariance matrix of Z , and you get the eigenvalues of $E^{-1}H$. Repeat with X and Y variables interchanged, and you get the same eigenvalues.

To show this relationship between canonical correlation and principal components, note that $P'P = H$, $R'R = E$, and $QQ' = mE^{-1}$. Let the covariance matrix of Z be G . Then $G = Z'Z/m = (PQ)'PQ/m = Q'P'PQ/m = Q'HQ/m$. Let u be an eigenvector of G and κ be the corresponding eigenvalue. Then by definition, $Gu = \kappa u$; hence $Q'HQu/m = \kappa u$. Premultiplying both sides by Q yields $QQ'HQu/m = \kappa Qu$ and thus $E^{-1}HQu = \kappa Qu$. Hence Qu is an eigenvector of $E^{-1}H$ and κ is also an eigenvalue of $E^{-1}H$.
5. If the covariance matrices are replaced by correlation matrices, the preceding formulas yield standardized canonical coefficients instead of raw canonical coefficients.

The formulas for multivariate test statistics are shown in the section “[Multivariate Tests](#)” on page 92 in Chapter 4, “[Introduction to Regression Procedures](#).” Formulas for linear regression are provided in other sections of that chapter.

Output Data Sets

OUT= Data Set

The OUT= data set contains all the variables in the original data set plus new variables containing the canonical variable scores. The number of new variables is twice that specified by the NCAN= option. The names of the new variables are formed by concatenating the values given by the VPREFIX= and WPREFIX= options (the defaults are V and W) with the numbers 1, 2, 3, and so on. The new variables have mean 0 and variance equal to 1. An OUT= data set cannot be created if the DATA= data set is TYPE=CORR, COV, FACTOR, SSCP, UCORR, or UCOV.

If you use a PARTIAL statement, the OUT= data set also contains the residuals from predicting the VAR variables from the PARTIAL variables. The names of the residual variables are formed by concatenating the values given by the PARPREFIX= option (the default is R_) with the numbers 1, 2, 3, and so on.

OUTSTAT= Data Set

The OUTSTAT= data set is similar to the TYPE=CORR or TYPE=UCORR data set produced by the CORR procedure, but it contains several results in addition to those produced by PROC CORR.

The new data set contains the following variables:

- the BY variables, if any
- two new character variables, _TYPE_ and _NAME_
- Intercept, if the INT option is used
- the variables analyzed (those in the VAR statement and the WITH statement)

Each observation in the new data set contains some type of statistic as indicated by the _TYPE_ variable. The values of the _TYPE_ variable are as follows.

TYPE	Contents
MEAN	means
STD	standard deviations
USTD	uncorrected standard deviations. When you specify the NOINT option in the PROC CANCELL statement, the OUTSTAT= data set contains standard deviations not corrected for the mean (_TYPE_='USTD').
N	number of observations on which the analysis is based. This value is the same for each variable.
SUMWGT	sum of the weights if a WEIGHT statement is used. This value is the same for each variable.
CORR	correlations. The _NAME_ variable contains the name of the variable corresponding to each row of the correlation matrix.
UCORR	uncorrected correlation matrix. When you specify the NOINT option in the PROC CANCELL statement, the OUTSTAT= data set contains a matrix of correlations not corrected for the means.
CORRB	correlations among the regression coefficient estimates
STB	standardized regression coefficients. The _NAME_ variable contains the name of the dependent variable.

B	raw regression coefficients
SEB	standard errors of the regression coefficients
LCLB	95% lower confidence limits for the regression coefficients
UCLB	95% upper confidence limits for the regression coefficients
T	<i>t</i> statistics for the regression coefficients
PROBT	probability levels for the <i>t</i> statistics
SPCORR	semipartial correlations between regressors and dependent variables
SQSPCORR	squared semipartial correlations between regressors and dependent variables
PCORR	partial correlations between regressors and dependent variables
SQPCORR	squared partial correlations between regressors and dependent variables
RSQUARED	R squares for the multiple regression analyses
ADJRSQ	adjusted R squares
LCLRSQ	approximate 95% lower confidence limits for the R squares
UCLRSQ	approximate 95% upper confidence limits for the R squares
F	<i>F</i> statistics for the multiple regression analyses
PROBF	probability levels for the <i>F</i> statistics
CANCORR	canonical correlations
SCORE	standardized canonical coefficients. The <code>_NAME_</code> variable contains the name of the canonical variable. To obtain the canonical variable scores, these coefficients should be multiplied by the standardized data, using means obtained from the observation with <code>_TYPE_='MEAN'</code> and standard deviations obtained from the observation with <code>_TYPE_='STD'</code> .
RAWSCORE	raw canonical coefficients. To obtain the canonical variable scores, these coefficients should be multiplied by the raw data centered by means obtained from the observation with <code>_TYPE_='MEAN'</code> .
USCORE	scoring coefficients to be applied without subtracting the mean from the raw variables. These are standardized canonical coefficients computed under a NOINT model. To obtain the canonical variable scores, these coefficients should be multiplied by the data that are standardized by the uncorrected standard deviations obtained from the observation with <code>_TYPE_='USTD'</code> .
STRUCTUR	canonical structure.

Computational Resources

Notation

Let

n = number of observations

v = number of variables

w = number of WITH variables

p = $\max(v, w)$

q = $\min(v, w)$

b = $v + w$

t = total number of variables (VAR, WITH, and PARTIAL)

Time Requirements

The time required to compute the correlation matrix is roughly proportional to

$$n(p + q)^2$$

The time required for the canonical analysis is roughly proportional to

$$\frac{1}{6}p^3 + p^2q + \frac{3}{2}pq^2 + 5q^3$$

but the coefficient for q^3 varies depending on the number of QR iterations in the singular value decomposition.

Memory Requirements

The minimum memory required is approximately

$$4(v^2 + w^2 + t^2)$$

bytes. Additional memory is required if you request the VDEP or WDEP option.

Displayed Output

If the SIMPLE option is specified, PROC CANCORR produces means and standard deviations for each input variable. If the CORR option is specified, PROC CANCORR produces correlations among the input variables. Unless the NOPRINT option is specified, PROC CANCORR displays a table of canonical correlations containing the following:

- Canonical Correlations. These are always nonnegative.
- Adjusted Canonical Correlations (Lawley 1959), which are asymptotically less biased than the raw correlations and can be negative. The adjusted canonical correlations might not be computable, and they are displayed as missing values if two canonical correlations are nearly equal or if some are close to zero. A missing value is also displayed if an adjusted canonical correlation is larger than a previous adjusted canonical correlation.
- Approx Standard Errors, which are the approximate standard errors of the canonical correlations
- Squared Canonical Correlations
- Eigenvalues of $INV(E)*H$, which are equal to $CanRsqr/(1-CanRsqr)$, where $CanRsqr$ is the corresponding squared canonical correlation. Also displayed for each eigenvalue is the Difference from the next eigenvalue, the Proportion of the sum of the eigenvalues, and the Cumulative proportion.
- Likelihood Ratio for the hypothesis that the current canonical correlation and all smaller ones are zero in the population. The likelihood ratio for all canonical correlations equals Wilks' lambda.
- Approx F statistic based on Rao's approximation to the distribution of the likelihood ratio (Rao 1973, p. 556; Kshirsagar 1972, p. 326)
- Num DF and Den DF (numerator and denominator degrees of freedom) and $Pr > F$ (probability level) associated with the F statistic

Unless you specify the NOPRINT option, PROC CANCORR produces a table of multivariate statistics for the null hypothesis that all canonical correlations are zero in the population. These statistics, as described in the section "[Multivariate Tests](#)" on page 92 in Chapter 4, "[Introduction to Regression Procedures](#)," are as follows:

- Wilks' lambda
- Pillai's trace
- Hotelling-Lawley trace
- Roy's greatest root

For each of the preceding statistics, PROC CANCORR displays the following, depending on the specification of the MSTAT= option.

If you specify MSTAT=FAPPROX (also the default value), the following statistics are displayed:

- an F approximation or upper bound
- Num DF, the numerator degrees of freedom

- Den DF, the denominator degrees of freedom
- $Pr > F$, the probability level

If you specify `MSTAT=EXACT`, the following statistic is displayed:

- a t value

Unless you specify the `SHORT` or `NOPRINT` option, PROC CANCELL displays the following:

- both Raw (unstandardized) and Standardized Canonical Coefficients normalized to give canonical variables with unit variance. Standardized coefficients can be used to compute canonical variable scores from the standardized (zero mean and unit variance) input variables. Raw coefficients can be used to compute canonical variable scores from the input variables without standardizing them.
- all four Canonical Structure matrices, giving Correlations Between the canonical variables and the original variables

If you specify the `REDUNDANCY` option, PROC CANCELL displays the following:

- the Canonical Redundancy Analysis (Stewart and Love 1968; Cooley and Lohnes 1971), including Raw (unstandardized) and Standardized Variance and Cumulative Proportion of the Variance of each set of variables Explained by Their Own Canonical Variables and Explained by The Opposite Canonical Variables
- the Squared Multiple Correlations of each variable with the first m canonical variables of the opposite set, where m varies from 1 to the number of canonical correlations

If you specify the `VDEP` option, PROC CANCELL performs multiple regression analyses with the VAR variables as dependent variables and the WITH variables as regressors. If you specify the `WDEP` option, PROC CANCELL performs multiple regression analyses with the WITH variables as dependent variables and the VAR variables as regressors. If you specify the `VDEP` or `WDEP` option and also specify the `ALL` option, PROC CANCELL displays the following items. You can also specify individual options to request a subset of the output generated by the `ALL` option; or you can suppress the output by specifying the `NOPRINT` option.

SMC	Squared Multiple Correlations and F Tests. For each regression model, identified by its dependent variable name, PROC CANCELL displays the R square, Adjusted R square (Wherry 1931), F Statistic, and $Pr > F$. Also for each regression model, PROC CANCELL displays an Approximate 95% Confidence Interval for the population R square Helland (1987). These confidence limits are valid only when the regressors are random and when the regressors and dependent variables are approximately distributed according to a multivariate normal distribution. The average R squares for the models considered, unweighted and weighted by variance, are also given.
CORRB	Correlations Among the Regression Coefficient Estimates
STB	Standardized Regression Coefficients
B	Raw Regression Coefficients

SEB	Standard Errors of the Regression Coefficients
CLB	95% confidence limits for the regression coefficients
T	T Statistics for the Regression Coefficients
PROBT	Probability > T for the Regression Coefficients
SPCORR	Semipartial Correlations between regressors and dependent variables, Removing from Each Regressor the Effects of All Other Regressors
SQSPCORR	Squared Semipartial Correlations between regressors and dependent variables, Removing from Each Regressor the Effects of All Other Regressors
PCORR	Partial Correlations between regressors and dependent variables, Removing the Effects of All Other Regressors from Both Regressor and Criterion
SQPCORR	Squared Partial Correlations between regressors and dependent variables, Removing the Effects of All Other Regressors from Both Regressor and Criterion

ODS Table Names

PROC CANCORR assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 28.2](#).

For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

All of the tables in [Table 28.2](#) are created with the specification of the PROC CANCORR statement; a few tables need an additional PARTIAL statement.

Table 28.2 ODS Tables Produced by PROC CANCORR

ODS Table Name	Description	Statement and Option
AvgRSquare	Average R squares (weighted and unweighted)	VDEP, WDEP, SMC, or ALL
CanCorr	Canonical correlations	default
CanStructureVCan	Correlations between the VAR canonical variables and the VAR and WITH variables	default (if SHORT is not specified)
CanStructureWCan	Correlations between the WITH canonical variables and the WITH and VAR variables	default (if SHORT is not specified)
ConfidenceLimits	95% confidence limits for the regression coefficients	VDEP, WDEP, CLB, or ALL
Corr	Correlations among the original variables	CORR or ALL
CorrOnPartial	Partial correlations	PARTIAL statement with CORR or ALL
CorrRegCoefEst	Correlations among the regression coefficient estimates	VDEP, WDEP, CORRB, or ALL
MultStat	Multivariate statistics	default

Table 28.2 continued

ODS Table Name	Description	Statement and Option
NObsNVar	Number of observations and variables	SIMPLE or ALL
ParCorr	Partial correlations	VDEP, WDEP, PCORR, or ALL
ProbtRegCoef	Prob > t for the regression coefficients	VDEP, WDEP, PROBT, or ALL
RawCanCoefV	Raw canonical coefficients for the VAR variables	default (if SHORT is not specified)
RawCanCoefW	Raw canonical coefficients for the WITH variables	default (if SHORT is not specified)
RawRegCoef	Raw regression coefficients	VDEP, WDEP, B, or ALL
Redundancy	Canonical redundancy analysis	REDUNDANCY or ALL
Regression	Squared multiple correlations and F tests	VDEP, WDEP, SMC, or ALL
RSquareRMSEOnPartial	R squares and RMSEs on PARTIAL variables	PARTIAL statement with CORR or ALL
SemiParCorr	Semipartial correlations	VDEP, WDEP, SPCORR, or ALL
SimpleStatistics	Simple statistics	SIMPLE or ALL
SqMultCorr	Canonical redundancy analysis: squared multiple correlations	REDUNDANCY or ALL
SqParCorr	Squared partial correlations	VDEP, WDEP, SQPCORR, or ALL
SqSemiParCorr	Squared semipartial correlations	VDEP, WDEP, SQSPCORR, or ALL
StdCanCoefV	Standardized canonical coefficients for the VAR variables	default (if SHORT is not specified)
StdCanCoefW	Standardized canonical coefficients for the WITH variables	default (if SHORT is not specified)
StdErrRawRegCoef	Standard errors of the raw regression coefficients	VDEP, WDEP, SEB, or ALL
StdRegCoef	Standardized regression coefficients	VDEP, WDEP, STB, or ALL
StdRegCoefOnPartial	Standardized regression coefficients on PARTIAL variables	PARTIAL statement with CORR or ALL
tValueRegCoef	t values for the regression coefficients	VDEP, WDEP, T, or ALL

Example: CANCERR Procedure

Example 28.1: Canonical Correlation Analysis of Fitness Club Data

Three physiological and three exercise variables are measured on 20 middle-aged men in a fitness club. You can use the CANCERR procedure to determine whether the physiological variables are related in any way to the exercise variables. The following statements create the SAS data set Fit and produce [Output 28.1.1](#) through [Output 28.1.5](#):

```
data Fit;
  input Weight Waist Pulse Chins Situps Jumps;
  datalines;
191 36 50 5 162 60
189 37 52 2 110 60
193 38 58 12 101 101
162 35 62 12 105 37
189 35 46 13 155 58
182 36 56 4 101 42
211 38 56 8 101 38
167 34 60 6 125 40
176 31 74 15 200 40
154 33 56 17 251 250
169 34 50 17 120 38
166 33 52 13 210 115
154 34 64 14 215 105
247 46 50 1 50 50
193 36 46 6 70 31
202 37 62 12 210 120
176 37 54 4 60 25
157 32 52 11 230 80
156 33 54 15 225 73
138 33 68 2 110 43
;

proc cancorr data=Fit all
  vprefix=Physiological vname='Physiological Measurements'
  wprefix=Exercises wname='Exercises';
  var Weight Waist Pulse;
  with Chins Situps Jumps;
  title 'Middle-Aged Men in a Health Fitness Club';
  title2 'Data Courtesy of Dr. A. C. Linnerud, NC State Univ';
run;
```

Output 28.1.1 Correlations among the Original Variables

Middle-Aged Men in a Health Fitness Club			
Data Courtesy of Dr. A. C. Linnerud, NC State Univ			
The CANCERR Procedure			
Correlations Among the Original Variables			
Correlations Among the Physiological Measurements			
	Weight	Waist	Pulse
Weight	1.0000	0.8702	-0.3658
Waist	0.8702	1.0000	-0.3529
Pulse	-0.3658	-0.3529	1.0000
Correlations Among the Exercises			
	Chins	Situps	Jumps
Chins	1.0000	0.6957	0.4958
Situps	0.6957	1.0000	0.6692
Jumps	0.4958	0.6692	1.0000
Correlations Between the Physiological Measurements and the Exercises			
	Chins	Situps	Jumps
Weight	-0.3897	-0.4931	-0.2263
Waist	-0.5522	-0.6456	-0.1915
Pulse	0.1506	0.2250	0.0349

Output 28.1.1 displays the correlations among the original variables. The correlations between the physiological and exercise variables are moderate, the largest being -0.6456 between Waist and Situps. There are larger within-set correlations: 0.8702 between Weight and Waist, 0.6957 between Chins and Situps, and 0.6692 between Situps and Jumps.

Output 28.1.2 Canonical Correlations and Multivariate Statistics

<p style="text-align: center;">Middle-Aged Men in a Health Fitness Club Data Courtesy of Dr. A. C. Linnerud, NC State Univ</p> <p style="text-align: center;">The CANCELL Procedure</p> <p style="text-align: center;">Canonical Correlation Analysis</p>

As [Output 28.1.2](#) shows, the first canonical correlation is 0.7956, which would appear to be substantially larger than any of the between-set correlations. The probability level for the null hypothesis that all the canonical correlations are zero in the population is only 0.0635, so no firm conclusions can be drawn. The remaining canonical correlations are not worthy of consideration, as can be seen from the probability levels and especially from the negative adjusted canonical correlations.

Because the variables are not measured in the same units, the standardized coefficients rather than the raw coefficients should be interpreted. The correlations given in the canonical structure matrices should also be examined.

Output 28.1.3 Raw and Standardized Canonical Coefficients

Raw Canonical Coefficients for the Physiological Measurements			
	Physiological1	Physiological2	Physiological3
Weight	-0.031404688	-0.076319506	-0.007735047
Waist	0.4932416756	0.3687229894	0.1580336471
Pulse	-0.008199315	-0.032051994	0.1457322421
Raw Canonical Coefficients for the Exercises			
	Exercises1	Exercises2	Exercises3
Chins	-0.066113986	-0.071041211	-0.245275347
Situps	-0.016846231	0.0019737454	0.0197676373
Jumps	0.0139715689	0.0207141063	-0.008167472
Standardized Canonical Coefficients for the Physiological Measurements			
	Physiological1	Physiological2	Physiological3
Weight	-0.7754	-1.8844	-0.1910
Waist	1.5793	1.1806	0.5060
Pulse	-0.0591	-0.2311	1.0508
Standardized Canonical Coefficients for the Exercises			
	Exercises1	Exercises2	Exercises3
Chins	-0.3495	-0.3755	-1.2966
Situps	-1.0540	0.1235	1.2368
Jumps	0.7164	1.0622	-0.4188

The first canonical variable for the physiological variables, displayed in [Output 28.1.3](#), is a weighted difference of Waist (1.5793) and Weight (-0.7754), with more emphasis on Waist. The coefficient for Pulse is near 0. The correlations between Waist and Weight and the first canonical variable are both positive, 0.9254 for Waist and 0.6206 for Weight. Weight is therefore a suppressor variable, meaning that its coefficient and its correlation have opposite signs.

The first canonical variable for the exercise variables also shows a mixture of signs, subtracting Situps (-1.0540) and Chins (-0.3495) from Jumps (0.7164), with the most weight on Situps. All the correlations are negative, indicating that Jumps is also a suppressor variable.

It might seem contradictory that a variable should have a coefficient of opposite sign from that of its correlation with the canonical variable. In order to understand how this can happen, consider a simplified situation: predicting Situps from Waist and Weight by multiple regression. In informal terms, it seems plausible that obese people should do fewer sit-ups than skinny people. Assume that the men in the sample do

not vary much in height, so there is a strong correlation between Waist and Weight (0.8702). Examine the relationships between obesity and the independent variables:

- People with large waists tend to be more obese than people with small waists. Hence, the correlation between Waist and Situps should be negative.
- People with high weights tend to be more obese than people with low weights. Therefore, Weight should correlate negatively with Situps.
- For a fixed value of Weight, people with large waists tend to be shorter and more obese. Thus, the multiple regression coefficient for Waist should be negative.
- For a fixed value of Waist, people with higher weights tend to be taller and skinnier. The multiple regression coefficient for Weight should therefore be positive, of opposite sign from the correlation between Weight and Situps.

Therefore, the general interpretation of the first canonical correlation is that Weight and Jumps act as suppressor variables to enhance the correlation between Waist and Situps. This canonical correlation might be strong enough to be of practical interest, but the sample size is not large enough to draw definite conclusions.

The canonical redundancy analysis (Output 28.1.4) shows that neither of the first pair of canonical variables is a good overall predictor of the opposite set of variables, the proportions of variance explained being 0.2854 and 0.2584. The second and third canonical variables add virtually nothing, with cumulative proportions for all three canonical variables being 0.2969 and 0.2767.

Output 28.1.4 Canonical Redundancy Analysis

Middle-Aged Men in a Health Fitness Club Data Courtesy of Dr. A. C. Linnerud, NC State Univ					
The CANCORR Procedure					
Canonical Redundancy Analysis					
Standardized Variance of the Physiological Measurements Explained by Their Own Canonical Variables			The Opposite Canonical Variables		
Canonical Variable Number	Proportion	Cumulative Proportion	Canonical R-Square	Proportion	Cumulative Proportion
1	0.4508	0.4508	0.6330	0.2854	0.2854
2	0.2470	0.6978	0.0402	0.0099	0.2953
3	0.3022	1.0000	0.0053	0.0016	0.2969

Output 28.1.4 *continued*

Canonical Variable Number	Standardized Variance of the Exercises Explained by Their Own Canonical Variables			The Opposite Canonical Variables	
	Proportion	Cumulative Proportion	Canonical R-Square	Proportion	Cumulative Proportion
1	0.4081	0.4081	0.6330	0.2584	0.2584
2	0.4345	0.8426	0.0402	0.0175	0.2758
3	0.1574	1.0000	0.0053	0.0008	0.2767

The squared multiple correlations ([Output 28.1.5](#)) indicate that the first canonical variable of the physiological measurements has some predictive power for Chins (0.3351) and Situps (0.4233) but almost none for Jumps (0.0167). The first canonical variable of the exercises is a fairly good predictor of Waist (0.5421), a poorer predictor of Weight (0.2438), and nearly useless for predicting Pulse (0.0701).

Output 28.1.5 Canonical Redundancy Analysis

Squared Multiple Correlations Between the Physiological Measurements and the First M Canonical Variables of the Exercises				
M	1	2	3	
Weight	0.2438	0.2678	0.2679	
Waist	0.5421	0.5478	0.5478	
Pulse	0.0701	0.0702	0.0749	
Squared Multiple Correlations Between the Exercises and the First M Canonical Variables of the Physiological Measurements				
M	1	2	3	
Chins	0.3351	0.3374	0.3396	
Situps	0.4233	0.4365	0.4365	
Jumps	0.0167	0.0536	0.0539

Overview: CANDISC Procedure

Canonical discriminant analysis is a dimension-reduction technique related to principal component analysis and canonical correlation. The methodology used in deriving the canonical coefficients parallels that of a one-way MANOVA. MANOVA tests for equality of the mean vector across class levels. Canonical discriminant analysis finds linear combinations of the quantitative variables that provide maximal separation between classes or groups. Given a classification variable and several quantitative variables, the CANDISC procedure derives *canonical variables*, linear combinations of the quantitative variables that summarize between-class variation in much the same way that principal components summarize total variation.

The CANDISC procedure performs a canonical discriminant analysis, computes squared Mahalanobis distances between class means, and performs both univariate and multivariate one-way analyses of variance. Two output data sets can be produced: one containing the canonical coefficients and another containing, among other things, scored canonical variables. The canonical coefficients output data set can be rotated

by the FACTOR procedure. It is customary to standardize the canonical coefficients so that the canonical variables have means that are equal to zero and pooled within-class variances that are equal to one. PROC CANDISC displays both standardized and unstandardized canonical coefficients. Correlations between the canonical variables and the original variables as well as the class means for the canonical variables are also displayed; these correlations, sometimes known as loadings, are called canonical structures. To aid the visual interpretation of group differences, you can use ODS Graphics to display graphs of pairs of canonical variables from the scored canonical variables output data set.

Given two or more groups of observations with measurements on several quantitative variables, canonical discriminant analysis derives a linear combination of the variables that has the highest possible multiple correlation with the groups. This maximal multiple correlation is called the *first canonical correlation*. The coefficients of the linear combination are the *canonical coefficients* or *canonical weights*. The variable defined by the linear combination is the *first canonical variable* or *canonical component*. The second canonical correlation is obtained by finding the linear combination uncorrelated with the first canonical variable that has the highest possible multiple correlation with the groups. The process of extracting canonical variables can be repeated until the number of canonical variables equals the number of original variables or the number of classes minus one, whichever is smaller.

The first canonical correlation is at least as large as the multiple correlation between the groups and any of the original variables. If the original variables have high within-group correlations, the first canonical correlation can be large even if all the multiple correlations are small. In other words, the first canonical variable can show substantial differences between the classes, even if none of the original variables do. Canonical variables are sometimes called *discriminant functions*, but this usage is ambiguous because the DISCRIM procedure produces very different functions for classification that are also called discriminant functions.

For each canonical correlation, PROC CANDISC tests the hypothesis that it and all smaller canonical correlations are zero in the population. An F approximation (Rao 1973; Kshirsagar 1972) is used that gives better small-sample results than the usual chi-square approximation. The variables should have an approximate multivariate normal distribution within each class, with a common covariance matrix in order for the probability levels to be valid.

Canonical discriminant analysis is equivalent to canonical correlation analysis between the quantitative variables and a set of dummy variables coded from the class variable. Canonical discriminant analysis is also equivalent to performing the following steps:

1. Transform the variables so that the pooled within-class covariance matrix is an identity matrix.
2. Compute class means on the transformed variables.
3. Perform a principal component analysis on the means, weighting each mean by the number of observations in the class. The eigenvalues are equal to the ratio of between-class variation to within-class variation in the direction of each principal component.
4. Back-transform the principal components into the space of the original variables, obtaining the canonical variables.

An interesting property of the canonical variables is that they are uncorrelated whether the correlation is calculated from the total sample or from the pooled within-class correlations. The canonical coefficients are not orthogonal, however, so the canonical variables do not represent perpendicular directions through the space of the original variables.

Getting Started: CANDISC Procedure

The data in this example are measurements of 159 fish caught in Finland's lake Laengelmavesi; this data set is available from the Puranen. For each of the seven species (bream, roach, whitefish, parkki, perch, pike, and smelt) the weight, length, height, and width of each fish are tallied. Three different length measurements are recorded: from the nose of the fish to the beginning of its tail, from the nose to the notch of its tail, and from the nose to the end of its tail. The height and width are recorded as percentages of the third length variable. The fish data set is available from the Sashelp library.

The following step uses PROC CANDISC to find the three canonical variables that best separate the species of fish in the Sashelp.Fish data and create the output data set outcan. With the NCAN=3 option, only the first three canonical variables are displayed. The ODS EXCLUDE statement is specified to exclude the canonical structure tables and most of the canonical coefficient tables in order to obtain a more compact set of results. The TEMPLATE and SGRENDER procedures are used to create a plot of the first two canonical variables. The following statements produce [Figure 29.1](#) through [Figure 29.6](#):

```

title 'Fish Measurement Data';

proc candisc data=sashelp.fish ncan=3 out=outcan;
  ods exclude tstruc bstruc pstruc tcoef pcoef;
  class Species;
  var Weight Length1 Length2 Length3 Height Width;
run;

proc template;
  define statgraph scatter;
    begingraph;
    entrytitle 'Fish Measurement Data';
    layout overlayequated / equatetype=fit
      xaxisopts=(label='Canonical Variable 1')
      yaxisopts=(label='Canonical Variable 2');
    scatterplot x=Can1 y=Can2 / group=species name='fish';
    layout gridded / autoalign=(topright);
      discretelegend 'fish' / border=false opaque=false;
    endlayout;
  endlayout;
endgraph;
end;
run;

proc sgrender data=outcan template=scatter;
run;

```

PROC CANDISC begins by displaying summary information about the variables in the analysis. This information includes the number of observations, the number of quantitative variables in the analysis (specified with the VAR statement), and the number of classes in the classification variable (specified with the CLASS statement). The frequency of each class is also displayed.

Figure 29.1 Summary Information

Fish Measurement Data				
The CANDISC Procedure				
Total Sample Size	158	DF Total	157	
Variables	6	DF Within Classes	151	
Classes	7	DF Between Classes	6	
Number of Observations Read		159		
Number of Observations Used		158		
Class Level Information				
Species	Variable Name	Frequency	Weight	Proportion
Bream	Bream	34	34.0000	0.215190
Parkki	Parkki	11	11.0000	0.069620
Perch	Perch	56	56.0000	0.354430
Pike	Pike	17	17.0000	0.107595
Roach	Roach	20	20.0000	0.126582
Smelt	Smelt	14	14.0000	0.088608
Whitefish	Whitefish	6	6.0000	0.037975

PROC CANDISC performs a multivariate one-way analysis of variance (one-way MANOVA) and provides four multivariate tests of the hypothesis that the class mean vectors are equal. These tests, shown in Figure 29.2, indicate that not all of the mean vectors are equal ($p < .0001$).

Figure 29.2 MANOVA and Multivariate Tests

Fish Measurement Data					
The CANDISC Procedure					
Multivariate Statistics and F Approximations					
S=6 M=-0.5 N=72					
Statistic	Value	F Value	Num DF	Den DF	Pr > F
Wilks' Lambda	0.00036325	90.71	36	643.89	<.0001
Pillai's Trace	3.10465132	26.99	36	906	<.0001
Hotelling-Lawley Trace	52.05799676	209.24	36	413.64	<.0001
Roy's Greatest Root	39.13499776	984.90	6	151	<.0001
NOTE: F Statistic for Roy's Greatest Root is an upper bound.					

The first canonical correlation is the greatest possible multiple correlation with the classes that can be achieved by using a linear combination of the quantitative variables. The first canonical correlation, displayed in Figure 29.3, is 0.987463. A likelihood ratio test is displayed of the hypothesis that the current canonical correlation and all smaller ones are zero. The first line is equivalent to Wilks' lambda multivariate test.

Figure 29.3 Canonical Correlations

Fish Measurement Data					
The CANDISC Procedure					
	Canonical Correlation	Adjusted Canonical Correlation	Approximate Standard Error	Squared Canonical Correlation	
1	0.987463	0.986671	0.001989	0.975084

5	0.1344	0.1343	0.0026	1.0000	
6	0.0000		0.0000	1.0000	
Test of H0: The canonical correlations in the current row and all that follow are zero					
	Likelihood Ratio	Approximate F Value	Num DF	Den DF	Pr > F
1	0.00036325	90.71	36	643.89	<.0001
2	0.01457896	46.46	25	547.58	<.0001
3	0.15671134	23.61	16	452.79	<.0001
4	0.52820347	12.09	9	362.78	<.0001
5	0.88152702	4.88	4	300	0.0008
6	0.99996749	0.00	1	151	0.9442

The first canonical variable, Can1, shows that the linear combination of the centered variables $\text{Can1} = -0.0006 \times \text{Weight} - 0.33 \times \text{Length1} + 2.49 \times \text{Length2} + 2.60 \times \text{Length3} + 1.12 \times \text{Height} - 1.45 \times \text{Width}$ separates the species most effectively (see Figure 29.4).

Figure 29.4 Raw Canonical Coefficients

Fish Measurement Data			
The CANDISC Procedure			
Raw Canonical Coefficients			
Variable	Can1	Can2	Can3
Weight	-0.000648508	-0.005231659	-0.005596192
Length1	-0.329435762	-0.626598051	-2.934324102
Length2	-2.486133674	-0.690253987	4.045038893
Length3	2.595648437	1.803175454	-1.139264914
Height	1.121983854	-0.714749340	0.283202557
Width	-1.446386704	-0.907025481	0.741486686

PROC CANDISC computes the means of the canonical variables for each class. The first canonical variable is the linear combination of the variables Weight, Length1, Length2, Length3, Height, and Width that provides the greatest difference (in terms of a univariate F test) between the class means. The second canonical variable provides the greatest difference between class means while being uncorrelated with the first canonical variable.

Figure 29.5 Class Means for Canonical Variables

Class Means on Canonical Variables			
Species	Can1	Can2	Can3
Bream	10.94142464	0.52078394	0.23496708
Parkki	2.58903743	-2.54722416	-0.49326158
Perch	-4.47181389	-1.70822715	1.29281314
Pike	-4.89689441	8.22140791	-0.16469132
Roach	-0.35837149	0.08733611	-1.10056438
Smelt	-4.09136653	-2.35805841	-4.03836098
Whitefish	-0.39541755	-0.42071778	1.06459242

A plot of the first two canonical variables (Figure 29.6) shows that Can1 discriminates between three groups: 1) bream; 2) whitefish, roach, and parkki; and 3) smelt, pike, and perch. Can2 best discriminates between pike and the other species.

Figure 29.6 Plot of First Two Canonical Variables

Syntax: CANDISC Procedure

The following statements are available in the CANDISC procedure:

```
PROC CANDISC < options > ;
  CLASS variable ;
  BY variables ;
  FREQ variable ;
  VAR variables ;
  WEIGHT variable ;
```

The BY, CLASS, FREQ, VAR, and WEIGHT statements are described after the PROC CANDISC statement.

PROC CANDISC Statement

PROC CANDISC <options> ;

The PROC CANDISC statement invokes the CANDISC procedure. Table 29.1 summarizes the options available in the PROC CANDISC statement.

Table 29.1 CANDISC Procedure Options

Option	Description
Input Data Set	
DATA=	Specifies input SAS data set
Output Data Sets	
OUT=	Specifies output data set with canonical scores
OUTSTAT=	Specifies output statistics data set
Method Details	
NCAN=	Specifies the number of canonical variables
PREFIX=	Specifies a prefix for naming the canonical variables
SINGULAR=	Specifies the singularity criterion
Control Displayed Output	
ALL	Displays all output
ANOVA	Displays univariate statistics
BCORR	Displays between correlations
BCOV	Displays between covariances
BSSCP	Displays between SSCPs
DISTANCE	Displays squared Mahalanobis distances
NOPRINT	Suppresses all displayed output
PCORR	Displays pooled correlations
PCOV	Displays pooled covariances
PSSCP	Displays pooled SSCPs
SHORT	Suppresses some displayed output
SIMPLE	Displays simple descriptive statistics
STDMEAN	Displays standardized class means
TCORR	Displays total correlations
TCOV	Displays total covariances
TSSCP	Displays total SSCPs
WCORR	Displays within correlations
WCOV	Displays within covariances
WSSCP	Displays within SSCPs

ALL

activates all of the display options.

ANOVA

displays univariate statistics for testing the hypothesis that the class means are equal in the population for each variable.

BCORR

displays between-class correlations.

BCOV

displays between-class covariances. The between-class covariance matrix equals the between-class SSCP matrix divided by $n(c - 1)/c$, where n is the number of observations and c is the number of classes. The between-class covariances should be interpreted in comparison with the total-sample and within-class covariances, not as formal estimates of population parameters.

BSSCP

displays the between-class SSCP matrix.

DATA=SAS-data-set

specifies the data set to be analyzed. The data set can be an ordinary SAS data set or one of several specially structured data sets created by SAS statistical procedures. These specially structured data sets include TYPE=CORR, COV, CSSCP, and SSCP. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

DISTANCE**MAHALANOBIS**

displays squared Mahalanobis distances between the group means, F statistics, and the corresponding probabilities of greater squared Mahalanobis distances between the group means.

NCAN= n

specifies the number of canonical variables to be computed. The value of n must be less than or equal to the number of variables. If you specify NCAN=0, the procedure displays the canonical correlations, but not the canonical coefficients, structures, or means. A negative value suppresses the canonical analysis entirely. Let v be the number of variables in the VAR statement, and let c be the number of classes. If you omit the NCAN= option, only $\min(v, c - 1)$ canonical variables are generated; if you also specify an OUT= output data set, v canonical variables are generated, and the last $v - (c - 1)$ canonical variables have missing values.

NOPRINT

suppresses the normal display of results. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, “[Using the Output Delivery System](#),” for more information.

OUT=SAS-data-set

creates an output SAS data set containing the original data and the canonical variable scores. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

OUTSTAT=SAS-data-set

creates a TYPE=CORR output SAS data set that contains various statistics, including class means, standard deviations, correlations, canonical correlations, canonical structures, canonical coefficients, and means of canonical variables for each class. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

PCORR

displays pooled within-class correlations (partial correlations based on the pooled within-class covariances).

PCOV

displays pooled within-class covariances.

PREFIX=name

specifies a prefix for naming the canonical variables. By default the names are Can1, Can2, Can3, and so forth. If you specify PREFIX=Abc, the components are named Abc1, Abc2, and so on. The number of characters in the prefix plus the number of digits required to designate the canonical variables should not exceed 32. The prefix is truncated if the combined length exceeds 32.

PSSCP

displays the pooled within-class corrected SSCP matrix.

SHORT

suppresses the display of canonical structures, canonical coefficients, and class means on canonical variables; only tables of canonical correlations and multivariate test statistics are displayed.

SIMPLE

displays simple descriptive statistics for the total sample and within each class.

SINGULAR=p

specifies the criterion for determining the singularity of the total-sample correlation matrix and the pooled within-class covariance matrix, where $0 < p < 1$. The default is SINGULAR=1E-8.

Let S be the total-sample correlation matrix. If the R square for predicting a quantitative variable in the VAR statement from the variables preceding it exceeds $1 - p$, then S is considered singular. If S is singular, the probability levels for the multivariate test statistics and canonical correlations are adjusted for the number of variables with R square exceeding $1 - p$.

If S is considered singular and the inverse of S (squared Mahalanobis distances) is required, a quasi inverse is used instead. For details see the section “[Quasi-inverse](#)” on page 2083 in Chapter 33, “[The DISCRIM Procedure](#).”

STDMEAN

displays total-sample and pooled within-class standardized class means.

TCORR

displays total-sample correlations.

TCOV

displays total-sample covariances.

TSSCP

displays the total-sample corrected SSCP matrix.

WCORR

displays within-class correlations for each class level.

WCOV

displays within-class covariances for each class level.

WSSCP

displays the within-class corrected SSCP matrix for each class level.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC CANDISC to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the CANDISC procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* ;

The values of the CLASS variable define the groups for analysis. Class levels are determined by the formatted values of the CLASS variable. The CLASS variable can be numeric or character. A CLASS statement is required.

FREQ Statement

FREQ *variable* ;

If a variable in the data set represents the frequency of occurrence for the other values in the observation, include the name of the variable in a FREQ statement. The procedure then treats the data set as if each observation appears n times, where n is the value of the FREQ variable for the observation. The total number of observations is considered to be equal to the sum of the FREQ variable when the procedure determines degrees of freedom for significance probabilities.

If the value of the FREQ variable is missing or is less than one, the observation is not used in the analysis. If the value is not an integer, the value is truncated to an integer.

VAR Statement

VAR *variables* ;

You specify the quantitative variables to include in the analysis by using a VAR statement. If you do not use a VAR statement, the analysis includes all numeric variables not listed in other statements.

WEIGHT Statement

WEIGHT *variable* ;

To use relative weights for each observation in the input data set, place the weights in a variable in the data set and specify the name in a WEIGHT statement. This is often done when the variance associated with each observation is different and the values of the WEIGHT variable are proportional to the reciprocals of the variances. If the value of the WEIGHT variable is missing or is less than zero, then a value of zero for the weight is assumed.

The WEIGHT and FREQ statements have a similar effect except that the WEIGHT statement does not alter the degrees of freedom.

Details: CANDISC Procedure

Missing Values

If an observation has a missing value for any of the quantitative variables, it is omitted from the analysis. If an observation has a missing CLASS value but is otherwise complete, it is not used in computing the canonical correlations and coefficients; however, canonical variable scores are computed for that observation for the OUT= data set.

Computational Details

General Formulas

Canonical discriminant analysis is equivalent to canonical correlation analysis between the quantitative variables and a set of dummy variables coded from the class variable. In the following notation the dummy variables are denoted by y and the quantitative variables by x . The total sample covariance matrix for the x and y variables is

$$S = \begin{bmatrix} S_{xx} & S_{xy} \\ S_{yx} & S_{yy} \end{bmatrix}$$

When c is the number of groups, n_t is the number of observations in group t , and S_t is the sample covariance matrix for the x variables in group t , the within-class pooled covariance matrix for the x variables is

$$S_p = \frac{1}{\sum n_t - c} \sum (n_t - 1) S_t$$

The canonical correlations, ρ_i , are the square roots of the eigenvalues, λ_i , of the following matrix. The corresponding eigenvectors are v_i .

$$S_p^{-1/2} S_{xy} S_{yy}^{-1} S_{yx} S_p^{-1/2}$$

Let V be the matrix with the eigenvectors v_i that correspond to nonzero eigenvalues as columns. The raw canonical coefficients are calculated as follows:

$$R = S_p^{-1/2} V$$

The pooled within-class standardized canonical coefficients are

$$P = \text{diag}(S_p)^{1/2} R$$

The total sample standardized canonical coefficients are

$$T = \text{diag}(S_{xx})^{1/2} R$$

Let \mathbf{X}_c be the matrix with the centered x variables as columns. The canonical scores can be calculated by any of the following:

$$\mathbf{X}_c \mathbf{R}$$

$$\mathbf{X}_c \text{diag}(\mathbf{S}_p)^{-1/2} \mathbf{P}$$

$$\mathbf{X}_c \text{diag}(\mathbf{S}_{xx})^{-1/2} \mathbf{T}$$

For the multivariate tests based on $\mathbf{E}^{-1} \mathbf{H}$,

$$\mathbf{E} = (n - 1)(\mathbf{S}_{yy} - \mathbf{S}_{yx} \mathbf{S}_{xx}^{-1} \mathbf{S}_{xy})$$

$$\mathbf{H} = (n - 1) \mathbf{S}_{yx} \mathbf{S}_{xx}^{-1} \mathbf{S}_{xy}$$

where n is the total number of observations.

Input Data Set

The input DATA= data set can be an ordinary SAS data set or one of several specially structured data sets created by statistical procedures available with SAS/STAT software. For more information about special types of data sets, see Appendix A, “[Special SAS Data Sets](#).” The BY variable in these data sets becomes the CLASS variable in PROC CANDISC. These specially structured data sets include the following:

- TYPE=CORR data sets created by PROC CORR by using a BY statement
- TYPE=COV data sets created by PROC PRINCOMP by using both the COV option and a BY statement
- TYPE=CSSCP data sets created by PROC CORR by using the CSSCP option and a BY statement, where the OUT= data set is assigned TYPE=CSSCP with the TYPE= data set option
- TYPE=SSCP data sets created by PROC REG by using both the OUTSSCP= option and a BY statement.

When the input data set is TYPE=CORR, TYPE=COV, or TYPE=CSSCP, then PROC CANDISC reads the number of observations for each class from the observations with `_TYPE_='N'` and the variable means in each class from the observations with `_TYPE_='MEAN'`. The CANDISC procedure then reads the within-class correlations from the observations with `_TYPE_='CORR'`, the standard deviations from the observations with `_TYPE_='STD'` (data set TYPE=CORR), the within-class covariances from the observations with `_TYPE_='COV'` (data set TYPE=COV), or the within-class corrected sums of squares and crossproducts from the observations with `_TYPE_='CSSCP'` (data set TYPE=CSSCP).

When the data set does not include any observations with `_TYPE_='CORR'` (data set `TYPE=CORR`), `_TYPE_='COV'` (data set `TYPE=COV`), or `_TYPE_='CSSCP'` (data set `TYPE=CSSCP`) for each class, PROC CANDISC reads the pooled within-class information from the data set. In this case, PROC CANDISC reads the pooled within-class correlations from the observations with `_TYPE_='PCORR'`, the pooled within-class standard deviations from the observations with `_TYPE_='PSTD'` (data set `TYPE=CORR`), the pooled within-class covariances from the observations with `_TYPE_='PCOV'` (data set `TYPE=COV`), or the pooled within-class corrected SSP matrix from the observations with `_TYPE_='PSSCP'` (data set `TYPE=CSSCP`).

When the input data set is `TYPE=SSCP`, then PROC CANDISC reads the number of observations for each class from the observations with `_TYPE_='N'`, the sum of weights of observations from the variable `INTERCEPT` in observations with `_TYPE_='SSCP'` and `_NAME_='INTERCEPT'`, the variable sums from the analysis variables in observations with `_TYPE_='SSCP'` and `_NAME_='INTERCEPT'`, and the uncorrected sums of squares and crossproducts from the analysis variables in observations with `_TYPE_='SSCP'` and `_NAME_=variablenames`.

Output Data Sets

OUT= Data Set

The `OUT=` data set contains all the variables in the original data set plus new variables containing the canonical variable scores. You determine the number of new variables by using the `NCAN=` option. The names of the new variables are formed as described in the `PREFIX=` option. The new variables have means equal to zero and pooled within-class variances equal to one. An `OUT=` data set cannot be created if the `DATA=` data set is not an ordinary SAS data set.

OUTSTAT= Data Set

The `OUTSTAT=` data set is similar to the `TYPE=CORR` data set produced by the `CORR` procedure but contains many results in addition to those produced by the `CORR` procedure.

The `OUTSTAT=` data set is `TYPE=CORR`, and it contains the following variables:

- the `BY` variables, if any
- the `CLASS` variable
- `_TYPE_`, a character variable of length 8 that identifies the type of statistic
- `_NAME_`, a character variable of length 32 that identifies the row of the matrix or the name of the canonical variable
- the quantitative variables (those in the `VAR` statement, or if there is no `VAR` statement, all numeric variables not listed in any other statement)

The observations, as identified by the variable `_TYPE_`, have the following `_TYPE_` values:

<code>_TYPE_</code>	Contents
N	number of observations both for the total sample (CLASS variable missing) and within each class (CLASS variable present)
SUMWGT	sum of weights both for the total sample (CLASS variable missing) and within each class (CLASS variable present) if a WEIGHT statement is specified
MEAN	means both for the total sample (CLASS variable missing) and within each class (CLASS variable present)
STDMEAN	total-standardized class means
PSTDMEAN	pooled within-class standardized class means
STD	standard deviations both for the total sample (CLASS variable missing) and within each class (CLASS variable present)
PSTD	pooled within-class standard deviations
BSTD	between-class standard deviations
RSQUARED	univariate R squares

The following kinds of observations are identified by the combination of the variables `_TYPE_` and `_NAME_`. When the `_TYPE_` variable has one of the following values, the `_NAME_` variable identifies the row of the matrix:

<code>_TYPE_</code>	Contents
CSSCP	corrected SSCP matrix for the total sample (CLASS variable missing) and within each class (CLASS variable present)
PSSCP	pooled within-class corrected SSCP matrix
BSSCP	between-class SSCP matrix
COV	covariance matrix for the total sample (CLASS variable missing) and within each class (CLASS variable present)
PCOV	pooled within-class covariance matrix
BCOV	between-class covariance matrix
CORR	correlation matrix for the total sample (CLASS variable missing) and within each class (CLASS variable present)
PCORR	pooled within-class correlation matrix
BCORR	between-class correlation matrix

When the `_TYPE_` variable has one of the following values, the `_NAME_` variable identifies the canonical variable:

<code>_TYPE_</code>	Contents
CANCORR	canonical correlations
STRUCTUR	canonical structure

BSTRUCT	between canonical structure
PSTRUCT	pooled within-class canonical structure
SCORE	total sample standardized canonical coefficients
PSCORE	pooled within-class standardized canonical coefficients
RAWSCORE	raw canonical coefficients
CANMEAN	means of the canonical variables for each class

You can use this data set with PROC SCORE to get scores on the canonical variables for new data by using one of the following forms:

```
* The CLASS variable C is numeric;
proc score data=NewData score=Coef(where=(c = . )) out=Scores;
run;

* The CLASS variable C is character;
proc score data=NewData score=Coef(where=(c = ' ')) out=Scores;
run;
```

The WHERE clause is used to exclude the within-class means and standard deviations. PROC SCORE standardizes the new data by subtracting the original variable means that are stored in the `_TYPE_='MEAN'` observations, and dividing by the original variable standard deviations from the `_TYPE_='STD'` observations. Then PROC SCORE multiplies the standardized variables by the coefficients from the `_TYPE_='SCORE'` observations to get the canonical scores.

Computational Resources

In the following discussion, let

- n = number of observations
- c = number of class levels
- v = number of variables in the VAR list
- l = length of the CLASS variable

Memory Requirements

The amount of memory in bytes for temporary storage needed to process the data is

$$c(4v^2 + 28v + 4l + 68) + 16v^2 + 96v + 4l$$

With the ANOVA option, the temporary storage must be increased by $16v$ bytes. The DISTANCE option requires an additional temporary storage of $4v^2 + 4v$ bytes.

Time Requirements

The following factors determine the time requirements of the CANDISC procedure:

- The time needed for reading the data and computing covariance matrices is proportional to nv^2 . PROC CANDISC must also look up each class level in the list. This is faster if the data are sorted by the CLASS variable. The time for looking up class levels is proportional to a value ranging from n to $n \log(c)$.
- The time for inverting a covariance matrix is proportional to v^3 .
- The time required for the canonical discriminant analysis is proportional to v^3 .

Each of the preceding factors has a different constant of proportionality.

Displayed Output

The displayed output from PROC CANDISC includes the class level information table. For each level of the classification variable, the following information is provided: the output data set variable name, frequency sum, weight sum, and the proportion of the total sample.

The optional output from PROC CANDISC includes the following:

- Within-class SSCP matrices for each group
- Pooled within-class SSCP matrix
- Between-class SSCP matrix
- Total-sample SSCP matrix
- Within-class covariance matrices for each group
- Pooled within-class covariance matrix
- Between-class covariance matrix, equal to the between-class SSCP matrix divided by $n(c - 1)/c$, where n is the number of observations and c is the number of classes
- Total-sample covariance matrix
- Within-class correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the within-class population correlation coefficients are zero
- Pooled within-class correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the partial population correlation coefficients are zero
- Between-class correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the between-class population correlation coefficients are zero
- Total-sample correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the total population correlation coefficients are zero

- Simple statistics, including N (the number of observations), sum, mean, variance, and standard deviation both for the total sample and within each class
- Total-sample standardized class means, obtained by subtracting the grand mean from each class mean and dividing by the total sample standard deviation
- Pooled within-class standardized class means, obtained by subtracting the grand mean from each class mean and dividing by the pooled within-class standard deviation
- Pairwise squared distances between groups
- Univariate test statistics, including total-sample standard deviations, pooled within-class standard deviations, between-class standard deviations, R square, $R^2/(1 - R^2)$, F , and $\text{Pr} > F$ (univariate F values and probability levels for one-way analyses of variance)

By default, PROC CANDISC displays these statistics:

- Multivariate statistics and F approximations including Wilks' lambda, Pillai's trace, Hotelling-Lawley trace, and Roy's greatest root with F approximations, numerator and denominator degrees of freedom (Num DF and Den DF), and probability values ($\text{Pr} > F$). Each of these four multivariate statistics tests the hypothesis that the class means are equal in the population. See the section "[Multivariate Tests](#)" on page 92 in Chapter 4, "[Introduction to Regression Procedures](#)," for more information.
- Canonical correlations
- Adjusted canonical correlations (Lawley 1959). These are asymptotically less biased than the raw correlations and can be negative. The adjusted canonical correlations might not be computable and are displayed as missing values if two canonical correlations are nearly equal or if some are close to zero. A missing value is also displayed if an adjusted canonical correlation is larger than a previous adjusted canonical correlation.
- Approximate standard error of the canonical correlations
- Squared canonical correlations
- Eigenvalues of $\mathbf{E}^{-1}\mathbf{H}$. Each eigenvalue is equal to $\rho^2/(1 - \rho^2)$, where ρ^2 is the corresponding squared canonical correlation and can be interpreted as the ratio of between-class variation to pooled within-class variation for the corresponding canonical variable. The table includes Eigenvalues, Differences between successive eigenvalues, the Proportion of the sum of the eigenvalues, and the Cumulative proportion.
- Likelihood ratio for the hypothesis that the current canonical correlation and all smaller ones are zero in the population. The likelihood ratio for the hypothesis that all canonical correlations equal zero is Wilks' lambda.
- Approx F statistic based on Rao's approximation to the distribution of the likelihood ratio (Rao 1973, p. 556; Kshirsagar 1972, p. 326)
- Numerator degrees of freedom (Num DF), denominator degrees of freedom (Den DF), and $\text{Pr} > F$, the probability level associated with the F statistic

The following statistics can be suppressed with the SHORT option:

- Total canonical structure, giving total-sample correlations between the canonical variables and the original variables
- Between canonical structure, giving between-class correlations between the canonical variables and the original variables
- Pooled within canonical structure, giving pooled within-class correlations between the canonical variables and the original variables
- Total-sample standardized canonical coefficients, standardized to give canonical variables with zero mean and unit pooled within-class variance when applied to the total-sample standardized variables
- Pooled within-class standardized canonical coefficients, standardized to give canonical variables with zero mean and unit pooled within-class variance when applied to the pooled within-class standardized variables
- Raw canonical coefficients, standardized to give canonical variables with zero mean and unit pooled within-class variance when applied to the centered variables
- Class means on the canonical variables

ODS Table Names

PROC CANDISC assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 29.2. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 29.2 ODS Tables Produced by PROC CANDISC

ODS Table Name	Description	PROC CANDISC Option
ANOVA	Univariate statistics	ANOVA
AveRSquare	Average R square	ANOVA
BCorr	Between-class correlations	BCORR
BCov	Between-class covariances	BCOV
BSSCP	Between-class SSCP matrix	BSSCP
BStruc	Between canonical structure	default
CanCorr	Canonical correlations	default
CanonicalMeans	Class means on canonical variables	default
Counts	Number of observations, variables, classes, df	default
CovDF	DF for covariance matrices, not printed	any *COV option
Dist	Squared distances	DISTANCE
DistFValues	F statistics based on squared distances	DISTANCE
DistProb	Probabilities for F statistics from squared distances	DISTANCE

Example: CANDISC Procedure

Example 29.1: Analysis of Iris Data With PROC CANDISC

The iris data published by Fisher (1936) have been widely used for examples in discriminant analysis and cluster analysis. The sepal length, sepal width, petal length, and petal width are measured in millimeters on 50 iris specimens from each of three species: *Iris setosa*, *I. versicolor*, and *I. virginica*. The iris data set is available from the Sashelp library.

This example is a canonical discriminant analysis that creates an output data set containing scores on the canonical variables and plots the canonical variables.

The following statements produce [Output 29.1.1](#) through [Output 29.1.6](#):

```

title 'Fisher (1936) Iris Data';

proc candisc data=sashelp.iris out=outcan distance anova;
  class Species;
  var SepalLength SepalWidth PetalLength PetalWidth;
run;

```

PROC CANDISC first displays information about the observations and the classes in the data set in [Output 29.1.1](#).

Output 29.1.1 Iris Data: Summary Information

Fisher (1936) Iris Data				
The CANDISC Procedure				
Total Sample Size	150	DF Total	149	
Variables	4	DF Within Classes	147	
Classes	3	DF Between Classes	2	
Number of Observations Read		150		
Number of Observations Used		150		
Class Level Information				
Species	Variable Name	Frequency	Weight	Proportion
Setosa	Setosa	50	50.0000	0.333333
Versicolor	Versicolor	50	50.0000	0.333333
Virginica	Virginica	50	50.0000	0.333333

The DISTANCE option in the PROC CANDISC statement displays squared Mahalanobis distances between class means. Results from the DISTANCE option are shown in [Output 29.1.2](#).

Output 29.1.2 Iris Data: Squared Mahalanobis Distances and Distance Statistics

Fisher (1936) Iris Data				
The CANDISC Procedure				
Squared Distance to Species				
From Species	Setosa	Versicolor	Virginica	
Setosa	0	89.86419	179.38471	
Versicolor	89.86419	0	17.20107	
Virginica	179.38471	17.20107	0	

Output 29.1.2 *continued*

F Statistics, NDF=4, DDF=144 for Squared Distance to Species				
From Species	Setosa	Versicolor	Virginica	
Setosa	0	550.18889	1098	
Versicolor	550.18889	0	105.31265	
Virginica	1098	105.31265	0	

Prob > Mahalanobis Distance for Squared Distance to Species				
From Species	Setosa	Versicolor	Virginica	
Setosa	1.0000	<.0001	<.0001	
Versicolor	<.0001	1.0000	<.0001	
Virginica	<.0001	<.0001	1.0000	

The ANOVA option uses univariate statistics to test the hypothesis that the class means are equal. The resulting R-square values (see [Output 29.1.3](#)) range from 0.4008 for SepalWidth to 0.9414 for PetalLength, and each variable is significant at the 0.0001 level. The multivariate test for differences between the classes (which is displayed by default) is also significant at the 0.0001 level; you would expect this from the highly significant univariate test results.

Output 29.1.3 Iris Data: Univariate and Multivariate Statistics

Fisher (1936) Iris Data								
The CANDISC Procedure								
Univariate Test Statistics								
F Statistics, Num DF=2, Den DF=147								
Variable	Label	Total Standard Deviation	Pooled Standard Deviation	Between Standard Deviation	R-Square	R-Square / (1-RSq)	F Value	Pr > F
Sepal Length	Sepal Length (mm)	8.2807	5.1479	7.9506	0.6187	1.6226	119.26	<.0001
Sepal Width	Sepal Width (mm)	4.3587	3.3969	3.3682	0.4008	0.6688	49.16	<.0001
Petal Length	Petal Length (mm)	17.6530	4.3033	20.9070	0.9414	16.0566	1180.16	<.0001
Petal Width	Petal Width (mm)	7.6224	2.0465	8.9673	0.9289	13.0613	960.01	<.0001

Output 29.1.3 *continued*

Average R-Square					
Unweighted		0.7224358			
Weighted by Variance		0.8689444			
Multivariate Statistics and F Approximations					
S=2		M=0.5	N=71		
Statistic	Value	F Value	Num DF	Den DF	Pr > F
Wilks' Lambda	0.02343863	199.15	8	288	<.0001
Pillai's Trace	1.19189883	53.47	8	290	<.0001
Hotelling-Lawley Trace	32.47732024	582.20	8	203.4	<.0001
Roy's Greatest Root	32.19192920	1166.96	4	145	<.0001
NOTE: F Statistic for Roy's Greatest Root is an upper bound.					
NOTE: F Statistic for Wilks' Lambda is exact.					

The R square between Can1 and the class variable, 0.969872, is much larger than the corresponding R square for Can2, 0.222027. This is displayed in [Output 29.1.4](#).

Output 29.1.4 Iris Data: Canonical Correlations and Eigenvalues

Fisher (1936) Iris Data					
The CANDISC Procedure					
	Canonical Correlation	Adjusted Canonical Correlation	Approximate Standard Error	Squared Canonical Correlation	
1	0.984821	0.984508	0.002468	0.969872

Overview: CATMOD Procedure

The CATMOD procedure performs categorical data modeling of data that can be represented by a contingency table. PROC CATMOD fits linear models to functions of response frequencies, and it can be used for linear modeling, log-linear modeling, logistic regression, and repeated measurement analysis. PROC CATMOD uses the following estimation methods:

- weighted least squares (WLS) estimation of parameters for a wide range of general linear models
- maximum likelihood (ML) estimation of parameters for log-linear models and the analysis of generalized logits

The CATMOD procedure provides a wide variety of categorical data analyses, many of which are generalizations of continuous data analysis methods. For example, analysis of variance, in the traditional sense, refers to the analysis of means and the partitioning of variation among the means into various sources. Here, the term *analysis of variance* is used in a generalized sense to denote the analysis of response functions and the partitioning of variation among those functions into various sources. The response functions might be mean scores if the dependent variables are ordinally scaled. But they can also be marginal probabilities, cumulative logits, or other functions that incorporate the essential information from the dependent variables.

NOTE: PROC CATMOD specializes in WLS modeling and analysis of a wide range of models on contingency tables. For ML modeling on standard models, especially with continuous predictors, it might be more appropriate to use a procedure such as PROC GENMOD or PROC LOGISTIC; see Chapter 40, “The GENMOD Procedure,” and Chapter 54, “The LOGISTIC Procedure,” for more information.

Types of Input Data

The data that PROC CATMOD analyzes are usually supplied in one of two ways. First, you can supply raw data, where each observation is a subject. Second, you can supply cell count data, where each observation is a cell in a contingency table. (A third way, which uses direct input of the covariance matrix, is also available; details are given in the section “[Inputting Response Functions and Covariances Directly](#)” on page 1820.)

Suppose detergent brand preference is related to three other categorical variables: water softness, water temperature, and previous use of a brand of detergent. In the raw data case, each observation in the input data set identifies a given respondent in the study and contains information about all four variables. The data set contains the same number of observations as the survey had respondents. In the cell count case, each observation identifies a given cell in the four-way table of water softness, water temperature, previous use of brand, and brand preference. A fifth variable contains the number of respondents in the cell. In the analysis, this fifth variable is identified in a **WEIGHT** statement. The data set contains the same number of observations as the number of cross-classifications formed by the four categorical variables. For more about this particular example, see [Example 30.1](#). For additional details, see the section “[Input Data Sets](#)” on page 1818.

Most of the examples in this chapter use cell counts as input and use a **WEIGHT** statement.

Types of Statistical Analyses

This section illustrates, by example, the wide variety of categorical data analyses that PROC CATMOD provides. For each type of analysis, a brief description of the statistical problem and the SAS statements to provide the analysis are given. For each analysis, assume that the input data set consists of a set of cell counts from a contingency table. The variable specified in the **WEIGHT** statement contains these counts. In all these analyses, both the dependent and independent variables are categorical.

Linear Model Analysis

Suppose you want to analyze the relationship between the dependent variables (r_1 , r_2) and the independent variables (a , b). Analyze the marginal probabilities of the dependent variables, and use a main-effects model:

```
proc catmod;
  weight wt;
  response marginals;
  model r1*r2=a b;
quit;
```

Log-Linear Model Analysis

Suppose you want to analyze the nominal dependent variables (r_1 , r_2 , r_3) with a log-linear model. Use maximum likelihood analysis, include the main effects and the r_1*r_2 interaction in the model, and obtain the predicted cell frequencies:

```
proc catmod;
  weight wt;
  model r1*r2*r3=_response_ / pred=freq;
  loglin r1|r2 r3;
quit;
```

Logistic Regression

Suppose you want to analyze the relationship between the nominal dependent variable (r) and the independent variables (x1, x2) with a logistic regression analysis. Use maximum likelihood estimation:

```
proc catmod;
  weight wt;
  direct x1 x2;
  model r=x1 x2;
quit;
```

If x1 and x2 are continuous so that each observation has a unique value of these two variables, then it might be more appropriate to use the [LOGISTIC](#) or [GENMOD](#) procedure. (See the section “[Logistic Regression](#)” on page 1826.)

Repeated Measures Analysis

Suppose the dependent variables (r1, r2, r3) represent the same type of measurement taken at three different times. Analyze the relationship among the dependent variables, the repeated measurement factor (time), and the independent variable (a):

```
proc catmod;
  weight wt;
  response marginals;
  model r1*r2*r3=_response_|a;
  repeated time 3 / _response_=time;
quit;
```

Analysis of Variance

Suppose you want to investigate the relationship between the dependent variable (r) and the independent variables (a, b). Analyze the mean of the dependent variable, and include all main effects and interactions in the model:

```
proc catmod;
  weight wt;
  response mean;
  model r=a|b;
quit;
```

Linear Regression

PROC CATMOD can analyze the relationship between the dependent variables (r1, r2) and the independent variables (x1, x2). Use a linear regression analysis to analyze the marginal probabilities of the dependent variables:

```
proc catmod;
  weight wt;
  direct x1 x2;
  response marginals;
  model r1*r2=x1 x2;
quit;
```

Logistic Analysis of Ordinal Data

Suppose you want to analyze the relationship between the ordinally scaled dependent variable (r) and the independent variable (a). Use cumulative logits to take into account the ordinal nature of the dependent variable, and use weighted least squares estimation:

```
proc catmod;
  weight wt;
  response clogits;
  model r=_response_ a;
quit;
```

Sample Survey Analysis

Suppose the data set contains estimates of a vector of four functions and their covariance matrix, estimated in such a way as to correspond to the sampling process that is used. Analyze the functions with respect to the independent variables (a , b), and use a main-effects model:

```
proc catmod;
  response read b1-b10;
  model _f=_response_;
  factors a 2 , b 5 / _response_=a b;
quit;
```

Background: The Underlying Model

The CATMOD procedure analyzes data that can be represented by a two-dimensional contingency table. The rows of the table correspond to populations (or samples) formed on the basis of one or more independent variables. The columns of the table correspond to observed responses formed on the basis of one or more dependent variables. The frequency in the (i, j) cell is the number of subjects in the i th population that have the j th response. The frequencies in the table are assumed to follow a product multinomial distribution, corresponding to a sampling design in which a simple random sample is taken for each population. The contingency table can be represented as shown in [Table 30.1](#).

Table 30.1 Contingency Table Representation

Sample	Response				Total
	1	2	...	<i>r</i>	
1	n_{11}	n_{12}	...	n_{1r}	n_1
2	n_{21}	n_{22}	...	n_{2r}	n_2
\vdots	\vdots	\vdots	\ddots	\vdots	\vdots
s	n_{s1}	n_{s2}	...	n_{sr}	n_s

For each sample i , the probability of the j th response (π_{ij}) is estimated by the sample proportion, $p_{ij} = n_{ij}/n_i$. The vector (\mathbf{p}) of all such proportions is then transformed into a vector of functions, denoted by $\mathbf{F} = \mathbf{F}(\mathbf{p})$. If $\boldsymbol{\pi}$ denotes the vector of true probabilities for the entire table, then the functions of the true probabilities, denoted by $\mathbf{F}(\boldsymbol{\pi})$, are assumed to follow a linear model

$$\mathbf{E}_A(\mathbf{F}) = \mathbf{F}(\boldsymbol{\pi}) = \mathbf{X}\boldsymbol{\beta}$$

where \mathbf{E}_A denotes asymptotic expectation, \mathbf{X} is the design matrix containing fixed constants, and $\boldsymbol{\beta}$ is a vector of parameters to be estimated.

PROC CATMOD provides two estimation methods:

- The weighted least squares method minimizes the weighted residual sum of squares for the model. The weights are contained in the inverse covariance matrix of the functions $\mathbf{F}(\mathbf{p})$. According to central limit theory, if the sample sizes within populations are sufficiently large, the elements of \mathbf{F} and \mathbf{b} (the estimate of $\boldsymbol{\beta}$) are distributed approximately as multivariate normal. This allows the computation of statistics for testing the goodness of fit of the model and the significance of other sources of variation. For details of the theory, see Grizzle, Starmer, and Koch (1969) or Koch et al. (1977, Appendix 1). Weighted least squares estimation is available for all types of response functions.
- The maximum likelihood method estimates the parameters of the linear model so as to maximize the value of the joint multinomial likelihood function of the responses. Maximum likelihood estimation is available only for the standard response functions, logits and generalized logits, which are used for logistic regression analysis and log-linear model analysis. Two methods of maximization are available: Newton-Raphson and iterative proportional fitting. For details of the theory, see Bishop, Fienberg, and Holland (1975).

Following parameter estimation, hypotheses about linear combinations of the parameters can be tested. For that purpose, PROC CATMOD computes generalized Wald (1943) statistics, which are approximately chi-square distributed if the sample sizes are sufficiently large and the null hypotheses are true.

Linear Models Contrasted with Log-Linear Models

Linear model methods typified by the Grizzle, Starmer, and Koch (1969) approach make a very clear distinction between independent and dependent variables. The emphasis of these methods is estimation and hypothesis testing of the model parameters. Therefore, it is easy to test for differences among probabilities,

perform repeated measures analysis, and test for marginal homogeneity, but it is difficult to test for independence and generalized independence. These methods are a natural extension of the usual ANOVA approach for continuous data.

In contrast, log-linear model methods typified by the Bishop, Fienberg, and Holland (1975) approach do not make an a priori distinction between independent and dependent variables, although model specifications that allow for the distinction can be made. The emphasis of these methods is on model building, goodness-of-fit tests, and estimation of cell frequencies or probabilities for the underlying contingency table. With these methods, it is easy to test independence and generalized independence, but it is difficult to test for differences among probabilities, do repeated measures analysis, and test for marginal homogeneity.

Using PROC CATMOD Interactively

You can use the CATMOD procedure interactively. After specifying a model with a MODEL statement and running PROC CATMOD with a RUN statement, you can execute any statement without reinvoking PROC CATMOD. You can execute the statements singly or in groups by following the single statement or group of statements with a RUN statement. Note that you can use more than one MODEL statement; this is an important difference from the GLM procedure.

If you use PROC CATMOD interactively, you can end the CATMOD procedure with a DATA step, another PROC step, an ENDSAS statement, or a QUIT statement. The syntax of the QUIT statement is as follows:

```
quit;
```

When you are using PROC CATMOD interactively, additional RUN statements do not end the procedure run but tell the procedure to execute additional statements.

When the CATMOD procedure detects a BY statement, it disables interactive processing; that is, once the BY statement and the next RUN statement are encountered, processing proceeds for each BY group in the data set, and no additional statements are accepted by the procedure. For example, the following statements perform three analyses: one for the entire data set, one for males, and one for females:

```
proc catmod;
  weight wt;
  response marginals;
  model r1*r2=a|b;
run;
  by sex;
run;
```

Note that the BY statement can appear after the first RUN statement; this is an important difference from PROC GLM, which requires that the BY statement appear before the first RUN statement.

Getting Started: CATMOD Procedure

The CATMOD procedure is a general modeling procedure for categorical data analysis, and it can be used for sophisticated analyses that require matrix specification of the response function and the design matrix.

It can also be used to perform basic analysis-of-variance-type analyses that require only a few statements. The following is a basic example.

Weighted Least Squares Analysis of Mean Response

Consider the data in Table 30.2 (Stokes, Davis, and Koch 2000).

Table 30.2 Colds in Children

Sex	Residence	Periods with Colds			Total
		0	1	2	
Female	Rural	45	64	71	180
Female	Urban	80	104	116	300
Male	Rural	84	124	82	290
Male	Urban	106	117	87	310

For male and female children in rural and urban counties, the number of periods (of two) in which subjects report cold symptoms are recorded. So 45 subjects who are female and in rural counties report no cold symptoms, and 71 subjects who are female and from rural counties report colds in both periods.

The question of interest is whether the mean number of periods with colds reported is associated with gender or type of county. There is no reason to believe that the mean number of periods with colds is normally distributed, so a weighted least squares analysis of these data is performed with PROC CATMOD instead of an analysis of variance with PROC ANOVA or PROC GLM.

The input data for categorical data are often recorded in frequency form, with the counts for each particular profile being the input values. For the colds data, the input SAS data set colds is created with the following statements. The variable count contains the frequency of observations that have the particular profile described by the values of the other variables in that input line.

```
data colds;
  input sex $ residence $ periods count @@;
  datalines;
female rural 0 45 female rural 1 64 female rural 2 71
female urban 0 80 female urban 1 104 female urban 2 116
male rural 0 84 male rural 1 124 male rural 2 82
male urban 0 106 male urban 1 117 male urban 2 87
;
```

In order to fit a model to the mean number of periods with colds, you have to specify the response function in PROC CATMOD. The default response function is the logit if the response variable has two values, and it is generalized logits if the response variable has more than two values. If you want a different response function, then you specify that function in the **RESPONSE** statement. To request the mean number of periods with colds, you specify the **MEANS** option in the **RESPONSE** statement.

You can request a model consisting of the main effects and interaction of the variables **sex** and **residence** just as you would in the GLM procedure. Unlike the GLM procedure, PROC CATMOD does not require you to use a **CLASS** statement to treat a variable as a classification variable. In the CATMOD procedure, all variables in the **MODEL** statement are treated as classification variables unless you specify otherwise with

a **DIRECT** statement. To verify that your model is specified correctly, you can specify the **DESIGN** option in the **MODEL** statement to display the design matrix.

The PROC CATMOD statements needed to model mean periods of colds with a main-effects and interaction model are as follows:

```
proc catmod data=colds;
  weight count;
  response means;
  model periods = sex residence sex*residence / design;
run;
```

The results of this analysis are shown in [Figure 30.1](#) through [Figure 30.3](#).

In [Figure 30.1](#), the CATMOD procedure first displays a summary of the contingency table you are analyzing. The “Population Profiles” table lists the values of the explanatory variables that define each population, or row of the underlying contingency table, and labels each group with a sample number. The number of observations in each population is also displayed. The “Response Profiles” table lists the variable levels that define the response, or columns of the underlying contingency table.

Figure 30.1 Model Information and Profile Tables

The CATMOD Procedure			
Data Summary			
Response	periods	Response Levels	3
Weight Variable	count	Populations	4
Data Set	COLDS	Total Frequency	1080
Frequency Missing	0	Observations	12
Population Profiles			
Sample	sex	residence	Sample Size
1	female	rural	180
2	female	urban	300
3	male	rural	290
4	male	urban	310
Response Profiles			
Response	periods		
1	0		
2	1		
3	2		

The “Response Functions and Design Matrix” table in [Figure 30.2](#) contains the observed response functions—in this case, the mean number of periods with colds for each of the populations—and the design matrix. The first column of the design matrix contains the coefficients for the intercept parameter. The second column contains the coefficients for the sex parameter. (Note that the sum-to-zero constraint of the

default full-rank parameterization `PARAM=EFFECT` implies that the coefficient for males is the negative of that for females; the parameter is called the *differential effect* for females.) The third column is similarly set up for residence, and the last column is for the interaction.

Figure 30.2 Observed Response Functions and Design Matrix

Response Functions and Design Matrix					
Sample	Response Function	Design Matrix			
		1	2	3	4
1	1.14444	1	1	1	1
2	1.12000	1	1	-1	-1
3	0.99310	1	-1	1	-1
4	0.93871	1	-1	-1	1

The model-fitting results are displayed in the “Analysis of Variance” table (Figure 30.3), which is similar to an ANOVA table. The effects from the right side of the MODEL statement are listed in the Source column.

Figure 30.3 ANOVA Table for the Saturated Model

Analysis of Variance			
Source	DF	Chi-Square	Pr > ChiSq
Intercept	1	1841.13	<.0001
sex	1	11.57	0.0007
residence	1	0.65	0.4202
sex*residence	1	0.09	0.7594
Residual	0	.	.

You can see in Figure 30.3 that the interaction effect is nonsignificant, so the data are reanalyzed using a main-effects model. Since PROC CATMOD is an interactive procedure, you can analyze the main-effects model by simply submitting the new MODEL statement as follows. The resulting tables are displayed in Figure 30.4 and Figure 30.5.

```
model periods = sex residence / design;
run;
```

From the ANOVA table in Figure 30.4, you can see that the goodness-of-fit chi-square statistic is 0.09 with one degree of freedom and a *p*-value of 0.7594; hence, the model fits the data. Note that the chi-square tests in Figure 30.4 check whether all the parameters for a given effect are zero. In this model, each effect has only one parameter and therefore only one degree of freedom.

Figure 30.4 Main-Effects Model

The CATMOD Procedure				
Data Summary				
Response	periods	Response Levels	3	
Weight Variable	count	Populations	4

2	female	urban	300	
3	male	rural	290	
4	male	urban	310	
Response Profiles				
Response		periods		
1		0		
2		1		
3		2		
Response Functions and Design Matrix				
Sample	Response Function	Design Matrix		
		1	2	3
1	1.14444	1	1	1
2	1.12000	1	1	-1
3	0.99310	1	-1	1
4	0.93871	1	-1	-1
Analysis of Variance				
Source	DF	Chi-Square	Pr > ChiSq	
Intercept	1	1882.77	<.0001	
sex	1	12.08	0.0005	
residence	1	0.76	0.3839	
Residual	1	0.09	0.7594	

The “Analysis of Weighted Least Squares Estimates” table in [Figure 30.5](#) lists the parameters and their estimates for the model, as well as the standard errors, Wald statistics, and p -values. These chi-square tests are one-degree-of-freedom tests that the individual parameter is equal to zero. They are equal to the tests shown in [Figure 30.4](#) since each effect is composed of exactly one parameter.

Figure 30.5 Parameter Estimates for the Main-Effects Model

Analysis of Weighted Least Squares Estimates					
Parameter	Estimate	Standard Error	Chi-Square	Pr > ChiSq	
Intercept	1.0501	0.0242	1882.77	<.0001	
sex female	0.0842	0.0242	12.08	0.0005	
residence rural	0.0210	0.0241	0.76	0.3839	

You can compute the mean number of periods with colds for the first population (Sample 1, females in rural residences) from [Table 30.2](#) as follows:

$$\text{mean colds} = 0 \times \frac{45}{180} + 1 \times \frac{64}{180} + 2 \times \frac{71}{180} = 1.1444$$

This is the same value reported in the Response Function column for Sample 1 in the “Response Functions and Design Matrix” table displayed in [Figure 30.4](#).

PROC CATMOD is fitting a model to the mean number of colds in each population as follows:

$$\begin{bmatrix} \text{Expected number of colds for rural females} \\ \text{urban females} \\ \text{rural males} \\ \text{urban males} \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & 1 \\ 1 & -1 & -1 \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \end{bmatrix}$$

where the design matrix is the same one displayed in [Figure 30.4](#), β_0 is the mean number of colds averaged over all the populations, β_1 is the differential effect for females, and β_2 is the differential effect for rural residences. The parameter estimates are shown in [Figure 30.5](#); the expected number of periods with colds for rural females from this model is computed as

$$1 \times 1.0501 + 1 \times 0.0842 + 1 \times 0.0210 = 1.1553$$

and the expected number for rural males from this model is

$$1 \times 1.0501 - 1 \times 0.0842 + 1 \times 0.0210 = 0.9869$$

Notice also, in [Figure 30.5](#), that the differential effect for residence is nonsignificant ($p = 0.3839$). If you continue the analysis by fitting a single-effect model (sex), you need to include a **POPULATION** statement to maintain the same underlying contingency table:

```
population sex residence;
model periods = sex;
run;
```

Generalized Logits Model

Over the course of one school year, third-graders from three different schools are exposed to three different styles of mathematics instruction: a self-paced computer-learning style, a team approach, and a traditional

class approach. The students are asked which style they prefer, and their responses, classified by the type of program they are in (a regular school day versus a regular school day supplemented with an afternoon school program), are displayed in [Table 30.3](#). The data set is from Stokes, Davis, and Koch (2000), and it is also analyzed in the section “[Example 54.4: Nominal Response Data: Generalized Logits Model](#)” on page 4327 of Chapter 54, “[The LOGISTIC Procedure](#).”

Table 30.3 School Program Data

School	Program	Learning Style Preference		
		Self	Team	Class
1	Regular	10	17	26
1	Afternoon	5	12	50
2	Regular	21	17	26
2	Afternoon	16	12	36
3	Regular	15	15	16
3	Afternoon	12	12	20

The levels of the response variable (self, team, and class) have no essential ordering, so a logistic regression is performed on the generalized logits. The model to be fit is

$$\log \left(\frac{\pi_{hij}}{\pi_{hir}} \right) = \alpha_j + \mathbf{x}'_{hi} \boldsymbol{\beta}_j$$

where π_{hij} is the probability that a student in school h and program i prefers teaching style j , $j \neq r$, and style r is the class style. There are separate sets of intercept parameters α_j and regression parameters β_j for each logit, and the matrix \mathbf{x}_{hi} is the set of explanatory variables for the hi population. Thus, two logits are modeled for each school and program combination (population): the logit comparing self to class and the logit comparing team to class.

The following statements create the data set `school` and request the analysis. Generalized logits are the default response functions, and maximum likelihood estimation is the default method for analyzing generalized logits, so only the `WEIGHT` and `MODEL` statements are required. The option `ORDER=DATA` means that the response variable levels are ordered as they exist in the data set: self, team, and class; the logits are formed by comparing self to class and by comparing team to class. The results of this analysis are shown in [Figure 30.6](#) and [Figure 30.7](#).

```
data school;
  length Program $ 9;
  input School Program $ Style $ Count @@;
  datalines;
1 regular self 10 1 regular team 17 1 regular class 26
1 afternoon self 5 1 afternoon team 12 1 afternoon class 50
2 regular self 21 2 regular team 17 2 regular class 26
2 afternoon self 16 2 afternoon team 12 2 afternoon class 36
3 regular self 15 3 regular team 15 3 regular class 16
3 afternoon self 12 3 afternoon team 12 3 afternoon class 20
;
```

```
proc catmod order=data;
  weight Count;
  model Style=School Program School*Program;
run;
```

A summary of the data set is displayed in [Figure 30.6](#); the variable levels that form the three responses and six populations are listed in the “Response Profiles” and “Population Profiles” tables, respectively.

Figure 30.6 Model Information and Profile Tables

The CATMOD Procedure			
Data Summary			
Response	Style	Response Levels	3
Weight Variable	Count	Populations	6
Data Set	SCHOOL	Total Frequency	338
Frequency Missing	0	Observations	18
Population Profiles			
Sample	School	Program	Sample Size
1	1	regular	53
2	1	afternoon	67
3	2	regular	64
4	2	afternoon	64
5	3	regular	46
6	3	afternoon	44
Response Profiles			
Response	Style		
1	self		
2	team		
3	class		

The analysis of variance table is displayed in [Figure 30.7](#). Since this is a saturated model, there are no degrees of freedom remaining for a likelihood ratio test, and missing values are displayed in the table. The interaction effect is clearly nonsignificant, so a main-effects model is fit.

Figure 30.7 Saturated Model: ANOVA Table

Maximum Likelihood Analysis of Variance			
Source	DF	Chi-Square	Pr > ChiSq
Intercept	2	40.05	<.0001
School	4	14.55	0.0057
Program	2	10.48	0.0053
School*Program	4	1.74	0.7827
Likelihood Ratio	0	.	.

Since PROC CATMOD is an interactive procedure, you can analyze the main-effects model by simply submitting the new MODEL statement as follows:

```
model Style=School Program;
run;
```

You can check the population and response profiles (not shown) to confirm that they are the same as those in Figure 30.6. The analysis of variance table is shown in Figure 30.8. The likelihood ratio chi-square statistic is 1.78 with a p -value of 0.7766, indicating a good fit; the Wald chi-square tests for the school and program effects are also significant. Since School has three levels, two parameters are estimated for each of the two logits they modeled, for a total of four degrees of freedom. Since Program has two levels, one parameter is estimated for each of the two logits, for a total of two degrees of freedom.

Figure 30.8 Main-Effects Model: ANOVA Table

Maximum Likelihood Analysis of Variance			
Source	DF	Chi-Square	Pr > ChiSq
Intercept	2	39.88	<.0001
School	4	14.84	0.0050
Program	2	10.92	0.0043
Likelihood Ratio	4	1.78	0.7766

The parameter estimates and tests for individual parameters are displayed in Figure 30.9. The order of the parameters corresponds to the order of the population and response variables as shown in the profile tables (see Figure 30.6), with the levels of the response variables varying most rapidly. The first response function is the logit that compares self to class, and the corresponding parameters have Function Number=1. The second logit (Function Number=2) compares team to class. The School=1 parameters are the differential effects versus School=3 for their respective logits, and the School=2 parameters are likewise differential effects versus School=3. The Program parameters are the differential effects of ‘regular’ versus ‘afternoon’ for the two response functions.

Figure 30.9 Parameter Estimates

Analysis of Maximum Likelihood Estimates					
Parameter		Function Number	Estimate	Standard Error	Chi- Square Pr > ChiSq
Intercept		1	-0.7979	0.1465	29.65 <.0001
		2	-0.6589	0.1367	23.23 <.0001
School	1	1	-0.7992	0.2198	13.22 0.0003
	1	2	-0.2786	0.1867	2.23 0.1356
	2	1	0.2836	0.1899	2.23 0.1352
	2	2	-0.0985	0.1892	0.27 0.6028
Program	regular	1	0.3737	0.1410	7.03 0.0080
	regular	2	0.3713	0.1353	7.53 0.0061

The Program variable has nearly the same effect on both logits, while School=1 has the largest effect of the schools.

Syntax: CATMOD Procedure

The following statements are available in the CATMOD procedure:

```

PROC CATMOD < options > ;
  DIRECT < variables > ;
  MODEL response-effect = design-effects < / options > ;
  CONTRAST 'label' row-description < , ... , row-description > < / options > ;
  BY variables ;
  FACTORS factor-description < , ... , factor-description > < / options > ;
  LOGLIN effects < / option > ;
  POPULATION variables ;
  REPEATED factor-description < , ... , factor-description > < / options > ;
  RESPONSE < function > < / options > ;
  RESTRICT parameter=value < ... parameter=value > ;
  WEIGHT variable ;

```

You can use all of the statements in PROC CATMOD interactively. The first RUN statement executes all of the previous statements. Any subsequent RUN statement executes only those statements that appear between the previous RUN statement and the current one. However, if you specify a BY statement, interactive processing is disabled. That is, all statements through the following RUN statement are processed for each BY group in the data set, but no additional statements are accepted by the procedure.

If more than one CONTRAST statement appears between two RUN statements, all the CONTRAST statements are processed. If more than one RESPONSE statement appears between two RUN statements, then analyses associated with each RESPONSE statement are produced. For all other statements, there can be only one occurrence of the statement between any two RUN statements. For example, if there are two LOGLIN statements between two RUN statements, the first LOGLIN statement is ignored.

The PROC CATMOD and MODEL statements are required. If specified, the DIRECT statement must precede the MODEL statement. As a result, if you use the DIRECT statement interactively, you need to specify a MODEL statement in the same RUN group. See the section “[DIRECT Statement](#)” on page 1795 for an example.

The CONTRAST statements, if any, must follow the MODEL statement.

You can specify only one of the LOGLIN, REPEATED, and FACTORS statements between any two RUN statements, because they all specify the same information: how to partition the variation among the response functions within a population.

A QUIT statement executes any statements that have not been processed and then ends the CATMOD procedure run.

The purpose of each statement, other than the PROC CATMOD statement, is summarized in the following list:

BY	determines groups in which data are to be processed separately.
CONTRAST	specifies a hypothesis to test.
DIRECT	specifies independent variables that are to be treated quantitatively (like continuous variables) rather than qualitatively (like classification or discrete variables). These variables also help to determine the rows of the contingency table and distinguish response functions in one population from those in other populations.
FACTORS	specifies (1) the factors that distinguish response functions from others in the same population and (2) model effects, based on these factors, which help to determine the design matrix.
LOGLIN	specifies log-linear model effects.
MODEL	specifies (1) dependent variables, which determine the columns of the contingency table, (2) independent variables, which distinguish response functions in one population from those in other populations, and (3) model effects, which determine the design matrix and the way in which total variation among the response functions is partitioned.
POPULATION	specifies variables that determine the rows of the contingency table and distinguish response functions in one population from those in other populations.
REPEATED	specifies (1) the repeated measurement factors that distinguish response functions from others in the same population and (2) model effects, based on these factors, which help to determine the design matrix.
RESPONSE	determines the response functions that are to be modeled.
RESTRICT	restricts values of parameters to the values you specify.
WEIGHT	specifies a variable containing frequency counts.

PROC CATMOD Statement

PROC CATMOD < options > ;

The PROC CATMOD statement invokes the CATMOD procedure. [Table 30.4](#) summarizes the options available in the PROC CATMOD statement.

Table 30.4 PROC CATMOD Statement Options

Option	Description
DATA=	Names the input SAS data set
NAMELEN=	Specifies the length of effect names
NOPRINT	Suppresses the normal display of results
ORDER=	Specifies the sort order for the levels of classification variables

You can specify the following options.

DATA=SAS-data-set

names the SAS data set containing the data to be analyzed. By default, the CATMOD procedure uses the most recently created SAS data set. For details, see the section “[Input Data Sets](#)” on page 1818.

NAMELEN=*n*

specifies the length of effect names in tables and output data sets to be *n* characters long, where *n* is a value between 24 and 200. The default length is 24 characters.

NOPRINT

suppresses the normal display of results. The NOPRINT option is useful when you only want to create output data sets with the **OUT=** or **OUTEST=** option in the **RESPONSE** statement. A **NOPRINT** option is also available in the **MODEL** statement. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, “[Using the Output Delivery System](#),” for more information.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of classification variables. This affects the ordering of the populations, responses, and parameters, as well as the definitions of the parameters. The default, **ORDER=INTERNAL**, orders the variable levels by their unformatted values (for example, numeric order or alphabetical order).

The following table shows how PROC CATMOD interprets values of the **ORDER=** option.

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, **ORDER=INTERNAL**. For **ORDER=FORMATTED** and **ORDER=INTERNAL**, the sort order is machine dependent. See the section “[Ordering of Populations and Responses](#)” on page 1821 for more information and examples. For more information about sort order, see the chapter on the **SORT** procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC CATMOD to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the CATMOD procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

You can specify one or more *variables* in the input data set on the BY statement.

When you specify a BY statement with PROC CATMOD, no further interactive processing is possible. In other words, once the BY statement appears, all statements up to the associated RUN statement are executed for each BY group in the data set. After the RUN statement, no further statements are accepted by the procedure.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CONTRAST Statement

CONTRAST *'label'* *row-description* < , ... , *row-description* > < / *options* > ;

where a *row-description* is defined as follows:

< @*n* > *effect values* < ... < @*n* > *effect values* >

The CONTRAST statement constructs and tests linear functions of the parameters in the MODEL statement or effects listed in the LOGLIN statement. Each set of effects (separated by commas) specifies one row or set of rows of the matrix **C** that PROC CATMOD uses to test the hypothesis $C\beta = 0$.

CONTRAST statements must be preceded by the MODEL statement, and by the LOGLIN statement, if one is used. You can specify the following terms in the CONTRAST statement.

'label' specifies up to 256 characters of identifying information displayed with the test. The *'label'* is required.

effect is one of the effects specified in the MODEL or [LOGLIN](#) statement, INTERCEPT (for the intercept parameter), or ALL_PARMS (for the complete set of parameters).

The ALL_PARMS option is regarded as an effect with the same number of parameters as the number of columns in the design matrix. This is particularly useful when the design matrix is input directly, as in the following example:

```
model y=(1 0 0 0,
          1 0 1 0,
          1 1 0 0,
          1 1 1 1);
contrast 'Main Effect of B' all_parms 0 1 0 0;
contrast 'Main Effect of C' all_parms 0 0 1 0;
contrast 'B*C Interaction ' all_parms 0 0 0 1;
```

values are numbers that form the coefficients of the parameters associated with the given effect. If there are fewer values than parameters for an effect, the remaining coefficients become zero. For example, if you specify two values and the effect actually has five parameters, the final three are set to zero.

@n points to the parameters in the *n*th set when the model has a separate set of parameters for each of the response functions. The *@n* notation is seldom needed. It enables you to test the variation among response functions in the same population. However, it is usually easier to model and test such variation by using the `_RESPONSE_` effect in the MODEL statement or by using the ALL_PARMS designation. Usually, contrasts are performed with respect to all of the response functions, and this is what the CONTRAST statement does by default (in this case, do not use the *@n* notation).

For example, if there are three response functions per population, then the following contrast results in a three-degree-of-freedom test comparing the first two levels of A simultaneously on the three response functions.

```
contrast 'Level 1 vs. Level 2' A 1 -1 0;
```

If, however, you want to specify a contrast with respect to the parameters in the *n*th set only, then use a single *@n* in a *row-description*. For example, the following statement tests that the first parameter of A and the first parameter of B are zero in the third response function:

```
contrast 'A=0, B=0, Function 3' @3 A 1 B 1;
```

To specify a contrast with respect to parameters in two or more different sets of effects, use *@n* with each effect. For example:

```
contrast 'Average over Functions' @1 A 1 0 -1
                                @2 A 1 1 -2;
```

When the model does not have a separate set of parameters for each of the response functions, the *@n* notation is invalid. This type of model is called AVERAGED. For details, see the description of the [AVERAGED](#) option and the section “[Generation of the Design Matrix](#)” on page 1832.

You can specify the following options in the CONTRAST statement after a slash.

ALPHA=*value*

specifies the significance level of the confidence interval for each contrast when the **ESTIMATE=** option is specified. The default is ALPHA=0.05, resulting in a 95% confidence interval for each contrast.

ESTIMATE=*keyword*

EST=*keyword*

requests that each individual contrast (that is, each row, $c_i\beta$, of $C\beta$) or exponentiated contrast ($\exp(c_i\beta)$) be estimated and tested. PROC CATMOD displays the point estimate, its standard error, a Wald confidence interval, and a Wald chi-square test for each contrast. The significance level of the confidence interval is controlled by the **ALPHA=** option.

You can estimate the contrast or the exponentiated contrast, or both, by specifying one of the following keywords:

PARM	specifies that the contrast itself be estimated.
EXP	specifies that the exponentiated contrast be estimated.
BOTH	specifies that both the contrast and the exponentiated contrast be estimated.

Specifying Contrasts

PROC CATMOD is parameterized differently than PROC GLM, so you must be careful not to use the same contrasts that you would with PROC GLM. Since PROC CATMOD uses full-rank parameterizations, all estimable parameters are directly estimable without involving other parameters.

For example, suppose a classification variable **A** has four levels and uses the default parameterization (**PARAM=EFFECT**). Then there are four parameters ($\alpha_1, \alpha_2, \alpha_3, \alpha_4$), of which PROC CATMOD uses only the first three. The fourth parameter is related to the others by the equation

$$\alpha_4 = -\alpha_1 - \alpha_2 - \alpha_3$$

To test the first versus the fourth level of **A**, you would test $\alpha_1 = \alpha_4$, which is

$$\alpha_1 = -\alpha_1 - \alpha_2 - \alpha_3$$

or, equivalently,

$$2\alpha_1 + \alpha_2 + \alpha_3 = 0$$

Therefore, you would use the following CONTRAST statement:

```
contrast '1 vs. 4' A 2 1 1;
```

To contrast the third level with the average of the first two levels, you would test

$$\frac{\alpha_1 + \alpha_2}{2} = \alpha_3$$

or, equivalently,

$$\alpha_1 + \alpha_2 - 2\alpha_3 = 0$$

Therefore, you would use the following CONTRAST statement:

```
contrast '1&2 vs. 3' A 1 1 -2;
```

Other CONTRAST statements are constructed similarly. For example:

```
contrast '1 vs. 2' A 1 -1 0;
contrast '1&2 vs. 4' A 3 3 2;
contrast '1&2 vs. 3&4' A 2 2 0;
contrast 'Main Effect' A 1 0 0,
                      A 0 1 0,
                      A 0 0 1;
```

The actual form of the C matrix depends on the effects in the model. The remaining examples in this section assume a single response function for each population.

Recall that the statements to test the first versus the fourth level of A are as follows:

```
proc catmod;
  model y=a;
  contrast '1 vs. 4' A 2 1 1;
run;
```

Since the first parameter corresponds to the intercept, the C matrix for the preceding statements is

$$C = [0 \ 2 \ 1 \ 1]$$

But suppose you have a variable B with three levels and you use the following statements:

```
proc catmod;
  model y=b a;
  contrast '1 vs. 4' A 2 1 1;
run;
```

Then the CONTRAST statement produces the C matrix

$$C = [0 \ 0 \ 0 \ 2 \ 1 \ 1]$$

since the first parameter corresponds to the intercept and the next two correspond to the B main effect.

You can also use the CONTRAST statement to test the joint effect of two or more effects in the MODEL statement. For example, the joint effect of A and B in the previous model has five degrees of freedom and is obtained by specifying the following:

```
contrast 'Joint Effect of A&B' A 1 0 0,
                                A 0 1 0,
                                A 0 0 1,
                                B 1 0,
                                B 0 1;
```

The ordering of variable levels is determined by the **ORDER=** option in the PROC CATMOD statement. Whenever you specify a contrast that depends on the order of the variable levels, you should verify the order from the “Population Profiles” table, the “Response Profiles” table, or the “One-Way Frequencies” table.

DIRECT Statement

DIRECT *variables* ;

The DIRECT statement lists numeric independent variables to be treated in a quantitative, rather than qualitative, way. The DIRECT statement is useful for logistic regression, which is described in the section “[Logistic Regression](#)” on page 1826. For limitations of models involving continuous variables, see the section “[Continuous Variables](#)” on page 1827.

CAUTION: If a DIRECT variable is formatted, then the unformatted (internal) values are used in the analysis and the formatted values are displayed. If you use a format to group the internal values into one formatted value, then the first internal value is used in the analysis. If specified, the DIRECT statement must precede the MODEL statement. For example:

```
proc catmod;
  direct X;
  model Y=X;
run;
```

Suppose X has five levels. Then the main effect X adds only one column to the design matrix rather than four. The values inserted into the design matrix are the actual values of X.

You can interactively change the variables declared as DIRECT variables by using the statement without listing any variables. The following statements are valid:

```
proc catmod;
  direct X;
  model Y=X;
  weight wt;
run;
direct;
model Y=X;
run;
```

The first MODEL statement uses the actual values of X, and the second MODEL statement uses the four variables created when PROC CATMOD generates the design matrix. Note that the preceding statements can be run without a **WEIGHT** statement if the input data are raw data rather than cell counts.

For more details, see the discussions of main and direct effects in the section “[Generation of the Design Matrix](#)” on page 1832.

FACTORS Statement

FACTORS *factor-description* < , . . . , *factor-description* > < / *options* > ;

where a *factor-description* is defined as follows:

factor-name < \$ > < *levels* >

and *factor-descriptions* are separated from each other by a comma. The \$ is required for character-valued factors. The value of *levels* provides the number of levels of the factor identified by a given *factor-name*. For only one factor, *levels* is optional; for two or more factors, it is required.

The FACTORS statement identifies factors that distinguish response functions from others in the same population. It also specifies how those factors are incorporated into the model. You can use the FACTORS statement whenever there is more than one response function per population and the keyword `_RESPONSE_` is specified in the MODEL statement. You can specify the name, type, and number of levels of each factor and the identification of each level.

The FACTORS statement is most useful when the response functions and their covariance matrix are read directly from the input data set. In this case, PROC CATMOD reads the response functions as though they are from one population (this poses no problem in the multiple-population case because the appropriately constructed covariance matrix is also read directly). Thus, you can use the FACTORS statement to partition the variation among the response functions into appropriate sources, even when the functions actually represent separate populations.

The format of the FACTORS statement is identical to that of the [REPEATED](#) statement. In fact, repeated measurement factors are simply special cases of factors in which some of the response functions correspond to multiple dependent variables that are measurements on the same experimental (or sampling) units.

You cannot specify the FACTORS statement for an analysis that also contains the [REPEATED](#) or [LOGLIN](#) statement since all of them specify the same information: how to partition the variation among the response functions within a population.

You can specify the following terms in the FACTORS statement:

<i>factor-name</i>	names a factor that corresponds to two or more response functions. This name must be a valid SAS variable name, and it should not be the same as the name of a variable that already exists in the data set being analyzed.
\$	indicates that the factor is character-valued. If the \$ is omitted, then the CATMOD procedure assumes that the factor is numeric. The type of the factor is relevant only when you use the <code>PROFILE=</code> option or when the <code>_RESPONSE=</code> option (described later in this section) specifies nested-by-value effects.
<i>levels</i>	specifies the number of levels of the corresponding factor. If there is only one such factor, and the number is omitted, then PROC CATMOD assumes that the number of levels is equal to the number of response functions per population (<i>q</i>). Unless you specify the <code>PROFILE=</code> option, the number <i>q</i> must either be equal to or be a multiple of the product of the number of levels of all the factors.

You can specify the following options in the FACTORS statement after a slash.

PROFILE=(matrix)

specifies the values assumed by the factors for each response function. There should be one column for each factor, and the values in a given column (character or numeric) should match the type of the corresponding factor. Character values are restricted to 16 characters or less. If there are q response functions per population, then the matrix must have i rows, where q must either be equal to or be a multiple of i . Adjacent rows of the matrix should be separated by a comma.

The values in the PROFILE matrix are useful for specifying models in those situations where the study design is not a full factorial with respect to the factors. They can also be used to specify nested-by-value effects in the `_RESPONSE=` option. If you specify character values in both places (the PROFILE= option and the `_RESPONSE=` option), then the values must match with respect to whether or not they are enclosed in quotes (that is, enclosed in quotes in both places or in neither place).

For an example of using the PROFILE= option, see [Example 30.10](#).

_RESPONSE=effects

specifies design effects. The variables named in the effects must be *factor-names* that appear in the FACTORS statement. If the `_RESPONSE=` option is omitted, then PROC CATMOD builds a full factorial `_RESPONSE_` effect with respect to the factors.

TITLE='title'

displays the *title* at the top of certain pages of output that correspond to the current FACTORS statement.

For an example of how the FACTORS statement is useful, consider the case where the response functions and their covariance matrix are read directly from the input data set. The TYPE=EST data set might be created in the following manner:

```
data direct (type=est);
  input b1-b4 _type_ $ _name_ $8.;
  datalines;
0.590463    0.384720    0.273269    0.136458    parms    .
0.001690    0.000911    0.000474    0.000432    cov      b1
0.000911    0.001823    0.000031    0.000102    cov      b2
0.000474    0.000031    0.001056    0.000477    cov      b3
0.000432    0.000102    0.000477    0.000396    cov      b4
;
```

Suppose the response functions correspond to four populations that represent the cross-classification of age (two groups) by sex. You can use the FACTORS statement to identify these two factors and to name the effects in the model. The statements required to fit a main-effects model to these data are as follows:

```
proc catmod data=direct;
  response read b1-b4;
  model _f=_response_;
  factors age 2, sex 2 / _response_=age sex;
run;
```

If you want to specify some nested-by-value effects, you can change the FACTORS statement to the following:

```
factors age $ 2, sex $ 2 /
  _response_=age sex(age='under 30') sex(age='30 & over')
  profile=('under 30'   male,
           'under 30'   female,
           '30 & over'  male,
           '30 & over'  female);
```

If, by design or by chance, the study contains no male subjects under 30 years of age, then there are only three response functions, and you can specify a main-effects model as follows:

```
proc catmod data=direct;
  response read b2-b4;
  model _f=_response_;
  factors age $ 2, sex $ 2 / _response_=age sex
    profile=('under 30'   female,
             '30 & over'  male,
             '30 & over'  female);
run;
```

When you specify two or more factors and omit the PROFILE= option, PROC CATMOD presumes that the response functions are ordered so that the levels of the rightmost factor change most rapidly. For the preceding example, the order implied by the FACTORS statement is as follows:

Response Function	Dependent Variable	Age	Sex
1	b1	1	1
2	b2	1	2
3	b3	2	1
4	b4	2	2

For additional examples of how to use the FACTORS statement, see the section “[Repeated Measures Analysis](#)” on page 1830. All of the examples in that section are applicable, with the REPEATED statement replaced by the FACTORS statement.

LOGLIN Statement

LOGLIN *effects* < / *option* > ;

The LOGLIN statement is used to define log-linear model effects. It can be used whenever the default response functions (generalized logits) are used.

In the LOGLIN statement, *effects* are design effects that contain dependent variables in the MODEL statement, including interaction, nested, and nested-by-value effects. You can use the bar (|) and at (@) operators as well. The following lists of effects are equivalent:

a b c a*b a*c b*c

and

a|b|c @2

When you use the LOGLIN statement, the keyword `_RESPONSE_` should be specified in the MODEL statement. For further information about log-linear model analysis, see the section “[Log-Linear Model Analysis](#)” on page 1827.

You cannot specify the LOGLIN statement for an analysis that also contains the [REPEATED](#) or [FACTORS](#) statement since all of them specify the same information: how to partition the variation among the response functions within a population.

You can specify the following option in the LOGLIN statement after a slash.

TITLE=*'title'*

displays the *title* at the top of certain pages of output that correspond to this LOGLIN statement.

The following statements give an example of how to use the LOGLIN statement:

```
proc catmod;
  model a*b*c=_response_;
  loglin a|b|c @ 2;
run;
```

These statements yield a log-linear model analysis that contains all main effects and two-variable interactions. For more examples of log-linear model analysis, see the section “[Log-Linear Model Analysis](#)” on page 1827.

MODEL Statement

MODEL *response-effect* = < *design-effects* > < / *options* > ;

PROC CATMOD requires a MODEL statement. You can specify the following in a MODEL statement:

response-effect can be either a single variable, a crossed effect with two or more variables joined by asterisks, or `_F_`. The `_F_` specification indicates that the response functions and their estimated covariance matrix are to be read directly into the procedure (see the section “[Inputting Response Functions and Covariances Directly](#)” on page 1820 for details). The *response-effect* indicates the dependent variables that determine the response categories (the columns of the underlying contingency table).

design-effects specify potential sources of variation (such as main effects and interactions) in the model. These effects determine the number of model parameters, as well as the interpretation of such parameters. In addition, if there is no [POPULATION](#) statement, PROC CATMOD uses these variables to determine the populations (the rows of the underlying contingency table). When fitting the model, PROC CATMOD adjusts the independent effects in the model for all other independent effects in the model.

Design-effects can be any of those described in the section “[Specification of Effects](#)” on page 1822, or they can be defined by specifying the actual design matrix, enclosed in

parentheses (see the section “[Specifying the Design Matrix Directly](#)” on page 1806). In addition, you can use the keyword `_RESPONSE_` alone or as part of an effect. Effects cannot be nested within `_RESPONSE_`, so effects of the form `A(_RESPONSE_)` are invalid.

For more information, see the section “[Log-Linear Model Analysis](#)” on page 1827 and the section “[Repeated Measures Analysis](#)” on page 1830.

Some example MODEL statements are shown in the following table:

Example	Result
<code>model r=a b;</code>	Main effects only
<code>model r=a b a*b;</code>	Main effects with interaction
<code>model r=a b(a);</code>	Nested effect
<code>model r=a b;</code>	Complete factorial
<code>model r=a b(a=1) b(a=2);</code>	Nested-by-value effects
<code>model r*s=_response_;</code>	Log-linear model
<code>model r*s=a _response_(a);</code>	Nested repeated measurement factor
<code>model _f=_response_;</code>	Direct input of the response functions

The relationship between these specifications and the structure of the design matrix **X** is described in the section “[Generation of the Design Matrix](#)” on page 1832.

Table 30.5 summarizes the options available in the MODEL statement.

Table 30.5 MODEL Statement Options

Options	Task
Specify details of computation	
<code>ML=</code>	Generates the maximum likelihood estimates
<code>GLS</code>	Generates the weighted least squares estimates
<code>WLS</code>	
<code>NOINT</code>	Omits the intercept term from the model
<code>PARAM=</code>	Specifies the parameterization of classification variables
<code>ADDCELL=</code>	Adds a number to each cell frequency
<code>AVERAGED</code>	Averages the main effects across response functions
<code>EPSILON=</code>	Specifies the convergence criterion for maximum likelihood
<code>MAXITER=</code>	Specifies the number of iterations for maximum likelihood
<code>MISSING=</code>	Specifies how missing cells are treated
<code>ZERO=</code>	Specifies how zero cells are treated

Table 30.5 *continued*

Options	Task
Request additional computation and tables	
ALPHA=	Specifies the significance level of confidence intervals
CLPARM	Displays the Wald confidence intervals of estimates
CORRB	Displays the estimated correlation matrix of estimates
COV	Displays the covariance matrix of response functions
COVB	Displays the estimated covariance matrix of estimates
DESIGN	Displays the design and _RESPONSE_ matrix
FREQ	Displays the two-way frequency tables
ITPRINT	Displays the iterations for maximum likelihood
ONEWAY	Displays the one-way frequency tables
PRED=	Displays the predicted values
PREDICT	
PROB	Displays the probability estimates
PROFILE	Displays the population profiles
XPX	Displays the crossproducts matrix
TITLE=	Specifies the title
Suppress output	
NODESIGN	Suppresses the design matrix
NOPARM	Suppresses the parameter estimates
NOPREDVAR	Suppresses the variable levels
NOPROFILE	Suppresses the population and response profiles
NORESPONSE	Suppresses the _RESPONSE_ matrix

The following list describes these options in alphabetical order.

ADDCELL=number

adds *number* to the frequency count in each cell, where *number* is any positive number. This option has no effect on maximum likelihood analysis; it is used only for weighted least squares analysis.

ALPHA=number

sets the significance level for the Wald confidence intervals for parameter estimates. The value must be between 0 and 1. The default value of 0.05 results in the calculation of a 95% confidence interval. This option has no effect unless the **CLPARM** option is also specified.

AVERAGED

specifies that dependent variable effects can be modeled and that independent variable main effects are averaged across the response functions in a population. For further information about the effect of using (or not using) the **AVERAGED** option, see the section “[Generation of the Design Matrix](#)” on page 1832. Direct input of the design matrix or specification of the **_RESPONSE_** keyword in the MODEL statement automatically uses an **AVERAGED** model type.

CLPARM

produces Wald confidence limits for the parameter estimates. The confidence coefficient can be specified with the **ALPHA=** option.

CORRB

displays the estimated correlation matrix of the parameter estimates.

COV

displays S_i , which is the covariance matrix of the response functions for each population.

COVB

displays the estimated covariance matrix of the parameter estimates.

DESIGN

displays the design matrix **X** for WLS and ML analyses, and also displays the **_RESPONSE_** matrix for log-linear models. For further information, see the section “[Generation of the Design Matrix](#)” on page 1832.

EPSILON=number

specifies the convergence criterion for the maximum likelihood estimation of the parameters. The iterative estimation process stops when the proportional change in the log likelihood is less than *number*, or after the number of iterations specified by the [MAXITER=](#) option, whichever comes first. By default, EPSILON=1E-8.

FREQ

produces the two-way frequency table for the cross-classification of populations by responses.

ITPRINT

displays parameter estimates and other information at each iteration of a maximum likelihood analysis.

MAXITER=number

specifies the maximum number of iterations used for the maximum likelihood estimation of the parameters. By default, MAXITER=20.

ML <= NR | IPF<(ipf-options)>

computes maximum likelihood estimates (MLE) by using either a Newton-Raphson algorithm (NR) or an iterative proportional fitting algorithm (IPF).

The option ML=NR (or simply ML) is available when you use generalized logits, and also when you perform binary logistic regression with logits, cumulative logits, or adjacent category logits. For generalized logits (the default response functions), ML=NR is the default estimation method.

The option ML=IPF is available for fitting a hierarchical log-linear model with one population (no independent variables and no population variables). The use of bar notation to express the log-linear effects guarantees that the model is hierarchical (the presence of any interaction term in the model requires the presence of all its lower-order terms). If your table is *incomplete* (that is, your table has a zero or missing entry in at least one cell), then all missing cells and all cells with zero weight are treated as structural zeros by default; this behavior can be modified with the [ZERO=](#) and [MISSING=](#) options in the MODEL statement.

You can control the convergence of the two algorithms with the [EPSILON=](#) and [MAXITER=](#) options in the MODEL statement. You can select the convergence criterion for the IPF algorithm with the [CONVCRT=](#) option.

NOTE: The [RESTRICT](#) statement is not available with the ML=IPF option.

You can specify the following *ipf-options* within parentheses after the ML=IPF option.

CONVCRT=keyword

specifies the method that determines when convergence of the IPF algorithm occurs. You can specify one of the following *keywords*:

CELL	termination requires the maximum absolute difference between consecutive cell estimates to be less than 0.001 (or the value of the EPSILON= option, if specified).
LOGL	termination requires the relative difference between consecutive estimates of the log likelihood to be less than $1\text{E}-8$ (or the value of the EPSILON= option, if specified). This is the default.
MARGIN	termination requires the maximum absolute difference between consecutive margin estimates to be less than 0.001 (or the value of the EPSILON= option, if specified).

DF=keyword

specifies the method used to compute the degrees of freedom for the goodness-of-fit G^2 test (labeled “Likelihood Ratio” in the “Estimates” table).

For a *complete* table (a table having nonzero entries in every cell), the degrees of freedom are calculated as the number of cells in the table (n_c) minus the number of independent parameters specified in the model (n_p). For incomplete tables, these degrees of freedom can be adjusted by the number of fitted zeros (n_z , which includes the number of structural zeros) and the number of nonestimable parameters due to the zeros (n_n). If you are analyzing an incomplete table, you should verify that the degrees of freedom are correct.

You can specify one of the following *keywords*:

UNADJ	computes the unadjusted degrees of freedom as $n_c - n_p$. These are the same degrees of freedom you would get if all cells in the table were positive.
ADJ	computes the degrees of freedom as $(n_c - n_p) - (n_z - n_n)$ (Bishop, Fienberg, and Holland 1975), which adjusts for fitted zeros and nonestimable parameters. This is the default, and for complete tables it gives the same results as the UNADJ option.
ADJEST	computes the degrees of freedom as $(n_c - n_p) - n_z$, which adjusts for fitted zeros only. This gives a lower bound on the true degrees of freedom.

PARM

computes parameter estimates, generates the “ANOVA,” “Parameter Estimates,” and “Predicted Values of Response Functions” tables, and includes the predicted standard errors in the “Predicted Values of Frequencies and Probabilities” tables.

When you specify the PARM option, the algorithm used to obtain the maximum likelihood parameter estimates is weighted least squares on the IPF-predicted frequencies. This algorithm can be much faster than the Newton-Raphson algorithm that is used if you specify the **ML=NR** option. In the resulting ANOVA table, the likelihood ratio is computed from the initial IPF fit while the degrees of freedom are generated from the WLS analysis; the **DF=** option can override this. Also, the initial response function, which the WLS method usually computes from the raw data, is computed from the IPF-predicted frequencies.

If there are any zero marginals in the configurations that define the model, then there are predicted cell frequencies of zero and WLS cannot be used to compute the estimates. In this case, PROC CATMOD automatically changes the algorithm from ML=IPF to ML=NR and prints a note in the log.

MISSING=*keyword*

MISS=*keyword*

specifies whether a missing cell is treated as a sampling or structural zero.

Structural zero cells are removed from the analysis since their expected values are zero, while sampling zero cells can have nonzero expected value and might be estimable. For a single population, the missing cells are treated as structural zeros by default. For multiple populations, as long as some population has a nonzero count for a given population and response profile, the missing values are treated as sampling zeros by default.

The following table displays the available *keywords* and summarizes how PROC CATMOD treats missing values for one or more populations:

MISSING=	One Population	Multiple Populations
STRUCTURAL (default)	Structural zeros	Sampling zeros
SAMP SAMPLING <i>value</i>	Sampling zeros Sets missing weights and cells to <i>value</i>	Sampling zeros Sets missing weights and cells to <i>value</i>

NODESIGN

suppresses the display of the design matrix **X** when the **DESIGN** option is also specified. This enables you to display only the **_RESPONSE_** matrix for log-linear models.

NOINT

suppresses the intercept term in the model.

NOPARM

suppresses the display of the estimated parameters and the statistics for testing that each parameter is zero.

NOPREDVAR

suppresses the display of the variable levels in tables requested with the **PRED=** option and in the “Estimates” table. Population profiles are replaced with the sample number, classification variable levels are suppressed, and response profiles are replaced with a function number.

NOPRINT

suppresses the normal display of results. The NOPRINT option is useful when you only want to create output data sets with the **OUT=** or **OUTEST=** option in the **RESPONSE** statement. A NOPRINT option is also available in the PROC CATMOD statement. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, “Using the Output Delivery System,” for more information.

NOPROFILE

suppresses the display of the population profiles and the response profiles.

NORESPONSE

suppresses the display of the `_RESPONSE_` matrix for log-linear models when the [DESIGN](#) option is also specified. This enables you to display only the design matrix for log-linear models.

ONEWAY

produces a one-way table of frequencies for each variable used in the analysis. This table is useful in determining the order of the observed levels for each variable.

PARAM=EFFECT | REFERENCE

specifies the parameterization method for the classification variable or variables. The default is `PARAM=EFFECT`. Both the effect and reference parameterizations are full rank. See the section [“Generation of the Design Matrix”](#) on page 1832 for further details.

PREDICT**PRED=FREQ | PROB**

displays the observed and predicted values of the response functions for each population, together with their standard errors and the residuals (observed minus predicted). In addition, if the response functions are the standard ones (generalized logits), then the `PRED=FREQ` option specifies the computation and display of predicted cell frequencies, while `PRED=PROB` (or just `PREDICT`) specifies the computation and display of predicted cell probabilities.

The `OUT=` data set always contains the predicted probabilities. If the response functions are the generalized logits, the predicted cell probabilities are output unless the option `PRED=FREQ` is specified, in which case the predicted cell frequencies are output.

PROB

produces the two-way table of probability estimates for the cross-classification of populations by responses. These estimates sum to one across the response categories for each population.

PROFILE

displays all of the population profiles. If you have more than 60 populations, then by default only the first 40 profiles are displayed; the `PROFILE` option overrides this default behavior.

TITLE='title'

displays the *title* at the top of certain pages of output that correspond to this MODEL statement.

WLS**GLS**

computes weighted least squares estimates. This type of estimation is also called generalized least squares estimation. For response functions other than the default (of generalized logits), WLS is the default estimation method.

XPX

displays $X'S^{-1}X$, the crossproducts matrix for the normal equations.

ZERO=keyword

specifies whether a nonmissing cell with zero weight in the data set is treated as a sampling or structural zero.

Structural zero cells are removed from the analysis since their expected values are zero, while sampling zero cells have nonzero expected value and might be estimable. For a single population, the zero

cells are treated as structural zeros by default; with multiple populations, as long as some population has a nonzero count for a given population and response profile, the zeros are treated as sampling zeros by default.

The following table displays the available *keywords* and summarizes how PROC CATMOD treats zeros for one or more populations:

ZERO=	One Population	Multiple Populations
STRUCTURAL (default)	Structural zeros	Sampling zeros
SAMP SAMPLING	Sampling zeros	Sampling zeros
<i>value</i>	Sets zero weights to <i>value</i>	Sets zero weights to <i>value</i>

The preceding statements are appropriate when Group and Time each have three levels and R is dichotomous. The **POPULATION** statement produces nine populations, and $q = 1$ (since R is dichotomous), so $q \times s = 1 \times 9 = 9$.

If you input the design matrix directly but do not specify any subsets of the parameters to be tested, then PROC CATMOD tests the effect of MODEL | MEAN, which represents the significance of the model beyond what is explained by an overall mean. For the previous example, the MODEL | MEAN effect is the same as that obtained by specifying the following at the end of the MODEL statement:

```
(2 3 4='model|mean');
```

POPULATION Statement

POPULATION *variables* ;

The POPULATION statement specifies that populations are to be based only on cross-classifications of the specified *variables*. If you do not specify the POPULATION statement, then populations are based only on cross-classifications of the independent variables in the MODEL statement.

The POPULATION statement has two major uses:

- When you enter the design matrix directly, there are no independent variables in the MODEL statement; therefore, the POPULATION statement is the only way to produce more than one population.
- When you fit a reduced model, the POPULATION statement might be necessary if you want to form the same number of populations as there are for the saturated model.

To illustrate the first use, suppose you specify the following statements:

```
data one;
  input A $ B $ wt @@;
  datalines;
yes yes 23   yes no 31   no yes 47   no no 50
;

proc catmod;
  weight wt;
  population B;
  model A=(1 0,
           1 1);
run;
```

Since the dependent variable A has two levels, there is one response function per population. Since the variable B has two levels, there are two populations. The MODEL statement is valid since the number of rows in the design matrix (2) is the same as the total number of response functions. If the POPULATION statement is omitted, there would be only one population and one response function, and the MODEL statement would be invalid.

To illustrate the second use, suppose you specify the following statements:

```

data two;
  input A $ B $ Y wt @@;
  datalines;
yes  yes  1  23      yes  yes  2  63
yes  no   1  31      yes  no   2  70
no   yes  1  47      no   yes  2  80
no   no   1  50      no   no   2  84
;

proc catmod;
  weight wt;
  model Y=A B A*B / wls;
run;

```

These statements form four populations and produce the following design matrix and analysis of variance table:

$X = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{bmatrix}$	Source	DF	Chi-Square	Pr > ChiSq
	Intercept	1	48.10	<.0001
	A	1	3.47	0.0625
	B	1	0.25	0.6186
	A*B	1	0.19	0.6638
	Residual	0		

Since the B and A*B effects are nonsignificant ($p > 0.10$), fit the reduced model that contains only the A effect:

```

proc catmod;
  weight wt;
  model Y=A / wls;
run;

```

Now only two populations are formed, and the design matrix and the analysis of variance table are as follows:

$X = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$	Source	DF	Chi-Square	Pr > ChiSq
	Intercept	1	47.94	<.0001
	A	1	3.33	0.0678
	Residual	0		

However, you can form four populations by adding the POPULATION statement to the analysis:

```

proc catmod;
  weight wt;
  population A B;
  model Y=A / wls;
run;

```

The design matrix and the analysis of variance table resulting from these statements are as follows:

$X = \begin{bmatrix} 1 & 1 \\ 1 & 1 \\ 1 & -1 \\ 1 & -1 \end{bmatrix}$	Source	DF	Chi-Square	Pr > ChiSq
	Intercept	1	47.76	<.0001
	A	1	3.30	0.0694
	Residual	2	0.35	0.8374

The advantage of the latter analysis is that it retains four populations for the reduced model, thereby creating a built-in goodness-of-fit test: the residual chi-square. Such a test is important because the cumulative (or joint) effect of deleting two or more effects from the model can be significant, even if the individual effects are not.

The resulting differences between the two analyses are due to the fact that the latter analysis uses pure weighted least squares estimates with respect to the four populations that are actually sampled. The former analysis pools populations and therefore uses parameter estimates that can be regarded as weighted least squares estimates of maximum likelihood predicted cell frequencies. In any case, the estimation methods are asymptotically equivalent; therefore, the results are very similar. If you specify the [ML](#) option (instead of the [WLS](#) option) in the preceding MODEL statements, then the parameter estimates are identical for the two analyses.

CAUTION: If your model has different covariate profiles within any population, then the first profile is used in the analysis.

REPEATED Statement

REPEATED *factor-description* <, ..., *factor-description*> </ options> ;

where a *factor-description* is defined as follows:

factor-name <\$> <levels>

and *factor-descriptions* are separated from each other by a comma. The \$ is required for character-valued factors. The value of *levels* provides the number of levels of the repeated measurement factor identified by a given *factor-name*. For only one repeated measurement factor, *levels* is optional; for two or more repeated measurement factors, it is required. The REPEATED statement incorporates repeated measurement factors into the model. You can use this statement whenever there is more than one dependent variable and the keyword `_RESPONSE_` is specified in the MODEL statement. If the dependent variables correspond to one or more repeated measurement factors, you can use the REPEATED statement to define `_RESPONSE_` in terms of those factors. You can specify the name, type, and number of levels of each factor, as well as the identification of each level.

You cannot specify the REPEATED statement for an analysis that also contains the [FACTORS](#) or [LOGLIN](#) statement since all of them specify the same information: how to partition the variation among the response functions within a population.

You can specify the following terms in the REPEATED statement:

<i>factor-name</i>	names a repeated measurement factor that corresponds to two or more response functions. This name must be a valid SAS variable name, and it should not be the same as the name of a variable that already exists in the data set being analyzed.
\$	indicates that the factor is character-valued. If the \$ is omitted, then the CATMOD procedure assumes that the factor is numeric. The type of the factor is relevant only when you use the PROFILE= option or when the _RESPONSE= option specifies nested-by-value effects.
<i>levels</i>	specifies the number of levels of the corresponding repeated measurement factor. If there is only one such factor and the number is omitted, then PROC CATMOD assumes that the number of levels is equal to the number of response functions per population (q). Unless you specify the PROFILE= option, the number q must either be equal to or be a multiple of the product of the number of levels of all the factors.

You can specify the following options in the REPEATED statement after a slash.

PROFILE=(matrix)

specifies the values assumed by the factors for each response function. There should be one column for each factor, and the values in a given column should match the type (character or numeric) of the corresponding factor. Character values are restricted to 16 characters or less. If there are q response functions per population, then the matrix must have i rows, where q must either be equal to or be a multiple of i . Adjacent rows of the matrix should be separated by a comma.

The values in the PROFILE matrix are useful for specifying models in those situations where the study design is not a full factorial with respect to the factors. They can also be used to specify nested-with-value effects in the _RESPONSE= option. If you specify character values in both the PROFILE= option and the _RESPONSE= option, then the values must match with respect to whether or not they are enclosed in quotes (that is, they must be enclosed in quotes in both places or in neither place).

_RESPONSE=effects

specifies design effects. The variables named in the effects must be *factor-names* that appear in the REPEATED statement. If the _RESPONSE= option is omitted, then PROC CATMOD builds a full factorial _RESPONSE_ effect with respect to the repeated measurement factors. For example, the following two statements are equivalent in that they produce the same parameter estimates:

```
repeated Time 2, Treatment 2;
repeated Time 2, Treatment 2 / _response_=Time|Treatment;
```

However, the second statement produces tests of the Time, Treatment, and Time*Treatment effects in the “Analysis of Variance” table, whereas the first statement produces a single test for the combined effects in _RESPONSE_.

TITLE='title'

displays the *title* at the top of certain pages of output that correspond to this REPEATED statement.

For further information and numerous examples of the REPEATED statement, see the section “[Repeated Measures Analysis](#)” on page 1830.

RESPONSE Statement

RESPONSE < *function* > < / *options* > ;

The RESPONSE statement specifies functions of the response probabilities. The procedure models these response functions as linear combinations of the parameters.

By default, PROC CATMOD uses the standard response functions (generalized logits, which are explained in detail in the section “[Understanding the Standard Response Functions](#)” on page 1817). With these standard response functions, the default estimation method is maximum likelihood, but you can use the [WLS](#) option in the MODEL statement to request weighted least squares estimation. With other response functions (specified in the RESPONSE statement), the default (and only) estimation method is weighted least squares.

You can specify more than one RESPONSE statement, in which case each RESPONSE statement produces a separate analysis. If the computed response functions for any population are linearly dependent (yielding a singular covariance matrix), then PROC CATMOD displays an error message and stops processing. See the section “[Cautions](#)” on page 1842 for methods of dealing with this.

The *function* specification can be any of the items in the following list. For an example of response functions generated and formulas for q (the number of response functions), see the section “[More on Response Functions](#)” on page 1813.

Table 30.6 summarizes the options available in the RESPONSE statement.

Table 30.6 RESPONSE Statement Options

Option	Description
ALOGIT	Specifies response functions as adjacent-category logits
CLOGIT	Specifies that the response functions are cumulative logits
JOINT	Specifies that the response functions are the joint response probabilities
LOGIT	Specifies that the response functions are generalized logits
MARGINAL	Specifies that the response functions are marginal probabilities
MEAN	Specifies that the response functions are the means dependent variables
READ	Directly reads the response functions and their covariance matrix from the input data set
OUT=	Produces a SAS data set that contains predicted values, standard errors and residuals
OUTEST=	Produces a SAS data set that contains the estimated parameter vector and its estimated covariance matrix
TITLE=	Displays the <i>title</i>

ALOGIT

ALOGITS

specifies response functions as adjacent-category logits of the marginal probabilities for each of the dependent variables. For each dependent variable, the response functions are a set of linearly independent adjacent-category logits, obtained by taking the logarithms of the ratios of two probabilities. The denominator of the k th ratio is the marginal probability corresponding to the k th level of the vari-

able, and the numerator is the marginal probability corresponding to the $(k + 1)$ level. If a dependent variable has two levels, then the adjacent-category logit is the negative of the generalized logit.

CLOGIT

CLOGITS

specifies that the response functions are cumulative logits of the marginal probabilities for each of the dependent variables. For each dependent variable, the response functions are a set of linearly independent cumulative logits, obtained by taking the logarithms of the ratios of two probabilities. The denominator of the k th ratio is the cumulative probability, c_k , corresponding to the k th level of the variable, and the numerator is $1 - c_k$ (Agresti 1984, 113–114). If a dependent variable has two levels, then PROC CATMOD computes its cumulative logit as the negative of its generalized logit. You should use cumulative logits only when the dependent variables are ordinally scaled.

JOINT

specifies that the response functions are the joint response probabilities. A linearly independent set is created by deleting the last response probability. For the case of one dependent variable, the JOINT and [MARGINALS](#) specifications are equivalent.

LOGIT

LOGITS

specifies that the response functions are generalized logits of the marginal probabilities for each of the dependent variables. For each dependent variable, the response functions are a set of linearly independent generalized logits, obtained by taking the logarithms of the ratios of two probabilities. The denominator of each ratio is the marginal probability corresponding to the last observed level of the variable, and the numerators are the marginal probabilities corresponding to each of the other levels. If there is one dependent variable, then specifying LOGIT is equivalent to using the standard response functions.

MARGINAL

MARGINALS

specifies that the response functions are marginal probabilities for each of the dependent variables in the MODEL statement. For each dependent variable, the response functions are a set of linearly independent marginals, obtained by deleting the marginal probability corresponding to the last level.

MEAN

MEANS

specifies that the response functions are the means of the dependent variables in the MODEL statement. This specification requires that all of the dependent variables be numeric.

READ *variables*

specifies that the response functions and their covariance matrix are to be read directly from the input data set with one response function for each variable named. See the section “[Inputting Response Functions and Covariances Directly](#)” on page 1820 for more information.

transformation

specifies response functions that can be expressed by using successive applications of the four operations: LOG, EXP, * matrix literal, or + matrix literal. The operations are described in detail in the section “[Using a Transformation to Specify Response Functions](#)” on page 1815.

You can specify the following options in the RESPONSE statement after a slash.

OUT=SAS-data-set

produces a SAS data set that contains, for each population, the observed and predicted values of the response functions, their standard errors, and the residuals. Moreover, if you use the standard response functions, the data set also includes observed and predicted values of the cell frequencies or the cell probabilities. For further information, see the section “[Output Data Sets](#)” on page 1824.

OUTEST=SAS-data-set

produces a SAS data set that contains the estimated parameter vector and its estimated covariance matrix. For further information, see the section “[Output Data Sets](#)” on page 1824.

TITLE= 'title'

displays the *title* at the top of certain pages of output that correspond to this RESPONSE statement.

More on Response Functions

Suppose the dependent variable *A* has three levels and is the only *response-effect* in the MODEL statement. The following table shows the proportions upon which the response functions are defined:

Value of A:	1	2	3
Proportions:	p_1	p_2	p_3

Note that $\sum_j p_j = 1$. The following table shows the response functions generated for each population:

Function Specification	Value of q	Response Function
none*	2	$\ln\left(\frac{p_1}{p_3}\right), \ln\left(\frac{p_2}{p_3}\right)$
ALOGITS	2	$\ln\left(\frac{p_2}{p_1}\right), \ln\left(\frac{p_3}{p_2}\right)$
CLOGITS	2	$\ln\left(\frac{1-p_1}{p_1}\right), \ln\left(\frac{1-(p_1+p_2)}{p_1+p_2}\right)$
JOINT	2	p_1, p_2
LOGITS	2	$\ln\left(\frac{p_1}{p_3}\right), \ln\left(\frac{p_2}{p_3}\right)$
MARGINAL	2	p_1, p_2
MEAN	1	$1p_1 + 2p_2 + 3p_3$

*Without a function specification, the default response functions are generalized logits.

Now, suppose the dependent variables *A* and *B* each have three levels (valued 1, 2, and 3 each) and the *response-effect* in the MODEL statement is *A*B*. The following table shows the proportions upon which the response functions are defined:

Value of A:	1	1	1	2	2	2	3	3	3
Value of B:	1	2	3	1	2	3	1	2	3
Proportions:	p_1	p_2	p_3	p_4	p_5	p_6	p_7	p_8	p_9

The marginal totals for the preceding table are defined as follows:

$$\begin{aligned} p_{1\cdot} &= p_1 + p_2 + p_3 & p_{\cdot 1} &= p_1 + p_4 + p_7 \\ p_{2\cdot} &= p_4 + p_5 + p_6 & p_{\cdot 2} &= p_2 + p_5 + p_8 \\ p_{3\cdot} &= p_7 + p_8 + p_9 & p_{\cdot 3} &= p_3 + p_6 + p_9 \end{aligned}$$

where $\sum_j p_j = 1$. The following table shows the response functions generated for each population:

Function Specification	Value of q	Response Function
none*	8	$\ln\left(\frac{p_1}{p_9}\right), \ln\left(\frac{p_2}{p_9}\right), \ln\left(\frac{p_3}{p_9}\right), \dots, \ln\left(\frac{p_8}{p_9}\right)$
ALOGITS	4	$\ln\left(\frac{p_{2\cdot}}{p_{1\cdot}}\right), \ln\left(\frac{p_{3\cdot}}{p_{2\cdot}}\right), \ln\left(\frac{p_{\cdot 2}}{p_{\cdot 1}}\right), \ln\left(\frac{p_{\cdot 3}}{p_{\cdot 2}}\right)$
CLOGITS	4	$\ln\left(\frac{1-p_{1\cdot}}{p_{1\cdot}}\right), \ln\left(\frac{1-(p_{1\cdot}+p_{2\cdot})}{p_{1\cdot}+p_{2\cdot}}\right), \ln\left(\frac{1-p_{\cdot 1}}{p_{\cdot 1}}\right), \ln\left(\frac{1-(p_{\cdot 1}+p_{\cdot 2})}{p_{\cdot 1}+p_{\cdot 2}}\right)$
JOINT	8	$p_1, p_2, p_3, p_4, p_5, p_6, p_7, p_8$
LOGITS	4	$\ln\left(\frac{p_{1\cdot}}{p_{3\cdot}}\right), \ln\left(\frac{p_{2\cdot}}{p_{3\cdot}}\right), \ln\left(\frac{p_{\cdot 1}}{p_{\cdot 3}}\right), \ln\left(\frac{p_{\cdot 2}}{p_{\cdot 3}}\right)$
MARGINAL	4	$p_{1\cdot}, p_{2\cdot}, p_{\cdot 1}, p_{\cdot 2}$
MEAN	2	$1p_{1\cdot} + 2p_{2\cdot} + 3p_{3\cdot}, 1p_{\cdot 1} + 2p_{\cdot 2} + 3p_{\cdot 3}$

* Without a function specification, the default response functions are generalized logits.

The READ and *transformation* function specifications are not shown in the preceding table. For these two situations, there is not a general response function; the response functions that are generated depend on what you specify.

Another important aspect of the function specification is the number of response functions generated per population, q . Let m_i represent the number of levels for the i th dependent variable in the MODEL statement, and let d represent the number of dependent variables in the MODEL statement. Then, if the function specification is ALOGITS, CLOGITS, LOGITS, or MARGINALS, the number of response functions is

$$q = \sum_{i=1}^d (m_i - 1)$$

If the function specification is JOINT or the default (generalized logits), the number of response functions per population is

$$q = r - 1$$

where r is the number of response profiles. If every possible cross-classification of the dependent variables is observed in the samples, then

$$r = \prod_{i=1}^d m_i$$

Otherwise, r is the number of cross-classifications actually observed.

If the function specification is MEANS, the number of response functions per population is $q = d$.

Response Statement Examples

Some example response statements are shown in the following table:

Example	Result
<code>response marginals;</code>	Marginals for each dependent variable
<code>response means;</code>	The mean of each dependent variable
<code>response logits;</code>	Generalized logits of the marginal probabilities
<code>response clogits;</code>	Cumulative logits of the marginal probabilities
<code>response alogits;</code>	Adjacent-category logits of the marginal probabilities
<code>response joint;</code>	The joint probabilities
<code>response 1 -1 log;</code>	The logit
<code>response;</code>	Generalized logits
<code>response 1 2 3;</code>	The mean score, with scores of 1, 2, and 3 corresponding to the three response levels
<code>response read b1-b4;</code>	Four response functions and their covariance matrix, read directly from the input data set

Using a Transformation to Specify Response Functions

If you specify a *transformation*, it is applied to the vector that contains the sample proportions in each population. The *transformation* can be any combination of the following four operations:

Operation	Specification
linear combination	* matrix literal
linear combination	matrix literal
logarithm	LOG
exponential	EXP
adding constant	+ matrix literal

If more than one operation is specified, then PROC CATMOD applies the operations consecutively from right to left.

A matrix literal is a matrix of numbers with each row of the matrix separated from the next by a comma. If you specify a linear combination, in most cases the * is not needed. The following statement defines the response function $p_1 + 1$. The * is needed to separate the two matrix literals '1' and '1 0'.

```
response + 1 * 1 0;
```

The **LOG** of a vector transforms each element of the vector into its natural logarithm; the **EXP** of a vector transforms each element into its exponential function (antilogarithm).

In order to specify a linear response function for data that have $r = 3$ response categories, you can specify either of the following RESPONSE statements:

```
response * 1 0 0 , 0 1 0;
response 1 0 0 , 0 1 0;
```

The matrix literal in the preceding statements specifies a 2×3 matrix, which is applied to each population as follows:

$$\begin{bmatrix} F_1 \\ F_2 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} * \begin{bmatrix} p_1 \\ p_2 \\ p_3 \end{bmatrix}$$

where p_1 , p_2 , and p_3 are sample proportions for the three response categories in a population, and F_1 and F_2 are the two response functions computed for that population. Therefore, this response function sets $F_1 = p_1$ and $F_2 = p_2$ in each population.

As another example of the linear response function, suppose you have two dependent variables corresponding to two observers who evaluate the same subjects. If the observers grade on the same three-point scale and if all nine possible responses are observed, then the following RESPONSE statement would compute the probability that the observers agree on their assessments:

```
response 1 0 0 0 1 0 0 0 1;
```

This response function is then computed as

$$F = p_{11} + p_{22} + p_{33} = \begin{bmatrix} 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \end{bmatrix} * \begin{bmatrix} p_{11} \\ p_{12} \\ p_{13} \\ p_{21} \\ p_{22} \\ p_{23} \\ p_{31} \\ p_{32} \\ p_{33} \end{bmatrix}$$

where p_{ij} denotes the probability that a subject gets a grade of i from the first observer and j from the second observer.

If the function is a compound function, requiring more than one operation to specify it, then the operations should be listed so that the first operation to be applied is on the right and the last operation to be applied is on the left. For example, if there are two response levels, you can have the following response function:

```
response 1 -1 log;
```

This is equivalent to the matrix expression

$$F = \begin{bmatrix} 1 & -1 \end{bmatrix} * \begin{bmatrix} \log(p_1) \\ \log(p_2) \end{bmatrix} = \log(p_1) - \log(p_2) = \log\left(\frac{p_1}{p_2}\right)$$

which is the logit response function since $p_2 = 1 - p_1$ when there are only two response levels.

The following statement specifies another example of a compound response function:

```
response exp 1 -1 * 1 0 0 1, 0 1 1 0 log;
```

This is equivalent to the matrix expression

$$F = \text{EXP}(A * B * \text{LOG}(P))$$

where P is the vector of sample proportions for some population,

$$A = \begin{bmatrix} 1 & -1 \end{bmatrix} \text{ and } B = \begin{bmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{bmatrix}$$

If the four responses are based on two dependent variables, each with two levels, then the function can also be written as

$$F = \frac{p_{11}p_{22}}{p_{12}p_{21}}$$

which is the odds (crossproduct) ratio for a 2×2 table.

Understanding the Standard Response Functions

If no RESPONSE statement is specified, PROC CATMOD computes the standard response functions, which contrast the log of each response probability with the log of the probability for the last response category. If there are r response categories, then there are $r - 1$ standard response functions. For example, if there are four response categories, using no RESPONSE statement is equivalent to specifying the following:

```
response 1 0 0 -1,
          0 1 0 -1,
          0 0 1 -1 log;
```

This results in three response functions:

$$F = \begin{bmatrix} F_1 \\ F_2 \\ F_3 \end{bmatrix} = \begin{bmatrix} \log(p_1/p_4) \\ \log(p_2/p_4) \\ \log(p_3/p_4) \end{bmatrix}$$

If there are only two response levels, the resulting response function would be a logit, which is why the standard response functions are called generalized logits. They are useful in dealing with the log-linear model:

$$\pi = \text{EXP}(X\beta)$$

If C denotes the matrix in the preceding RESPONSE statement, then because of the restriction that the probabilities sum to 1, it follows that an equivalent model is

$$C * \text{LOG}(\pi) = (CX)\beta$$

But $C * \text{LOG}(P)$ is simply the vector of standard response functions. Thus, fitting a log-linear model on the cell probabilities is equivalent to fitting a linear model on the generalized logits.

RESTRICT Statement

RESTRICT *parameter=value* < ... *parameter=value* > ;

where *parameter* is the letter B followed by a number; for example, B3 specifies the third parameter in the model. The *value* is the value to which the parameter is restricted. The RESTRICT statement restricts values of parameters to the values you specify, so that the estimation of the remaining parameters is subject to these restrictions. Consider the following statement:

```
restrict b1=1 b4=0 b6=0;
```

This restricts the values of three parameters. The first parameter is set to 1, and the fourth and sixth parameters are set to zero.

The RESTRICT statement is interactive. A new RESTRICT statement replaces any previous ones. In addition, if you submit two or more MODEL, [LOGLIN](#), [FACTORS](#), or [REPEATED](#) statements, then the subsequent occurrences of these statements also delete the previous RESTRICT statement.

WEIGHT Statement

WEIGHT *variable* ;

You can use a WEIGHT statement to refer to a variable containing the cell frequencies, which do not need to be integers. The WEIGHT statement lets you use summary data sets containing a count variable. See the section “[Input Data Sets](#)” on page 1818 for further information about the WEIGHT statement.

Details: CATMOD Procedure

Missing Values

Observations with missing values for any variable listed in the MODEL or [POPULATION](#) statement are omitted from the analysis.

If the [WEIGHT](#) variable for an observation has a missing value, the observation is by default omitted from the analysis. You can modify this behavior by specifying the [MISSING=](#) option in the MODEL statement. The option [MISSING=value](#) sets all missing weights to *value* and all missing cells to *value*. The option [MISSING=SAMPLING](#) causes all missing cells in a contingency table to be treated as sampling zeros.

Any observation with nonpositive weight is also, by default, omitted from the analysis. If it has zero weight, then you can specify the [ZERO=](#) option in the MODEL statement.

Input Data Sets

Data to be analyzed by PROC CATMOD must be in a SAS data set containing one of the following:

- raw data values (variable values for every subject)
- frequency counts and the corresponding variable values
- response function values and their covariance matrix

If you specify a **WEIGHT** statement, then PROC CATMOD uses the values of the WEIGHT variable as the frequency counts. If the **READ** function is specified in the **RESPONSE** statement, then the procedure expects the input data set to contain the values of response functions and their covariance matrix. Otherwise, PROC CATMOD assumes that the SAS data set contains raw data values.

Raw Data Values

If you use raw data, PROC CATMOD first counts the number of observations having each combination of values for all variables specified in the MODEL or **POPULATION** statement. For example, suppose the variables A and B each take on the values 1 and 2, and their frequencies can be represented as follows:

		A	
		1	2
B	1	2	1
	2	3	1

The SAS data set Raw containing the raw data might be as follows:

Observation	A	B
1	1	1
2	1	1
3	1	2
4	1	2
5	1	2
6	2	1
7	2	2

And the statements for PROC CATMOD are as follows:

```
proc catmod data=Raw;
  model A=B;
run;
```

For discussions of how to handle structural and random zeros with raw data as input data, see the section “Zero Frequencies” on page 1843 and [Example 30.5](#).

Frequency Counts

If your data set contains frequency counts, then use the **WEIGHT** statement to specify the variable containing the frequencies. For example, you could create and analyze the Summary data set as follows:

```
data Summary;
  input A B Count;
  datalines;
1 1 2
1 2 3
2 1 1
```

```

2 2 1
;

proc catmod data=Summary;
    weight Count;
    model A=B;
run;

```

The data set Summary can also be created from the data set Raw by using the FREQ procedure:

```

proc freq data=Raw;
    tables A*B / out=Summary;
run;

```

Inputting Response Functions and Covariances Directly

If you want to read in the response functions and their covariance matrix, rather than have PROC CATMOD compute them, create a TYPE=EST data set. In addition to having one variable name for each function, the data set should have two additional variables: `_TYPE_` and `_NAME_`, both character variables of length 8. The variable `_TYPE_` should have the value 'PARMS' when the observation contains the response functions; it should have the value 'COV' when the observation contains elements of the covariance matrix of the response functions. The variable `_NAME_` is used only when `_TYPE_=COV`, in which case it should contain the name of the variable that has its covariance elements stored in that observation. In the following data set, for example, the covariance between the second and fourth response functions is 0.000102:

```

data direct(type=est);
    input b1-b4 _type_ $ _name_ $8.;
    datalines;
0.590463    0.384720    0.273269    0.136458    PARMS    .
0.001690    0.000911    0.000474    0.000432    COV      B1
0.000911    0.001823    0.000031    0.000102    COV      B2
0.000474    0.000031    0.001056    0.000477    COV      B3
0.000432    0.000102    0.000477    0.000396    COV      B4
;

```

In order to tell PROC CATMOD that the input data set contains the values of response functions and their covariance matrix, do the following:

- specify the `READ` function in the `RESPONSE` statement
- specify `_F_` as the dependent variable in the `MODEL` statement

For example, suppose the response functions correspond to four populations that represent the cross-classification of two age groups by two race groups. You can use the `FACTORS` statement to identify these two factors and to name the effects in the model. The following statements are required to fit a main-effects model to these data:

```

proc catmod data=direct;
    response read b1-b4;
    model _f_=_response_;
    factors age 2, race 2 / _response_=age race;
run;

```

Ordering of Populations and Responses

By default, populations and responses are sorted in standard SAS order as follows:

- alphabetical order for character variables
- increasing numeric order for numeric variables

Suppose you specify the following statements:

```
data one;
  length A B $ 6;
  input A $ B $ wt @@;
  datalines;
low      low  23  low   medium  31 low   high  38
medium   low  40  medium medium  42 medium high  50
high     low  52  high   medium  54 high   high  61
;

proc catmod;
  weight wt;
  model A=B / oneway;
run;
```

The ordering of populations and responses corresponds to the alphabetical order of the levels of the character variables. You can specify the **ONEWAY** option to display the ordering of the variables, while the “Population Profiles” and “Response Profiles” tables display the ordering of the populations and the responses, respectively.

Population Profiles		Response Profiles	
Sample	B	Response	A
1	high	1	high
2	low	2	low
3	medium	3	medium

In this example, if you want to have the levels ordered in the natural order of ‘low,’ ‘medium,’ ‘high,’ you can specify the **ORDER=DATA** option:

```
proc catmod order=data;
  weight wt;
  model a=b / oneway;
run;
```

The resulting ordering of populations and responses is as follows:

Population Profiles		Response Profiles	
Sample	B	Response	A
1	low	1	low
2	medium	2	medium
3	high	3	high

You can use the **ORDER=DATA** option to ensure that populations and responses are ordered in a specific way. But since this also affects the definitions and the ordering of the parameters, you must exercise caution when using the **_RESPONSE_** effect, the **CONTRAST** statement, or direct input of the design matrix.

An alternative method of ensuring that populations and responses are ordered in a specific way is to assign a format to your variables and specify the **ORDER=FORMATTED** option. The levels are then ordered according to their formatted values.

Another method is to replace any character variables with numeric variables and to assign formatted values such as ‘yes’ and ‘no’ to the numeric levels. Since **ORDER=INTERNAL** is the default ordering, PROC CATMOD orders the populations and responses according to the numeric values but displays the formatted values.

Specification of Effects

By default, the CATMOD procedure treats all variables as classification variables. As a result, there is no **CLASS** statement in PROC CATMOD. The values of a classification variable can be numeric or character. PROC CATMOD builds a set of effects-coded variables to represent the levels of the classification variable and then uses these to fit the model (for details, see the section “[Generation of the Design Matrix](#)” on page 1832). You can modify the default by using the **DIRECT** statement to treat numeric independent continuous variables as continuous variables. The classification variables, combinations of classification variables, and continuous variables are then used in fitting linear models to data.

The parameters of a linear model are generally divided into subsets that correspond to meaningful sources of variation in the response functions. These sources, called *effects*, can be specified in the **MODEL**, **LOGLIN**, **FACTORS**, **REPEATED**, and **CONTRAST** statements. Effects can be specified in any of the following ways:

- A main effect is a single classification variable (that is, it produces class levels): **A B C**.
- A crossed effect (or interaction) is two or more classification variables joined by asterisks—for example: **A*B A*B*C**.
- A nested effect is a main effect or an interaction, followed by a parenthetical field containing a main effect or an interaction. Multiple variables within the parentheses are assumed to form a crossed effect even when the asterisk is absent. In the following list, the last two effects are identical: **B(A) C(A*B) A*B(C*D) A*B(C D)**.
- A nested-by-value effect is the same as a nested effect except that any variable in the parentheses can be followed by an equal sign and a value: **B(A=1) C(A B=1) C*D(A=1 B=1) A(C='low')**.
- A direct effect is a variable specified in a **DIRECT** statement: **X Y**.
- Direct effects can be crossed with other effects: **X*Y X*X*X X*A*B(C D=1)**.

The variables for crossed and nested effects remain in the order in which they are first encountered. For example, in the following model, the effect **A*B** is reported as **B*A** since **B** appears before **A** in the statement:

```
model R=B A A*B C(A B);
```

Also, $C(A\ B)$ is interpreted as $C(A*B)$ and is therefore reported as $C(B*A)$.

Bar Notation

You can shorten the specification of multiple effects by using bar notation. For example, the following statements illustrate two methods of writing a full three-way factorial model:

```
proc catmod;
  model y=a b c a*b a*c b*c a*b*c;
run;

proc catmod;
  model y=a|b|c;
run;
```

When you use the bar (|) notation, the right and left sides become effects, and the interaction between them becomes an effect. Multiple bars are permitted. The expressions are expanded from left to right, using rules 1 through 4 given in Searle (1971, p. 390):

- Multiple bars are evaluated left to right. For example, $A|B|C$ is evaluated as follows:

$$\begin{aligned} A|B|C &\rightarrow \{A|B\}|C \\ &\rightarrow \{A\ B\ A*B\}|C \\ &\rightarrow A\ B\ A*B\ C\ A*C\ B*C\ A*B*C \end{aligned}$$
- Crossed and nested groups of variables are combined. For example, $A(B)|C(D)$ generates $A*C(B\ D)$, among other terms.
- Duplicate variables are removed. For example, $A(C)|B(C)$ generates $A*B(C\ C)$, among other terms, and the extra C is removed.
- Effects are discarded if a variable occurs on both the crossed and nested sides of an effect. For instance, $A(B)|B(D\ E)$ generates $A*B(B\ D\ E)$, but this effect is deleted.

You can also specify the maximum number of variables involved in any effect that results from bar evaluation by specifying that maximum number, preceded by an @ sign, at the end of the bar effect. For example, the specification $A|B|C\ @\ 2$ would result in only those effects that contain two or fewer variables; in this case, the effects A , B , $A*B$, C , $A*C$, and $B*C$ are generated.

Other examples of the bar notation follow:

$A C(B)$	is equivalent to	$A\ C(B)\ A*C(B)$
$A(B) C(B)$	is equivalent to	$A(B)\ C(B)\ A*C(B)$
$A(B) B(D\ E)$	is equivalent to	$A(B)\ B(D\ E)$
$A B(A) C$	is equivalent to	$A\ B(A)\ C\ A*C\ B*C(A)$
$A B(A) C@2$	is equivalent to	$A\ B(A)\ C\ A*C$
$A B C D@2$	is equivalent to	$A\ B\ A*B\ C\ A*C\ B*C\ D\ A*D\ B*D\ C*D$

For details about how the effects specified lead to a design matrix, see the section “[Generation of the Design Matrix](#)” on page 1832.

Output Data Sets

OUT= Data Set

For each population, the **OUT=** data set contains the observed and predicted values of the response functions, their standard errors, the residuals, and variables that describe the population and response profiles. In addition, if you use the standard response functions, the data set includes observed and predicted values for the cell frequencies or the cell probabilities, together with their standard errors and residuals.

Number of Observations

For the standard response functions, there are $s \times (2q - 1)$ observations in the data set for each BY group, where s is the number of populations and q is the number of response functions per population. Otherwise, there are $s \times q$ observations in the data set for each BY group.

Variables in the OUT= Data Set

The data set contains the following variables:

BY variables	If you use a BY statement, the BY variables are included in the OUT= data set.
dependent variables	If the response functions are the default ones (generalized logits), then the dependent variables, which describe the response profiles, are included in the OUT= data set. When <code>_TYPE_=FUNCTION</code> , the values of these variables are missing.
independent variables	The independent variables, which describe the population profiles, are included in the OUT= data set.
<code>_NUMBER_</code>	the sequence number of the response function or the cell probability or the cell frequency
<code>_OBS_</code>	the observed value
<code>_PRED_</code>	the predicted value
<code>_RESID_</code>	the residual (observed minus predicted)
<code>_SAMPLE_</code>	the population number. This matches the sample number in the “Population Profile” section of the output.
<code>_SEOBS_</code>	the standard error of the observed value
<code>_SEPRED_</code>	the standard error of the predicted value
<code>_TYPE_</code>	specifies a character variable with three possible values. When <code>_TYPE_=FUNCTION</code> , the observed and predicted values are values of the response functions. When <code>_TYPE_=PROB</code> , they are values of the cell probabilities. When <code>_TYPE_=FREQ</code> , they are values of the cell frequencies. Cell probabilities or frequencies are provided only when the default response functions are modeled. In this case, cell probabilities are provided by default, and cell frequencies are provided if you specify the option <code>PRED=FREQ</code> .

OUTEST= Data Set

This TYPE=EST output data set contains the estimated parameter vector and its estimated covariance matrix. If you specify both the **ML** and **WLS** options in the MODEL statement, the **OUTEST=** data set contains both sets of estimates. For each BY group, there are $p + 1$ observations in the data set for each estimation method, where p is the number of estimated parameters. The data set contains the following variables:

B1, B2, and so on	variables for the estimated parameters. The OUTEST= data set contains one variable for each estimated parameter.
BY variables	If you use a BY statement, the BY variables are included in the OUT= data set.
METHOD	the method used to obtain parameter estimates. For weighted least squares estimation, _METHOD_=WLS, and for maximum likelihood estimation, _METHOD_=ML.
NAME	identifies parameter names. When _TYPE_=PARMS, _NAME_ is blank, but when _TYPE_=COV, _NAME_ has one of the values B1, B2, and so on, corresponding to the parameter names.
STATUS	indicates whether the estimates have converged
TYPE	identifies the statistics contained in the variables for parameter estimates (B1, B2, and so on). When _TYPE_=PARMS, the variables contain parameter estimates; when _TYPE_=COV, they contain covariance estimates.

The variables _METHOD_, _NAME_, and _TYPE_ are character variables; the BY variables can be either character or numeric; and the variables for estimated parameters are numeric.

See Appendix A, “[Special SAS Data Sets](#),” for more information about special SAS data sets.

Logistic Analysis

In a logistic analysis, the response functions are the logits of the dependent variable.

PROC CATMOD can compute the three following types of logits with the use of keywords in the **RESPONSE** statement. Note that other types of response functions can be generated by specifying appropriate transformations in the **RESPONSE** statement.

- Generalized logits are used primarily for nominally scaled dependent variables, but they can also be used for ordinal data modeling. Maximum likelihood estimation is available for the analysis of these logits.
- Cumulative logits are used for ordinally scaled dependent variables. Except for dependent variables with two response levels, only weighted least squares estimation is available for the analysis of these logits.
- Adjacent-category logits are equivalent to generalized logits, but they have some advantages for ordinal data analysis because they automatically incorporate integer scores for the levels of the dependent variable. Except for dependent variables with two response levels, only weighted least squares estimation is available for the analysis of these logits.

If the dependent variable has only two responses, then the cumulative logit and the adjacent-category logit are the negative of the generalized logit, as computed by PROC CATMOD. Consequently, parameter estimates obtained by using these logits are the negative of those obtained from using generalized logits. A simple logistic analysis of variance uses statements like the following:

```
proc catmod;
    model r=a|b;
run;
```

Logistic Regression

If the independent variables are treated quantitatively (like continuous variables), then a logistic analysis is known as a *logistic regression*. If you want PROC CATMOD to treat the independent variables as quantitative variables, specify them in both the **DIRECT** and **MODEL** statements, as follows:

```
proc catmod;
    direct x1 x2 x3;
    model r=x1 x2 x3;
run;
```

Since the preceding statements do not include a **RESPONSE** statement, generalized logits are computed. See [Example 30.3](#) for another example.

The parameter estimates from the CATMOD procedure are the same as those from a logistic regression program such as PROC LOGISTIC (see Chapter 54, “[The LOGISTIC Procedure](#)”). The chi-square statistics and the predicted values are also identical. In the binary response case, PROC CATMOD can be made to model the probability of the maximum value by either (1) organizing the input data so that the maximum value occurs first and specifying **ORDER=DATA** in the PROC CATMOD statement or (2) specifying cumulative logits (CLOGITS) in the **RESPONSE** statement.

CAUTION: Computational difficulties might occur if you use a continuous variable with a large number of unique values in a **DIRECT** statement. See the section “[Continuous Variables](#)” on page 1827 for more details.

Cumulative Logits

If your dependent variable is ordinally scaled, you can specify the analysis of cumulative logits that take into account the ordinal nature of the dependent variable:

```
proc catmod;
    response clogits;
    direct x;
    model r=a x;
run;
```

The preceding statements correspond to a simple analysis that addresses the question of existence of an association between the independent variables and the ordinal dependent variable. However, there are some commonly used models for the analysis of ordinal data (Agresti 1984) that address the structure of association (in terms of odds ratios), as well as its existence.

If the independent variables are classification variables, a typical analysis for such a model uses the following statements:

```
proc catmod;
  weight wt;
  response clogits;
  model r=_response_ a b;
run;
```

On the other hand, if the independent variables are ordinally scaled, you might specify numeric scores in variables `x1` and `x2`, and use the following statements:

```
proc catmod;
  weight wt;
  direct x1 x2;
  response clogits;
  model r=_response_ x1 x2;
run;
```

See Agresti (1984) for additional details of estimation, testing, and interpretation.

Continuous Variables

Computational difficulties might occur if you have a continuous variable with a large number of unique values and you use this variable in a **DIRECT** statement, since an observation often represents a separate population of size one. At this extreme of sparseness, the weighted least squares method is inappropriate since there are too many zero frequencies. Therefore, you should use the maximum likelihood method. PROC CATMOD is not designed optimally for continuous variables; therefore, it might be less efficient and unable to allocate sufficient memory to handle this problem, as compared with a procedure designed specifically to handle continuous data. In these situations, consider using the **LOGISTIC** or **GENMOD** procedure to analyze your data.

Log-Linear Model Analysis

When the response functions are the default generalized logits, then inclusion of the keyword `_RESPONSE_` in every effect in the right side of the MODEL statement fits a log-linear model. The keyword `_RESPONSE_` tells PROC CATMOD that you want to model the variation among the dependent variables. You then specify the actual model in the **LOGLIN** statement.

When you perform log-linear model analysis, you can request weighted least squares estimates, maximum likelihood estimates, or both. By default, PROC CATMOD calculates maximum likelihood estimates when the default response functions are used. The following table provides appropriate MODEL statements for the combinations of types of estimates:

Estimation Desired	MODEL Statement
Maximum likelihood (Newton-Raphson)	<code>model a*b=_response_;</code>
Maximum likelihood (Iterative Proportional Fitting)	<code>model a*b=_response_ / ml=ipf;</code>
Weighted least squares	<code>model a*b=_response_ / wls;</code>
Maximum likelihood and weighted least squares	<code>model a*b=_response_ / wls ml;</code>

CAUTION: Sampling zeros in the input data set should be specified with the **ZERO=** option to ensure that these sampling zeros are not treated as structural zeros. Alternatively, you can replace cell counts for sampling zeros with some positive number close to zero (such as 1E-20) in a DATA step. Data containing sampling zeros should be analyzed with maximum likelihood estimation. See the section “**Cautions**” on page 1842 and [Example 30.5](#) for further information and an illustration that uses both cell count data and raw data.

One Population

The usual log-linear model analysis has one population, which means that all of the variables are dependent variables. For example, the following statements yield a maximum likelihood analysis of a saturated log-linear model for the dependent variables *r1* and *r2*:

```
proc catmod;
  weight wt;
  model r1*r2=_response_;
  loglin r1|r2;
run;
```

If you want to fit a reduced model with respect to the dependent variables (for example, a model of independence or conditional independence), specify the reduced model in the **LOGLIN** statement. For example, the following statements yield a main-effects log-linear model analysis of the factors *r1* and *r2*:

```
proc catmod;
  weight wt;
  model r1*r2=_response_ / pred;
  loglin r1 r2;
run;
```

The output includes Wald statistics for the individual effects *r1* and *r2*, as well as predicted cell probabilities. Moreover, the goodness-of-fit statistic is the likelihood ratio test for the hypothesis of independence between *r1* and *r2* or, equivalently, a test of *r1***r2*.

Multiple Populations

You can do log-linear model analysis with multiple populations by using a **POPULATION** statement or by including effects on the right side of the MODEL statement that contain independent variables. Each effect must include the **_RESPONSE_** keyword.

For example, suppose the dependent variables *r1* and *r2* are dichotomous, and the independent variable group has three levels. Then the following statements specify a saturated model (three degrees of freedom for **_RESPONSE_** and six degrees of freedom for the interaction between **_RESPONSE_** and group):

```
proc catmod;
  weight wt;
  model r1*r2=_response_ group*_response_;
  loglin r1|r2;
run;
```

From another point of view, `_RESPONSE_*group` can be regarded as a main effect for `group` with respect to the three response functions, while `_RESPONSE_` can be regarded as an intercept effect with respect to the functions. In other words, the following statements give essentially the same results as the logistic analysis:

```
proc catmod;
  weight wt;
  model r1*r2=group;
run;
```

The ability to model the interaction between the independent and the dependent variables becomes particularly useful when a reduced model is specified for the dependent variables. For example, the following statements specify a model with two degrees of freedom for `_RESPONSE_` (one for `r1` and one for `r2`) and four degrees of freedom for the interaction of `_RESPONSE_*group`:

```
proc catmod;
  weight wt;
  model r1*r2=_response_ group*_response_;
  loglin r1 r2;
run;
```

The likelihood ratio goodness-of-fit statistic (three degrees of freedom) tests the hypothesis that `r1` and `r2` are independent in each of the three groups.

Iterative Proportional Fitting

You can use the iterative proportional fitting (IPF) algorithm to fit a hierarchical log-linear model with no independent variables and no population variables.

The advantage of IPF over the Newton-Raphson (NR) algorithm and over the weighted least squares (WLS) method is that, when the contingency table has several dimensions and the parameter vector is large, you can obtain the log likelihood, the goodness-of-fit G^2 , and the predicted frequencies or probabilities without performing potentially expensive parameter estimation and covariance matrix calculations. This enables you to do the following:

- compare two models by computing the likelihood ratio statistics to test the significance of the contribution of the variables in one model that are not in the other model
- compute predicted values of the cell probabilities or frequencies for the final model

Each iteration of the IPF algorithm is generally faster than an iteration of the NR algorithm; however, the IPF algorithm converges to the MLEs more slowly than the NR algorithm. Both NR and WLS are more general methods that are able to perform more complex analyses than IPF can.

Repeated Measures Analysis

If there are multiple dependent variables and the variables represent repeated measurements of the same observational unit, then the variation among the dependent variables can be attributed to one or more repeated measurement factors. The factors can be included in the model by specifying `_RESPONSE_` on the right side of the MODEL statement and by using a **REPEATED** statement to identify the factors.

To perform a repeated measures analysis, you also need to specify a **RESPONSE** statement, since the standard response functions (generalized logits) cannot be used. Typically, the **MEANS** or **MARGINALS** response functions are specified in a repeated measures analysis, but other response functions can also be reasonable.

One Population

Consider an experiment in which each subject is measured at three times, and the response functions are marginal probabilities for each of the dependent variables. If the dependent variables each have k levels, then PROC CATMOD computes $k-1$ response functions for each time. Differences among the response functions with respect to these times could be attributed to the repeated measurement factor Time. To incorporate the Time variation into the model, specify the following statements:

```
proc catmod;
  response marginals;
  model t1*t2*t3=_response_;
  repeated Time 3 / _response_=Time;
run;
```

These statements produce a Time effect that has $2(k-1)$ degrees of freedom since there are $k-1$ response functions at each time point. For a dichotomous variable, the Time effect has two degrees of freedom.

Now suppose that at each time point, each subject has X-rays taken, and the X-rays are read by two different radiologists. This creates six dependent variables that represent the 3×2 cross-classification of the repeated measurement factors Time and Reader. A saturated model with respect to these factors can be obtained by specifying the following statements:

```
proc catmod;
  response marginals;
  model r11*r12*r21*r22*r31*r32=_response_;
  repeated Time 3, Reader 2
    / _response_=Time Reader Time*Reader;
run;
```

If you want to fit a main-effects model with respect to Time and Reader, then change the **REPEATED** statement to the following:

```
repeated Time 3, Reader 2 / _response_=Time Reader;
```

If you want to fit a main-effects model for Time but for only one of the readers, the **REPEATED** statement might look like the following:

```

repeated Time $ 3, Reader $ 2
  /_response_=Time(Reader=Smith)
  profile =('1'  Smith,
            '1'  Jones,
            '2'  Smith,
            '2'  Jones,
            '3'  Smith,
            '3'  Jones);

```

If Jones had been unavailable for a reading at time 3, then there would be only $5(k - 1)$ response functions, even though PROC CATMOD would be expecting some multiple of 6 ($= 3 \times 2$). In that case, the **PROFILE=** option would be necessary to indicate which repeated measurement profiles were actually represented:

```

repeated Time $ 3, Reader $ 2
  /_response_=Time(Reader=Smith)
  profile =('1'  Smith,
            '1'  Jones,
            '2'  Smith,
            '2'  Jones,
            '3'  Smith);

```

When two or more repeated measurement factors are specified, PROC CATMOD presumes that the response functions are ordered so that the levels of the rightmost factor change most rapidly. This means that the dependent variables should be specified in the same order. For this example, the order implied by the **REPEATED** statement is as follows, where the variable r_{ij} corresponds to Time i and Reader j :

Response Function	Dependent Variable	Time	Reader
1	r_{11}	1	1
2	r_{12}	1	2
3	r_{21}	2	1
4	r_{22}	2	2
5	r_{31}	3	1
6	r_{32}	3	2

The order of dependent variables in the MODEL statement must agree with the order implied by the **REPEATED** statement.

Multiple Populations

When there are variables specified in the **POPULATION** statement or on the right side of the MODEL statement, these variables produce multiple populations. PROC CATMOD can then model these independent variables, the repeated measurement factors, and the interactions between the two.

For example, suppose that there are five groups of subjects, that each subject in the study is measured at three different times, and that the dichotomous dependent variables are labeled t1, t2, and t3. The following statements compute three response functions for each population:

```
proc catmod;
  weight wt;
  population Group;
  response marginals;
  model t1*t2*t3=_response_;
  repeated Time / _response_=Time;
run;
```

PROC CATMOD then regards `_RESPONSE_` as a variable with three levels corresponding to the three response functions in each population and forms an effect with two degrees of freedom. The `MODEL` and `REPEATED` statements tell PROC CATMOD to fit the main effect of Time.

In general, the `MODEL` statement tells PROC CATMOD how to integrate the independent variables and the repeated measurement factors into the model. For example, again suppose that there are five groups of subjects, that each subject is measured at three times, and that the dichotomous independent variables are labeled t1, t2, and t3. If you use the same `WEIGHT`, `POPULATION`, `RESPONSE`, and `REPEATED` statements as in the preceding program, the following `MODEL` statements result in the indicated analyses:

<code>model t1*t2*t3=Group / averaged;</code>	Specifies the Group main effect (with 4 degrees of freedom)
<code>model t1*t2*t3=_response_;</code>	Specifies the Time main effect (with 2 degrees of freedom)
<code>model t1*t2*t3=_response_*Group;</code>	Specifies the interaction between Time and Group (with 8 degrees of freedom)
<code>model t1*t2*t3=_response_ Group;</code>	Specifies both main effects, and the interaction between Time and Group (with a total of 14 degrees of freedom)
<code>model t1*t2*t3=_response_(Group);</code>	Specifies a Time main effect within each Group (with 10 degrees of freedom)

However, the following `MODEL` statement is invalid since effects cannot be nested within `_RESPONSE_`:

```
model t1*t2*t3=Group(_response_);
```

Generation of the Design Matrix

Each row of the design matrix (corresponding to a population) is generated by a unique combination of independent variable values. Each column of the design matrix corresponds to a model parameter. The columns are produced from the effect specifications in the `MODEL`, `LOGLIN`, `FACTORS`, and `REPEATED` statements. For details about effect specifications, see the section “[Specification of Effects](#)” on page 1822.

This section is divided into three parts:

- one response function per population
- [two or more](#) response functions per population (excluding log-linear models), beginning on page 1835
- [log-linear models](#), beginning on page 1839

This section assumes that the default effect parameterization is used. Specifying the [reference parameterization](#) replaces the “-1”s with zeros in the design matrix for the main effects of classification variables, and makes appropriate changes to interaction terms.

You can display the design matrix by specifying the [DESIGN](#) option in the MODEL statement.

One Response Function per Population

Intercept

When there is one response function per population, all design matrices start with a column of 1s for the intercept unless the [NOINT](#) option is specified or the design matrix is input directly.

Main Effects

If a classification variable A has k levels, then its main effect has $k - 1$ degrees of freedom, and the design matrix has $k - 1$ columns that correspond to the first $k - 1$ levels of A. The i th column contains a 1 in the i th row, a -1 in the last row, and 0s everywhere else. If α_i denotes the parameter that corresponds to the i th level of variable A, then the $k - 1$ columns yield estimates of the independent parameters, $\alpha_1, \alpha_i, \dots, \alpha_{k-1}$. The last parameter is not needed because PROC CATMOD constrains the k parameters to sum to zero. In other words, PROC CATMOD uses a full-rank center-point parameterization to build design matrices. Here are two examples:

Variable	Data Levels	Effect Parameterization	
		Design Matrix	
A	1	1	0
	2	0	1
	3	-1	-1
B	1	-1	
	2	-1	

For an effect with three levels, such as A, PROC CATMOD produces two parameter estimates for each response function. By default, the first (corresponding to the first row in the design columns) estimates the effect of level 1 of A compared to the average effect of the three levels of A. The second (corresponding to the second row in the design columns) estimates the effect of level 2 of A compared to the average effect of the three levels of A. The sum-to-zero constraint requires the effect of level 3 of A to be the negative of the sum of the level 1 and 2 effects (as shown by the third row in the design columns).

Crossed Effects (Interactions)

Crossed effects (such as A*B) are formed by the horizontal direct products of main effects, as illustrated in the following table:

Data Levels		Design Matrix				
A	B	A		B	A*B	
1	1	1	0	1	1	0
1	2	1	0	-1	-1	0
2	1	0	1	1	0	1
2	2	0	1	-1	0	-1
3	1	-1	-1	1	-1	-1
3	2	-1	-1	-1	1	1

The number of degrees of freedom for a crossed effect (that is, the number of design matrix columns) is equal to the product of the numbers of degrees of freedom for the separate effects.

Nested Effects

The effect A(B) is read “A within B” and is the same as specifying an A main effect for every value of B. If n_a and n_b are the number of levels in A and B, respectively, then the number of columns for A(B) is $(n_a - 1)n_b$ when every combination of levels exists in the data. The following table gives an example:

Data Levels		Design Matrix			
B	A	A(B)			
1	1	1	0	0	0
1	2	0	1	0	0
1	3	-1	-1	0	0
2	1	0	0	1	0
2	2	0	0	0	1
2	3	0	0	-1	-1

CAUTION: PROC CATMOD actually allocates a column for all possible combinations of values even though some combinations are not present in the data. This can be of particular concern if the data are not balanced with respect to the nested levels.

Nested-by-Value Effects

Instead of nesting an effect within all values of the main effect, you can nest an effect within specified values of the nested variable (A(B=1), for example). The four degrees of freedom for the A(B) effect shown in the preceding section can also be obtained by specifying the two separate nested effects with values, as the following table shows:

Data Levels		Design Matrix			
B	A	A(B=1)		A(B=2)	
1	1	1	0	0	0
1	2	0	1	0	0
1	3	-1	-1	0	0
2	1	0	0	1	0
2	2	0	0	0	1
2	3	0	0	-1	-1

Each effect has $n_a - 1$ degrees of freedom, assuming a complete combination, so each effect in this example has two degrees of freedom.

The procedure compares nested values to data values on the basis of formatted values. If a format is not specified for the variable, the procedure formats internal data values to BEST16, left-justified. The nested values specified in nested-by-value effects are also converted to a BEST16 formatted value, left-justified.

For example, if the numeric variable B has internal data values 1 and 2, then A(B=1), A(B=1.0), and A(B=1E0) are all valid nested-by-value effects. However, if the data value 1 is formatted as ‘one’, then A(B=‘one’) is a valid effect, but A(B=1) is not since the formatted nested value (1) does not match the formatted data value (one).

To ensure correct nested-by-value effects, look at the tables of population and response profiles. These are displayed by default, and they contain the formatted data values. In addition, the population and response profiles are displayed when you specify the **ONEWAY** option in the **MODEL** statement.

Direct Effects

To request that the actual values of a variable be inserted into the design matrix, declare the variable in a **DIRECT** statement, and specify the effect by the variable name. For example, specifying the effects **X1** and **X2** in both the **MODEL** and **DIRECT** statements results in the following:

Data Levels		Design Columns	
X1	X2	X1	X2
1	1	1	1
2	4	2	4
3	9	3	9

Unless there is a **POPULATION** statement that excludes the direct variables, the direct variables help to define the sample populations. In general, the variables should not be continuous in the sense that every subject has a different value because this would create a separate population for each subject (note, however, that such a strategy is used purposely for logistic regression).

If there is a **POPULATION** statement that omits mention of the direct variables, then the values of the direct variables must be identical for all subjects in a given population since there can be only one independent variable profile for each population.

Two or More Response Functions per Population

When there is more than one response function per population, the structure of the design matrix depends on whether or not the model type is **AVERAGED** (see the **AVERAGED** option in the **MODEL** statement). The model type is **AVERAGED** if independent variable effects are averaged over the multiple responses within a population rather than being nested in them.

The following subsections illustrate the effect of specifying (or not specifying) an **AVERAGED** model type. This section does not apply to log-linear models; for these models, see the section “**Log-Linear Model Design Matrices**” on page 1839.

Model Type Not AVERAGED

Suppose the variable **A** has two levels, and you specify the following statements:

```
proc catmod;
  model Y=A / design;
run;
```

If the variable **Y** has two levels, then there is only one response function per population, and the design matrix is as follows:

Sample	Design Matrix	
	Intercept	A
1	1	1
2	1	-1

But if the variable Y has three levels, then there are two response functions per population, and the preceding design matrix is assumed to hold for each of the two response functions. The response functions are always ordered so that the multiple response functions within a population are grouped together. For this example, the design matrix would be as follows:

Sample	Response Function Number	Design Matrix			
		Intercept		A	
1	1	1	0	1	0
1	2	0	1	0	1
2	1	1	0	-1	0
2	2	0	1	0	-1

Since the same submatrix applies to each of the multiple response functions, PROC CATMOD displays only the submatrix (that is, the one it would create if there were only one response function per population) rather than the entire design matrix. PROC CATMOD displays

$$\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$$

Ordering of Parameters

This grouping of multiple response functions within populations also has an effect in the table of parameter estimates displayed by PROC CATMOD. The following table shows some parameter estimates, where the four rows of the table correspond to the four columns in the preceding design matrix:

Effect	Parameter	Estimate
Intercept	1	1.4979
	2	0.8404
A	3	0.1116
	4	-0.3296

Notice that the intercept and the A effect each have two parameter estimates associated with them. The first estimate in each pair is associated with the first response function, and the second in each pair is associated with the second response function. Consequently, 0.1116 is the effect of the first level of A on the first response function. In any table of parameter estimates displayed by PROC CATMOD, as you read down the column of estimates, the response function level changes before levels of the variables making up the effect.

Model Type AVERAGED

When the model type is **AVERAGED** (for example, when the AVERAGED option is specified in the MODEL statement, when `_RESPONSE_` is used in the MODEL statement, or when the design matrix is input directly in the MODEL statement), PROC CATMOD does not assume that the same submatrix applies to each of the q response functions per population. Rather, it averages any independent variable effects across the functions, and it enables you to study variation among the q functions. The first column of the design matrix is always a column of 1s corresponding to the intercept, unless the **NOINT** option is specified in the MODEL statement or the design matrix is input directly. Also, since the design matrix does not have any special submatrix structure, PROC CATMOD displays the entire matrix.

For example, suppose the dependent variable *Y* has three levels, the independent variable *A* has two levels, and you specify the following statements:

```
proc catmod;
  response marginals;
  model y=a / averaged design;
run;
```

Then there are two response functions per population, and the response functions are always ordered so that the multiple response functions within a population are grouped together. For this example, the design matrix would be as follows:

Sample	Response Function Number	Design Matrix	
		Intercept	A
1	1	1	1
1	2	1	1
2	1	1	-1
2	2	1	-1

Note that the model now has only two degrees of freedom. The remaining two degrees of freedom in the residual correspond to variation among the three levels of the dependent variable. Generally, that variation tends to be statistically significant and therefore should not be left out of the model. You can include it in the model by including the two effects, `_RESPONSE_` and `_RESPONSE_*A`, but if the study is not a repeated measures study, those sources of variation tend to be uninteresting. The usual solution for this type of study (one dependent variable) is to exclude the `AVERAGED` option from the `MODEL` statement.

An `AVERAGED` model type is automatically used whenever you use the `_RESPONSE_` keyword in the `MODEL` statement. The `_RESPONSE_` effect models variation among the q response functions per population. If there is no `REPEATED`, `FACTORS`, or `LOGLIN` statement, then `PROC CATMOD` builds a main effect with $q - 1$ degrees of freedom. For example, three response functions would produce the following design columns:

Response Function Number	Design Columns	
	<code>_RESPONSE_</code>	
1	1	0
2	0	1
3	-1	-1

If there is more than one population, then the `_RESPONSE_` effect is averaged over the populations. Also, the `_RESPONSE_` effect can be crossed with any other effect, or it can be nested within an effect.

If there is a `REPEATED` statement that contains only one repeated measurement factor, then `PROC CATMOD` builds the design columns for `_RESPONSE_` in the same way, except that the output labels the main effect with the factor name rather than with the word `_RESPONSE_`. For example, suppose an independent variable *A* has two levels, and the input statements are as follows:

```
proc catmod;
  response marginals;
  model Time1*Time2=A _response_ A*_response_ / design;
  repeated Time 2 / _response_=Time;
run;
```

If Time1 and Time2 each have two levels (so that they each have one independent marginal probability), then the **RESPONSE** statement makes PROC CATMOD compute two response functions per population. The design matrix is as follows:

Sample	Response Function Number	Design Matrix			
		Intercept	A	Time	A*Time
1	1	1	1	1	1
1	2	1	1	-1	-1
2	1	1	-1	1	-1
2	2	1	-1	-1	1

However, if Time1 and Time2 each have three levels (so that they each have two independent marginal probabilities), then the **RESPONSE** statement causes PROC CATMOD to compute four response functions per population. In that case, since Time has two levels, PROC CATMOD groups the functions into sets of 2 ($= 4/2$) and constructs the preceding submatrix for each function in the set. This results in the following design matrix, which is obtained from the previous one by multiplying each element by an identity matrix of order two:

Sample	Response Function	Design Matrix							
		Intercept		A		Time		A*Time	
1	P(Time1=1)	1	0	1	0	1	0	1	0
1	P(Time1=2)	0	1	0	1	0	1	0	1
1	P(Time2=1)	1	0	1	0	-1	0	-1	0
1	P(Time2=2)	0	1	0	1	0	-1	0	-1
2	P(Time1=1)	1	0	-1	0	1	0	-1	0
2	P(Time1=2)	0	1	0	-1	0	1	0	-1
2	P(Time2=1)	1	0	-1	0	-1	0	1	0
2	P(Time2=2)	0	1	0	-1	0	-1	0	1

If there is a **REPEATED** statement that contains two or more repeated measurement factors, then PROC CATMOD builds the design columns for **_RESPONSE_** according to the definition of **_RESPONSE_** in the **REPEATED** statement. For example, suppose you specify the following statements:

```
proc catmod;
  response marginals;
  model R11*R12*R21*R22=_response_ / design;
  repeated Time 2, Place 2 / _response_=Time Place;
run;
```

If each of the dependent variables has two levels, then PROC CATMOD builds four response functions. The **_RESPONSE_** effect generates a main-effects model with respect to Time and Place, and the design matrix is as follows:

Response Function Number	Variable	Time	Place	Design Matrix		
				Intercept	_RESPONSE_	
1	R11	1	1	1	1	1
2	R12	1	2	1	1	-1
3	R21	2	1	1	-1	1
4	R22	2	2	1	-1	-1

Log-Linear Model Design Matrices

When the response functions are the standard ones (generalized logits), then inclusion of the keyword `_RESPONSE_` in every design effect fits a log-linear model. The design matrix for a log-linear model looks different from a standard design matrix because the standard one is transformed by the same linear transformation that converts the r response probabilities to $r - 1$ generalized logits. For example, suppose the dependent variables X and Y each have two levels, and you specify a saturated log-linear model analysis:

```
proc catmod;
  model X*Y=_response_ / design;
  loglin X Y X*Y;
run;
```

Then the cross-classification of X and Y yields four response probabilities, p_{11} , p_{12} , p_{21} , and p_{22} , which are then reduced to three generalized logit response functions, $F_1 = \log(p_{11}/p_{22})$, $F_2 = \log(p_{12}/p_{22})$, and $F_3 = \log(p_{21}/p_{22})$.

Since the saturated log-linear model implies that

$$\begin{aligned}
 \begin{bmatrix} \log(p_{11}) \\ \log(p_{12}) \\ \log(p_{21}) \\ \log(p_{22}) \end{bmatrix} &= \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{bmatrix} \boldsymbol{\gamma} - \lambda \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} \\
 &= \begin{bmatrix} 1 & 1 & 1 \\ 1 & -1 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & 1 \end{bmatrix} \boldsymbol{\beta} - \delta \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix}
 \end{aligned}$$

where γ and β are parameter vectors, and λ and δ are normalizing constants required by the restriction that the probabilities sum to 1, it follows that the MODEL statement yields

$$\begin{aligned} \begin{bmatrix} F_1 \\ F_2 \\ F_3 \end{bmatrix} &= \begin{bmatrix} 1 & 0 & 0 & -1 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & -1 \end{bmatrix} \times \begin{bmatrix} \log(p_{11}) \\ \log(p_{12}) \\ \log(p_{21}) \\ \log(p_{22}) \end{bmatrix} \\ &= \begin{bmatrix} 1 & 0 & 0 & -1 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & -1 \end{bmatrix} \times \begin{bmatrix} 1 & 1 & 1 \\ 1 & -1 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & 1 \end{bmatrix} \beta \\ &= \begin{bmatrix} 2 & 2 & 0 \\ 2 & 0 & -2 \\ 0 & 2 & -2 \end{bmatrix} \beta \end{aligned}$$

The design matrix is as follows:

Sample	Response Function Number	Design Matrix		
		X	Y	X*Y
1	1	2	2	0
1	2	2	0	-2
1	3	0	2	-2

Design matrices for reduced models are constructed similarly. For example, suppose you request a main-effects log-linear model analysis of the factors X and Y:

```
proc catmod;
  model X*Y=_response_ / design;
  loglin X Y;
run;
```

Since the main-effects log-linear model implies that

$$\begin{aligned} \begin{bmatrix} \log(p_{11}) \\ \log(p_{12}) \\ \log(p_{21}) \\ \log(p_{22}) \end{bmatrix} &= \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & 1 \\ 1 & -1 & -1 \end{bmatrix} \gamma - \lambda \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} \\ &= \begin{bmatrix} 1 & 1 \\ 1 & -1 \\ -1 & 1 \\ -1 & -1 \end{bmatrix} \beta - \delta \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} \end{aligned}$$

it follows that the MODEL statement yields

$$\begin{aligned}
 \begin{bmatrix} F_1 \\ F_2 \\ F_3 \end{bmatrix} &= \begin{bmatrix} 1 & 0 & 0 & -1 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & -1 \end{bmatrix} \times \begin{bmatrix} \log(p_{11}) \\ \log(p_{12}) \\ \log(p_{21}) \\ \log(p_{22}) \end{bmatrix} \\
 &= \begin{bmatrix} 1 & 0 & 0 & -1 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & -1 \end{bmatrix} \times \begin{bmatrix} 1 & 1 \\ 1 & -1 \\ -1 & 1 \\ -1 & -1 \end{bmatrix} \boldsymbol{\beta} \\
 &= \begin{bmatrix} 2 & 2 \\ 2 & 0 \\ 0 & 2 \end{bmatrix} \boldsymbol{\beta}
 \end{aligned}$$

Therefore, the corresponding design matrix is as follows:

Sample	Response		Design Matrix	
	Function	Number	X	Y
1	1	1	2	2
1	2	2	2	0
1	3	3	0	2

Since it is difficult to tell from the final design matrix whether PROC CATMOD used the parameterization that you intended, the procedure displays the untransformed `_RESPONSE_` matrix for log-linear models. For example, specifying the main-effects model in the preceding example displays the following matrix:

Response	_RESPONSE_ Matrix	
	Function	Number
1	1	1
2	1	-1
3	-1	1
4	-1	-1

You can suppress the display of this matrix by specifying the `NORESPONSE` option in the MODEL statement.

Cautions

Effective Sample Size

Since the method depends on asymptotic approximations, you need to be careful that the sample sizes are sufficiently large to support the asymptotic normal distributions of the response functions. A general guideline is that you would like to have an effective sample size of at least 25 to 30 for each response function that is being analyzed. For example, if you have one dependent variable and $r = 4$ response levels, and you use the standard response functions to compute three generalized logits for each population, then you would like the sample size of each population to be at least 75. Moreover, the subjects should be dispersed throughout the table so that less than 20 percent of the response functions have an effective sample size less than 5. For example, if each population had less than 5 subjects in the first response category, then it would be wiser to pool this category with another category rather than to assume the asymptotic normality of the first response function. Or, if the dependent variable is ordinally scaled, an alternative is to request the mean score response function rather than three generalized logits.

If there is more than one dependent variable, and you specify **RESPONSE MEANS**, then the effective sample size for each response function is the same as the actual sample size. Thus, a sample size of 30 could be sufficient to support four response functions, provided that the functions are the means of four dependent variables.

A Singular Covariance Matrix

If there is a singular (noninvertible) covariance matrix for the response functions in any population, then PROC CATMOD writes an error message and stops processing. You have several options available to correct this problem:

- You can reduce the number of response functions according to how many can be supported by the populations with the smallest sample sizes.
- If there are three or more levels for any independent variable, you can pool the levels into a fewer number of categories, thereby reducing the number of populations. However, your interpretation of results must be done more cautiously since such pooling implies a different sampling scheme and masks any differences that existed among the pooled categories.
- If there are two or more independent variables, you can delete at least one of them from the model. However, this is just another form of pooling, and the same cautions that apply to the previous option also apply here.
- If there is one independent variable, then, in some situations, you might simply eliminate the populations that are causing the covariance matrices to be singular.
- You can use the **ADDCELL=** option in the MODEL statement to add a small amount (for example, 0.5) to every cell frequency, but this can seriously bias the results if the cell frequencies are small.

Zero Frequencies

There are two types of zero cells in a contingency table: structural and sampling. A structural zero cell has an expected value of zero, while a sampling zero cell can have nonzero expected value and can be estimable.

If you use the standard response functions and there are zero frequencies, you should use maximum likelihood estimation (the default is **ML=NR**) rather than weighted least squares to analyze the data. For weighted least squares analysis, the CATMOD procedure always computes the observed response functions and might need to take the logarithm of a zero proportion. In this case, PROC CATMOD issues a warning and then takes the log of a small value ($0.5/n_i$ for the probability) in order to continue, but this can produce invalid results if the cells contain too few observations. Maximum likelihood analysis, on the other hand, does not require computation of the observed response functions and therefore yields valid results for the parameter estimates and all of the predicted values.

For a log-linear model analysis with **WLS** or **ML=NR**, PROC CATMOD creates response profiles only for the observed profiles. For any log-linear model analysis with one population (the usual case), the contingency table does not contain zeros, which means that all zero frequencies are treated as structural zeros. If there is more than one population, then a zero in the body of the contingency table is treated as a sampling zero (as long as some population has a nonzero count for that profile). If you fit the log-linear model by using **ML=IPF**, the contingency table is incomplete and the zeros are treated like structural zeros. If you want zero frequencies that PROC CATMOD would normally treat as structural zeros to be interpreted as sampling zeros, you can specify the **ZERO=SAMPLING** and **MISSING=SAMPLING** options in the MODEL statement. Alternatively, you can specify **ZERO=1E-20** and **MISSING=1E-20**.

See Bishop, Fienberg, and Holland (1975) for a discussion of the issues and [Example 30.5](#) for an illustration of a log-linear model analysis of data that contain both structural and sampling zeros.

If you perform a weighted least squares analysis on a contingency table that contains zero cell frequencies, then avoid using the LOG transformation as the first transformation on the observed proportions. In general, it is better to change the response functions or to pool some of the response categories than to settle for the 0.5 correction or to use the **ADDCELL=** option.

Testing the Wrong Hypothesis

If you use the keyword **_RESPONSE_** in the MODEL statement, and you specify **MARGINALS**, **LOGITS**, **ALOGITS**, or **CLOGITS** in your **RESPONSE** statement, you might receive the following warning message:

```
Warning: The _RESPONSE_ effect may be testing the wrong
         hypothesis since the marginal levels of the
         dependent variables do not coincide. Consult the
         response profiles and the CATMOD documentation.
```

The following examples illustrate situations in which the **_RESPONSE_** effect tests the wrong hypothesis.

Zeros in the Marginal Frequencies

Suppose you specify the following statements:

```

data A1;
    input Time1 Time2 @@;
    datalines;
1 2    2 3    1 3
;

proc catmod;
    response marginals;
    model Time1*Time2=_response_;
    repeated Time 2 / _response_=Time;
run;

```

One marginal probability is computed for each dependent variable, resulting in two response functions. The model is a saturated one: one degree of freedom for the intercept and one for the main effect of Time. Except for the warning message, PROC CATMOD produces an analysis with no apparent errors, but the “Response Profiles” table displayed by PROC CATMOD is as follows:

Response Profiles		
Response	Time1	Time2
1	1	2
2	1	3
3	2	3

Since **RESPONSE MARGINALS** yields marginal probabilities for every level but the last, the two response functions being analyzed are Prob(Time1=1) and Prob(Time2=2). The Time effect is testing the hypothesis that Prob(Time1=1)=Prob(Time2=2). What it *should* be testing is the hypothesis that

```

Prob(Time1=1) = Prob(Time2=1)
Prob(Time1=2) = Prob(Time2=2)
Prob(Time1=3) = Prob(Time2=3)

```

but there are not enough data to support the test (assuming that none of the probabilities are structural zeros by the design of the study).

The ORDER=DATA Option

Suppose you specify the following statements:

```

data a1;
    input Time1 Time2 @@;
    datalines;
2 1    2 2    1 1    1 2    2 1
;

proc catmod order=data;
    response marginals;
    model Time1*Time2=_response_;
    repeated Time 2 / _response_=Time;
run;

```

As in the preceding example, one marginal probability is computed for each dependent variable, resulting in two response functions. The model is also the same: one degree of freedom for the intercept and one for the main effect of Time. PROC CATMOD issues the warning message and displays the following “Response Profiles” table:

Response Profiles		
Response	Time1	Time2
1	2	1
2	2	2
3	1	1
4	1	2

Although the marginal levels are the same for the two dependent variables, they are not in the same order because the `ORDER=DATA` option specified that they be ordered according to their appearance in the input stream. Since `RESPONSE MARGINALS` yields marginal probabilities for every level except the last, the two response functions being analyzed are $\text{Prob}(\text{Time1}=2)$ and $\text{Prob}(\text{Time2}=1)$. The Time effect is testing the hypothesis that $\text{Prob}(\text{Time1}=2)=\text{Prob}(\text{Time2}=1)$. What it *should* be testing is the hypothesis that

$$\begin{aligned}\text{Prob}(\text{Time1}=1) &= \text{Prob}(\text{Time2}=1) \\ \text{Prob}(\text{Time1}=2) &= \text{Prob}(\text{Time2}=2)\end{aligned}$$

Whenever the warning message appears, look at the “Response Profiles” table or the “One-Way Frequencies” table to determine what hypothesis is actually being tested. For the latter example, a correct analysis can be obtained by deleting the `ORDER=DATA` option or by reordering the data so that the (1,1) observation is first.

Computational Method

The notation used in PROC CATMOD differs slightly from that used in the literature. The following table provides a summary of the basic dimensions and the notation for a contingency table. See the section “Computational Formulas” on page 1846 for a complete description.

Summary of Basic Dimensions

- s = number of populations or samples (= number of rows in the underlying contingency table)
- r = number of response categories (= number of columns in the underlying contingency table)
- q = number of response functions computed for each population
- d = number of parameters

Notation

\mathbf{j}	Denotes a column vector of 1s.
\mathbf{J}	Denotes a square matrix of 1s.
\sum_k	Denotes the sum over all the possible values of k .
n_i	Denotes the row sum $\sum_j n_{ij}$.
$\text{DIAG}_n(\mathbf{p})$	Denotes the diagonal matrix formed from the first n elements of the vector \mathbf{p} .
$\text{DIAG}_n^{-1}(\mathbf{p})$	Denotes the inverse of $\text{DIAG}_n(\mathbf{p})$.
$\text{DIAG}(\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_k)$	Denotes a block diagonal matrix with the \mathbf{A} matrices on the main diagonal.

Input data can be represented by a contingency table, as shown in [Table 30.7](#).

Table 30.7 Input Data Represented by a Contingency Table

Population	Response				Total
	1	2	...	r	
1	n_{11}	n_{12}	...	n_{1r}	n_1
2	n_{21}	n_{22}	...	n_{2r}	n_2
\vdots	\vdots	\vdots	\ddots	\vdots	\vdots
s	n_{s1}	n_{s2}	...	n_{sr}	n_s

Computational Formulas

The following formulas are shown for each population and for all populations combined.

Source	Formula	Dimension
Probability Estimates		
j th response	$p_{ij} = \frac{n_{ij}}{n_i}$	1×1
i th population	$\mathbf{p}_i = \begin{bmatrix} p_{i1} \\ p_{i2} \\ \vdots \\ p_{ir} \end{bmatrix}$	$r \times 1$
all populations	$\mathbf{p} = \begin{bmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \\ \vdots \\ \mathbf{p}_s \end{bmatrix}$	$sr \times 1$

Source	Formula	Dimension
Variance of Probability Estimates		
<i>i</i> th population	$V_i = \frac{1}{n_i}(\text{DIAG}(\mathbf{p}_i) - \mathbf{p}_i \mathbf{p}_i')$	$r \times r$
all populations	$V = \text{DIAG}(V_1, V_2, \dots, V_s)$	$sr \times sr$
Response Functions		
<i>i</i> th population	$F_i = F(\mathbf{p}_i)$	$q \times 1$
all populations	$F = \begin{bmatrix} F_1 \\ F_2 \\ \vdots \\ F_s \end{bmatrix}$	$sq \times 1$
Derivative of Function with Respect to Probability Estimates		
<i>i</i> th population	$H_i = \frac{\partial F(\mathbf{p}_i)}{\partial \mathbf{p}_i}$	$q \times r$
all populations	$H = \text{DIAG}(H_1, H_2, \dots, H_s)$	$sq \times sr$
Variance of Functions		
<i>i</i> th population	$S_i = H_i V_i H_i'$	$q \times q$
all populations	$S = \text{DIAG}(S_1, S_2, \dots, S_s)$	$sq \times sq$
Inverse Variance of Functions		
<i>i</i> th population	$S^i = (S_i)^{-1}$	$q \times q$
all populations	$S^{-1} = \text{DIAG}(S^1, S^2, \dots, S^s)$	$sq \times sq$

Derivative Table for Compound Functions: $\mathbf{Y}=\mathbf{F}(\mathbf{G}(\mathbf{p}))$

In the following table, let $\mathbf{G}(\mathbf{p})$ be a vector of functions of \mathbf{p} , and let \mathbf{D} denote $\partial \mathbf{G} / \partial \mathbf{p}$, which is the first derivative matrix of \mathbf{G} with respect to \mathbf{p} :

Function	$\mathbf{Y} = \mathbf{F}(\mathbf{G})$	Derivative ($\partial \mathbf{Y} / \partial \mathbf{p}$)
Multiply matrix	$\mathbf{Y} = \mathbf{A} * \mathbf{G}$	$\mathbf{A} * \mathbf{D}$
Logarithm	$\mathbf{Y} = \text{LOG}(\mathbf{G})$	$\text{DIAG}^{-1}(\mathbf{G}) * \mathbf{D}$
Exponential	$\mathbf{Y} = \text{EXP}(\mathbf{G})$	$\text{DIAG}(\mathbf{Y}) * \mathbf{D}$
Add constant	$\mathbf{Y} = \mathbf{G} + \mathbf{A}$	\mathbf{D}

Default Response Functions: Generalized Logits

In the following table, subscripts i for the population are suppressed. Also denote $f_j = \log\left(\frac{p_j}{p_r}\right)$ for $j = 1, \dots, r-1$ for each population $i = 1, \dots, s$.

Formula	
Inverse of Response Functions for a Population	
p_j	$= \frac{\exp(f_j)}{1 + \sum_k \exp(f_k)} \text{ for } j = 1, \dots, r-1$
p_r	$= \frac{1}{1 + \sum_k \exp(f_k)}$
Form of F and Derivative for a Population	
\mathbf{F}	$= \mathbf{KLOG}(\mathbf{p}) = (\mathbf{I}_{r-1}, -\mathbf{j}) \mathbf{LOG}(\mathbf{p})$
\mathbf{H}	$= \frac{\partial \mathbf{F}}{\partial \mathbf{p}} = \left(\mathbf{DIAG}_{r-1}^{-1}(\mathbf{p}), \frac{-1}{p_r} \mathbf{j} \right)$
Covariance Results for a Population	
\mathbf{S}	$= \mathbf{H} \mathbf{V} \mathbf{H}'$
	$= \frac{1}{n} \left(\mathbf{DIAG}_{r-1}^{-1}(\mathbf{p}) + \frac{1}{p_r} \mathbf{J}_{r-1} \right)$
	where \mathbf{V} , \mathbf{H} , and \mathbf{J} are as previously defined.
\mathbf{S}^{-1}	$= n(\mathbf{DIAG}_{r-1}(\mathbf{p}) - \mathbf{q} \mathbf{q}') \text{ , where } \mathbf{q} = \mathbf{DIAG}_{r-1}(\mathbf{p}) \mathbf{j}$
$\mathbf{S}^{-1} \mathbf{F}$	$= n \mathbf{DIAG}_{r-1}(\mathbf{p}) \mathbf{F} - (n \sum_j p_j f_j) \mathbf{q}$
$\mathbf{F}' \mathbf{S}^{-1} \mathbf{F}$	$= n \sum_j p_j f_j^2 - n \left(\sum_j p_j f_j \right)^2$

The following calculations are shown for each population and then for all populations combined:

Source	Formula	Dimension
Design Matrix		
i th population	\mathbf{X}_i	$q \times d$
all populations	$\mathbf{X} = \begin{bmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \\ \vdots \\ \mathbf{X}_s \end{bmatrix}$	$sq \times d$

Source	Formula	Dimension
Crossproduct of Design Matrix		
i th population	$C_i = \mathbf{X}_i' \mathbf{S}^i \mathbf{X}_i$	$d \times d$
all populations	$\mathbf{C} = \mathbf{X}' \mathbf{S}^{-1} \mathbf{X} = \sum_i C_i$	$d \times d$

In the following table, z_p is the 100 p th percentile of the standard normal distribution:

Formula	Dimension
Crossproduct of Design Matrix with Function	
$\mathbf{R} = \mathbf{X}' \mathbf{S}^{-1} \mathbf{F} = \sum_i \mathbf{X}_i' \mathbf{S}^i \mathbf{F}_i$	$d \times 1$
Weighted Least Squares Estimates	
$\mathbf{b} = \mathbf{C}^{-1} \mathbf{R} = (\mathbf{X}' \mathbf{S}^{-1} \mathbf{X})^{-1} (\mathbf{X}' \mathbf{S}^{-1} \mathbf{F})$	$d \times 1$
Covariance of Weighted Least Squares Estimates	
$\text{COV}(\mathbf{b}) = \mathbf{C}^{-1}$	$d \times d$
Wald Confidence Limits for Parameter Estimates	
$b_k \pm z_{1-\alpha/2} C_{kk}^{-1}$	$k = 1, \dots, d$
Predicted Response Functions	
$\hat{\mathbf{F}} = \mathbf{X} \mathbf{b}$	$sq \times 1$
Covariance of Predicted Response Functions	
$\mathbf{V}_{\hat{\mathbf{F}}} = \mathbf{X} \mathbf{C}^{-1} \mathbf{X}'$	$sq \times sq$
Residual Chi-Square	
$\text{RSS} = \mathbf{F}' \mathbf{S}^{-1} \mathbf{F} - \hat{\mathbf{F}}' \mathbf{S}^{-1} \hat{\mathbf{F}}$	1×1
Chi-Square for $H_0: \mathbf{L}\boldsymbol{\beta} = 0$	
$\mathbf{Q} = (\mathbf{L} \mathbf{b})' (\mathbf{L} \mathbf{C}^{-1} \mathbf{L}')^{-1} (\mathbf{L} \mathbf{b})$	1×1

Maximum Likelihood Method

Let \mathbf{C} be the Hessian matrix and \mathbf{G} be the gradient of the log-likelihood function (both functions of $\boldsymbol{\pi}$ and the parameters $\boldsymbol{\beta}$). Let \mathbf{p}_i^* denote the vector containing the first $r - 1$ sample proportions from population i , and let $\boldsymbol{\pi}_i^*$ denote the corresponding vector of probability estimates from the current iteration. Starting with the least squares estimates \mathbf{b}_0 of $\boldsymbol{\beta}$ (if you use the **ML** and **WLS** options; with the **ML** option alone, the procedure starts with $\mathbf{0}$), the probabilities $\boldsymbol{\pi}(\mathbf{b})$ are computed, and \mathbf{b} is calculated iteratively by the Newton-Raphson method until it converges (see the **EPSILON=** option). The factor λ is a step-halving factor that equals one at the start of each iteration. For any iteration in which the likelihood decreases, PROC CATMOD uses a series of subiterations in which λ is iteratively divided by two. The subiterations continue until the likelihood is greater than that of the previous iteration. If the likelihood has not reached that point after 10 subiterations, then convergence is assumed, and a warning message is displayed.

Sometimes, infinite parameters are present in the model, either because of the presence of one or more zero frequencies or because of a poorly specified model with collinearity among the estimates. If an estimate is tending toward infinity, then PROC CATMOD flags the parameter as infinite and holds the estimate fixed in subsequent iterations. PROC CATMOD regards a parameter to be infinite when two conditions apply:

- The absolute value of its estimate exceeds five divided by the range of the corresponding variable.
- The standard error of its estimate is at least three times greater than the estimate itself.

The estimator of the asymptotic covariance matrix of the maximum likelihood predicted probabilities is given by Imrey, Koch, and Stokes (1981, eq. 2.18).

The following equations summarize the method:

$$\mathbf{b}_{k+1} = \mathbf{b}_k - \lambda \mathbf{C}^{-1} \mathbf{G}$$

where

$$\mathbf{C} = \mathbf{X}' \mathbf{S}^{-1}(\boldsymbol{\pi}) \mathbf{X}$$

$$\mathbf{N} = \begin{bmatrix} n_1(\mathbf{p}_1^* - \boldsymbol{\pi}_1^*) \\ \vdots \\ n_s(\mathbf{p}_s^* - \boldsymbol{\pi}_s^*) \end{bmatrix}$$

$$\mathbf{G} = \mathbf{X}' \mathbf{N}$$

Iterative Proportional Fitting

The algorithm used by PROC CATMOD for iterative proportional fitting is described in Bishop, Fienberg, and Holland (1975); Haberman (1972); Agresti (2002). To illustrate the method, consider the observed three-dimensional table $\{m_{ijk}\}$ for the variables X , Y , and Z , and the following hierarchical model:

$$\log(m_{ijk}) = \mu + \lambda_i^X + \lambda_j^Y + \lambda_k^Z + \lambda_{ij}^{XY} + \lambda_{ik}^{XZ} + \lambda_{jk}^{YZ}$$

The following statements request that PROC CATMOD use IPF to fit the preceding model:

```
model X*Y*Z = _response_ / ml=ipf;
loglin X|Y|Z@2;
```

Begin with a table of initial cell estimates $\{\hat{m}_{ijk}^{(0)}\}$. PROC CATMOD produces the initial estimates by setting the n_{sz} structural zero cells to 0 and all other cells to $n/(n_c - n_{sz})$, where n is the total weight of the table and n_c is the total number of cells in the table. Iteratively adjust the estimates at step $s - 1$ to the observed marginal tables specified in the model by cycling through the following three-stage process to produce the estimates at step s :

$$\begin{aligned}\hat{m}_{ijk}^{(s_1)} &= \hat{m}_{ijk}^{(s-1)} \frac{n_{ij\cdot}}{\hat{m}_{ij\cdot}^{(s-1)}} \\ \hat{m}_{ijk}^{(s_2)} &= \hat{m}_{ijk}^{(s_1)} \frac{n_{i\cdot k}}{\hat{m}_{i\cdot k}^{(s_1)}} \\ \hat{m}_{ijk}^{(s)} &= \hat{m}_{ijk}^{(s_2)} \frac{n_{\cdot jk}}{\hat{m}_{\cdot jk}^{(s_2)}}\end{aligned}$$

The subscript “.” indicates summation over the missing subscript. The log-likelihood l_s is estimated at each step s by

$$l_s = \sum_{i,j,k} n_{ijk} \log \left(\frac{\hat{m}_{ijk}^{(s)}}{n} \right)$$

When the function $|(l_{s-1} - l_s)/l_{s-1}|$ is less than 10^{-8} , the iterations terminate. You can change the comparison value with the **EPSILON=** option, and you can change the convergence criterion with the **CONVCRT=** option. The option **CONVCRT=CELL** uses the maximum cell difference

$$\max_{i,j,k} |\hat{m}_{ijk}^{(s-1)} - \hat{m}_{ijk}^{(s)}|$$

as the criterion while the option **CONVCRT=MARGIN** computes the maximum difference of the margins

$$\text{Maximum of } \left\{ \max_{i,j} |\hat{m}_{ij\cdot}^{(s-1)} - \hat{m}_{ij\cdot}^{(s)}|, \max_{i,k} |\hat{m}_{i\cdot k}^{(s-1)} - \hat{m}_{i\cdot k}^{(s)}|, \max_{j,k} |\hat{m}_{\cdot jk}^{(s-1)} - \hat{m}_{\cdot jk}^{(s)}| \right\}$$

Memory and Time Requirements

The memory and time required by PROC CATMOD are proportional to the number of parameters in the model.

Displayed Output

PROC CATMOD displays the following information in the “Data Summary” table:

- the response effect
- the weight variable, if one is specified
- the data set name
- the number of response levels
- the number of samples or populations
- the total frequency, which is the total sample size
- the number of observations from the data set (the number of data records)
- the frequency of missing observations, labeled as “Frequency Missing”

Except for the analysis of variance table, all of the following items can be displayed or suppressed, depending on your specification of statements and options.

- The **ONEWAY** option produces the “One-Way Frequencies” table, which displays the frequencies of each variable value used in the analysis.
- The populations (or samples) are defined in a table labeled “Population Profiles.” The sample size and the values of the defining variables are displayed for each sample. This table is suppressed if the **NOPROFILE** option is specified.
- The observed responses are defined in a table labeled “Response Profiles.” The values of the defining variables are displayed for each response. This table is suppressed if the **NOPROFILE** option is specified.
- If the **FREQ** option is specified, then the “Response Frequencies” table is displayed, which shows the frequency of each response for each population.
- If the **PROB** option is specified, then the “Response Probabilities” table is produced. This table displays the probability of each response for each population.
- If the **COV** option is specified, the “Response Functions, Covariance Matrix” table, which shows the covariance matrix of the response functions for each sample, is displayed.
- If the **DESIGN** option is specified, the response functions are displayed in the “Response Functions, Design Matrix” table. If the **COV** option is also specified, the response functions are displayed in the “Response Functions, Covariance Matrix” table.
- If the **DESIGN** option is specified, the design matrix is displayed in the “Response Functions, Design Matrix” table, and if a log-linear model is being fit, the **_RESPONSE_** matrix is displayed in the “_Response_ Matrix” table. If the model type is **AVERAGED**, then the design matrix is displayed with $q * s$ rows, assuming q response functions for each of s populations. Otherwise, the design matrix is displayed with only s rows since the model is the same for each of the q response functions.

- The “ $X' \text{Inv}(S) X$ ” matrix is displayed for weighted least squares analyses if the **XPX** option is specified.
- The “Analysis of Variance” table for the weighted least squares analysis reports the results of significance tests for each of the *design-effects* on the right side of the MODEL statement. If **_RESPONSE_** is a *design-effect* and is defined explicitly in the **LOGLIN**, **FACTORS**, or **REPEATED** statement, then the table contains test statistics for the individual effects constituting the **_RESPONSE_** effect. If the design matrix is input directly, then the content of the displayed output depends on whether you specify any subsets of the parameters to be tested. If you specify one or more subsets, then the table contains one test for each subset. Otherwise, the table contains one test for the effect **MODEL | MEAN**. In every case, the table also contains the residual goodness-of-fit test. Produced for each test of significance are the source of variation, the number of degrees of freedom (DF), the Wald chi-square value, and the significance probability ($\text{Pr} > \text{ChiSq}$).
- The “Analysis of Weighted Least Squares Estimates” table lists, for each parameter in the model, the least squares estimate, the estimated standard error of the parameter estimate, the Wald chi-square value (calculated as $((\text{parameter estimate})/(\text{standard error}))^2$) for testing that the parameter is zero, and the significance probability ($\text{Pr} > \text{ChiSq}$) of the test. If the **CLPARM** option is specified, then 95% Wald confidence intervals are displayed.

Each row in the table is labeled with the parameter (the model effect and the class levels) and the response function number; however, if the **NOPREDVAR** option or a **REPEATED** or **FACTORS** statement is specified or if the design matrix is directly input, the rows are labeled by the effect in the model for which parameters are formed and the parameter number.
- The “Covariance Matrix of the Parameter Estimates” table for the weighted least squares analysis displays the estimated covariance matrix of the least squares estimates of the parameters, provided that the **COVB** option is specified.
- The “Correlation Matrix of the Parameter Estimates” table for the weighted least squares analysis displays the estimated correlation matrix of the least squares estimates of the parameters, provided that the **CORRB** option is specified.
- The “Maximum Likelihood Analysis” table is produced when the **ML** and **ITPRINT** options are specified for the standard response functions. It displays the iteration number, the number of step-halving sub-iterations, $-2 \log$ likelihood for that iteration, the convergence criterion, and the parameter estimates for each iteration.
- The “Maximum Likelihood Analysis of Variance” table, displayed when the **ML** option is specified for the standard response functions, is similar to the table produced for the least squares analysis. The Wald chi-square test for each effect is based on the information matrix from the likelihood calculations. The likelihood ratio statistic compares the specified model with the unrestricted (saturated) model and is an appropriate goodness-of-fit test for the model.
- The “Analysis of Maximum Likelihood Estimates” table, displayed when the **ML** option is specified for the standard response functions, is similar to the one produced for the least squares analysis. The table includes the maximum likelihood estimates, the estimated standard errors based on the information matrix, and the Wald chi-square statistics based on estimated standard errors.
- The “Covariance Matrix of the Maximum Likelihood Estimates” table displays the estimated covariance matrix of the maximum likelihood estimates of the parameters, provided that the **COVB** and **ML** options are specified for the standard response functions.

- The “Correlation Matrix of the Maximum Likelihood Estimates” table displays the estimated correlation matrix of the maximum likelihood estimates of the parameters, provided that the **CORRB** and **ML** options are specified for the standard response functions.
- For each source of variation specified in a **CONTRAST** statement, the “Contrasts” table lists the label for the source (Contrast), the number of degrees of freedom (DF), the Wald chi-square value, and the significance probability ($\text{Pr} > \text{ChiSq}$). If the **ESTIMATE=** option is specified, the “Analysis of Contrasts” table displays, for each row of the contrast, the label (Contrast), the type (PARM or EXP), the row of the contrast, the estimate and its standard error, a Wald confidence interval, the Wald chi-square, and the p -value ($\text{Pr} > \text{ChiSq}$) for 1 degree of freedom.
- Specification of the **PREDICT** option in the MODEL statement has the following effect. Produced for each response function within each population are the observed and predicted function values, their standard errors, and the residual (observed minus predicted). If the response functions are the default ones (generalized logits), additional information displayed for each response within each population includes the observed and predicted cell probabilities, their standard errors, and the residual. However, specifying **PRED=FREQ** in the MODEL statement results in the display of the predicted cell frequencies rather than the predicted cell probabilities. The displayed output includes the population profiles and, for the response function table, the function number, while the probability and frequency tables display the response profiles. If the **NOPREDVAR** option is specified in the MODEL statement, the population profiles are replaced with the sample numbers, and the response profiles are replaced with the labels “ P_n ” for the n th cell probability, and “ F_n ” for the n th cell frequency.
- When there are multiple **RESPONSE** statements, the output for each statement starts on a new page. For each **RESPONSE** statement, the corresponding title, if specified, is displayed at the top of each page.
- If the **ADDCELL=** option is specified in the MODEL statement, and if there is a weighted least squares analysis specified, the adjusted sample size for each population (with number added to each cell) is labeled “Adjusted Sample Size” in the “Population Profiles” table. Similarly, the adjusted response frequencies and probabilities are displayed in the “Adjusted Response Frequencies” and “Adjusted Response Probabilities” tables, respectively.
- If **_RESPONSE_** is defined explicitly in the **LOGLIN**, **FACTORS**, or **REPEATED** statement, then the definition is displayed as a note whenever **_RESPONSE_** appears in the output.

ODS Table Names

PROC CATMOD assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

Table 30.12 ODS Tables Produced by PROC CATMOD

ODS Table Name	Description	Statement	Option
ANOVA	Analysis of variance	MODEL	default
Contrasts	Contrasts	CONTRAST	default
ContrastEstimates	Analysis of contrasts	CONTRAST	ESTIMATE=
ConvergenceStatus	Convergence status	MODEL	ML
CorrB	Correlation matrix of the estimates	MODEL	CORRB
CovB	Covariance matrix of the estimates	MODEL	COVB
DataSummary	Data summary	PROC	default
Estimates	Analysis of estimates	MODEL	default, unless NOPARM
MaxLikelihood	Maximum likelihood analysis	MODEL	ML and ITPRINT
OneWayFreqs	One-way frequencies	MODEL	ONEWAY
PopProfiles	Population profiles	MODEL	default, unless NOPROFILE
PredictedFreqs	Predicted frequencies	MODEL	PRED=FREQ
PredictedProbs	Predicted probabilities	MODEL	PREDICT or PRED=PROB
PredictedValues	Predicted values	MODEL	PREDICT or PRED=
ResponseCov	Response functions, covariance matrix	MODEL	COV
ResponseDesign	Response functions, design matrix	MODEL	DESIGN, unless NODESIGN
ResponseFreqs	Response frequencies	MODEL	FREQ
ResponseMatrix	_RESPONSE_ matrix	MODEL and LOGLIN	DESIGN, unless NORESPONSE
ResponseProbs	Response probabilities	MODEL	PROB
ResponseProfiles	Response profiles	MODEL	default, unless NOPROFILE
XPX	$\mathbf{X}' * \text{Inv}(\mathbf{S}) * \mathbf{X}$ matrix	MODEL	XPX, for WLS*

* WLS estimation is the default for response functions other than the default (generalized logits).

Examples: CATMOD Procedure

Example 30.1: Linear Response Function, $r=2$ Responses

In an example from Ries and Smith (1963), the choice of detergent brand (Brand = M or X) is related to three other categorical variables: the softness of the laundry water (Softness = soft, medium, or hard), the temperature of the water (Temperature = high or low), and whether the subject was a previous user of Brand M (Previous = yes or no). The linear response function, which could also be specified as [RESPONSE MARGINALS](#), yields one probability, $\Pr(\text{brand preference}=\text{M})$, as the response function to be analyzed. Two models are fit in this example: the first model is a saturated one, containing all of the main effects and interactions, while the second is a reduced model containing only the main effects. The following statements produce [Output 30.1.1](#) through [Output 30.1.4](#):

```
data detergent;
  input Softness $ Brand $ Previous $ Temperature $ Count @@;
  datalines;
soft X yes high 19    soft X yes low 57
soft X no high 29     soft X no low 63
soft M yes high 29    soft M yes low 49
soft M no high 27     soft M no low 53
med X yes high 23     med X yes low 47
med X no high 33      med X no low 66
med M yes high 47     med M yes low 55
med M no high 23      med M no low 50
hard X yes high 24    hard X yes low 37
hard X no high 42     hard X no low 68
hard M yes high 43    hard M yes low 52
hard M no high 30     hard M no low 42
;

title 'Detergent Preference Study';
proc catmod data=detergent;
  response 1 0;
  weight Count;
  model Brand=Softness|Previous|Temperature / freq prob;
  title2 'Saturated Model';
run;
```

The “Data Summary” table ([Output 30.1.1](#)) indicates that you have two response levels and twelve populations.

Output 30.1.1 Detergent Preference Study: Linear Model Analysis

Detergent Preference Study			
Saturated Model			
The CATMOD Procedure			
Data Summary			
Response	Brand	Response Levels	2
Weight Variable	Count	Populations	12
Data Set	DETERGENT	Total Frequency	1008
Frequency Missing	0	Observations	24

The “Population Profiles” table in [Output 30.1.2](#) displays the ordering of independent variable levels as used in the table of parameter estimates.

Output 30.1.2 Population Profiles

Population Profiles				
Sample	Softness	Previous	Temperature	Sample Size
1	hard	no	high	72
2	hard	no	low	110
3	hard	yes	high	67
4	hard	yes	low	89
5	med	no	high	56
6	med	no	low	116
7	med	yes	high	70
8	med	yes	low	102
9	soft	no	high	56
10	soft	no	low	116
11	soft	yes	high	48
12	soft	yes	low	106

Since Brand M is the first level in the “Response Profiles” table ([Output 30.1.3](#)), the **RESPONSE** statement causes $\text{Pr}(\text{Brand}=\text{M})$ to be the single response function modeled.

Output 30.1.3 Response Profiles, Frequencies, and Probabilities

Response Profiles	
Response	Brand
1	M
2	X

Output 30.1.3 *continued*

Response Frequencies		
Sample	Response Number	
	1	2
1	30	42
2	42	68
3	43	24
4	52	37
5	23	33
6	50	66
7	47	23
8	55	47
9	27	29
10	53	63
11	29	19
12	49	57

Response Probabilities

	1	2
1	0.41667	0.58333
2	0.38182	0.61818
3	0.64179	0.35821
4	0.58427	0.41573
5	0.41071	0.58929
6	0.43103	0.56897
7	0.67143	0.32857
8	0.53922	0.46078
9	0.48214	0.51786
10	0.45690	0.54310
11	0.60417	0.39583
12	0.46226	0.53774

The “Analysis of Variance” table in [Output 30.1.4](#) shows that all of the interactions are nonsignificant.

Output 30.1.4 Analysis of Variance

Analysis of Variance			
Source	DF	Chi-Square	Pr > ChiSq
Intercept	1	983.13	<.0001
Softness	2	0.09	0.9575
Previous	1	22.68	<.0001
Softness*Previous	2	3.85	0.1457
Temperature	1	3.67	0.0555
Softness*Temperature	2	0.23	0.8914
Previous*Temperature	1	2.26	0.1324
Softnes*Previous*Temperat	2	0.76	0.6850
Residual	0	.	.

Therefore, a main-effects model is fit with the following statements:

```

model Brand=Softness Previous Temperature
      / clparm noprofile design;
title2 'Main-Effects Model';
run;
quit;

```

The PROC CATMOD statement is not required due to the interactive capability of the CATMOD procedure. The **NOPROFILE** option suppresses the redisplay of the “Response Profiles” table. The **CLPARM** option produces 95% confidence limits for the parameter estimates. [Output 30.1.5](#) through [Output 30.1.7](#) are produced.

The design matrix in [Output 30.1.5](#) displays the results of the differential-effects modeling used in PROC CATMOD.

Output 30.1.5 Main-Effects Design Matrix

Detergent Preference Study			
Main-Effects Model			
The CATMOD Procedure			
Data Summary			
Response	Brand	Response Levels	2
Weight Variable	Count	Populations	12
Data Set	DETERGENT	Total Frequency	1008
Frequency Missing	0	Observations	24

Output 30.1.5 *continued*

Response Functions and Design Matrix						
Sample	Response Function	Design Matrix				
		1	2	3	4	5
1	0.41667	1	1	0	1	1
2	0.38182	1	1	0	1	-1
3	0.64179	1	1	0	-1	1
4	0.58427	1	1	0	-1	-1
5	0.41071	1	0	1	1	1
6	0.43103	1	0	1	1	-1
7	0.67143	1	0	1	-1	1
8	0.53922	1	0	1	-1	-1
9	0.48214	1	-1	-1	1	1
10	0.45690	1	-1	-1	1	-1
11	0.60417	1	-1	-1	-1	1
12	0.46226	1	-1	-1	-1	-1

The analysis of variance table in [Output 30.1.6](#) shows that previous use of Brand M, together with the temperature of the laundry water, is a significant factor in whether a subject prefers Brand M laundry detergent. The table also shows that the additive model fits since the goodness-of-fit statistic (the residual chi-square) is nonsignificant.

Output 30.1.6 ANOVA Table for the Main-Effects Model

Analysis of Variance			
Source	DF	Chi-Square	Pr > ChiSq
Intercept	1	1004.93	<.0001
Softness	2	0.24	0.8859
Previous	1	20.96	<.0001
Temperature	1	3.95	0.0468
Residual	7	8.26	0.3100

The chi-square test in [Output 30.1.7](#) shows that the Softness parameters are not significantly different from zero; as expected, the Wald confidence limits for these two estimates contain zero. So softness of the water is not a factor in choosing Brand M.

Output 30.1.7 WLS Estimates for the Main-Effects Model

Analysis of Weighted Least Squares Estimates							
Parameter		Estimate	Standard Error	Chi-Square	Pr > ChiSq	95% Confidence Limits	
Intercept		0.5080	0.0160	1004.93	<.0001	0.4766	0.5394
Softness	hard	-0.00256	0.0218	0.01	0.9066	-0.0454	0.0402
	med	0.0104	0.0218	0.23	0.6342	-0.0323	0.0530
Previous	no	-0.0711	0.0155	20.96	<.0001	-0.1015	-0.0407
Temperature	high	0.0319	0.0161	3.95	0.0468	0.000446	0.0634

The negative coefficient for Previous (−0.0711) indicates that the first level of Previous (which is shown to be ‘no’) is associated with a smaller probability of preferring Brand M than the second level of Previous (with coefficient constrained to be 0.0711 since the parameter estimates for a given effect must sum to zero). In other words, previous users of Brand M are much more likely to prefer it than those who have never used it before.

Similarly, the positive coefficient for Temperature indicates that the first level of Temperature (which, from the “Population Profiles” table, is ‘high’) has a larger probability of preferring Brand M than the second level of Temperature. In other words, those who do their laundry in hot water are more likely to prefer Brand M than those who do their laundry in cold water.

Example 30.2: Mean Score Response Function, r=3 Responses

Four surgical operations for duodenal ulcers are compared in a clinical trial at four hospitals. The operations performed are as follows: Treatment = a, drainage and vagotomy; Treatment = b, 25% resection and vagotomy; Treatment = c, 50% resection and vagotomy; and Treatment = d, 75% resection. The response is severity of an undesirable complication called “dumping syndrome.” The data in the following statements are from Grizzle, Starmer, and Koch (1969, pp. 489–504).

```
data operate;
  input Hospital Treatment $ Severity $ wt @@;
  datalines;
1 a none 23      1 a slight 7      1 a moderate 2
1 b none 23      1 b slight 10     1 b moderate 5
1 c none 20      1 c slight 13     1 c moderate 5
1 d none 24      1 d slight 10     1 d moderate 6
2 a none 18      2 a slight 6      2 a moderate 1
2 b none 18      2 b slight 6      2 b moderate 2
2 c none 13      2 c slight 13     2 c moderate 2
2 d none 9       2 d slight 15     2 d moderate 2
3 a none 8       3 a slight 6      3 a moderate 3
3 b none 12      3 b slight 4      3 b moderate 4
3 c none 11      3 c slight 6      3 c moderate 2
3 d none 7       3 d slight 7      3 d moderate 4
4 a none 12      4 a slight 9      4 a moderate 1
4 b none 15      4 b slight 3      4 b moderate 2
```

```

4 c none 14      4 c slight 8      4 c moderate 3
4 d none 13      4 d slight 6      4 d moderate 4
;

```

The response variable (Severity) is ordinally scaled with three levels, so assignment of scores is appropriate (0 = none, 0.5 = slight, 1 = moderate). For these scores, the response function yields the mean score. The following statements produce [Output 30.2.1](#) through [Output 30.2.3](#):

```

title 'Dumping Syndrome Data';
proc catmod data=operate order=data ;
  weight wt;
  response 0 0.5 1;
  model Severity=Treatment Hospital / freq oneway design;
  title2 'Main-Effects Model';
quit;

```

The **ORDER=** option is specified so that the levels of the response variable remain in the correct order. A main-effects model is fit. The **ONEWAY** option produces a table of the number of subjects within each variable level, and the **FREQ** option displays the frequency of each response within each sample ([Output 30.2.1](#)).

Output 30.2.1 Surgical Data: Analysis of Mean Scores

Dumping Syndrome Data			
Main-Effects Model

5	23	10	5
6	18	6	2
7	12	4	4
8	15	3	2
9	20	13	5
10	13	13	2
11	11	6	2
12	14	8	3
13	24	10	6
14	9	15	2
15	7	7	4
16	13	6	4

You can use the one-way frequencies and the response profiles from [Output 30.2.1](#) to verify that the response levels are in the desired order (none, slight, moderate) so that the response scores (0, 0.5, 1.0) are applied appropriately. If the `ORDER=DATA` option had not been used, the levels would have been in a different order.

The analysis of variance table ([Output 30.2.2](#)) shows that the additive model fits (since the residual chi-square is not significant), that the Treatment effect is significant, and that the Hospital effect is not significant.

Output 30.2.2 Surgical Data: Analysis of Mean Scores

Response Functions and Design Matrix								
Sample	Response Function	1	2	Design Matrix

15	0.41667	1	-1	-1	-1	0	0	1
16	0.30435	1	-1	-1	-1	-1	-1	-1

Analysis of Variance			
Source	DF	Chi-Square	Pr > ChiSq
Intercept	1	248.77	<.0001
Treatment	3	8.90	0.0307
Hospital	3	2.33	0.5065
Residual	9	6.33	0.7069

The coefficients of Treatment in [Output 30.2.3](#) show that the first two treatments (with negative coefficients) have lower mean scores than the last two treatments (the fourth coefficient, not shown, must be positive since the four coefficients must sum to zero). In other words, the less severe treatments (the first two) cause significantly less severe dumping syndrome complications.

Output 30.2.3 Surgical Data: Analysis of Mean Scores

Logistic regression analysis is often used to investigate the relationship between discrete response variables and continuous explanatory variables. For logistic regression, the continuous *design-effects* are declared in a **DIRECT** statement. The following statements produce [Output 30.3.1](#) through [Output 30.3.6](#):

```
title 'Maximum Likelihood Logistic Regression';
proc catmod data=ingots;
  weight Count;
  direct Heat Soak;
  model Y=Heat Soak / freq covb corrb itprint design;
quit;
```

You can verify that the populations are defined as you intended by looking at the “Population Profiles” table in [Output 30.3.1](#).

Output 30.3.1 Maximum Likelihood Logistic Regression

Maximum Likelihood Logistic Regression

Maximum likelihood computations converged.

The analysis of variance table (Output 30.3.5) shows that the model fits since the likelihood ratio goodness-of-fit test is nonsignificant. It also shows that the length of heating time is a significant factor with respect to readiness but that length of soaking time is not.

Output 30.3.5 Analysis of Variance Table

Maximum Likelihood Analysis of Variance			
Source	DF	Chi-Square	Pr > ChiSq
Intercept	1	24.65	<.0001
Heat	1	11.95	0.0005
Soak	1	0.03	0.8639
Likelihood Ratio	16	13.75	0.6171

From the table of maximum likelihood estimates in Output 30.3.6, the fitted model is

$$E(\logit(p)) = 5.559 - 0.082(\text{Heat}) - 0.057(\text{Soak})$$

For example, for Sample 1 with Heat = 7 and Soak = 1, the estimate is

$$E(\logit(p)) = 5.559 - 0.082(7) - 0.057(1) = 4.9284$$

Output 30.3.6 Maximum Likelihood Estimates, Covariances, and Correlations

Analysis of Maximum Likelihood Estimates				
Parameter	Estimate	Standard Error	Chi-Square	Pr > ChiSq
Intercept	5.5592	1.1197	24.65	<.0001
Heat	-0.0820	0.0237	11.95	0.0005
Soak	-0.0568	0.3312	0.03	0.8639

Covariance Matrix of the Maximum Likelihood Estimates				
Row	Parameter	Col1	Col2	Col3
1	Intercept	1.2537133	-0.0215664	-0.2817648
2	Heat	-0.0215664	0.0005633	0.0026243
3	Soak	-0.2817648	0.0026243	0.1097020

Correlation Matrix of the Maximum Likelihood Estimates				
Row	Parameter	Col1	Col2	Col3
1	Intercept	1.00000	-0.81152	-0.75977
2	Heat	-0.81152	1.00000	0.33383
3	Soak	-0.75977	0.33383	1.00000

Predicted values of the logits, as well as the probabilities of readiness, could be obtained by specifying **PRED=PROB** in the MODEL statement. For the example of Sample 1 with Heat = 7 and Soak = 1, PRED=PROB would give an estimate of the probability of readiness equal to 0.9928 since

$$4.9284 = \log\left(\frac{\hat{p}}{1 - \hat{p}}\right)$$

implies that

$$\hat{p} = \frac{e^{4.9284}}{1 + e^{4.9284}} = 0.9928$$

As another consideration, since soaking time is nonsignificant, you could fit another model that deleted the variable Soak.

Example 30.4: Log-Linear Model, Three Dependent Variables

This analysis reproduces the predicted cell frequencies for Bartlett's data by using a log-linear model of no three-variable interaction (Bishop, Fienberg, and Holland 1975, p. 89). Cuttings of two different lengths (Length=short or long) are planted at one of two time points (Time=now or spring), and their survival status (Status=dead or alive) is recorded.

As in the text, the variable levels are simply labeled 1 and 2. The following statements produce [Output 30.4.1](#) through [Output 30.4.3](#):

```

data bartlett;
    input Length Time Status wt @@;
    datalines;

Example 30.5: Log-Linear Model, Structural and Sampling Zeros

This example illustrates a log-linear model of independence, by using data that contain structural zero frequencies as well as sampling (random) zero frequencies.

In a population of six squirrel monkeys, the joint distribution of genital display with respect to active or passive role was observed. The data are from Fienberg (1980, Table 8-2). Since a monkey cannot have both the active and passive roles in the same interaction, the diagonal cells of the table are structural zeros. See Agresti (2002) for more information about the quasi-independence model.

The DATA step replaces the structural zeros with missing values, and the **MISSING=STRUCTURAL** option is specified in the MODEL statement to remove these zeros from the analysis. The **ZERO=SAMPLING** option treats the off-diagonal zeros as sampling zeros. Also, the row for Monkey 't' is deleted since it contains all zeros; therefore, the cell frequencies predicted by a model of independence are also zero. In addition, the **CONTRAST** statement compares the behavior of the two monkeys labeled 'u' and 'v'. See the section “**Structural and Sampling Zeros with Raw Data**” on page 1877 for information about how to perform this analysis when you have raw data. The following statements produce **Output 30.5.1** through **Output 30.5.8**:

```
data Display;
  input Active $ Passive $ wt @@;
  if Active ne 't';
  if Active eq Passive then wt=.;
  datalines;
r r 0   r s 1   r t 5   r u 8   r v 9   r w 0

1	13

The analysis of variance table ([Output 30.5.5](#)) shows that the model of independence does not fit since the likelihood ratio test for the interaction is significant. In other words, active and passive behaviors of the squirrel monkeys are dependent behavior roles.

Output 30.5.5 Analysis of Variance Table

Maximum Likelihood Analysis of Variance			
Source	DF	Chi-Square	Pr > ChiSq
Active	4	56.58	<.0001
Passive	5	47.94	<.0001
Likelihood Ratio	15	135.17	<.0001

If the model fit these data, then the contrasts in [Output 30.5.6](#) show that monkeys 'u' and 'v' appear to have similar passive behavior patterns but very different active behavior patterns.

Output 30.5.6 Contrasts between Monkeys 'u' and 'v'

Contrasts of Maximum Likelihood Estimates			
Contrast	DF	Chi-Square	Pr > ChiSq
Passive, U vs. V	1	1.31	0.2524
Active, U vs. V	1	14.87	0.0001

Output 30.5.7 displays the predicted response functions and Output 30.5.8 displays predicted cell frequencies (from the `PRED=FREQ` option), but since the model does not fit, these should be ignored. Note that, since the response function is the generalized logit with the 25th response as the baseline, the observed response functions for the sampling zeros are missing.

Output 30.5.7 Response Function Predicted Values

Structural and Sampling Zeros with Raw Data

The preceding PROC CATMOD step uses cell count data as input. Prior to invoking the CATMOD procedure, structural and sampling zeros are easily identified and manipulated in a single DATA step. For the situation where structural or sampling zeros (or both) exist and the input data set is raw data, use the following steps:

1. Run PROC FREQ on the raw data (see Chapter 38, “[The FREQ Procedure](#)”). In the TABLES statement, list all dependent and independent variables, separated by asterisks, and use the SPARSE option and the OUT= option. This creates an output data set that contains all possible zero frequencies. Since the tabled output can be huge, you should also specify the NOPRINT option in the TABLES statement.
2. Use a DATA step to change the zero frequencies associated with either sampling zeros or structural zeros to missing.
3. Use the resulting data set as input to PROC CATMOD, specify the statement **WEIGHT COUNT** to use adjusted frequencies, and specify the **ZERO=** and **MISSING=** options to define your sampling and structural zeros.

For example, suppose the data set RawDisplay contains the raw data for the squirrel monkey data. The following statements show how to obtain the same analysis as shown previously:

```
proc freq data=RawDisplay;
    tables Active*Passive / sparse out=Combos noprint;
run;

data Combos2;
    set Combos;
    if Active ne 't';
    if Active eq Passive then count=.;
run;

proc catmod data=Combos2;
    weight count;
    model Active*Passive=_response_ /
        zero=sampling missing=structural
        freq pred=freq noparm noresponse;
    loglin Active Passive;
quit;
```

The first IF statement in the DATA step is needed only for this particular example; since observations for Monkey 't' were deleted from the Display data set, they also need to be deleted from Combos2.

Example 30.6: Repeated Measures, 2 Response Levels, 3 Populations

In this multiple-population repeated measures example, from Guthrie (1981), subjects from three groups have their responses (0 or 1) recorded in each of four trials. The analysis of the marginal probabilities is directed at assessing the main effects of the repeated measurement factor (Trial) and the independent variable (Group), as well as their interaction. Although the contingency table is incomplete (only 13 of the 16 possible responses are observed), this poses no problem in the computation of the marginal probabilities. The following statements produce [Output 30.6.1](#):

```
data group;
    input a b c d Group wt @@;
    datalines;

The analysis of variance table in [Output 30.6.1](#) shows that there is a significant interaction between the independent variable Group and the repeated measurement factor Trial. An intermediate model (not shown) is fit in which the effects Trial and Group* Trial are replaced by Trial(Group=1), Trial(Group=2), and Trial(Group=3). Of these three effects, only the last is significant, so it is retained in the final model. The following statements produce [Output 30.6.2](#) and [Output 30.6.3](#):

```

model a*b*c*d=Group _response_(Group=3)
      / noprofile noparm design;
title2 'Trial Nested within Group 3';
quit;

```

Output 30.6.2 displays the design matrix resulting from retaining the nested effect.

Output 30.6.2 Final Model: Design Matrix

Example 30.7: Repeated Measures, 4 Response Levels, 1 Population

This example illustrates a repeated measures analysis in which there are more than two levels of response. In this study, from Grizzle, Starmer, and Koch (1969, p. 493), 7,477 women aged 30–39 are tested for vision in both right and left eyes. Since there are four response levels for each dependent variable, the **RESPONSE** statement computes three marginal probabilities for each dependent variable, resulting in six response functions for analysis. Since the model contains a repeated measurement factor (**Side**) with two levels (Right, Left), PROC CATMOD groups the functions into sets of three ($=6/2$). Therefore, the **Side** effect has three degrees of freedom (one for each marginal probability), and it is the appropriate test of marginal homogeneity. The following statements produce [Output 30.7.1](#):

```

The analysis of variance table in [Output 30.7.1](#) shows that the Side effect is significant, so there is not marginal homogeneity between left-eye vision and right-eye vision. In other words, the distribution of the quality of right-eye vision differs significantly from the distribution of the quality of left-eye vision in the same subjects. The test of the Side effect is equivalent to Bhapkar's test (Agresti 1990).

Example 30.8: Repeated Measures, Logistic Analysis of Growth Curve

The following data, from a longitudinal study reported in Koch et al. (1977), are from patients in four populations (2 diagnostic groups \times 2 treatments) who are measured at three times to assess their response (n=normal or a=abnormal) to treatment:

```

title 'Growth Curve Analysis';
data growth2;

The analysis of variance table in [Output 30.8.3](#) shows that the data can be adequately modeled by two parameters that represent diagnosis effects at week 1 and two log-linear time effects (one for each treatment). Both of the time effects are significant.

Since the estimate of the logit for the severe diagnosis effect (parameter 2) is more negative than it is for the mild diagnosis effect (parameter 1), there is a smaller predicted probability of the first response (normal) for the severe diagnosis group.

Output 30.8.3 ANOVA and Parameter Estimates

Analysis of Variance			
Source	DF	Chi-Square	Pr > ChiSq
Mild diagnosis, week 1	1	0.28	0.5955
Severe diagnosis, week 1	1	100.48	<.0001
Time effect for std trt	1	26.35	<.0001

Residual	8	4.20	0.8387

Output 30.8.3 *continued*

Analysis of Weighted Least Squares Estimates					
Effect	Parameter	Estimate	Standard Error	Chi-Square	Pr > ChiSq
Model	1	-0.0716	0.1348	0.28	0.5955
	2	-1.3529	0.1350	100.48	<.0001
	3	0.4944	0.0963	26.35	<.0001
	4	1.4552	0.1301	125.09	<.0001

The analysis of contrasts ([Output 30.8.4](#)) shows that the diagnosis effect at week 1 is highly significant. In other words, those subjects with a severe diagnosis have a significantly higher probability of abnormal response at week 1 than those subjects with a mild diagnosis.

Output 30.8.4 Contrasts

Analysis of Contrasts			
Contrast	DF	Chi-Square	Pr > ChiSq
Diagnosis effect, week 1	1	77.02	<.0001
Equal time effects	1	59.12	<.0001

The analysis of contrasts ([Output 30.8.4](#)) also shows that the time effect for the standard treatment is significantly different from the one for the new treatment. The table of parameter estimates ([Output 30.8.3](#)) shows that the time effect for the new treatment (parameter 4) is stronger than it is for the standard treatment (parameter 3).

Example 30.9: Repeated Measures, Two Repeated Measurement Factors

This example, from MacMillan et al. (1981), illustrates a repeated measures analysis in which there are two repeated measurement factors. Two diagnostic procedures (standard and test) are performed on each subject, and the results of both are evaluated at each of two times as being positive or negative. In the following DATA step, std1 and std2 are the two measurements of the standard procedure, and test1 and test2 are the two measurements of the test procedure:

```
data a;
  input std1 $ test1 $ std2 $ test2 $ wt @@;
  datalines;
neg neg neg neg 509 neg neg neg pos 4 neg neg pos neg 17
neg neg pos pos 3 neg pos neg neg 13 neg pos neg pos 8
neg pos pos pos 8 pos neg neg neg 14 pos neg neg pos 1
pos neg pos neg 17 pos neg pos pos 9 pos pos neg neg 7
pos pos neg pos 4 pos pos pos neg 9 pos pos pos pos 170
;
```

For the initial model, the response functions are marginal probabilities, and the repeated measurement factors are Time and Treatment. The model is a saturated one, containing effects for Time, Treatment, and Time*Treatment. The following statements produce [Output 30.9.1](#):

```
proc catmod data=a;
  title2 'Marginal Symmetry, Saturated Model';
  weight wt;
  response marginals;
  model std1*test1*std2*test2=_response_ / freq design noparm;
  repeated Time 2, Treatment 2 / _response_=Time Treatment
    Time*Treatment;
run;
```

The analysis of variance table in [Output 30.9.1](#) shows that there is no significant effect of Time, either by itself or in its interaction with Treatment. The second model includes only the Treatment effect. Again, the response functions are marginal probabilities, and the repeated measurement factors are Time and Treatment.

			1	2	3	4
1	1	0.70870	1	1	1	1
	2	0.72383	1	1	-1	-1
	3	0.70618	1	-1	1	-1
	4	0.73897	1	-1	-1	1

Output 30.9.1 *continued*

Analysis of Variance			
Source	DF	Chi-Square	Pr > ChiSq
Intercept	1	2385.34	<.0001
Time	1	0.85	0.3570
Treatment	1	8.20	0.0042
Time*Treatment	1	2.40	0.1215
Residual	0	.	.

A main effect model with respect to Treatment is fit. The following statements produces [Output 30.9.2](#):

```

title2 'Marginal Symmetry, Reduced Model';
model std1*test1*std2*test2=_response_ / corrb design noprofile;
repeated Time 2, Treatment 2 / _response_=Treatment;
run;

```

The analysis of variance table for the reduced model ([Output 30.9.2](#)) shows that the model fits (since the residual chi-square is nonsignificant) and that the treatment effect is significant. The negative parameter estimate for Treatment shows that the first level of treatment (std) has a smaller probability of the first response level (neg) than the second level of treatment (test). In other words, the standard diagnostic procedure gives a significantly higher probability of a positive response than the test diagnostic procedure.

Output 30.9.2 Diagnosis Data: Reduced Model

The next example illustrates a **RESPONSE** statement that, at each time, computes the sensitivity and specificity of the test diagnostic procedure with respect to the standard procedure. Since these are measures of the relative accuracy of the two diagnostic procedures, the repeated measurement factors in this case are labeled Time and Accuracy. Only 15 of the 16 possible responses are observed, so additional care must be taken in formulating the **RESPONSE** statement for computation of sensitivity and specificity.

The following statements produce **Output 30.9.3** and **Output 30.9.4**:

```

title2 'Sensitivity and Specificity Analysis, '
      'Main-Effects Model';
model std1*test1*std2*test2=_response_ / covb design noprofile;
repeated Time 2, Accuracy 2 / _response_=Time Accuracy;
response exp 1 -1 0 0 0 0 0 0 0,
             0 0 1 -1 0 0 0 0 0,
             0 0 0 0 1 -1 0 0 0,
             0 0 0 0 0 0 1 -1
           log 0 0 0 0 0 0 0 0 0 0 1 1 1 1,
             0 0 0 0 0 0 0 1 1 1 1 1 1 1,
             1 1 1 1 0 0 0 0 0 0 0 0 0 0,

             1 0 0 0 1 0 0 1 0 0 0 1 0 0 0,
             1 1 0 0 1 1 0 1 1 0 0 1 1 0 0;

quit;

```

For the sensitivity and specificity analysis, the four response functions displayed next to the design matrix (Output 30.9.3) represent the following:

1. sensitivity, time 1
2. specificity, time 1
3. sensitivity, time 2
4. specificity, time 2

The sensitivities and specificities are for the test diagnostic procedure relative to the standard procedure.

Output 30.9.3 Diagnosis Data: Sensitivity and Specificity Analysis

Diagnostic Procedure Comparison					
Sensitivity and Specificity Analysis, Main-Effects Model					
The CATMOD Procedure					
Data Summary					
Response	std1*test1*std2*test2		Response Levels	15	
Weight Variable	wt		Populations	1	
Data Set	A		Total Frequency	793	
Frequency Missing	0		Observations	15	
Response Functions and Design Matrix					
Sample	Function Number	Response Function	Design Matrix		
			1	2	3
1	1	0.82251	1	1	1
	2	0.94840	1	1	-1
	3	0.81545	1	-1	1
	4	0.96964	1	-1	-1
Analysis of Variance

Example 30.10: Direct Input of Response Functions and Covariance Matrix

This example illustrates the ability of PROC CATMOD to operate on an existing vector of functions and the corresponding covariance matrix. The estimates under investigation are composite indices summarizing the responses to 18 psychological questions pertaining to general well-being. These estimates are computed for domains corresponding to an age-by-sex cross-classification, and the covariance matrix is calculated using the method of balanced repeated replications. The analysis is directed at obtaining a description of the variation among these domain estimates. The data are from Koch and Stokes (1979).

In the following statements, the first row of the `fbeing` data set contains the response functions for the variables `b1`–`b10`, while the remaining rows contain the covariance matrix. From the PROC CATMOD statements, the `READ` option in the `RESPONSE` statement says that you are inputting the response functions and their covariance matrix, while the `PROFILE=` option in the `FACTORS` statement tells you that the variables `b1`–`b5` correspond to the effects for `sex='male'` at the five different age groupings, and `b6`–`b10` likewise correspond to the effects for `sex='female'`. See the section “[Inputting Response Functions and Covariances Directly](#)” on page 1820 for more information about using the `READ` option.

	3	-0.1304	0.0448	8.49	0.0036

The analysis of variance table in [Output 30.10.3](#) shows that the model fits (note that the goodness-of-fit statistic is the sum of the previous one ([Output 30.10.1](#)) plus the chi-square for the contrast matrix in [Output 30.10.2](#)). The age and sex effects are significant. Since the second parameter in the table of estimates is positive, males (the first level for the sex variable) have a higher predicted index of well-being than females. Since the third parameter estimate is negative, those younger than age 65 (the first level of age) have a lower predicted index of well-being than those 65 and older.

Example 30.11: Predicted Probabilities

Suppose you have collected marketing research data to examine the relationship between a prospect's likelihood of buying your product and the person's education and income. Specifically, the variables are as follows:

Variable	Levels	Interpretation
Education	high, low	Prospect's education level
Income	high, low	Prospect's income level
Purchase	yes, no	Did prospect purchase product?

The following statements first create a data set, `loan`, that contains the marketing research data. Then the CATMOD procedure fits a model, obtains the parameter estimates, and obtains the predicted probabilities of interest. These statements produce [Output 30.11.1](#) and [Output 30.11.2](#).

```
data loan;
  input Education $ Income $ Purchase $ wt;
  datalines;
high high yes 54
high high no 23
high low yes 41
high low no 12
low high yes 35
low high no 42
low low yes 19
low low no 8
;

ods output PredictedValues=Predicted (keep=Education Income PredFunction);
proc catmod data=loan order=data;
  weight wt;
  response marginals;
  model Purchase=Education Income / pred design;
run;

proc sort data=Predicted;
  by descending PredFunction;
run;
proc print data=Predicted;
run;
```

Notice that the preceding statements use the Output Delivery System (ODS) to output the parameter estimates instead of the `OUT=` option, though either can be used.

Parameter		Estimate	Standard Error	Chi-Square	Pr > ChiSq		
Intercept		0.6481	0.0317	418.36	<.0001		
Education high		0.0924	0.0311	8.85	0.0029		
Income high		-0.0675	0.0312	4.70	0.0302		

Predicted Values for Response Functions							
		Function	-----Observed-----		-----Predicted-----		
Education	Income	Number	Function	Standard Error	Function	Standard Error	Residual
high	high	1	0.701299	0.052158	0.67294	0.047794	0.028359
high	low	1	0.773585	0.057487	0.808034	0.051586	-0.03445
low	high	1	0.454545	0.056744	0.48811	0.051077	-0.03356
low	low	1	0.703704	0.087877	0.623204	0.064867	0.080499

Output 30.11.2 Predicted Probabilities Data Set

Complex Sample Survey Analysis				
	Obs	Education	Income	Pred Function
	1	high	low	0.808034
	2	high	high	0.67294
	3	low	low	0.623204
	4	low	high	0.48811

You can use the predicted values (values of PredFunction in [Output 30.11.2](#)) as scores representing the likelihood that a randomly chosen subject from one of these populations will purchase the product. Notice that the “Response Profiles” table in [Output 30.11.1](#) shows you that the first sorted level of Purchase is ‘yes’, indicating that the predicted probabilities are for $\Pr(\text{Purchase}=\text{'yes'})$. For example, someone with high education and low income has an estimated probability of purchase of 0.808. Like any response function estimate given by PROC CATMOD, this estimate can be obtained by cross-multiplying the row from the design matrix corresponding to the sample (sample number 2 in this case) with the vector of parameter estimates: $(1 * 0.6481) + (1 * 0.0924) + (-1 * (-0.0675))$.

This ranking of scores can help in decision making (for example, with respect to allocation of advertising dollars, choice of advertising media, choice of print media, and so on).

Overview: CLUSTER Procedure

The CLUSTER procedure hierarchically clusters the observations in a SAS data set by using one of 11 methods. The data can be coordinates or distances. If the data are coordinates, PROC CLUSTER computes (possibly squared) Euclidean distances. If you want non-Euclidean distances, use the DISTANCE procedure (see [Chapter 34](#)) to compute an appropriate distance data set that can then be used as input to PROC CLUSTER.

The clustering methods are: average linkage, the centroid method, complete linkage, density linkage (including Wong's hybrid and k th-nearest-neighbor methods), maximum likelihood for mixtures of spherical multivariate normal distributions with equal variances but possibly unequal mixing proportions, the flexible-beta method, McQuitty's similarity analysis, the median method, single linkage, two-stage density linkage, and Ward's minimum-variance method. Each method is described in the section “[Clustering Methods](#)” on page 1926.

All methods are based on the usual agglomerative hierarchical clustering procedure. Each observation begins in a cluster by itself. The two closest clusters are merged to form a new cluster that replaces the two old clusters. Merging of the two closest clusters is repeated until only one cluster is left. The various clustering methods differ in how the distance between two clusters is computed.

The CLUSTER procedure is not practical for very large data sets because the CPU time is roughly proportional to the square or cube of the number of observations. The FASTCLUS procedure (see [Chapter 36](#)) requires time proportional to the number of observations and thus can be used with much larger data sets than PROC CLUSTER. If you want to cluster a very large data set hierarchically, use PROC FASTCLUS for a preliminary cluster analysis to produce a large number of clusters. Then use PROC CLUSTER to cluster the preliminary clusters hierarchically. This method is illustrated in [Example 31.3](#).

PROC CLUSTER displays a history of the clustering process, showing statistics useful for estimating the number of clusters in the population from which the data are sampled. It creates a dendrogram when ODS Graphics is enabled. PROC CLUSTER also creates an output data set that can be used by the TREE procedure to output the cluster membership at any desired level. For example, to obtain the six-cluster solution, you could first use PROC CLUSTER with the OUTTREE= option, and then use this output data set as the input data set to the TREE procedure. With PROC TREE, specify the NCLUSTERS=6 and the OUT= options to obtain the six-cluster solution. For an example, see [Example 98.1](#) in Chapter 98, “[The TREE Procedure](#).”

For coordinate data, Euclidean distances are computed from differences between coordinate values. The use of differences has several important consequences:

- For differences to be valid, the variables must have an interval or stronger scale of measurement. Ordinal or ranked data are generally not appropriate for cluster analysis.
- For Euclidean distances to be comparable, equal differences should have equal practical importance. You might need to transform the variables linearly or nonlinearly to satisfy this condition. For example, if one variable is measured in dollars and one in euros, you might need to convert to the same currency. Or, if ratios are more meaningful than differences, take logarithms.

- Variables with large variances tend to have more effect on the resulting clusters than variables with small variances. If you consider all variables to be equally important, you can use the STD option in PROC CLUSTER to standardize the variables to mean 0 and standard deviation 1. However, standardization is not always appropriate. See Milligan and Cooper (1987) for a Monte Carlo study on various methods of variable standardization. You should remove outliers before using PROC CLUSTER with the STD option unless you specify the TRIM= option. The STDIZE procedure (see [Chapter 87](#)) provides additional methods for standardizing variables and imputing missing values.

The ACECLUS procedure (see [Chapter 23](#)) is useful for linear transformations of the variables if any of the following conditions hold:

- You have no idea how the variables should be scaled.
- You want to detect natural clusters regardless of whether some variables have more influence than others.
- You want to use a clustering method designed for finding compact clusters, but you want to be able to detect elongated clusters.

Agglomerative hierarchical clustering is discussed in all standard references on cluster analysis, such as Anderberg (1973); Sneath and Sokal (1973); Hartigan (1975); Everitt (1980); Spath (1980). An especially good introduction is given by Massart and Kaufman (1983). Anyone considering doing a hierarchical cluster analysis should study the Monte Carlo results of Milligan (1980); Milligan and Cooper (1985); Cooper and Milligan (1988).

Other essential, though more advanced, references on hierarchical clustering include Hartigan (1977, pp. 60–68; 1981), Wong (1982); Wong and Schaack (1982); Wong and Lane (1983). For a discussion of the confusing terminology in hierarchical cluster analysis, see Blashfield and Aldenderfer (1978).

Getting Started: CLUSTER Procedure

This example shows how you can use the CLUSTER procedure to compute hierarchical clusters of observations in a SAS data set.

Suppose you want to determine whether national figures for birth rates, death rates, and infant death rates can be used to categorize countries. Previous studies indicate that the clusters computed from this type of data can be elongated and elliptical. Thus, you need to perform a linear transformation on the raw data before the cluster analysis.

The following data¹ from Rouncefield (1995) are birth rates, death rates, and infant death rates for 97 countries. The DATA step creates the SAS data set Poverty:

```
data Poverty;
    input Birth Death InfantDeath Country $20. @@;
    datalines;
24.7  5.7  30.8 Albania                12.5 11.9  14.4 Bulgaria
13.4 11.7  11.3 Czechoslovakia        12   12.4   7.6 Former E. Germany
11.6 13.4  14.8 Hungary                14.3 10.2   16 Poland
13.6 10.7  26.9 Romania                14    9  20.2 Yugoslavia

    ... more lines ...

41.7 10.3    66 Zimbabwe
;
```

The data set Poverty contains the character variable Country and the numeric variables Birth, Death, and InfantDeath, which represent the birth rate per thousand, death rate per thousand, and infant death rate per thousand. The \$20. in the INPUT statement specifies that the variable Country is a character variable with a length of 20. The double trailing at sign (@@) in the INPUT statement holds the input line for further iterations of the DATA step, specifying that observations are input from each line until all values are read.

Because the variables in the data set do not have equal variance, you must perform some form of scaling or transformation. One method is to standardize the variables to mean zero and variance one. However, when you suspect that the data contain elliptical clusters, you can use the ACECLUS procedure to transform the data such that the resulting within-cluster covariance matrix is spherical. The procedure obtains approximate estimates of the pooled within-cluster covariance matrix and then computes canonical variables to be used in subsequent analyses.

The following statements perform the ACECLUS transformation by using the SAS data set Poverty. The OUT= option creates an output SAS data set called Ace that contains the canonical variable scores:

```
proc aceclus data=Poverty out=Ace p=.03 noprint;
    var Birth Death InfantDeath;
run;
```

The P= option specifies that approximately 3% of the pairs are included in the estimation of the within-cluster covariance matrix. The NOPRINT option suppresses the display of the output. The VAR statement specifies that the variables Birth, Death, and InfantDeath are used in computing the canonical variables.

The following statements invoke the CLUSTER procedure, using the SAS data set Ace created in the previous PROC ACECLUS run:

```
ods graphics on;

proc cluster data=Ace method=ward ccc pseudo print=15 out=tree
    plots=den(height=rsq);
    var can1-can3;
    id country;
run;

ods graphics off;
```

¹ These data have been compiled from the *United Nations Demographic Yearbook 1990* (United Nations publications, Sales No. E/F.91.XII.1, copyright 1991, United Nations, New York) and are reproduced with the permission of the United Nations.

The ODS GRAPHICS ON statement enables ODS Graphics. Ward's minimum-variance clustering method is specified by the METHOD= option. The CCC option displays the cubic clustering criterion, and the PSEUDO option displays pseudo F and t^2 statistics. The PRINT=15 option displays only the last 15 generations of the cluster history. By default, when ODS Graphics is enabled, a dendrogram displaying the semipartial R square is displayed on the X axis. The option PLOTS=DEN(HEIGHT=RSQ) requests a dendrogram with R square displayed instead.

The VAR statement specifies that the canonical variables computed in the ACECLUS procedure are used in the cluster analysis. The ID statement selects the variable Country as the Y axis variable in the dendrogram and also specifies that Country should be added to the Tree output data set.

PROC CLUSTER first displays the table of eigenvalues of the covariance matrix (Figure 31.1). These eigenvalues are used in the computation of the cubic clustering criterion. The first two columns list each eigenvalue and the difference between the eigenvalue and its successor. The last two columns display the individual and cumulative proportion of variation associated with each eigenvalue.

Figure 31.1 Table of Eigenvalues of the Covariance Matrix

The CLUSTER Procedure				
Ward's Minimum Variance Cluster Analysis				
Eigenvalues of the Covariance Matrix				
	Eigenvalue	Difference	Proportion	Cumulative
1	64.5500051	54.7313223	0.8091	0.8091
2	9.8186828	4.4038309	0.1231	0.9321
3	5.4148519		0.0679	1.0000
Root-Mean-Square Total-Sample Standard Deviation				5.156987
Root-Mean-Square Distance Between Observations				12.63199

Figure 31.2 displays the last 15 generations of the cluster history. First listed are the number of clusters and the names of the clusters joined. The observations are identified either by the ID value or by CLn , where n is the number of the cluster. Next, PROC CLUSTER displays the number of observations in the new cluster and the semipartial R square. The latter value represents the decrease in the proportion of variance accounted for by joining the two clusters.

Figure 31.2 Cluster History

Cluster History									T i
NCL	-----Clusters Joined-----	Freq	SpRSq	RSq	ERSq	CCC	Ps F	Pst2 e	
15	Oman	CL37	5	0.0039	.957	.933	6.03	132	12.1
14	CL31	CL22	13	0.0040	.953	.928	5.81	131	9.7
13	CL41	CL17	32	0.0041	.949	.922	5.70	131	13.1
12	CL19	CL21	10	0.0045	.945	.916	5.65	132	6.4
11	CL39	CL15	9	0.0052	.940	.909	5.60	134	6.3
10	CL76	CL27	6	0.0075	.932	.900	5.25	133	18.1
9	CL23	CL11	15	0.0130	.919	.890	4.20	125	12.4
8	CL10	Afghanistan	7	0.0134	.906	.879	3.55	122	7.3
7	CL9	CL25	17	0.0217	.884	.864	2.26	114	11.6
6	CL8	CL20	14	0.0239	.860	.846	1.42	112	10.5
5	CL14	CL13	45	0.0307	.829	.822	0.65	112	59.2
4	CL16	CL7	28	0.0323	.797	.788	0.57	122	14.8
3	CL12	CL6	24	0.0323	.765	.732	1.84	153	11.6
2	CL3	CL4	52	0.1782	.587	.613	-.82	135	48.9
1	CL5	CL2	97	0.5866	.000	.000	0.00	.	135

Next listed is the squared multiple correlation, R square, which is the proportion of variance accounted for by the clusters. Figure 31.2 shows that, when the data are grouped into three clusters, the proportion of variance accounted for by the clusters (R square) is just under 77%. The approximate expected value of R square is given in the ERSq column. This expectation is approximated under the null hypothesis that the data have a uniform distribution instead of forming distinct clusters.

The next three columns display the values of the cubic clustering criterion (CCC), pseudo F (PSF), and t^2 (PST2) statistics. These statistics are useful for estimating the number of clusters in the data.

The final column in Figure 31.2 lists ties for minimum distance; a blank value indicates the absence of a tie. A tie means that the clusters are indeterminate and that changing the order of the observations might change the clusters. See Example 31.4 for ways to investigate the effects of ties.

Figure 31.3 plots the three statistics for estimating the number of clusters. Peaks in the plot of the cubic clustering criterion with values greater than 2 or 3 indicate good clusters; peaks with values between 0 and 2 indicate possible clusters. Large negative values of the CCC can indicate outliers. In Figure 31.3, there is a local peak of the CCC when the number of clusters is three. The CCC drops at four clusters and then steadily increases, leveling off at eleven clusters.

Another method of judging the number of clusters in a data set is to look at the pseudo F statistic (PSF). Relatively large values indicate good numbers of clusters. In Figure 31.3, the pseudo F statistic suggests three clusters or eleven clusters.

Figure 31.3 Plot of Statistics for Estimating the Number of Clusters

To interpret the values of the pseudo t^2 statistic, look down the column or look at the plot from right to left until you find the first value that is markedly larger than the previous value, then move back up the column or to the right in the plot by one step in the cluster history. In [Figure 31.3](#), you can see possibly good clustering levels at eleven clusters, six clusters, three clusters, and two clusters.

Considered together, these statistics suggest that the data can be clustered into eleven clusters or three clusters. The following statements examine the results of clustering the data into three clusters.

[Figure 31.4](#) displays the dendrogram. The figure provides a graphical view of the information in [Figure 31.2](#). As the number of branches grows to the left from the root, the R square approaches 1; the first three clusters (branches of the tree) account for over half of the variation (about 77%, from [Figure 31.4](#)). In other words, only three clusters are necessary to explain over three-fourths of the variation.

Figure 31.4 Dendrogram of Clusters versus R-Square Values

You can use PROC TREE and the output data set from PROC CLUSTER to create a new data set that contains information about cluster membership as follows:

```
proc tree data=Tree out=New nclusters=3 noprint;
  height _rsq_;
  copy can1 can2;
  id country;
run;
```

The SAS data set Tree is input. The OUT= option creates an output SAS data set named New that contains information about cluster membership. The NCLUSTERS= option specifies the number of clusters desired in the data set New. The results can be displayed in a scatter plot.

The following statements use the SGPLOT procedure to display the results that are in the SAS data set New:

```
proc sgplot data=New;
  scatter y=can2 x=can1 / group=cluster;
run;
```

The SCATTER statement requests a plot of the two canonical variables, using the value of the variable cluster, which is produced by PROC TREE as the identification variable. The results are displayed in Figure 31.5.

Figure 31.5 Plot of Canonical Variables and Cluster for Three Clusters

The statistics in Figure 31.2 and Figure 31.3, the dendrogram in Figure 31.4, and the plot of the canonical variables in Figure 31.5 assist in the estimation of the number of clusters in the data. There seems to be reasonable separation in the clusters. However, you must use this information, along with experience and knowledge of the field, to help in deciding the correct number of clusters.

Syntax: CLUSTER Procedure

The following statements are available in the CLUSTER procedure:

```
PROC CLUSTER METHOD=name < options > ;
BY variables ;
COPY variables ;
FREQ variable ;
ID variable ;
RMSSTD variable ;
VAR variables ;
```

Only the PROC CLUSTER statement is required, except that the FREQ statement is required when the RMSSTD statement is used; otherwise the FREQ statement is optional. Usually only the VAR statement and possibly the ID and COPY statements are needed in addition to the PROC CLUSTER statement. The rest of this section provides detailed syntax information for each of the preceding statements, beginning with the PROC CLUSTER statement. The remaining statements are covered in alphabetical order.

PROC CLUSTER Statement

```
PROC CLUSTER METHOD=name < options > ;
```

The PROC CLUSTER statement invokes the CLUSTER procedure. It also specifies a clustering method, and optionally specifies details for clustering methods, data sets, data processing, and displayed output.

Table 31.1 summarizes the options available in the PROC CLUSTER statement.

Table 31.1 PROC CLUSTER Statement Options

Option	Description
Specify input and output data sets	
DATA=	Specifies input data set
OUTTREE=	Creates output data set
Specify clustering methods	
BETA=	Specifies beta value for flexible beta method
HYBRID	Specifies Wong's hybrid clustering method
METHOD=	Specifies clustering method
MODE=	Specifies the minimum number of members for modal clusters
PENALTY=	Specifies the penalty coefficient for maximum likelihood
Control data processing prior to clustering	
NOEIGEN	Suppresses computation of eigenvalues
NONORM	Suppresses normalizing of distances
NOSQUARE	Suppresses squaring of distances
STANDARD	Standardizes variables
TRIM=	Omits points with low probability densities
Control density estimation	
K=	Specifies number of neighbors for <i>k</i> th-nearest-neighbor density estimation

Table 31.1 *continued*

Option	Description
R=	Specifies radius of sphere of support for uniform-kernel density estimation
Ties	
NOTIE	Suppresses checking for ties
Control display of the cluster history	
CCC	Displays cubic clustering criterion
NOID	Suppresses display of ID values
PRINT=	Specifies number of generations to display
PSEUDO	Displays pseudo F and t^2 statistics
RMSSTD	Displays root mean square standard deviation
RSQUARE	Displays R square and semipartial R square
Control other aspects of output	
NOPRINT	Suppresses display of all output
PLOTS=	Specifies ODS graphics details
SIMPLE	Displays simple summary statistics

METHOD=*name*

The METHOD= specification determines the clustering method used by the procedure. Any one of the following 11 methods can be specified for *name*:

AVERAGE AVE	requests average linkage (group average, unweighted pair-group method using arithmetic averages, UPGMA). Distance data are squared unless you specify the NOSQUARE option.
CENTROID CEN	requests the centroid method (unweighted pair-group method using centroids, UPGMC, centroid sorting, weighted-group method). Distance data are squared unless you specify the NOSQUARE option.
COMPLETE COM	requests complete linkage (furthest neighbor, maximum method, diameter method, rank order typal analysis). To reduce distortion of clusters by outliers, the TRIM= option is recommended.
DENSITY DEN	requests density linkage, which is a class of clustering methods using non-parametric probability density estimation. You must also specify either the K=, R=, or HYBRID option to indicate the type of density estimation to be used. See also the MODE= and DIM= options in this section.
EML	requests maximum-likelihood hierarchical clustering for mixtures of spherical multivariate normal distributions with equal variances but possibly unequal mixing proportions. Use METHOD=EML only with coordinate data. See the PENALTY= option for details. The NONORM option does not affect the reported likelihood values but does affect other unrelated criteria. The EML method is much slower than the other methods in the CLUSTER procedure.
FLEXIBLE FLE	requests the Lance-Williams flexible-beta method. See the BETA= option in this section.

MCQUITTY MCQ	requests McQuitty's similarity analysis (weighted average linkage, weighted pair-group method using arithmetic averages, WPGMA).
MEDIAN MED	requests Gower's median method (weighted pair-group method using centroids, WPGMC). Distance data are squared unless you specify the NOSQUARE option.
SINGLE SIN	requests single linkage (nearest neighbor, minimum method, connectedness method, elementary linkage analysis, or dendritic method). To reduce chaining, you can use the TRIM= option with METHOD=SINGLE.
TWOSTAGE TWO	requests two-stage density linkage. You must also specify the K=, R=, or HYBRID option to indicate the type of density estimation to be used. See also the MODE= and DIM= options in this section.
WARD WAR	requests Ward's minimum-variance method (error sum of squares, trace W). Distance data are squared unless you specify the NOSQUARE option. To reduce distortion by outliers, the TRIM= option is recommended. See the NONORM option.

The following list provides details about the other options.

BETA=*n*

specifies the beta parameter for METHOD=FLEXIBLE. The value of *n* should be less than 1, usually between 0 and -1. By default, BETA=-0.25. Milligan (1987) suggests a somewhat smaller value, perhaps -0.5, for data with many outliers.

CCC

displays the cubic clustering criterion and approximate expected R square under the uniform null hypothesis (Sarle 1983). The statistics associated with the RSQUARE option, R square and semipartial R square, are also displayed. The CCC option applies only to coordinate data. The CCC option is not appropriate with METHOD=SINGLE because of the method's tendency to chop off tails of distributions. Computation of the CCC requires the eigenvalues of the covariance matrix. If the number of variables is large, computing the eigenvalues requires much computer time and memory.

DATA=SAS-data-set

names the input data set that contains observations to be clustered. By default, the procedure uses the most recently created SAS data set. If the data set is TYPE=DISTANCE, the data are interpreted as a distance matrix; the number of variables must equal the number of observations in the data set or in each BY group. The distances are assumed to be Euclidean, but the procedure accepts other types of distances or dissimilarities. If the data set is not TYPE=DISTANCE, the data are interpreted as coordinates in a Euclidean space, and Euclidean distances are computed. For more about TYPE=DISTANCE data sets, see Chapter A, "[Special SAS Data Sets](#)."

Data set types (such as TYPE=DISTANCE) do not persist when you copy or modify a data set. You must specify the TYPE= data set option for the new data set, as in the following example:

```
data dist2(type=distance);
    set dist;
run;
```

If you do not specify the TYPE=DISTANCE data set option, the new data set is the default TYPE=DATA. If you use the new data set in a procedure that accepts both TYPE=DATA or TYPE=DISTANCE data sets (such as PROC CLUSTER or PROC MODECLUS), the results will be incorrect.

You cannot use a TYPE=CORR data set as input to PROC CLUSTER, since the procedure uses dissimilarity measures. Instead, you can use a DATA step or the IML procedure to extract the correlation matrix from a TYPE=CORR data set and transform the values to dissimilarities such as $1 - r$ or $1 - r^2$, where r is the correlation.

All methods produce the same results when used with coordinate data as when used with Euclidean distances computed from the coordinates. However, the DIM= option must be used with distance data if you specify METHOD=TWOSTAGE or METHOD=DENSITY or if you specify the TRIM= option.

Certain methods that are most naturally defined in terms of coordinates require *squared* Euclidean distances to be used in the combinatorial distance formulas (Lance and Williams 1967). For this reason, distance data are automatically squared when used with METHOD=AVERAGE, METHOD=CENTROID, METHOD=MEDIAN, or METHOD=WARD. If you want the combinatorial formulas to be applied to the (unsquared) distances with these methods, use the NOSQUARE option.

DIM= n

specifies the dimensionality used when computing density estimates with the TRIM= option, METHOD=DENSITY, or METHOD=TWOSTAGE. The values of n must be greater than or equal to 1. The default is the number of variables if the data are coordinates; the default is 1 if the data are distances.

HYBRID

requests the Wong (1982) hybrid clustering method in which density estimates are computed from a preliminary cluster analysis using the k -means method. The DATA= data set must contain means, frequencies, and root mean square standard deviations of the preliminary clusters (see the FREQ and RMSSTD statements). To use HYBRID, you must use either a FREQ statement or a DATA= data set that contains a _FREQ_ variable, and you must also use either an RMSSTD statement or a DATA= data set that contains an _RMSSTD_ variable.

The MEAN= data set produced by the FASTCLUS procedure is suitable for input to the CLUSTER procedure for hybrid clustering. Since this data set contains _FREQ_ and _RMSSTD_ variables, you can use it as input and then omit the FREQ and RMSSTD statements.

You must specify either METHOD=DENSITY or METHOD=TWOSTAGE with the HYBRID option. You cannot use this option in combination with the TRIM=, K=, or R= option.

K= n

specifies the number of neighbors to use for k th-nearest-neighbor density estimation (Silverman 1986, pp. 19–21 and 96–99). The number of neighbors (n) must be at least two but less than the number of observations. See the MODE= option, which follows.

Density estimation is used with the TRIM=, METHOD=DENSITY, and METHOD=TWOSTAGE options.

MODE=*n*

specifies that, when two clusters are joined, each must have at least *n* members in order for either cluster to be designated a modal cluster. If you specify `MODE=1`, each cluster must also have a maximum density greater than the fusion density in order for either cluster to be designated a modal cluster.

Use the `MODE=` option only with `METHOD=DENSITY` or `METHOD=TWOSTAGE`. With `METHOD=TWOSTAGE`, the `MODE=` option affects the number of modal clusters formed. With `METHOD=DENSITY`, the `MODE=` option does not affect the clustering process but does determine the number of modal clusters reported on the output and identified by the `_MODE_` variable in the output data set.

If you specify the `K=` option, the default value of `MODE=` is the same as the value of `K=` because the use of *k*th-nearest-neighbor density estimation limits the resolution that can be obtained for clusters with fewer than *k* members. If you do not specify the `K=` option, the default is `MODE=2`.

If you specify `MODE=0`, the default value is used instead of 0.

If you specify a `FREQ` statement or if a `_FREQ_` variable appears in the input data set, the `MODE=` value is compared with the number of actual observations in the clusters being joined, not with the sum of the frequencies in the clusters.

NOEIGEN

suppresses computation of the eigenvalues of the covariance matrix and substitutes the variances of the variables for the eigenvalues when computing the cubic clustering criterion. The `NOEIGEN` option saves time if the number of variables is large, but it should be used only if the variables are nearly uncorrelated. If you specify the `NOEIGEN` option and the variables are highly correlated, the cubic clustering criterion might be very liberal. The `NOEIGEN` option applies only to coordinate data.

NOID

suppresses the display of ID values for the clusters joined at each generation of the cluster history.

NONORM

prevents the distances from being normalized to unit mean or unit root mean square with most methods. With `METHOD=WARD`, the `NONORM` option prevents the between-cluster sum of squares from being normalized by the total sum of squares to yield a squared semipartial correlation. The `NONORM` option does not affect the reported likelihood values with `METHOD=EML`, but it does affect other unrelated criteria, such as the `_DIST_` variable.

NOPRINT

suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, [“Using the Output Delivery System.”](#)

NOSQUARE

prevents input distances from being squared with `METHOD=AVERAGE`, `METHOD=CENTROID`, `METHOD=MEDIAN`, or `METHOD=WARD`.

If you specify the `NOSQUARE` option with distance data, the data are assumed to be squared Euclidean distances for computing R-square and related statistics defined in a Euclidean coordinate system.

If you specify the `NOSQUARE` option with coordinate data with `METHOD=CENTROID`, `METHOD=MEDIAN`, or `METHOD=WARD`, then the combinatorial formula is applied to un-

squared Euclidean distances. The resulting cluster distances do not have their usual Euclidean interpretation and are therefore labeled “False” in the output.

NOTIE

prevents PROC CLUSTER from checking for ties for minimum distance between clusters at each generation of the cluster history. If your data are measured with such precision that ties are unlikely, then you can specify the NOTIE option to reduce slightly the time and space required by the procedure. See the section “[Ties](#)” on page 1937 for more information.

OUTTREE=*SAS-data-set*

creates an output data set that can be used by the TREE procedure to draw a tree diagram. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*. If you omit the OUTTREE= option, the data set is named by using the DATA_n convention and is not permanently saved. If you do not want to create an output data set, use OUTTREE=_NULL_.

PENALTY=*p*

specifies the penalty coefficient used with METHOD=EML. See the section “[Clustering Methods](#)” on page 1926 for more information. Values for *p* must be greater than zero. By default, PENALTY=2.

PLOTS <(global-plot-options)> <= plot-request >

PLOTS <(global-plot-options)> <= (plot-request <... plot-request >)>

controls the plots produced through ODS Graphics.

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;

proc cluster method=ward plots=all;
run;

ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

By default, PROC CLUSTER produces a dendrogram. PROC CLUSTER can also produce plots of the cubic clustering criterion, the pseudo *F* statistic, and the pseudo t^2 statistic from the cluster history table. These statistics are useful for estimating the number of clusters. Each statistic is plotted against the number of clusters. You can request that PROC CLUSTER create these graphs by specifying the CCC or PSEUDO options, or by specifying the statistics in a *plot-request* in the PLOT option. PROC CLUSTER might be unable to compute the statistics in some cases; for details, see the CCC and PSEUDO options. If a statistic cannot be computed, it cannot be plotted. PROC CLUSTER plots all of these statistics that are computed unless you tell it specifically what to plot using PLOTS=.

PROC CLUSTER has a CCC and PSEUDO option as well as CCC and PSEUDO plot requests. All four options are illustrated in the following step:

```
ods graphics on;

proc cluster ccc pseudo plots=(ccc pseudo);
run;

ods graphics off;
```

The maximum number of clusters shown in all the plots is the minimum of the following quantities:

- the number of observations
- the value of the PRINT= option, if that option is specified
- the maximum number of clusters for which CCC is computed, if the CCC is plotted

The *global-plot-options* apply to all plots generated by the CLUSTER procedure. The *global-plot-options* are as follows:

MAXCLUS=*n*

right-truncates the CCC, PSF, and PST2 plots at the *n* value. This prevents these plots from losing resolution when a large number of clusters are plotted. The default is MAXCLUS=200.

MAXPOINTS=*n*

MAXPTS=*n*

suppresses the dendrogram when the number of clusters exceeds the *n* value. This prevents an unreadable plot from being produced. The default is MAXPOINTS=200.

UNPACKPANEL

UNPACK

breaks a plot that is otherwise paneled into separate plots for each statistic.

ONLY

suppresses the default plots. Only plots specifically requested are displayed.

The following *plot-requests* can be specified:

ALL
