The semivariogram of the Gaussian-Gaussian model with the parameters shown in [Output 49.1.5](#) is depicted in [Output 49.1.6](#).

Output 49.1.6 Gaussian-Gaussian Semivariogram Model Used in Kriging Predictions

Output 49.1.7 is a map of the kriging prediction of the arsenic concentration values $\log As$ in the specified domain. The prediction error surface shows a naturally increasing error as you move farther away from the observation locations. Interestingly, kriging predicts a small area of increased arsenic concentration values located in the central-eastern part of the domain. The WHO threshold of $10 \mu\text{g}/\text{lt}$ for the maximum allowed arsenic concentration in water translates into about 2.3 in the log scale, and the particular area exhibits values in excess of 3. Due to the suggested violation of the WHO standard, this particular area is very likely to be the focus of further environmental risk analysis.

Output 49.1.7 Predicted Arsenic Logarithm Values with Gaussian-Gaussian Covariance

Next, PROC KRIGE2D performs prediction with the exponential model. The model parameters are also read from the SemivAsStore item store and are shown in **Output 49.1.8**.

Output 49.1.8 Information about the Exponential Model

Spatial Prediction of Log-Arsenic Concentration	
The KRIGE2D Procedure	
Dependent Variable: logAs	
Prediction: Pred1, Model: ExpModel	
Covariance Model Information for ExpModel	
Type	Exponential
Sill	1.6779788
Range	24.537294
Effective Range	73.611882
Nugget Effect	0

Output 49.1.9 illustrates the semivariogram of the nested exponential model where its parameter values are those shown in Output 49.1.8.

Output 49.1.9 Exponential Semivariogram Model Used in Kriging Predictions

The prediction plot for the exponential model is shown in [Output 49.1.10](#). Prediction values and spatial patterns are similar overall to those of the Gaussian-Gaussian case. Clearly, although both models predict the same basic characteristics for the arsenic logarithm concentration distribution, the exponential model suggests a more limited spatial variability in closely neighboring locations. The lack of a nugget effect in the exponential model justifies this behavior. Also, the exponential model predictions seem less inclined to deviate farther away from the near-zero mean than the Gaussian-Gaussian model predictions. The prediction error reaches about the same upper values for both models, though its low values are slightly smaller in the exponential model.

Output 49.1.10 Predicted Arsenic Logarithm Values with Exponential Covariance

In the following two-step computation, you proceed to compute the percentage of the study area where the arsenic concentration exceeds the WHO regulatory standard according to your predictions. First, a DATA step marks the arsenic predicted values in excess of the WHO concentration threshold of $10 \mu\text{g/l}$ and saves the outcome into an indicator variable `OverLimit`. The DATA step input is the prediction `Pred` output data set, where the logarithm arsenic prediction is stored in the estimate variable. The DATA step also transforms the arsenic logarithm values back into arsenic concentration values to compare them to the threshold value. You use the following statements:

```

data AsOverLimit;
  set Pred;
  OverLimit = (exp(estimate) > 10) * 100;
run;

```

The second step uses the MEANS procedure to express the selected nodes population, where the WHO arsenic concentration limit violation occurs, as a percentage of the entire domain area. You study the results of each correlation model separately by specifying the BY statement in the PROC MEANS. The BY variable is the Label variable in the AsOverLimit and Pred data sets. You need to sort the AsOverLimit data prior to using PROC MEANS. You run the following statements:

```

proc sort data=AsOverLimit;
  by Label;
run;
proc means data=AsOverLimit mean;
  var OverLimit;
  by label;
  label Overlimit="Percent above WHO threshold";
run;

ods graphics off;

```

The Gaussian-Gaussian model prediction produces the result in [Output 49.1.11](#). The analysis suggests a minimal occurrence of excessive arsenic concentration in drinking water in about 0.43% of the study region.

Output 49.1.11 Violation of Arsenic Concentration Threshold Using Gaussian-Gaussian Model

Spatial Prediction of Log-Arsenic Concentration	
----- Label for the PREDICT/MODEL combination=Pred1.SelModel -----	
The MEANS Procedure	
Analysis Variable : OverLimit Percent above WHO threshold	
	Mean

	0.4313303

The exponential model predicts that the WHO arsenic concentration threshold is exceeded in about 0.27% of the domain, as shown in [Output 49.1.12](#). Although this is still a minimal occurrence of the threshold violation across the region, the exponential model estimates the impact to be at about two thirds of the Gaussian-Gaussian model percentage.

Output 49.1.12 Violation of Arsenic Concentration Threshold Using Exponential Model

```

      Spatial Prediction of Log-Arsenic Concentration

----- Label for the PREDICT/MODEL combination=Pred1.ExpModel -----

              The MEANS Procedure

Analysis Variable : OverLimit Percent above WHO threshold

              Mean
              -----
              0.2744829
              -----

```

The results in [Output 49.1.11](#) and [Output 49.1.12](#) suggest that it might not be possible to provide a unique answer about the area percentage that is affected by increased arsenic concentration. You chose to examine two different correlation models whose performance is relatively similar, and they provide impact estimates that differ by about 37%.

You might conclude that the answer to the initial question about the percentage value lies in the neighborhood of the results given by the two correlation models. Further analysis with more models is necessary to validate this assumption. It is important to note that apart from the continuity model choice, additional factors contribute to this investigation. Such factors could be the use of local instead of global kriging, or even going back to the empirical semivariogram computation stage and repeating the analysis for different possible spatial continuity empirical estimates. A sensible approach to tackle this analysis would be to investigate the range of the impact suggested by all candidate correlation models and to proceed by defining the best and worst case scenarios for the size of the affected area.

Eventually, when it comes to using your findings, it is important to account for the subjective nature of stochastic analysis and multiple possible answers to your questions. In that sense, some scientific questions might be more sensible than others to interpret your results correctly. For instance, you might want to investigate only whether the adversely affected domain percentage is below 1%, rather than attempting to provide a specific value for it. Then, you might consider the preceding findings sufficient, despite any fluctuations in the estimated percentage. In a different scenario, the areas with high pollutant concentration could be populated. Hence, any local health standard violation is probably unacceptable, and it can be crucial that you provide solid and more detailed assessment in that case.

The section “[Example 85.3: Risk Analysis with Simulation](#)” on page 7423 in the SIM2D procedure investigates a different aspect of this study and offers additional perspective about spatial analysis.

Example 49.2: Investigating the Effect of Model Specification on Spatial Prediction

It is generally believed that spatial prediction is robust against model specification, while the standard error computation is not so robust. This example investigates the effect of using these different models on the prediction and associated standard errors.

In the section “[Theoretical Semivariogram Model Fitting](#)” on page 8571 in the VARIOGRAM procedure, a particular theoretical semivariogram is fitted to the coal seam thickness data empirical semivariogram. The chosen semivariogram is Gaussian with a scale (sill) of $c_0 = 7.2881$ and a range of $a_0 = 30.6239$.

Another possible model choice could be the spherical semivariogram. First, use a DATA step to input the thickness data:

```
title 'Effect of Model Specification on Prediction';

data thick;
  input East North Thick @@;
  label Thick='Coal Seam Thickness';

  ;
```

Fitting of the Gaussian model is performed in the section “[Theoretical Semivariogram Model Fitting](#)” on page 8571 in the VARIOGRAM procedure, and the fitting parameters are saved in the SemivStoreGau item store with the following statements:

```
ods graphics on;

proc variogram data=thick noprint;
  store out=SemivStoreGau / label='Thickness Gaussian Model';
  compute lagd=7 maxlag=10;
  coord xc=East yc=North;
  model form=gau;
  var Thick;
run;
```

For prediction with the saved Gaussian model, you use the following statements to run the KRIGE2D procedure with input from the SemivStoreGau item store. You invoke the item store with the **RESTORE** statement. The **STORESELECT** option in the **MODEL** statement that specifies that you want to use the selected model in the item store as input for your prediction.

```
proc krige2d data=thick outest=pred1 noprint;
  restore in=SemivStoreGau;
  coordinates xc=East yc=North;
  predict var=Thick r=60;
  model storeselect;
  grid x=0 to 100 by 10 y=0 to 100 by 10;
run;
```

Then, you run the KRIGE2D procedure by using a spherical model. Start by using the VARIOGRAM procedure to fit a spherical model to the thick data set empirical semivariogram. You specify the **STORE** statement again in PROC VARIOGRAM to save the spherical model estimated parameters in an item store with the name SemivStoreSph. You use the following statements:

```
proc variogram data=thick plots(only)=fit;
  store out=SemivStoreSph / label='Thickness Sph Model';
  compute lagd=7 maxlag=10;
  coord xc=East yc=North;
  model form=sph;
  var Thick;
run;
```

The VARIOGRAM procedure fits the spherical model successfully, and the estimated parameters for this fit are shown in [Output 49.2.1](#).

Output 49.2.1 Spherical Model Fitting Parameter Estimates

Effect of Model Specification on Prediction					
The VARIOGRAM Procedure					
Dependent Variable: Thick					
Angle: Omnidirectional					
Current Model: Spherical					
Parameter Estimates					
Parameter	Estimate	Approx Std Error	DF	t Value	Approx Pr > t
Nugget	0	0	8	.	.
Scale	7.1914	0.2827	8	25.44	<.0001
Range	63.2351	4.1050	8	15.40	<.0001

The fit summary is displayed in [Output 49.2.2](#). When compared to the corresponding result in the section “[Theoretical Semivariogram Model Fitting](#)” on page 8571 in the VARIOGRAM procedure, the goodness-of-fit criteria indicate a worse statistical fit for the spherical model compared to the Gaussian.

Output 49.2.2 Spherical Model Fit Summary

Fit Summary		
Model	Weighted SSE	AIC
Sph	52.26791	23.14336

Output 49.2.3 suggests an acceptable fit of the spherical model to the thick data set. Obviously, the fit of the spherical model in the sensitive area near the semivariogram origin is less faithful to the empirical semivariance than the Gaussian model. The following analysis explores the consequence in the kriging prediction of this discrepancy.

Output 49.2.3 Fitted Spherical and Empirical Thick Semivariogram

For the next step, you run the KRIGE2D procedure by using the spherical model parameters stored in the SemivStoreSph item store. You use the following statements:

```

proc krige2d data=thick outest=pred2 noprint;
  restore in=SemivStoreSph;
  coordinates xc=East yc=North;
  predict var=Thick r=60;
  model storeselect;
  grid x=0 to 100 by 10 y=0 to 100 by 10;
run;

```

Eventually, you compare the prediction results and errors of the two models. You use a DATA step to compute the relative difference of the predicted values and the prediction error for each one of the Gaussian and the spherical models. You store the prediction relative difference in the `prdRelDif` variable and the prediction relative error in the `stdRelDif` variable. You save the output in the `compare` data set with the following statements:

```

data compare;
  merge pred1(rename=(estimate=g_prd stderr=g_std))
        pred2(rename=(estimate=s_prd stderr=s_std));
  prdRelDif = ((g_prd-s_prd) / s_prd) * 100;
  stdRelDif = ((g_std-s_std) / s_std) * 100;
run;

```

The MEANS procedure uses the `compare` data set to produce statistics about the prediction relative difference and error for each one of the `prdRelDif` and `stdRelDif` variables with the following statements:

```

proc means data=compare;
  var prdRelDif stdRelDif;
run;

ods graphics off;

```

[Output 49.2.4](#) shows that on average the predicted values are very close for the two semivariogram models. The mean relative difference in the prediction values is close to zero with a low standard deviation, whereas the relative difference values fluctuate with an absolute maximum of about 5%.

However, note that the mean relative standard error is about -96%. According to the definition of the `stdRelDif` variable, the high negative value indicates that the prediction error difference between the two models is very close to the spherical model prediction error. Hence, the prediction standard error of the spherical model is substantially larger than that of the Gaussian model. In fact, the prediction relative error never gets smaller than about 66% for the two models, where the negative sign in the Minimum and Maximum columns in [Output 49.2.4](#) means that the prediction error is always greater for the spherical model.

Output 49.2.4 Comparison of Gaussian and Spherical Models

Effect of Model Specification on Prediction					
The MEANS Procedure					
Variable	N	Mean	Std Dev	Minimum	Maximum
prdRelDif	121	-0.0544593	1.3384023	-5.0751449	5.1926236
stdRelDif	121	-96.2515099	5.9400029	-99.8974418	-65.9275907

Example 49.3: Data Quality and Prediction with Missing Values

Kriging methods depend primarily on your data. The quantity and quality of your observations are important factors in minimizing prediction errors and increasing accuracy in your prediction analysis.

A typical aspect of data quality is measurement accuracy. In principle, the accuracy level of your data is not a parameter in kriging prediction; kriging assumes by definition that your data are perfectly accurate (hard) measurements. Whether you accept this assumption depends on your application. For example, an instrumentation error of $\pm 1\%$ in the data values might be regarded as considerable in one case, whereas the same level of uncertainty might be trivial within a different framework. Your experience and judgment are crucial when you consider whether observations in a data set might be too noisy for kriging predictions to be useful.

A second aspect of data quality involves the spatial arrangement of your observations. You need to have a sufficient number of observations in order to perform spatial prediction. Also, a key element in minimizing prediction errors is an adequate sampling density. Interpretation of the expressions “sufficient number” and “adequate sampling” is again case-specific. In any event, you want enough measurements so that you can deduce the underlying spatial correlation in the working domain; see also the discussion in the section “Choosing the Size of Classes” on page 8623 in the VARIOGRAM procedure.

This example focuses on the effects of different sampling densities on the prediction analysis. The demonstration is a slight variation of the example in the section “Getting Started: KRIGE2D Procedure” on page 3795. Specifically, you use the same correlation structure and prediction grid. However, the thick data set, is modified as follows: three values in the central area of the grid are assumed missing, namely the observation values at locations $s_1 = (x_1, y_1) = (55.8, 50.5)$, $s_2 = (x_2, y_2) = (52.8, 68.9)$, and $s_3 = (x_3, y_3) = (52.9, 32.7)$. These locations have been selected so that an extended area without observations is created in the domain. The following DATA step is the input for the modified thick data set:

```

;

```

```
ods graphics on;
```

NOTE: Here you assume prior knowledge of the correlation structure model, because its parameters are based on the complete thick data set. A covariance model extracted from the incomplete set with the missing values would be a covariance model coming from a different data set; hence, it is likely to have different parameters.

After you define the modified data set, you run PROC KRIGE2D and request the **OBSERVATIONS** plot with the **SHOWMISSING** suboption. You also request two instances of the **PREDICTION** plot: one that displays the prediction surface and contours, and another that plots the kriging standard error surface and contours. In both of these **PREDICTION** plots you specify that the observations be shown as gradient markers with outlines. The following statements compute the kriged predictions and produce the requested graphics:

```

proc krige2d data=thick outest=predictions
              plots(only)=(observ(showmissing)
                             pred(fill=pred line=pred obs=linegrad)
                             pred(fill=se line=se obs=linegrad));
  coordinates xc=East yc=North;
  predict var=Thick r=60;
  model scale=7.4599 range=30.1111 form=gauss;
  grid x=0 to 100 by 2.5 y=0 to 100 by 2.5;
run;

ods graphics off;

```

The number of observations table indicates the three missing values in [Output 49.3.1](#).

Output 49.3.1 Number of Observations for the Modified thick Data Set

Kriging Prediction in the Presence of Missing Values	
The KRIGE2D Procedure	
Dependent Variable: Thick	
Number of Observations Read	75
Number of Observations Used	72

Output 49.3.2 is a scatter plot of the modified observed data. The `SHOWMISSING` suboption produces marks in the observations plot that conveniently indicate the locations s_1 , s_2 , and s_3 of the missing values. Consequently, Output 49.3.2 displays an extended area with no observed Thick values in the central part of the domain.

Output 49.3.2 Scatter Plot of the Observations Spatial Distribution

Predictions at grid points with few neighboring data points rely heavily on the underlying covariance structure. The covariance model has a range of about 30,000 feet, which suggests that within this range a grid point might have no data neighbors at all and still obtain a prediction value on the basis of the correlation structure alone. This type of behavior is demonstrated in the Output 49.3.3, which shows a circular region in the center of the plot that has no data points. Predictions at the nodes in this area are mostly influenced by the covariance structure.

You can see the impact of this effect on the predictions if you compare the prediction contours in the Output 49.3.3 to the ones in Figure 49.4. Despite the contribution of the neighboring Thick data values to the predictions within the area of no observations, the outcome is clearly altered by the absence of observations at the locations s_1 , s_2 , and s_3 .

Output 49.3.3 Surface Plot and Contours of Kriged Coal Seam Thickness

A noticeable difference is also apparent in the plot of the prediction standard errors. [Output 49.3.4](#) displays these errors, and you can compare it to the standard error surface in [Figure 49.4](#). The comparison shows a slight difference in the color gradient within the area of the missing data values. [Output 49.3.4](#) uses standard error contours to enhance the effect of this difference.

The lack of information from the removed data results in an increase of the prediction uncertainty at the grid nodes that are most remotely situated from any observation in the central part of the domain. According to [Output 49.3.4](#), the standard error at these nodes is almost comparable to the error observed near the borders of the domain, where the nodes of the prediction grid have relatively fewer data neighbors than other nodes in the domain.

Output 49.3.4 Surface Plot and Contours of Prediction Standard Errors

On a side note, **PREDICTION** plots display only observations with nonmissing values, as the plots in [Output 49.3.3](#) and [Output 49.3.4](#) demonstrate.

Overview: LATTICE Procedure

The LATTICE procedure computes the analysis of variance and analysis of simple covariance for data from an experiment with a lattice design. PROC LATTICE analyzes balanced square lattices, partially balanced square lattices, and some rectangular lattices.

In balanced square lattices, the number of treatments is equal to the square of the number of units per block. Incomplete blocks are grouped to form mutually orthogonal replications. The number of replicates in the basic plan is always 1 plus the number of units per block.

Partially balanced square lattices are similar to balanced lattices, although the number of replicates can vary. Partially balanced designs are constructed of the replicates in the basic plan, but not all replicates are included the same number of times, and some might not be included at all.

In rectangular lattices, there are k units per block and $k(k + 1)$ treatments. As in square lattices, blocks are grouped to form mutually orthogonal replicates in the basic plan. PROC LATTICE can analyze simple rectangular lattices (two orthogonal replications) and triple rectangular lattices (three orthogonal replications). The experiment can include several repetitions of the basic plan.

The LATTICE procedure determines from the data set which type of design has been used. It also checks to see whether the design is valid and displays an appropriate message if it is not.

Getting Started: LATTICE Procedure

An example of a balanced square design is an experiment to investigate the effects of nine diets on the growth rate of pigs.

In some breeds of pigs, past experience has shown that a large part of the total variation in growth rates between animals can be attributed to the litter. Therefore, this experiment is planned so that litter differences do not contribute to the intrablock error.

First, the pigs are separated into sets of three litter-mates. Each block is assigned two sets of the three litter-mates. In a given block, one pig from each set receives a diet. Therefore, the experimental unit is a pair of pigs feeding in a particular pen on one of the nine diets. The response variable, growth rate, is the sum of the growth rates for the two pigs in a particular pen. To get the adjusted diet mean per pig, the adjusted treatment mean for the pen must be divided by 2.

The special numeric SAS variables named Group, Block, Treatment, and Rep must be used to define the design. In this example, the Treatment variable ranges from 1 to 9 and indicates the particular diet. The Block variable is 1, 2, or 3 and indicates the pen containing the two pigs. The Group variable ranges from 1 to 4 and specifies which replication within the basic plan includes the experimental unit. In this example, you would not use the Rep variable since the entire basic plan is not replicated.

You can use the following DATA step and PROC LATTICE statement to analyze this experiment. The response variable is Weight.

```

LSD at .05 Level		0.4543	
Efficiency Relative to RCBD		120.55	
Adjusted Treatment Means for Weight			
Treatment	Mean		
1	1.8035		
2	1.7544		
3	1.9643		
4	1.7267		
5	0.9393		
6	1.8448		
7	1.3870		
8	1.4347		
9	1.5004		

Diet 3 yields the highest mean growth rate at 1.9643 pounds for the two pigs (0.9822 per pig), while diet 5 has the lowest rate at 0.9393 (0.4696 per pig). The efficiency of the experiment relative to a randomized complete block design is 120.55 percent, so using the lattice design increased precision, producing more accurate estimates of the treatment effects. The different elements of the LATTICE procedure's output are discussed in the "Displayed Output" on page 3872 section.

Syntax: LATTICE Procedure

The following statements are available in the LATTICE procedure:

```
PROC LATTICE < options > ;  
    BY variables ;  
    VAR variables ;
```

Three specific numeric SAS variables, Group, Block, and Treatment, *must* be present in the data set to which PROC LATTICE is applied. For compatibility with previous releases, the variable Treatment can alternatively be named Treatmnt. A fourth numeric variable named Rep must be present when the design involves repetition of the entire basic plan. (See the “[Input Data Set](#)” on page 3871 section for more information.)

Every numeric variable other than Group, Block, Treatment, or Rep in the input SAS data set may be considered a response variable. A VAR statement tells PROC LATTICE that only the variables listed in the VAR statement are to be considered response variables. If the VAR statement is omitted, then all numeric variables, excluding Group, Block, Treatment, and Rep, are considered response variables. PROC LATTICE performs an analysis for each response variable.

PROC LATTICE Statement

```
PROC LATTICE < options > ;
```

The PROC LATTICE statement invokes the LATTICE procedure.

DATA=SAS-data-set

names the SAS data set to be used by PROC LATTICE. If you omit the DATA= option, the most recently created SAS data set is used.

COVARIANCE

COV

calculates sums of products for every possible pair of response variables. A sum of products is given for each source of variation in the analysis of variance table. For each pair of response variables, the one appearing later in the data set (or in the VAR statement) is the covariable.

BY Statement

```
BY variables ;
```

You can specify a BY statement with PROC LATTICE to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.

- Specify the NOTSORTED or DESCENDING option in the BY statement for the LATTICE procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

VAR Statement

VAR *variables* ;

The VAR statement specifies the response variables. If you do not include a VAR statement, all numeric variables in the data set are considered response variables (except Group, Block, Treatment, and Rep).

Details: LATTICE Procedure

Input Data Set

Four numeric SAS variables, Group, Block, Treatment, and Rep, are used in the input data set to define the lattice design. The Group, Block, and Treatment variables are required in the data set to which PROC LATTICE is applied. For compatibility with previous releases, the third variable can alternatively be named Treatmnt. The Rep variable must be present when the design involves repetition of the entire basic plan.

Group	specifies which orthogonal replication in the basic plan includes the experimental unit. Values of Group must be $1, 2, \dots, n$, where n is the number of replicates in the basic plan.
Block	specifies the block in which the experimental unit is present. Values of Block must be $1, 2, \dots, m$, where m is the number of blocks in a replication.
Treatment	specifies which treatment was applied to the experimental unit. Values of Treatment must be $1, 2, \dots, i$, where i is the number of treatments in a replication.
Rep	specifies which repetition of the basic plan includes the experimental unit. Values of Rep must be $1, 2, \dots, p$, where p is the number of replications of the entire basic plan. Thus, the experiment has a total of np replicates.

Missing Values

If a value of Group, Block, Treatment, or Rep is missing, the analysis is not performed and an appropriate error message is displayed.

If a value of a response variable is missing, this entire variable is dropped from the analysis. If other response variables exist that do not have missing values, they are analyzed.

Displayed Output

For each response variable, PROC LATTICE displays the following

- an “Analysis of Variance” table and related statistics, including the following as separate sources of variations:
 - Replications
 - Blocks within Replications (adjusted for treatments)
 - Treatments (unadjusted)
 - Intra-block Error
 - Randomized Complete Block Error

The Blocks within Replications sum of squares is further broken down into “Component A” and “Component B.” If there is no repetition of the basic plan, the Component B sum of squares is the same as the Blocks within Replications sum of squares. If there is repetition of the basic plan, the Component A sum of squares reflects the variation among blocks that contain the same treatments.

The source of variation called Randomized Complete Block Error is the sum of the Blocks within Replications sum of squares and the Intra-block Error sum of squares. It is the appropriate error term if the experimental design is a randomized complete block design, with the replications filling the roles of complete blocks.

- two values for the Variance of Means. For some lattice designs, these are only approximations. The first value is applicable when the two treatments appear in the same block; the other (when it appears) applies when the two treatments never appear in the same block (a possibility in partially balanced and rectangular designs).
- an Average of Variance. Except with small designs, it is sufficient to use this average variance of means for tests between treatments (whether the two treatments appear in the same block or not); see Cochran and Cox (1957).
- the Least Significant Differences (LSDs) at the 0.01 and 0.05 levels of significance, based on the Average of Variance
- Efficiency Relative to RCBD, the efficiency of the lattice design relative to a randomized complete block design. The efficiency is the ratio of the randomized complete block mean squared error to the effective error variance; see Cochran and Cox (1957).
- the Adjusted Treatment Means. These are adjusted for blocks if the relative precision is greater than 105%.

When you specify the COVARIANCE option, PROC LATTICE produces sums of products and the mean product for each source of variation in the analysis of variance table.

ODS Table Names

PROC LATTICE assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 50.1](#). For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

Table 50.1 ODS Tables Produced by PROC LATTICE

Overview: LIFEREG Procedure

The LIFEREG procedure fits parametric models to failure time data that can be uncensored, right censored, left censored, or interval censored. The models for the response variable consist of a linear effect composed of the covariates and a random disturbance term. The distribution of the random disturbance can be taken from a class of distributions that includes the extreme value, normal, logistic, and, by using a log transformation, the exponential, Weibull, lognormal, log-logistic, and three-parameter gamma distributions.

The model assumed for the response y is

$$y = \mathbf{X}\boldsymbol{\beta} + \sigma\epsilon$$

where y is a vector of response values, often the log of the failure times, \mathbf{X} is a matrix of covariates or independent variables (usually including an intercept term), $\boldsymbol{\beta}$ is a vector of unknown regression parameters, σ is an unknown scale parameter, and ϵ is a vector of errors assumed to come from a known distribution (such as the standard normal distribution). If an offset variable O is specified, the form of the model is $y = \mathbf{X}\boldsymbol{\beta} + O + \sigma\epsilon$, where O is a vector of values of the offset variable O . The distribution might also depend on additional shape parameters. These models are equivalent to accelerated failure time models when the log of the response is the quantity being modeled. The effect of the covariates in an accelerated failure time model is to change the scale, and not the location, of a baseline distribution of failure times.

The LIFEREG procedure estimates the parameters by maximum likelihood with a Newton-Raphson algorithm. PROC LIFEREG estimates the standard errors of the parameter estimates from the inverse of the observed information matrix.

The accelerated failure time model assumes that the effect of independent variables on an event time distribution is multiplicative on the event time. Usually, the scale function is $\exp(\mathbf{x}'_c\boldsymbol{\beta}_c)$, where \mathbf{x}_c is the vector of covariate values (not including the intercept term) and $\boldsymbol{\beta}_c$ is a vector of unknown parameters. Thus, if T_0 is an event time sampled from the baseline distribution corresponding to values of zero for the covariates,

then the accelerated failure time model specifies that, if the vector of covariates is \mathbf{x}_c , the event time is $T = \exp(\mathbf{x}_c' \boldsymbol{\beta}_c) T_0$. If $y = \log(T)$ and $y_0 = \log(T_0)$, then

$$y = \mathbf{x}_c' \boldsymbol{\beta}_c + y_0$$

This is a linear model with y_0 as the error term.

In terms of survival or exceedance probabilities, this model is

$$\Pr(T > t \mid \mathbf{x}_c) = \Pr(T_0 > \exp(-\mathbf{x}_c' \boldsymbol{\beta}_c) t)$$

The probability on the left-hand side of the equal sign is evaluated given the value \mathbf{x}_c for the covariates, and the right-hand side is computed using the baseline probability distribution but at a scaled value of the argument. The right-hand side of the equation represents the value of the baseline survival function evaluated at $\exp(-\mathbf{x}_c' \boldsymbol{\beta}_c) t$.

Models usually have an intercept parameter and a scale parameter. In terms of the original untransformed event times, the effects of the intercept term and the scale term are to scale the event time and to raise the event time to a power, respectively. That is, if

$$\log(T_0) = \mu + \sigma \log(T_\epsilon)$$

then

$$T_0 = \exp(\mu) T_\epsilon^\sigma$$

Although it is possible to fit these models to the original response variable by using the NOLOG option, it is more common to model the log of the response variable. Because of this log transformation, zero values for the observed failure times are not allowed unless the NOLOG option is specified. Similarly, small values for the observed failure times lead to large negative values for the transformed response. The NOLOG option should be used only if you want to fit a distribution appropriate for the untransformed response, such as the extreme value instead of the Weibull. If you specify the normal or logistic distributions, the responses are not log transformed; that is, the NOLOG option is implicitly assumed.

Parameter estimates for the normal distribution are sensitive to large negative values, and care must be taken that the fitted model is not unduly influenced by them. Large negative values for the normal distribution can occur when fitting the lognormal distribution by log transforming the response, and some response values are near zero. Likewise, values that are extremely large after the log transformation have a strong influence in fitting the Weibull distribution (that is, the extreme value distribution for log responses). You should examine the residuals and check the effects of removing observations with large residuals or extreme values of covariates on the model parameters. The logistic distribution gives robust parameter estimates in the sense that the estimates have a bounded influence function.

The standard errors of the parameter estimates are computed from large sample normal approximations by using the observed information matrix. In small samples, these approximations might be poor. See Lawless (2003) for additional discussion and references. You can sometimes construct better confidence intervals by transforming the parameters. For example, large sample theory is often more accurate for $\log(\sigma)$ than σ . Therefore, it might be more accurate to construct confidence intervals for $\log(\sigma)$ and transform these into confidence intervals for σ . The parameter estimates and their estimated covariance matrix are available in an output SAS data set and can be used to construct additional tests or confidence intervals for the parameters. Alternatively, tests of parameters can be based on log-likelihood ratios. See Cox and Oakes (1984) for a

discussion of the merits of some possible test methods including score, Wald, and likelihood ratio tests. Likelihood ratio tests are generally more reliable for small samples than tests based on the information matrix.

The log-likelihood function is computed using the log of the failure time as a response. This log likelihood differs from the log likelihood obtained using the failure time as the response by an additive term of $\sum \log(t_i)$, where the sum is over the uncensored failure times. This term does not depend on the unknown parameters and does not affect parameter or standard error estimates. However, many published values of log likelihoods use the failure time as the basic response variable and, hence, differ by the additive term from the value computed by the LIFEREG procedure.

The classic Tobit model also fits into this class of models but with data usually censored on the left. The data considered by Tobin (1958) in his original paper came from a survey of consumers where the response variable is the ratio of expenditures on durable goods to the total disposable income. The two explanatory variables are the age of the head of household and the ratio of liquid assets to total disposable income. Because many observations in this data set have a value of zero for the response variable, the model fit by Tobin is

$$y = \max(\mathbf{x}'\boldsymbol{\beta} + \epsilon, 0)$$

which is a regression model with left censoring, where $\mathbf{x}' = (1, \mathbf{x}'_c)$.

Bayesian analysis of parametric survival models can be requested by using the BAYES statement in the LIFEREG procedure. In Bayesian analysis, the model parameters are treated as random variables, and inference about parameters is based on the posterior distribution of the parameters, given the data. The posterior distribution is obtained using Bayes' theorem as the likelihood function of the data weighted with a prior distribution. The prior distribution enables you to incorporate knowledge or experience of the likely range of values of the parameters of interest into the analysis. If you have no prior knowledge of the parameter values, you can use a noninformative prior distribution, and the results of the Bayesian analysis will be very similar to a classical analysis based on maximum likelihood. A closed form of the posterior distribution is often not feasible, and a Markov chain Monte Carlo method by Gibbs sampling is used to simulate samples from the posterior distribution. See Chapter 7, [“Introduction to Bayesian Analysis Procedures,”](#) for an introduction to the basic concepts of Bayesian statistics. Also see the section [“Bayesian Analysis: Advantages and Disadvantages”](#) on page 132 for a discussion of the advantages and disadvantages of Bayesian analysis. See Ibrahim, Chen, and Sinha (2001) and Gilks, Richardson, and Spiegelhalter (1996) for more information about Bayesian analysis, including guidance in choosing prior distributions.

For Bayesian analysis, PROC LIFEREG generates a Gibbs chain for the posterior distribution of the model parameters. Summary statistics (mean, standard deviation, quartiles, HPD and credible intervals, correlation matrix) and convergence diagnostics (autocorrelations; Gelman-Rubin, Geweke, Raftery-Lewis, and Heidelberger and Welch tests; and the effective sample size) are computed for each parameter, as well as the correlation matrix of the posterior sample. Trace plots, posterior density plots, and autocorrelation function plots that are created using ODS Graphics are also provided for each parameter.

The LIFEREG procedure uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, [“Statistical Graphics Using ODS.”](#)

Getting Started: LIFEREG Procedure

The following examples demonstrate how you can use the LIFEREG procedure to fit a parametric model to failure time data.

Suppose you have a response variable *y* that represents failure time; a binary variable, *censor*, with *censor*=0 indicating censored values; and two linearly independent variables, *x1* and *x2*. The following statements perform a typical accelerated failure time model analysis. Higher-order effects such as interactions and nested effects are allowed in the independent variables list, but they are not shown in this example.

```
proc lifereg;
  model y*censor(0) = x1 x2;
run;
```

PROC LIFEREG can fit models to interval-censored data. The syntax for specifying interval-censored data is as follows:

```
proc lifereg;
  model (begin, end) = x1 x2;
run;
```

You can also model binomial data by using the *events/trials* syntax for the response, as illustrated in the following statements:

```
proc lifereg;
  model r/n=x1 x2;
run;
```

The variable *n* represents the number of trials, and the variable *r* represents the number of events.

Modeling Right-Censored Failure Time Data

The following example demonstrates how you can use the LIFEREG procedure to fit a model to right-censored failure time data.

Suppose you conduct a study of two headache pain relievers. You divide patients into two groups, with each group receiving a different type of pain reliever. You record the time taken (in minutes) for each patient to report headache relief. Because some of the patients never report relief for the entire study, some of the observations are censored.

The following DATA step creates the SAS data set *headache*:

```
data Headache;
  input Minutes Group Censor @@;
  datalines;
11 1 0 12 1 0 19 1 0 19 1 0
19 1 0 19 1 0 21 1 0 20 1 0
21 1 0 21 1 0 20 1 0 21 1 0
20 1 0 21 1 0 25 1 0 27 1 0
30 1 0 21 1 1 24 1 1 14 2 0
16 2 0 16 2 0 21 2 0 21 2 0
23 2 0 23 2 0 23 2 0 23 2 0
```

```

25 2 1    23 2 0    24 2 0    24 2 0
26 2 1    32 2 1    30 2 1    30 2 0
32 2 1    20 2 1
;

```

The data set *Headache* contains the variable *Minutes*, which represents the reported time to headache relief; the variable *Group*, the group to which the patient is assigned; and the variable *Censor*, a binary variable indicating whether the observation is censored. Valid values of the variable *Censor* are 0 (no) and 1 (yes).

Figure 51.1 shows the first five records of the data set *Headache*.

Figure 51.1 Headache Data

	Obs	Minutes	Group	Censor
	1	11	1	0
	2	12	1	0
	3	19	1	0
	4	19	1	0
	5	19	1	0

The following statements invoke the LIFEREG procedure:

```

proc lifereg data=Headache;
  class Group;
  model Minutes*Censor(1)=Group;
  output out=New cdf=Prob;
run;

```

The CLASS statement specifies the variable *Group* as the classification variable. The MODEL statement syntax indicates that the response variable *Minutes* is right censored when the variable *Censor* takes the value 1. The MODEL statement specifies the variable *Group* as the single explanatory variable. Because the MODEL statement does not specify the DISTRIBUTION= option, the LIFEREG procedure fits the default type 1 extreme-value distribution by using $\log(\text{Minutes})$ as the response. This is equivalent to fitting the Weibull distribution.

The OUTPUT statement creates the output data set *New*. In addition to containing the variables in the original data set *Headache*, the SAS data set *New* also contains the variable *Prob*. This new variable is created by the CDF= option to contain the estimates of the cumulative distribution function evaluated at the observed response.

The results of this analysis are displayed in the following figures.

Figure 51.2 Model Fitting Information from the LIFEREG Procedure

The LIFEREG Procedure		
Model Information		
Data Set	WORK.HEADACHE	
Dependent Variable	Log (Minutes)	
Censoring Variable	Censor	
Censoring Value(s)	1	
Number of Observations	38	
Noncensored Values	30	
Right Censored Values	8	
Left Censored Values	0	
Interval Censored Values	0	
Number of Parameters	3	
Name of Distribution	Weibull	
Log Likelihood	-9.37930239	
Class Level Information		
Name	Levels	Values
Group	2	1 2

Figure 51.2 displays the class level information and model fitting information. There are 30 uncensored observations and 8 right-censored observations. The log likelihood for the Weibull distribution is -9.3793 . The log-likelihood value can be used to compare the goodness of fit for nested models with different covariates, but with the same distribution.

Figure 51.3 Model Fit Statistics from the LIFEREG Procedure

Fit Statistics	
-2 Log Likelihood	18.759
AIC (smaller is better)	24.759
AICC (smaller is better)	25.464
BIC (smaller is better)	29.671
Fit Statistics (Unlogged Response)	
-2 Log Likelihood	199.747
Weibull AIC (smaller is better)	205.747
Weibull AICC (smaller is better)	206.453
Weibull BIC (smaller is better)	210.660

Figure 51.3 displays fit statistics for the model. The “Fit Statistics” table displays statistics based on the maximum extreme-value log likelihood fit by using $\log(\text{Minutes})$ as the response. These statistics are useful

in comparing the fit of a different model when the fit criteria from the model that you compare is also based on the log likelihood using log(Minutes) as the response. The “Fit Statistics (Unlogged Response)” table is based on the maximum Weibull log likelihood using Minutes as the response. The AIC, BIC, and AICC statistics in this table can be used to compare models with different covariates, in addition to models with different distributions, as long as the fit statistics for the models that you compare use Minutes as the response.

Figure 51.4 Model Parameter Estimates from the LIFEREG Procedure

Analysis of Maximum Likelihood Parameter Estimates								
Parameter	DF	Estimate	Standard Error	95% Confidence Limits		Chi-Square	Pr >	ChiSq
Intercept	1	3.3091	0.0589	3.1938	3.4245	3161.70	<.0001	
Group	1 1	-0.1933	0.0786	-0.3473	-0.0393	6.05	0.0139	
Group	2 0	0.0000	
Scale	1	0.2122	0.0304	0.1603	0.2809			
Weibull Shape	1	4.7128	0.6742	3.5604	6.2381			

The table of parameter estimates is displayed in Figure 51.4. Both the intercept and the slope parameter for the variable group are significantly different from 0 at the 0.05 level. Because the variable group has only one degree of freedom, parameter estimates are given for only one level of the variable group (group=1). However, the estimate for the intercept parameter provides a baseline for group=2.

The resulting model is as follows:

$$\log(\text{minutes}) = \begin{cases} 3.30911843 - 0.1933025 & \text{for group} = 1 \\ 3.30911843 & \text{for group} = 2 \end{cases}$$

Note that the Weibull shape parameter for this model is the reciprocal of the extreme-value scale parameter estimate shown in Figure 51.4 ($1/0.21219 = 4.7128$).

The following statements produce a graph of the cumulative distribution values versus the variable Minutes.

```
proc sgplot data=New;
  scatter x=Minutes y=Prob / group=Group;
  discretelegend;
run;
```

Figure 51.5 displays the estimated cumulative distribution function values contained in the output data set New for each group.

Figure 51.5 Plot of the Estimated Cumulative Distribution Function

Bayesian Analysis of Right-Censored Data

Nelson (1982) describes a study of the lifetimes of locomotive engine fans. This example shows how to use PROC LIFEREG to carry out a Bayesian analysis of the engine fan data. In this example, a lognormal distribution is used to model the engine lifetimes, but other survival time distributions, such as the Weibull, can also be used.

The following SAS statements create the SAS data set `Fan`. This data set contains a censoring indicator variable and right-censored survival times for the 70 locomotive engine fans in the study.

```
data Fan;
  input Lifetime Censor@@;
  datalines;
  450 0    460 1    1150 0    1150 0    1560 1
  1600 0    1660 1    1850 1    1850 1    1850 1
  1850 1    1850 1    2030 1    2030 1    2030 1
  2070 0    2070 0    2080 0    2200 1    3000 1
  3000 1    3000 1    3000 1    3100 0    3200 1
  3450 0    3750 1    3750 1    4150 1    4150 1
  4150 1    4150 1    4300 1    4300 1    4300 1
  4300 1    4600 0    4850 1    4850 1    4850 1
  4850 1    5000 1    5000 1    5000 1    6100 1
  6100 0    6100 1    6100 1    6300 1    6450 1
  6450 1    6700 1    7450 1    7800 1    7800 1
  8100 1    8100 1    8200 1    8500 1    8500 1
  8500 1    8750 1    8750 0    8750 1    9400 1
  9900 1    10100 1    10100 1    10100 1    11500 1
  ;
```

Some of the fans had not failed at the time the data were collected, and the unfailed units have right-censored lifetimes. The variable `Lifetime` represents either a failure time or a censoring time. The variable `Censor` is equal to 0 if the value of `Lifetime` is a failure time, and it is equal to 1 if the value is a censoring time.

The following SAS statements specify a Bayesian analysis that uses a lognormal model for the engine lifetimes. There are no covariates, so the model is an intercept-only model. The `OUTPOST=` option saves the samples from the posterior distribution in the SAS data set `Post` for further processing.

```
ods graphics on;
proc lifereg data=Fan;
  model Lifetime*Censor( 1 )= / dist=lognormal;
  bayes seed=1 outpost=Post;
run;
ods graphics off;
```

The `SEED=` option is specified to maintain reproducibility; no other options are specified in the `BAYES` statement. By default, a uniform prior distribution is assumed for the intercept coefficient. The uniform prior is a flat prior on the real line with a distribution that reflects ignorance of the location of the parameter, placing equal probability on all possible values the regression coefficient can take. Using the uniform prior in the following example, you would expect the Bayesian estimates to resemble the classical results of maximizing the likelihood. If you can elicit an informative prior on the regression coefficients, you should use the `COEFFPRIOR=` option to specify it. A default noninformative gamma prior is used for the lognormal scale parameter σ .

You should make sure that the posterior distribution samples have achieved convergence before using them for Bayesian inference. If you do not specify additional options, `PROC LIFEREG` produces by default three convergence diagnostics: autocorrelations of the posterior sample, effective sample size, and the Geweke statistic. See the section “[Assessing Markov Chain Convergence](#)” on page 139 for information about assessing the convergence of the chain of posterior samples. Trace plots, posterior density plots, and autocorrelation function plots that are created using ODS Graphics are also provided for each parameter. See the section “[Visual Analysis via Trace Plots](#)” on page 139 for help in interpreting these plots.

The “Analysis of Maximum Likelihood Parameter Estimates” table in [Figure 51.6](#) summarizes maximum likelihood estimates of the lognormal intercept and scale parameters.

Figure 51.6 Maximum Likelihood Estimates from the LIFEREG Procedure

The LIFEREG Procedure					
Bayesian Analysis					
Analysis of Maximum Likelihood Parameter Estimates					
Parameter	DF	Estimate	Standard Error	95% Confidence Limits	
Intercept	1	10.1432	0.5211	9.1219	11.1646
Scale	1	1.6796	0.3893	1.0664	2.6453

Since no prior distribution for the intercept was specified, the default uniform improper distribution shown in the “Uniform Prior for Regression Coefficients” table in [Figure 51.7](#) is used.

Noninformative prior distributions are appropriate if you have no prior knowledge of the likely range of values of the parameters, and if you want to make probability statements about the parameters or functions of the parameters. Refer, for example, to Ibrahim, Chen, and Sinha (2001) for more information about choosing prior distributions.

The default noninformative gamma prior distribution for the lognormal scale parameter is shown in the “Independent Prior Distributions for Model Parameters” table in [Figure 51.7](#).

Figure 51.7 Noninformative Prior Distributions

The LIFEREG Procedure					
Bayesian Analysis					
Uniform Prior for Regression Coefficients					
Parameter		Prior			
Intercept		Constant			
Independent Prior Distributions for Model Parameters					
Parameter	Prior Distribution	Hyperparameters			
Scale	Gamma	Shape	0.001	Inverse Scale	0.001

By default, posterior mode estimates of the model parameters are used as the starting value for the simulation. These are listed in the “Initial Values of the Chain” table in [Figure 51.8](#).

Figure 51.8 Markov Chain Initial Values

Initial Values of the Chain			
Chain	Seed	Intercept	Scale
1	1	10.0501	1.59544

Summary statistics for the posterior sample are displayed in the “Fit Statistics,” “Descriptive Statistics for the Posterior Sample,” “Interval Statistics for the Posterior Sample,” and “Posterior Correlation Matrix” tables in [Figure 51.9](#). Since noninformative prior distributions were used, these results are consistent with the maximum likelihood estimates shown in [Figure 51.6](#).

Figure 51.9 Posterior Sample Summary Statistics

Fit Statistics						
DIC (smaller is better)			87.245			
pD (effective number of parameters)			1.823

Posterior Correlation Matrix						
Parameter		Intercept	Scale			
Intercept		1.0000	0.8297			
Scale		0.8297	1.0000			

By default, PROC LIFEREG computes three convergence diagnostics: the lag1, lag5, lag10, and lag50 autocorrelations; the Geweke diagnostic; and the effective sample size. These are displayed in [Figure 51.10](#). There is no indication that the Markov chain has not converged. See the section “[Assessing Markov Chain Convergence](#)” on page 139 for more information about convergence diagnostics and their interpretation.

Figure 51.10 Posterior Sample Summary Statistics

The LIFEREG Procedure				
Bayesian Analysis				
Posterior Autocorrelations				
Parameter	Lag 1	Lag 5	Lag 10	Lag 50
Intercept	0.6973	0.1765	0.0190	-0.0017
Scale	0.6955	0.1713	0.0172	-0.0002
Geweke Diagnostics				
Parameter	z	Pr > z		
Intercept	-0.9183	0.3585		
Scale	-0.9233	0.3559		
Effective Sample Sizes				
Parameter	ESS	Autocorrelation		Efficiency
		Time		
Intercept	1772.8	5.6408		0.1773
Scale	1805.0	5.5400		0.1805

Summary statistics of the posterior distribution samples are produced by default. However, these statistics might not be sufficient for carrying out your Bayesian inference. The samples from the posterior distribution saved in the SAS data set Post created with the OUTPOST= option can be used for further analysis.

Trace, autocorrelation, and density plots for the three model parameters shown in Figure 51.11 and Figure 51.12 are useful in diagnosing whether the Markov chain of posterior samples has converged. These plots show no evidence that the chain has not converged. See the section “Visual Analysis via Trace Plots” on page 139 for more information about interpreting these types of diagnostic plots.

Figure 51.11 Diagnostic Plots

Figure 51.12 Diagnostic Plots

The fraction failing in the first 8000 hours of operation might be a quantity of interest. This kind of information could be useful, for example, in determining whether to improve the reliability of the engine components due to warranty considerations. The following SAS statements compute the mean and percentiles of the distribution of the fraction failing in the first 8000 hours from the posterior sample data set Post:

```
data Prob;
  set Post;
  Frac = ProbNorm(( log(8000) - Intercept ) / Scale );
  label Frac= 'Fraction Failing in 8000 Hours';
run;

proc means data = Prob(keep=Frac) n mean p10 p25 p50 p75 p90;
run;
```

The mean fraction of failures in the first 8000 hours, shown in Figure 51.13, is about 0.24, which could be used in further analysis of warranty costs. The 10th percentile is about 0.16 and the 90th percentile is about 0.32, which gives an assessment of the probable range of the fraction failing in the first 8000 hours.

Figure 51.13 Fraction Failing in 8000 Hours

The MEANS Procedure

0.3190883					

Syntax: LIFEREG Procedure

The following statements are available in the LIFEREG procedure:

```

PROC LIFEREG < options > ;
  BAYES < options > ;
  BY variables ;
  CLASS variables ;
  ESTIMATE < 'label' > estimate-specification < (divisor=n) >
    < , ... < 'label' > estimate-specification < (divisor=n) > > < / options > ;
  EFFECTPLOT < plot-type < (plot-definition-options) > > < / options > ;
  INSET < keyword-list > < / options > ;
  LSMEANS < model-effects > < / options > ;
  LSMESTIMATE model-effect < 'label' > values < (divisor=n) >
    < , ... < 'label' > values < (divisor=n) > > < / options > ;
  MODEL response = < effects > < / options > ;
  OUTPUT < OUT=SAS-data-set > < keyword=name ... keyword=name > < options > ;
  PROBPLOT < / options > ;
  SLICE model-effect < / options > ;
  STORE < OUT= > item-store-name < / LABEL= 'label' > ;
  TEST < model-effects > < / options > ;
  WEIGHT variable ;

```

The MODEL statement is required; it specifies both the variables that are used in the regression part of the model and the distribution that is used for the error (random) component of the model. Each invocation of the LIFEREG procedure can use only one MODEL statement. If multiple MODEL statements are present, only

the last is used. You can specify main effects and interaction terms in the **MODEL** statement, as in the GLM procedure. You can specify initial values in the **MODEL** statement or in an **INEST=** data set. If no initial values are specified, the starting estimates are obtained by ordinary least squares. The **CLASS** statement determines which explanatory variables are treated as categorical. The **WEIGHT** statement identifies a *variable* with values that are used to weight the observations. Observations with zero or negative weights are not used to fit the model, although predicted values can be computed for them. The **OUTPUT** statement creates an output data set that contains predicted values and residuals.

The **ESTIMATE**, **EFFECTPLOT**, **LSMEANS**, **LSMESTIMATE**, **SLICE**, **STORE**, and **TEST** statements are common to many procedures. Summary descriptions of functionality and syntax for these statements are also given after the **PROC LIFEREG** statement in alphabetical order, and full documentation about them is available in Chapter 19, “[Shared Concepts and Topics](#).”

PROC LIFEREG Statement

PROC LIFEREG < *options* > ;

The **PROC LIFEREG** statement invokes the LIFEREG procedure. [Table 51.1](#) summarizes the options available in the **PROC LIFEREG** statement.

Table 51.1 PROC LIFEREG Statement Options

Option	Description
COVOUT	Writes the estimated covariance matrix to the OUTEST= data set
DATA=	Specifies the input SAS data set
GOUT=	Specifies a graphics catalog
INEST=	Specifies an input SAS data set that contains initial estimates
NAMELEN=	Specifies the length of effect names
NOPRINT	Suppresses the display of the output
ORDER=	Specifies the sort order for the levels of the classification variables
OUTEST=	Specifies an output SAS data set
PLOTS=	Controls graphics created by ODS Graphics
XDATA=	Specifies a SAS input data containing values for the independent variables

You can specify the following *options* in the **PROC LIFEREG** statement.

COVOUT

writes the estimated covariance matrix to the **OUTEST=** data set if convergence is attained.

DATA=SAS-data-set

specifies the input SAS data set used by **PROC LIFEREG**. By default, the most recently created SAS data set is used.

GOUT=graphics-catalog

specifies a graphics catalog in which to save graphics output.

INEST=SAS-data-set

specifies an input SAS data set that contains initial estimates for all the parameters in the model. See the section “[INEST= Data Set](#)” on page 3945 for a detailed description of the contents of the INEST= data set.

NAMELEN=*n*

specifies the length of effect names in tables and output data sets to be *n* characters, where *n* is a value between 20 and 200. The default length is 20 characters.

NOPRINT

suppresses the display of the output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, “[Using the Output Delivery System](#).”

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of the classification variables (which are specified in the [CLASS](#) statement). This option applies to the levels for all classification variables, except when you use the (default) ORDER=FORMATTED option with numeric classification variables that have no explicit format. With this option, the levels of such variables are ordered by their internal value.

The ORDER= option can take the following values:

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent. For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

OUTEST=SAS-data-set

specifies an output SAS data set containing the parameter estimates, the maximized log likelihood, and, if the COVOUT option is specified, the estimated covariance matrix. See the section “[OUTEST= Data Set](#)” on page 3946 for a detailed description of the contents of the OUTEST= data set.

PLOTS=NONE | PROBPLOT

specifies options that control graphics created by ODS Graphics.

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;

proc lifereg plots=probplot;
  model y = x;
run;

ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The following plot requests are available.

- | | |
|----------|--|
| NONE | suppresses any plots created by ODS Graphics specified in other LIFEREG statements, such as the BAYES or PROBPLOT statement. |
| PROBPLOT | creates a default probability plot based on information in the MODEL statement. If a PROBPLOT option is also specified, the probability plot specified in the PROBPLOT statement is created, and this option is ignored. |

XDATA=SAS-data-set

specifies an input SAS data set that contains values for all the independent variables in the MODEL statement and variables in the CLASS statement for probability plotting. If there are covariates specified in a MODEL statement and a probability plot is requested with a PROBPLOT statement, you specify fixed values for the effects in the MODEL statement with the XDATA= data set. See the section “[XDATA= Data Set](#)” on page 3947 for a detailed description of the contents of the XDATA= data set.

BAYES Statement

BAYES <options> ;

The BAYES statement requests a Bayesian analysis of the regression model by using Gibbs sampling. The Bayesian posterior samples (also known as the chain) for the regression parameters are not tabulated. The Bayesian posterior samples (also known as the chain) for the model parameters can be output to a SAS data set.

Table 51.2 summarizes the options available in the BAYES statement.

Table 51.2 BAYES Statement Options

Option	Description
Monte Carlo Options	
INITIAL=	Specifies initial values of the chain
INITIALMLE	Specifies that maximum likelihood estimates be used as initial values of the chain

Table 51.2 (continued)

Option	Description
METROPOLIS=	Specifies the use of a Metropolis step
NBI=	Specifies the number of burn-in iterations
NMC=	Specifies the number of iterations after burn-in
SEED=	Specifies the random number generator seed
THINNING=	Controls the thinning of the Markov chain
Model and Prior Options	
COEFFPRIOR=	Specifies the prior of the regression coefficients
EXPONENTIALSCALEPRIOR=	Specifies the prior of the exponential scale parameter
GAMMASHAPEPRIOR=	Specifies the prior of the three-parameter gamma shape parameter
SCALEPRIOR=	Specifies the prior of the scale parameter
WEIBULLSCALEPRIOR=	Specifies the prior of the Weibull scale parameter
WEIBULLSHAPEPRIOR=	Specifies the prior of the Weibull shape parameter
Summary Statistics and Convergence Diagnostics	
DIAGNOSTICS=	Displays convergence diagnostics
PLOTS=	Displays diagnostic plots
STATISTICS=	Displays summary statistics of the posterior samples
Posterior Samples	
OUTPOST=	Names a SAS data set for the posterior samples

The following list describes these options and their suboptions.

COEFFPRIOR=UNIFORM | NORMAL <(normal-options)>

CPRIOR=UNIFORM | NORMAL <(option)>

COEFF=UNIFORM | NORMAL <(option)>

specifies the prior distribution for the regression coefficients. The default is COEFFPRIOR=UNIFORM. The available prior distributions are as follows:

NORMAL<(normal-option)>

specifies a normal distribution. The *normal-options* include the following:

CONDITIONAL

specifies that the normal prior, conditional on the current Markov chain value of the location-scale model precision parameter $\tau = \frac{1}{\sigma^2}$, is $N(\boldsymbol{\mu}, \tau^{-1}\boldsymbol{\Sigma})$, where $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are the mean and covariance of the normal prior specified by other normal options.

INPUT= SAS-data-set

specifies a SAS data set that contains the mean and covariance information of the normal prior. The data set must have a `_TYPE_` variable to represent the type of each observation and a variable for each regression coefficient. If the data set also contains a `_NAME_` variable, the values of this variable are used to identify the covariances for the `_TYPE_='COV'` observations; otherwise, the `_TYPE_='COV'` observations are assumed to be in the same order as the explanatory variables in the MODEL statement. PROC LIFEREG reads the

mean vector from the observation with `_TYPE_='MEAN'` and reads the covariance matrix from observations with `_TYPE_='COV'`. For an independent normal prior, the variances can be specified with `_TYPE_='VAR'`; alternatively, the precisions (inverse of the variances) can be specified with `_TYPE_='PRECISION'`.

RELVAR<=c>

specifies the normal prior $N(\mathbf{0}, c\mathbf{J})$, where \mathbf{J} is a diagonal matrix with diagonal elements equal to the variances of the corresponding ML estimator. By default, $c = 10^6$.

VAR<=c>

specifies the normal prior $N(\mathbf{0}, c\mathbf{I})$, where \mathbf{I} is the identity matrix.

If you do not specify an option, the normal prior $N(\mathbf{0}, 10^6\mathbf{I})$, where \mathbf{I} is the identity matrix, is used. See the section “[Normal Prior](#)” on page 3949 for more details.

UNIFORM

specifies a flat prior—that is, the prior that is proportional to a constant ($p(\beta_1, \dots, \beta_k) \propto 1$ for all $-\infty < \beta_i < \infty$).

DIAGNOSTICS=ALL | NONE | (keyword-list)

DIAG=ALL | NONE | (keyword-list)

controls the number of diagnostics produced. You can request all the following diagnostics by specifying `DIAGNOSTICS=ALL`. If you do not want any of these diagnostics, specify `DIAGNOSTICS=NONE`. If you want some but not all of the diagnostics, or if you want to change certain settings of these diagnostics, specify a subset of the following keywords. The default is `DIAGNOSTICS=(AUTOCORR ESS GEWEKE)`.

AUTOCORR <(LAGS= numeric-list)>

computes the autocorrelations of lags given by `LAGS=` list for each parameter. Elements in the list are truncated to integers and repeated values are removed. If the `LAGS=` option is not specified, autocorrelations of lags 1, 5, 10, and 50 are computed for each variable. See the section “[Autocorrelations](#)” on page 152 for details.

ESS

computes Carlin’s estimate of the effective sample size, the correlation time, and the efficiency of the chain for each parameter. See the section “[Effective Sample Size](#)” on page 152 for details.

GELMAN <(gelman-options)>

computes the Gelman and Rubin convergence diagnostics. You can specify one or more of the following *gelman-options*:

NCHAIN=number

N=number

specifies the number of parallel chains used to compute the diagnostic, and must be 2 or larger. The default is `NCHAIN=3`. If an `INITIAL=` data set is used, `NCHAIN` defaults to the number of rows in the `INITIAL=` data set. If any number other than this is specified with the `NCHAIN=` option, the `NCHAIN=` value is ignored.

ALPHA=value

specifies the significance level for the upper bound. The default is ALPHA=0.05, resulting in a 97.5% bound.

See the section “[Gelman and Rubin Diagnostics](#)” on page 145 for details.

GEWEKE <(geweke-options)>

computes the Geweke spectral density diagnostics, which are essentially a two-sample t test between the first f_1 portion and the last f_2 portion of the chain. The default is $f_1 = 0.1$ and $f_2 = 0.5$, but you can choose other fractions by using the following *geweke-options*:

FRAC1=value

specifies the fraction f_1 for the first window.

FRAC2=value

specifies the fraction f_2 for the second window.

See the section “[Geweke Diagnostics](#)” on page 146 for details.

HEIDELBERGER <(heidel-options)>

computes the Heidelberg and Welch diagnostic for each variable, which consists of a stationarity test of the null hypothesis that the sample values form a stationary process. If the stationarity test is not rejected, a halfwidth test is then carried out. Optionally, you can specify one or more of the following *heidel-options*:

SALPHA=value

specifies the α level ($0 < \alpha < 1$) for the stationarity test.

HALPHA=value

specifies the α level ($0 < \alpha < 1$) for the halfwidth test.

EPS=value

specifies a positive number ϵ such that if the halfwidth is less than ϵ times the sample mean of the retained iterates, the halfwidth test is passed.

See the section “[Heidelberg and Welch Diagnostics](#)” on page 148 for details.

MCSE**MCERROR**

computes the Monte Carlo standard error for each parameter. The Monte Carlo standard error, which measures the simulation accuracy, is the standard error of the posterior mean estimate and is calculated as the posterior standard deviation divided by the square root of the effective sample size. See the section “[Standard Error of the Mean Estimate](#)” on page 153 for details.

RAFTERY<(raftery-options)>

computes the Raftery and Lewis diagnostics that evaluate the accuracy of the estimated quantile ($\hat{\theta}_Q$ for a given $Q \in (0, 1)$) of a chain. $\hat{\theta}_Q$ can achieve any degree of accuracy when the chain is allowed to run for a long time. A stopping criterion is when the estimated probability $\hat{P}_Q = \Pr(\theta \leq \hat{\theta}_Q)$ reaches within $\pm R$ of the value Q with probability S ; that is, $\Pr(Q - R \leq \hat{P}_Q \leq Q + R) = S$. The following *raftery-options* enable you to specify Q , R , S , and a precision level ϵ for the test:

QUANTILE | Q=value

specifies the order (a value between 0 and 1) of the quantile of interest. The default is 0.025.

ACCURACY | R=value

specifies a small positive number as the margin of error for measuring the accuracy of estimation of the quantile. The default is 0.005.

PROBABILITY | S=value

specifies the probability of attaining the accuracy of the estimation of the quantile. The default is 0.95.

EPSILON | EPS=value

specifies the tolerance level (a small positive number) for the stationary test. The default is 0.001.

See the section “[Raftery and Lewis Diagnostics](#)” on page 149 for details.

EXPSCALEPRIOR=GAMMA<(options)> | IMPROPER**ESCALEPRIOR=GAMMA<(options)> | IMPROPER****ESCPRIOR=GAMMA<(options)> | IMPROPER**

specifies that Gibbs sampling be performed on the exponential distribution scale parameter and the prior distribution for the scale parameter. This prior distribution applies only when the exponential distribution and no covariates are specified.

A gamma prior $G(a, b)$ with density $f(t) = \frac{b(bt)^{a-1}e^{-bt}}{\Gamma(a)}$ is specified by EXPSCALEPRIOR=GAMMA, which can be followed by one of the following *gamma-options* enclosed in parentheses. The hyperparameters a and b are the shape and inverse-scale parameters of the gamma distribution, respectively. See the section “[Gamma Prior](#)” on page 3949 for more details. The default is $G(10^{-4}, 10^{-4})$.

RELSHAPE<=c>

specifies independent $G(c\hat{\alpha}, c)$ distribution, where $\hat{\alpha}$ is the MLE of the exponential scale parameter. With this choice of hyperparameters, the mean of the prior distribution is $\hat{\alpha}$ and the variance is $\frac{\hat{\alpha}}{c^2}$. By default, $c=10^{-4}$.

SHAPE=a**ISCALE=b**

when both specified, results in a $G(a, b)$ prior.

SHAPE=c

when specified alone, results in a $G(c, c)$ prior.

ISCALE=c

when specified alone, results in a $G(c, c)$ prior.

An improper prior with density $f(t)$ proportional to t^{-1} is specified with EXPSCALEPRIOR=IMPROPER.

GAMMASHAPEPRIOR=NORMAL<(options)>**GAMASHAPEPRIOR=NORMAL<(options)>****SHAPE1PRIOR=NORMAL<(options)>**

specifies the prior distribution for the gamma distribution shape parameter. If you do not specify any options in a gamma model, the $N(0, 10^6)$ prior for the shape is used. You can specify MEAN= and VAR= or RELVAR= options, either alone or together, to specify the mean and variance of the normal prior for the gamma shape parameter.

MEAN=*a*

specifies a normal prior $N(a, 10^6)$. By default, $a=0$.

RELVAR=<*b*>

specifies the normal prior $N(0, bJ)$, where J is the variance of the MLE of the shape parameter. By default, $b=10^6$.

VAR=*c*

specifies the normal prior $N(0, c)$. By default, $c=10^6$.

INITIAL=SAS-data-set

specifies the SAS data set that contains the initial values of the Markov chains. The INITIAL= data set must contain all the variables of the model. You can specify multiple rows as the initial values of the parallel chains for the Gelman-Rubin statistics, but posterior summaries, diagnostics, and plots are computed only for the first chain. If the data set also contains the variable `_SEED_`, the value of the `_SEED_` variable is used as the seed of the random number generator for the corresponding chain.

INITIALMLE

specifies that maximum likelihood estimates of the model parameters be used as initial values of the Markov chain. If this option is not specified, estimates of the mode of the posterior distribution obtained by optimization are used as initial values.

METROPOLIS=YES**METROPOLIS=NO**

specifies the use of a Metropolis step to generate Gibbs samples for posterior distributions that are not log concave. The default value is METROPOLIS=YES.

NBI=number

specifies the number of burn-in iterations before the chains are saved. The default is 2000.

NMC=number

specifies the number of iterations after the burn-in. The default is 10000.

OUTPOST=SAS-data-set**OUT=SAS-data-set**

names the SAS data set that contains the posterior samples. See the section “[OUTPOST= Output Data Set](#)” on page 3951 for more information. Alternatively, you can create the output data set by specifying an ODS OUTPUT statement as follows:

```
ODS OUTPUT POSTERIORSAMPLE=SAS-data-set
```

PLOTS<(global-plot-options)>= plot-request**PLOTS<(global-plot-options)>= (plot-request < ... plot-request>)**

controls the display of diagnostic plots. Three types of plots can be requested: trace plots, autocorrelation function plots, and kernel density plots. By default, the plots are displayed in panels unless the global plot option UNPACK is specified. Also, when specifying more than one type of plots, the plots are displayed by parameters unless the global plot option GROUPBY is specified. When you specify only one plot request, you can omit the parentheses around the plot request. For example:

```
plots=none
plots(unpack)=trace
plots=(trace autocorr)
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc lifereg;
  model y=x;
  bayes plots=trace;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The global plot options are as follows:

FRINGE

creates a fringe plot on the X axis of the density plot.

GROUPBY=PARAMETER

GROUPBY=TYPE

specifies how the plots are grouped when there is more than one type of plot.

GROUPBY=TYPE

specifies that the plots be grouped by type.

GROUPBY=PARAMETER

specifies that the plots be grouped by parameter.

GROUPBY=PARAMETER is the default.

LAGS=*n*

specifies that autocorrelations be plotted up to lag *n*. If this option is not specified, autocorrelations are plotted up to lag 50.

SMOOTH

displays a fitted penalized B-spline curve for each trace plot.

UNPACKPANEL

UNPACK

specifies that all paneled plots be unpacked, meaning that each plot in a panel is displayed separately.

The plot requests include the following:

ALL

specifies all types of plots. PLOTS=ALL is equivalent to specifying PLOTS=(TRACE AUTO-CORR DENSITY).

AUTOCORR

displays the autocorrelation function plots for the parameters.

DENSITY

displays the kernel density plots for the parameters.

NONE

suppresses all diagnostic plots.

TRACE

displays the trace plots for the parameters. See the section “[Visual Analysis via Trace Plots](#)” on page 139 for details.

SCALEPRIOR=GAMMA<(options)>

specifies that Gibbs sampling be performed on the location-scale model scale parameter and the prior distribution for the scale parameter.

A gamma prior $G(a, b)$ with density $f(t) = \frac{b(bt)^{a-1}e^{-bt}}{\Gamma(a)}$ is specified by SCALEPRIOR=GAMMA, which can be followed by one of the following *gamma-options* enclosed in parentheses. The hyperparameters a and b are the shape and inverse-scale parameters of the gamma distribution, respectively. See the section “[Gamma Prior](#)” on page 3949 for details. The default is $G(10^{-4}, 10^{-4})$.

RELSHAPE=<c>

specifies independent $G(c\hat{\sigma}, c)$ distribution, where $\hat{\sigma}$ is the MLE of the scale parameter. With this choice of hyperparameters, the mean of the prior distribution is $\hat{\sigma}$ and the variance is $\frac{\hat{\sigma}}{c}$. By default, $c=10^{-4}$.

SHAPE=a

ISCALE=b

when both specified, results in a $G(a, b)$ prior.

SHAPE=c

when specified alone, results in a $G(c, c)$ prior.

ISCALE=c

when specified alone, results in a $G(c, c)$ prior.

SEED=number

specifies an integer seed in the range 1 to $2^{31} - 1$ for the random number generator in the simulation. Specifying a seed enables you to reproduce identical Markov chains for the same specification. If the SEED= option is not specified, or if you specify a nonpositive seed, a random seed is derived from the time of day.

STATISTICS <(global-options)> = **ALL** | **NONE** | *keyword* | (*keyword-list*)

STATS <(global-statoptions)> = **ALL** | **NONE** | *keyword* | (*keyword-list*)

controls the number of posterior statistics produced. Specifying STATISTICS=ALL is equivalent to specifying STATISTICS= (SUMMARY INTERVAL COV CORR). If you do not want any posterior statistics, you specify STATISTICS=NONE. The default is STATISTICS=(SUMMARY INTERVAL). See the section “[Summary Statistics](#)” on page 153 for details. The *global-options* include the following:

ALPHA=*numeric-list*

controls the probabilities of the credible intervals. The ALPHA= values must be between 0 and 1. Each ALPHA= value produces a pair of 100(1-ALPHA)% equal-tail and HPD intervals for each parameters. The default is ALPHA=0.05, which yields the 95% credible intervals for each parameter.

PERCENT=*numeric-list*

requests the percentile points of the posterior samples. The PERCENT= values must be between 0 and 100. The default is PERCENT=25, 50, 75, which yields the 25th, 50th, and 75th percentile points, respectively, for each parameter.

The list of *keywords* includes the following:

CORR

produces the posterior correlation matrix.

COV

produces the posterior covariance matrix.

SUMMARY

produces the means, standard deviations, and percentile points for the posterior samples. The default is to produce the 25th, 50th, and 75th percentile points, but you can use the global PERCENT= option to request specific percentile points.

INTERVAL

produces equal-tail credible intervals and HPD intervals. The default is to produce the 95% equal-tail credible intervals and 95% HPD intervals, but you can use the global ALPHA= option to request intervals of any probabilities.

NONE

suppresses printing all summary statistics.

THINNING=*number*

THIN=*number*

controls the thinning of the Markov chain. Only one in every k samples is used when THINNING= k , and if NBI= n_0 and NMC= n , the number of samples kept is

$$\left[\frac{n_0 + n}{k} \right] - \left[\frac{n_0}{k} \right]$$

where $[a]$ represents the integer part of the number a . The default is THINNING=1.

WEIBULLSCALEPRIOR=GAMMA<(options)>

WSCALEPRIOR=GAMMA<(options)>

WSCPRIOR=GAMMA<(options)>

specifies that Gibbs sampling be performed on the Weibull model scale parameter and the prior distribution for the scale parameter. This option applies only when a Weibull distribution and no covariates are specified. When this option is specified, PROC LIFEREG performs Gibbs sampling on the Weibull scale parameter, which is defined as $\exp(\mu)$, where μ is the intercept term.

A gamma prior $G(a, b)$ is specified by **WEIBULLSCALEPRIOR=GAMMA**, which can be followed by one of the following *gamma-options* enclosed in parentheses. The gamma probability density is given by $g(t) = \frac{b(bt)^{a-1}e^{-bt}}{\Gamma(a)}$. The hyperparameters a and b are the shape and inverse-scale parameters of the gamma distribution, respectively. See the section “Gamma Prior” on page 3949 for details about the gamma prior. The default is $G(10^{-4}, 10^{-4})$.

RELSHAPE<= c >

specifies independent $G(c\hat{\alpha}, c)$ distribution, where $\hat{\alpha}$ is the MLE of the Weibull scale parameter. With this choice of hyperparameters, the mean of the prior distribution is $\hat{\alpha}$ and the variance is $\frac{\hat{\alpha}}{c}$. By default, $c=10^{-4}$.

SHAPE= a

ISCALE= b

when both specified, results in a $G(a, b)$ prior.

SHAPE= c

when specified alone, results in a $G(c, c)$ prior.

ISCALE= c

when specified alone, results in a $G(c, c)$ prior.

WEIBULLSHAPEPRIOR=GAMMA<(options)>

WSHAPEPRIOR=GAMMA<(options)>

WSPRIOR=GAMMA<(options)>

specifies that Gibbs sampling be performed on the Weibull model shape parameter and the prior distribution for the shape parameter. When this option is specified, PROC LIFEREG performs Gibbs sampling on the Weibull shape parameter, which is defined as σ^{-1} , where σ is the location-scale model scale parameter.

A gamma prior $G(a, b)$ with density $f(t) = \frac{b(bt)^{a-1}e^{-bt}}{\Gamma(a)}$ is specified by **WEIBULLSHAPEPRIOR=GAMMA**, which can be followed by one of the following *gamma-options* enclosed in parentheses. The hyperparameters a and b are the shape and inverse-scale parameters of the gamma distribution, respectively. See the section “Gamma Prior” on page 3949 for details about the gamma prior. The default is $G(10^{-4}, 10^{-4})$.

RELSHAPE<= c >

specifies independent $G(c\hat{\beta}, c)$ distribution, where $\hat{\beta}$ is the MLE of the Weibull shape parameter. With this choice of hyperparameters, the mean of the prior distribution is $\hat{\beta}$ and the variance is $\frac{\hat{\beta}}{c}$. By default, $c=10^{-4}$.

SHAPE < = *a* >

ISCALE = *b*

when both specified, results in a $G(a, b)$ prior.

SHAPE = *c*

when specified alone, results in a $G(c, c)$ prior.

ISCALE = *c*

when specified alone, results in a $G(c, c)$ prior.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC LIFEREG to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the LIFEREG procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* < / **TRUNCATE** > ;

The CLASS statement names the classification variables to be used in the model. Typical classification variables are Treatment, Sex, Race, Group, and Replication. If you use the CLASS statement, it must appear before the **MODEL** statement.

Classification variables can be either character or numeric. By default, class levels are determined from the entire set of formatted values of the CLASS variables.

NOTE: Prior to SAS 9, class levels were determined by using no more than the first 16 characters of the formatted values. To revert to this previous behavior, you can use the TRUNCATE option in the CLASS statement.

In any case, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussions of the FORMAT statement and SAS formats in *SAS*

Formats and Informats: Reference. You can adjust the order of CLASS variable levels with the **ORDER=** option in the **PROC LIFEREG** statement. You can specify the following option in the CLASS statement after a slash (/):

TRUNCATE

specifies that class levels should be determined by using only up to the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases prior to SAS 9.

EFFECTPLOT Statement

EFFECTPLOT < *plot-type* < (*plot-definition-options*) > > < / *options* > ;

The EFFECTPLOT statement produces a display of the fitted model and provides options for changing and enhancing the displays. Table 51.3 describes the available *plot-types* and their *plot-definition-options*.

Table 51.3 *Plot-Types and Plot-Definition-Options*

Plot-Type and Description	Plot-Definition-Options
BOX Displays a box plot of continuous response data at each level of a CLASS effect, with predicted values superimposed and connected by a line. This is an alternative to the INTERACTION <i>plot-type</i> .	PLOTBY= variable or CLASS effect X= CLASS variable or effect
CONTOUR Displays a contour plot of predicted values against two continuous covariates.	PLOTBY= variable or CLASS effect X= continuous variable Y= continuous variable
FIT Displays a curve of predicted values versus a continuous variable.	PLOTBY= variable or CLASS effect X= continuous variable
INTERACTION Displays a plot of predicted values (possibly with error bars) versus the levels of a CLASS effect. The predicted values are connected with lines and can be grouped by the levels of another CLASS effect.	PLOTBY= variable or CLASS effect SLICEBY= variable or CLASS effect X= CLASS variable or effect
SLICEFIT Displays a curve of predicted values versus a continuous variable grouped by the levels of a CLASS effect.	PLOTBY= variable or CLASS effect SLICEBY= variable or CLASS effect X= continuous variable

For full details about the syntax and options of the EFFECTPLOT statement, see the section “**EFFECTPLOT Statement**” on page 411 in Chapter 19, “**Shared Concepts and Topics**.”

ESTIMATE Statement

```
ESTIMATE <'label'> estimate-specification <(divisor=n)>
    < , ... <'label'> estimate-specification <(divisor=n)> >
    </ options> ;
```

The ESTIMATE statement provides a mechanism for obtaining custom hypothesis tests. Estimates are formed as linear estimable functions of the form $\mathbf{L}\boldsymbol{\beta}$. You can perform hypothesis tests for the estimable functions, construct confidence limits, and obtain specific nonlinear transformations.

Table 51.4 summarizes the options available in the ESTIMATE statement.

Table 51.4 ESTIMATE Statement Options

Option	Description
Construction and Computation of Estimable Functions	
DIVISOR=	Specifies a list of values to divide the coefficients
NOFILL	Suppresses the automatic fill-in of coefficients for higher-order effects
SINGULAR=	Tunes the estimability checking difference
Degrees of Freedom and p-values	
ADJUST=	Determines the method for multiple comparison adjustment of estimates
ALPHA= α	Determines the confidence level $(1 - \alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPPDOWN	Adjusts multiplicity-corrected p -values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits
CORR	Displays the correlation matrix of estimates
COV	Displays the covariance matrix of estimates
E	Prints the \mathbf{L} matrix
JOINT	Produces a joint F or chi-square test for the estimable functions
PLOTS=	Requests ODS statistical graphics if the analysis is sampling-based
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the ESTIMATE statement, see the section “ESTIMATE Statement” on page 437 in Chapter 19, “Shared Concepts and Topics.”

INSET Statement

INSET < keyword-list> < / options> ;

The box or table of summary information produced on plots made with the **PROBPLOT** statement is called an *inset*. You can use the **INSET** statement to customize the information that is displayed in the inset box as well as to customize the appearance of the inset box. To supply the information that is displayed in the inset box, you specify *keywords* corresponding to the information that you want shown. For example, the following statements produce a probability plot with the number of observations, the number of right-censored observations, the name of the distribution, and the estimated Weibull shape parameter in the inset:

```
proc lifereg data=epidemic;
  model life = dose / dist = Weibull;
  probplot;
  inset nobs right dist shape;
run;
```

By default, inset entries are identified with appropriate labels. However, you can provide a customized label by specifying the *keyword* for that entry followed by the equal sign (=) and the label in quotes. For example, the following **INSET** statement produces an inset containing the number of observations and the name of the distribution, labeled “Sample Size” and “Distribution” in the inset:

```
inset nobs='Sample Size' dist='Distribution';
```

If you specify a keyword that does not apply to the plot you are creating, then the keyword is ignored.

If you specify more than one **INSET** statement, only the first one is used.

Table 51.5 lists keywords available in the **INSET** statement to display summary statistics, distribution parameters, and distribution fitting information.

Table 51.5 INSET Statement Keywords

Keyword	Description
CONFIDENCE	Confidence coefficient for all confidence intervals
DIST	Name of the distribution
INTERVAL	Number of interval-censored observations
LEFT	Number of left-censored observations
NOBS	Number of observations
NMISS	Number of observations with missing values
RIGHT	Number of right-censored observations
SCALE	Value of the scale parameter
SHAPE	Value of the shape parameter
UNCENSORED	Number of uncensored observations

The following *options* control the appearance of the box when you use traditional graphics. These options are not available if ODS Graphics is enabled. Table 51.6 summarizes the options available in the **INSET** statement.

Table 51.6 INSET Statement Options

Option	Description
CFILL=	Specifies the color for the filling box
CFILLH=	Specifies the color for the filling box header
CFRAME=	Specifies the color for the frame
CHEADER=	Specifies the color for text in the header
CTEXT=	Specifies the color for the text
FONT=	Specifies the software font for the text
HEIGHT=	Specifies the height of the text
HEADER=	Specifies the text for the header or box title
NOFRAME	Omits the frame around the box
POS=	Determines the position of the inset
REFPOINT=	Specifies the reference point for an inset

All *options* are specified after the slash (/) in the INSET statement.

CFILL=*color*

specifies the color for the filling box.

CFILLH=*color*

specifies the color for the filling box header.

CFRAME=*color*

specifies the color for the frame.

CHEADER=*color*

specifies the color for text in the header.

CTEXT=*color*

specifies the color for the text.

FONT=*font*

specifies the software font for the text.

HEIGHT=*value*

specifies the height of the text.

HEADER='*quoted string*'

specifies the text for the header or box title.

NOFRAME

omits the frame around the box.

POS=*value* < **DATA** | **PERCENT** >

determines the position of the inset. The *value* can be a compass point (N, NE, E, SE, S, SW, W, NW) or a pair of coordinates (x, y) enclosed in parentheses. The coordinates can be specified in screen percentage units or axis data units. The default is screen percentage units.

REFPOINT=*name*

specifies the reference point for an inset that is positioned by a pair of coordinates with the POS= option. You use the REFPOINT= option in conjunction with the POS= coordinates. The REFPOINT= option specifies which corner of the inset frame you have specified with coordinates (x, y), and it can take the value of BR (bottom right), BL (bottom left), TR (top right), or TL (top left). The default is REFPOINT=BL. If the inset position is specified as a compass point, then the REFPOINT= option is ignored.

LSMEANS Statement

LSMEANS < *model-effects* > < / *options* > ;

The LSMEANS statement computes and compares least squares means (LS-means) of fixed effects. LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs.

Table 51.7 summarizes the options available in the LSMEANS statement.

Table 51.7 LSMEANS Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies the covariate value in computing LS-means
BYLEVEL	Computes separate margins
DIFF	Requests differences of LS-means
OM=	Specifies the weighting scheme for LS-means computation as determined by the input data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and <i>p</i>-values	
ADJUST=	Determines the method for multiple-comparison adjustment of LS-means differences
ALPHA= α	Determines the confidence level $(1 - \alpha)$
STEPDOWN	Adjusts multiple-comparison <i>p</i> -values further in a step-down fashion
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the L matrix
LINES	Produces a “Lines” display for pairwise LS-means differences
MEANS	Prints the LS-means
PLOTS=	Requests graphs of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the LSMEANS statement, see the section “[LSMEANS Statement](#)” on page 453 in Chapter 19, “[Shared Concepts and Topics](#).”

LSMESTIMATE Statement

```
LSMESTIMATE model-effect < 'label' > values < divisor=n >
            < , ... < 'label' > values < divisor=n > >
            < / options > ;
```

The LSMESTIMATE statement provides a mechanism for obtaining custom hypothesis tests among least squares means.

Table 51.8 summarizes the options available in the LSMESTIMATE statement.

Table 51.8 LSMESTIMATE Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies covariate values in computing LS-means
BYLEVEL	Computes separate margins
DIVISOR=	Specifies a list of values to divide the coefficients
OM=	Specifies the weighting scheme for LS-means computation as determined by a data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and <i>p</i>-values	
ADJUST=	Determines the method for multiple-comparison adjustment of LS-means differences
ALPHA= α	Determines the confidence level $(1 - \alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiple-comparison <i>p</i> -values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the L matrix
ELSM	Prints the K matrix
JOINT	Produces a joint <i>F</i> or chi-square test for the LS-means and LS-means differences
PLOTS=	Requests graphs of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers

For details about the syntax of the LSMESTIMATE statement, see the section “LSMESTIMATE Statement” on page 470 in Chapter 19, “Shared Concepts and Topics.”

MODEL Statement

```
<label> > MODEL response<*censor(list)> = effects </options> ;
```

```
<label> > MODEL (lower,upper)= effects </options> ;
```

```
<label> > MODEL events/trials = effects </options> ;
```

Only a single MODEL statement can be used with one invocation of the LIFEREG procedure. If multiple MODEL statements are present, only the last is used. The optional *label* is used to label the model estimates in the output SAS data set and OUTEST= data set.

The first MODEL syntax is appropriate for right censoring. The variable *response* is possibly right censored. If the *response* variable can be right censored, then a second variable, denoted *censor*, must appear after the *response* variable with a list of parenthesized values, separated by commas or blanks, to indicate censoring. That is, if the *censor* variable takes on a value given in the list, the *response* is a right-censored value; otherwise, it is an observed value.

The second MODEL syntax specifies two variables, *lower* and *upper*, that contain values of the endpoints of the censoring interval. If the two values are the same (and not missing), it is assumed that there is no censoring and the actual response value is observed. If the lower value is missing, then the upper value is used as a left-censored value. If the upper value is missing, then the lower value is taken as a right-censored value. If both values are present and the lower value is less than the upper value, it is assumed that the values specify a censoring interval. If the lower value is greater than the upper value or both values are missing, then the observation is not used in the analysis, although predicted values can still be obtained if none of the covariates are missing.

The following table summarizes the ways of specifying censoring.

<i>lower</i>	<i>upper</i>	Comparison	Interpretation
Not missing	Not missing	Equal	No censoring
Not missing	Not missing	Lower < upper	Censoring interval
Missing	Not missing		Upper used as left-censoring value
Not missing	Missing		Lower used as right-censoring value
Not missing	Not missing	Lower > upper	Observation not used
Missing	Missing		Observation not used

The third MODEL syntax specifies two variables that contain count data for a binary response. The value of the first variable, *events*, is the number of successes. The value of the second variable, *trials*, is the number of tries. The values of both *events* and (*trials-events*) must be nonnegative, and *trials* must be positive for the response to be valid. The values of the two variables do not need to be integers and are not modified to be integers.

The *effects* following the equal sign are the covariates in the model. Higher-order effects, such as interactions and nested terms, are allowed in the list, similar to the GLM procedure. Variable names and combinations of variable names representing higher-order terms are allowed to appear in this list. Classification, or CLASS, variables can be used as effects, and indicator variables are generated for the class levels. If you do not specify any covariates following the equal sign, an intercept-only model is fit.

Examples of three valid MODEL statements follow:

a: `model time*flag(1,3)=temp;`

b: `model (start, finish)=;`

c: `model r/n=dose;`

MODEL statement a indicates that the response is contained in a variable named time and that, if the variable flag takes on the values 1 or 3, the observation is right censored. The explanatory variable is temp, which could be a CLASS variable. MODEL statement b indicates that the response is known to be in the interval between the values of the variables start and finish and that there are no covariates except for a default intercept term. MODEL statement c indicates a binary response, with the variable r containing the number of responses and the variable n containing the number of trials.

Table 51.9 summarizes the options available in the MODEL statement.

Table 51.9 MODEL Statement Options

Option	Description
Model specification	
ALPHA=	Sets the significance level
DISTRIBUTION=	Specifies the distribution type for failure time
NOLOG	Requests no log transformation of response
INTERCEPT=	Specifies initial estimate for intercept term
NOINT	Holds the intercept term fixed
INITIAL=	Specifies initial estimates for regression parameters
OFFSET=	Specifies an offset variable
SCALE=	Initializes the scale parameter
NOSCALE	Holds the scale parameter fixed
SHAPE1=	Initializes the first shape parameter
NOSHAPE1	Holds the first shape parameter fixed
Model fitting	
CONVERGE=	Sets the convergence criterion
MAXITER=	Sets the maximum number of iterations
SINGULAR=	Sets the tolerance for testing singularity
Output	
CORRB	Displays the estimated correlation matrix
COVB	Displays the estimated covariance matrix
ITPRINT	Displays the iteration history, final gradient, and second derivative matrix

The following options can appear in the MODEL statement.

ALPHA=*value*

sets the significance level for the confidence intervals for regression parameters and estimated survival probabilities. The value must be between 0 and 1. By default, ALPHA=0.05.

CONVERGE=*value*

sets the convergence criterion. Convergence is declared when the maximum change in the parameter estimates between Newton-Raphson steps is less than the value specified. The change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change. By default, CONVERGE=1E-8.

CONVG=*value*

sets the relative Hessian convergence criterion; *value* must be between 0 and 1. After convergence is determined with the change in parameter criterion specified with the CONVERGE= option, the quantity $tc = \frac{\mathbf{g}'\mathbf{H}^{-1}\mathbf{g}}{|f|}$ is computed and compared to *value*, where \mathbf{g} is the gradient vector, \mathbf{H} is the Hessian matrix for the model parameters, and f is the log-likelihood function. If tc is greater than *value*, a warning that the relative Hessian convergence criterion has been exceeded is displayed. This criterion detects the occasional case where the change in parameter convergence criterion is satisfied, but a maximum in the log-likelihood function has not been attained. By default, CONVG=1E-4.

CORRB

produces the estimated correlation matrix of the parameter estimates.

COVB

produces the estimated covariance matrix of the parameter estimates.

DISTRIBUTION=*distribution-type*

DIST=*distribution-type*

D=*distribution-type*

specifies the distribution type assumed for the failure time. By default, PROC LIFEREG fits a type 1 extreme-value distribution to the log of the response. This is equivalent to fitting the Weibull distribution, since the scale parameter for the extreme-value distribution is related to a Weibull shape parameter and the intercept is related to the Weibull scale parameter in this case. When the NOLOG option is specified, PROC LIFEREG models the untransformed response with a type 1 extreme-value distribution as the default. See the section “[Supported Distributions](#)” on page 3933 for descriptions of the distributions. The following are valid values for *distribution-type*:

EXPONENTIAL	the exponential distribution, which is treated as a restricted Weibull distribution
GAMMA	a generalized gamma distribution (Lawless 2003, p. 240). The standard two-parameter gamma distribution is not available in PROC LIFEREG.
LLOGISTIC	a log-logistic distribution
LNORMAL	a lognormal distribution
LOGISTIC	a logistic distribution (equivalent to LLOGISTIC when the NOLOG option is specified)
NORMAL	a normal distribution (equivalent to LNORMAL when the NOLOG option is specified)

WEIBULL a Weibull distribution. If NOLOG is specified, it fits a type 1 extreme-value distribution to the raw, untransformed data.

By default, PROC LIFEREG transforms the response with the natural logarithm before fitting the specified model when you specify the GAMMA, LLOGISTIC, LNORMAL, or WEIBULL option. You can suppress the log transformation with the NOLOG option. The following table summarizes the resulting distributions when the preceding distribution options are used in combination with the NOLOG option.

NOLOG		
DISTRIBUTION=	Specified?	Resulting Distribution
EXPONENTIAL	No	Exponential
EXPONENTIAL	Yes	One-parameter extreme value
GAMMA	No	Generalized log-gamma using the log of the response. (This is the same as fitting the generalized gamma using the untransformed response.)
GAMMA	Yes	Generalized log-gamma with untransformed responses
LOGISTIC	No	Logistic
LOGISTIC	Yes	Logistic (NOLOG has no effect)
LLOGISTIC	No	Log-logistic
LLOGISTIC	Yes	Logistic
LNORMAL	No	Lognormal
LNORMAL	Yes	Normal
NORMAL	No	Normal
NORMAL	Yes	Normal (NOLOG has no effect)
WEIBULL	No	Weibull
WEIBULL	Yes	Extreme value

INITIAL=values

sets initial values for the regression parameters. This option can be helpful in the case of convergence difficulty. Specified values are used to initialize the regression coefficients for the covariates specified in the MODEL statement. The intercept parameter is initialized with the INTERCEPT= option and is not included here. The values are assigned to the variables in the MODEL statement in the same order in which they are listed in the MODEL statement. Note that a CLASS variable requires $k - 1$ values when the CLASS variable takes on k different levels. The order of the CLASS levels is determined by the ORDER= option. If there is no intercept term, the first CLASS variable requires k initial values. If a BY statement is used, all CLASS variables must take on the same number of levels in each BY group or no meaningful initial values can be specified. The INITIAL= option can be specified as follows.

Type of List	Specification
List separated by blanks	initial=3 4 5
List separated by commas	initial=3,4,5
x to y	initial=3 to 5
x to y by z	initial=3 to 5 by 1
Combination of methods	initial=1,3 to 5,9

By default, PROC LIFEREG computes initial estimates with ordinary least squares. See the section “[Computational Method](#)” on page 3931 for details.

NOTE: The INITIAL= option is overwritten by the INEST= option. See the section “[INEST= Data Set](#)” on page 3945 for details.

INTERCEPT=*value*

initializes the intercept term to *value*. By default, the intercept is initialized by an ordinary least squares estimate.

ITPRINT

displays the iteration history for computing maximum likelihood estimates, the final evaluation of the gradient, and the final evaluation of the negative of the second derivative matrix—that is, the negative of the Hessian. If you perform a Bayesian analysis by specifying the BAYES statement, the iteration history for computing the mode of the posterior distribution is also displayed.

MAXITER=*n*

sets the maximum allowable number of iterations during the model estimation. By default, MAXITER=50.

NOINT

holds the intercept term fixed. Because of the usual log transformation of the response, the intercept parameter is usually a scale parameter for the untransformed response, or a location parameter for a transformed response.

NOLOG

requests that no log transformation of the response variable be performed. By default, PROC LIFEREG models the log of the response variable for the GAMMA, LLOGISTIC, LOGNORMAL, and WEIBULL distribution options. NOLOG is implicitly assumed for the NORMAL and LOGISTIC distribution options.

NOSCALE

holds the scale parameter fixed. Note that if the log transformation has been applied to the response, the effect of the scale parameter is a power transformation of the original response. If no SCALE= value is specified, the scale parameter is fixed at the value 1.

NOSHAPE1

holds the first shape parameter, SHAPE1, fixed. If no SHAPE1= value is specified, SHAPE1 is fixed at a value that depends on the DISTRIBUTION type.

OFFSET=*variable*

specifies a variable in the input data set to be used as an offset variable. This variable cannot be a CLASS variable, and it cannot be the response variable or one of the explanatory variables.

SCALE=*value*

initializes the scale parameter to *value*. If the Weibull distribution is specified, this scale parameter is the scale parameter of the type 1 extreme-value distribution, not the Weibull scale parameter. Note that, with a log transformation, the exponential model is the same as a Weibull model with the scale parameter fixed at the value 1.

SHAPE1=*value*

initializes the first shape parameter to *value*. If the specified distribution does not depend on this parameter, then this option has no effect. The only distribution that depends on this shape parameter is the generalized gamma distribution. See the section “[Supported Distributions](#)” on page 3933 for descriptions of the parameterizations of the distributions.

SINGULAR=*value*

sets the tolerance for testing singularity of the information matrix and the crossproducts matrix for the initial least squares estimates. Roughly, the test requires that a pivot be at least this value times the original diagonal value. By default, SINGULAR=1E-12.

OUTPUT Statement

OUTPUT < **OUT=***SAS-data-set* > < *keyword=name* > ... < *keyword=name* > ;

The OUTPUT statement creates a new SAS data set containing statistics calculated after fitting the model. At least one specification of the form *keyword=name* is required.

All variables in the original data set are included in the new data set, along with the variables created as options for the OUTPUT statement. These new variables contain fitted values and estimated quantiles. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*. Each OUTPUT statement applies to the preceding MODEL statement. See [Example 51.1](#) for illustrations of the OUTPUT statement.

The following specifications can appear in the OUTPUT statement:

OUT=*SAS-data-set*

specifies the new data set. By default, the procedure uses the *DATA**n* convention to name the new data set.

keyword=name

specifies the statistics to include in the output data set and gives names to the new variables. Specify a keyword for each desired statistic (see the following list of keywords), an equal sign, and the variable to contain the statistic.

The keywords allowed and the statistics they represent are as follows:

CENSORED=*variable*

specifies a *variable* to signal whether an observation is censored, and the type of censoring. The variable takes on values according to [Table 51.10](#).

Table 51.10 Censoring Variable Values

Type of Response	CENSORED Variable Value
Uncensored	0
Right-censored	1
Left-censored	2
Interval-censored	3

CDF=variable

specifies a *variable* to contain the estimates of the cumulative distribution function evaluated at the observed response. If the data are interval censored, then the cumulative distribution function is evaluated at the response lower interval endpoint. See the section “[Predicted Values](#)” on page 3937 for more information.

CONTROL=variable

specifies a *variable* in the input data set to control the estimation of quantiles. See [Example 51.1](#) for an illustration. If the specified variable has the value 1, estimates for all the values listed in the QUANTILE= list are computed for that observation in the input data set; otherwise, no estimates are computed. If no CONTROL= variable is specified, all quantiles are estimated for all observations. If the response variable in the MODEL statement is binomial, then this option has no effect.

CRESIDUAL | CRES=variable

specifies a *variable* to contain the Cox-Snell residuals

$$-\log(S(u_i))$$

where S is the standard survival function and

$$u_i = \frac{y_i - \mathbf{x}_i' \mathbf{b}}{\sigma}$$

If the data are interval censored, residuals are computed for y_i values corresponding to lower interval endpoints. If the response variable in the corresponding model statement is binomial, then the residuals are not computed, and this variable contains missing values.

SRESIDUAL | SRES=variable

specifies a *variable* to contain the standardized residuals

$$\frac{y_i - \mathbf{x}_i' \mathbf{b}}{\sigma}$$

If the data are interval censored, residuals are computed for y_i values corresponding to lower interval endpoints. If the response variable in the corresponding model statement is binomial, then the residuals are not computed, and this variable contains missing values.

PREDICTED | P=variable

specifies a *variable* to contain the quantile estimates. If the response variable in the corresponding model statement is binomial, then this variable contains the estimated probabilities, $1 - F(-\mathbf{x}'\mathbf{b})$.

QUANTILES | QUANTILE | Q=value-list

gives a list of *values* for which quantiles are calculated. The values must be between 0 and 1, noninclusive. For each value, a corresponding quantile is estimated. This option is not used if the response variable in the corresponding MODEL statement is binomial.

By default, QUANTILES=0.5. When the response is not binomial, a numeric variable, _PROB_, is added to the OUTPUT data set whenever the QUANTILES= option is specified. The variable _PROB_ gives the probability value for the quantile estimates. These are the values taken from the QUANTILES= list and are given as values between 0 and 1, not as values between 0 and 100. The list of QUANTILES values can be specified as in [Table 51.11](#).

Table 51.11 Types of Value Lists

Type of List	Specification
List separated by blanks	.2 .4 .6 .8
List separated by commas	.2, .4, .6, .8
x to y	.2 to .8
x to y by z	.2 to .8 by .1
Combination of methods	.1, .2 to .8 by .2

STD_ERR | STD=*variable*

specifies a *variable* to contain the estimates of the standard errors of the estimated quantiles or $x'b$. If the response used in the MODEL statement is a binomial response, then these are the standard errors of $x'b$. Otherwise, they are the standard errors of the quantile estimates. These estimates can be used to compute confidence intervals for the quantiles. However, if the model is fit to the log of the event time, better confidence intervals can usually be computed by transforming the confidence intervals for the log response. See [Example 51.1](#) for such a transformation.

XBETA=*variable*

specifies a *variable* to contain the computed value of $x'b$, where x is the covariate vector and b is the vector of parameter estimates.

PROBPLOT Statement

PROBPLOT | PLOT </options> ;

You can use the PROBPLOT statement to create a probability plot from lifetime data. The data can be uncensored, right censored, or arbitrarily censored. You can specify any number of PROBPLOT statements after a MODEL statement. The syntax used for the response in the MODEL statement determines the type of censoring assumed in creating the probability plot. The model fit with the MODEL statement is plotted along with the data. If there are covariates in the model, they are set to constant values specified in the XDATA= data set when creating the probability plot. If no XDATA= data set is specified, continuous variables are set to their overall mean values and categorical variables specified in the CLASS statement are set to their highest levels.

[Table 51.12](#) summarizes the options available in the PROBPLOT statement.

Table 51.12 PROBPLOT Statement Options

Option	Description
Traditional Graphics	
ANNOTATE=	Specifies an Annotate data set
CAXIS=	Specifies the color used for the axes and tick marks
CCENSOR=	Specifies the color for filling the censor plot area
CENBIN	Plots censored data as frequency counts
CENCOLOR=	Specifies the color for the censor symbol
CENSYMBOL=	Specifies symbols for censored values

Table 51.12 continued

Option	Description
CFIT=	Specifies the color for the fitted probability line and confidence curves
CFRAME=	Specifies the color for the area enclosed by the axes and frame
CGRID=	Specifies the color for grid lines
CHREF=	Specifies the color for lines requested by the HREF= option
CTEXT=	Specifies the color for tick mark values and axis labels
CVREF=	Specifies the color for lines requested by the VREF= option
DESCRIPTION=	Specifies a description that appears in the PROC GREPLAY master menu
FONT=	Specifies a software font for reference line and axis labels
HCL	Computes and draws confidence limits
HEIGHT=	Specifies the height of text used outside framed areas
HLOWER=	Specifies the lower limit on the lifetime axis scale
HOFFSET=	Specifies the offset for the horizontal axis
HUPPER=	Specifies <i>value</i> as the upper lifetime axis tick mark
HREF	Draws reference lines perpendicular to the horizontal axis
HREFLABELS=	Specifies labels for the lines requested by the HREF= option
HREFLABPOS=	Specifies the vertical position of labels for HREF= lines
INBORDER	Requests a border around probability plots
INTERTILE=	Specifies the distance between tiles
ITPRINTM	Displays the iteration history for the Turnbull algorithm
JITTER=	Specifies the amount to jitter overlaying plot symbols, in units of symbol width
LFIT=	Specifies a line style for fitted curves and confidence limits
LGRID=	Specifies a line style for all grid lines
LHREF=	Specifies the line type for lines requested by the HREF= option
LVREF=	Specifies the line type for lines requested by the VREF= option
MAXITEM=	Specifies the maximum number of iterations for the Turnbull algorithm
NAME=	Specifies a name for the plot
NOCENPLOT	Suppresses the plotting of censored data points
NOCONF	Suppresses the default confidence bands
NODATA	Suppresses plotting of the estimated empirical probability plot
NOFIT	Suppresses the fitted probability (percentile) line and confidence bands
NOFRAME	Suppresses the frame around plotting areas
NOGRID	Suppresses grid lines
NOHLABEL	Suppresses horizontal label
NOHTICK	Suppresses horizontal tick marks
NOPOLISH	Suppresses setting small interval probabilities to zero
NOVLABEL	Suppresses vertical labels
NOVTICK	Suppresses vertical tick marks
NPINTERVALS=	Displays one of the two kinds of confidence limit
PCTLIST=	Specifies the list of percentages for which to compute percentile estimates
FLOWER=	Specifies the lower limit on the probability axis scale
PRINTPROBS	Displays intervals and associated probabilities for the Turnbull algorithm
PUPPER=	Specifies the upper limit on the probability axis scale
PPOS=	Specifies the plotting position type
PPOUT	Displays a table of the cumulative probabilities

Table 51.12 continued

Option	Description
PROBLIST=	Specifies the list of initial values for the Turnbull algorithm
ROTATE	Requests probability plots with probability scale on the horizontal axis
SQUARE	Makes the layout of the probability plots square
TOLLIKE=	Specifies the criterion for convergence in the Turnbull algorithm
TOLPROB=	Specifies the criterion for setting the interval probability to zero in the Turnbull algorithm
VAXISLABEL=	Specifies a label for the vertical axis
VREF	Draws reference lines perpendicular to the vertical axis
VREFLABELS=	Specifies labels for the lines requested by the VREF= option
VREFLABPOS=	Specifies the horizontal position of labels for VREF= lines
WAXIS=	Specifies line thickness for axes and frame
WFIT=	Specifies line thickness for fitted curves
WGRID=	Specifies line thickness for grids
WREFL=	Specifies line thickness for reference lines
ODS Graphics	
HCL	Computes and draws confidence limits for the predicted probabilities
HLOWER=	Specifies <i>value</i> as the lower lifetime axis tick mark
HUPPER=	Specifies <i>value</i> as the upper lifetime axis tick mark
HREF	Draws reference lines perpendicular to the horizontal axis
HREFLABELS=	Specifies labels for the lines requested by the HREF= option
ITPRINTM	Displays the iteration history for the Turnbull algorithm
MAXITEM=	Specifies the maximum number of iterations for the Turnbull algorithm
NOCENPLOT	Suppresses the plotting of censored data points
NOCONF	Suppresses the default confidence bands
NODATA	Suppresses plotting of the estimated empirical probability plot
NOFIT	Suppresses the fitted probability (percentile) line and confidence bands
NOFRAME	Suppresses the frame around plotting areas
NOGRID	Suppresses grid lines
NOPOLISH	Suppresses setting small interval probabilities to zero in the Turnbull algorithm
NPINTERVALS=	Displays one of the two kinds of confidence limits
PCTLIST=	Specifies the list of percentages for which to compute percentile estimates
PLOWER=	Specifies the lower limit on the probability axis scale
PRINTPROBS	Displays intervals and associated probabilities for the Turnbull algorithm
PUPPER=	Specifies the upper limit on the probability axis scale
PPOS=	Specifies the plotting position type
PPOUT	Displays a table of the cumulative probabilities
PROBLIST=	Specifies the list of initial values for the Turnbull algorithm
ROTATE	Requests probability plots with probability scale on the horizontal axis
SQUARE	Makes the layout of the probability plots square
TOLLIKE=	Specifies the criterion for convergence in the Turnbull algorithm
TOLPROB=	Specifies the criterion for setting the interval probability to zero in the Turnbull algorithm
VREF	Draws reference lines perpendicular to the vertical axis

You can specify the following options to control the content, layout, and appearance of a probability plot.

Traditional Graphics

The following options are available if you use traditional graphics—that is, if ODS Graphics is not enabled.

ANNOTATE=SAS-data-set

ANNO=SAS-data-set

specifies an Annotate data set, as described in *SAS/GRAPH: Reference*, that enables you to add features to the probability plot. The data set you specify with the ANNOTATE= option in the PROB-
PLOT statement provides the Annotate data set for all plots created by the statement.

CAXIS=color

CAXES=color

specifies the color used for the axes and tick marks. This option overrides any COLOR= specifications in an AXIS statement. The default is the first color in the device color list.

CCENSOR=color

specifies the color for filling the censor plot area. The default is the first color in the device color list.

CENBIN

plots censored data as frequency counts (rounding for noninteger frequency) rather than as individual points.

CENCOLOR=color

specifies the color for the censor symbol. The default is the first color in the device color list.

CENSYMBOL=symbol | (symbol list)

specifies symbols for censored values. The *symbol* is one of the symbol names (plus, star, square, diamond, triangle, hash, paw, point, dot, and circle) or a letter (A–Z). If you do not specify the CENSYMBOL= option, the symbol used for censored values is the same as for failures.

CFIT=color

specifies the color for the fitted probability line and confidence curves. The default is the first color in the device color list.

CFRAME=color

CFR=color

specifies the color for the area enclosed by the axes and frame. This area is not shaded by default.

CGRID=color

specifies the color for grid lines. The default is the first color in the device color list.

CHREF=color

CH=color

specifies the color for lines requested by the HREF= option. The default is the first color in the device color list.

CTEXT=color

specifies the color for tick mark values and axis labels. The default is the color specified for the CTEXT= option in the most recent GOPTIONS statement.

CVREF=*color*

CV=*color*

specifies the color for lines requested by the VREF= option. The default is the first color in the device color list.

DESCRIPTION='*string*'

DES='*string*'

specifies a description, up to 40 characters, that appears in the PROC GREPLAY master menu. The default is the variable name.

FONT=*font*

specifies a software font for reference line and axis labels. You can also specify fonts for axis labels in an AXIS statement. The FONT= font takes precedence over the FTEXT= font specified in the most recent GOPTIONS statement. Hardware characters are used by default.

HCL

computes and draws confidence limits for the predicted probabilities based on distribution percentiles instead of the default CDF limits. See the section "[Confidence Limits for Percentiles](#)" on page 3945 for details of the computation.

HEIGHT=*value*

specifies the height of text used outside framed areas. The default value is 3.846 (in percentage).

HLOWER=*value*

specifies the lower limit on the lifetime axis scale. The HLOWER= option specifies *value* as the lower lifetime axis tick mark. The tick mark interval and the upper axis limit are determined automatically.

HOFFSET=*value*

specifies the offset for the horizontal axis. The default value is 1.

HUPPER=*value*

specifies *value* as the upper lifetime axis tick mark. The tick mark interval and the lower axis limit are determined automatically.

HREF < (INTERSECT) > =*value-list*

requests reference lines perpendicular to the horizontal axis be drawn at horizontal axis values in the *value-list*. If (INTERSECT) is specified, a second reference line perpendicular to the vertical axis is drawn that intersects the fit line at the same point as the horizontal axis reference line. If a horizontal axis reference line label is specified with the HREFLABELS= option, the intersecting vertical axis reference line is labeled with the vertical axis value. See also the CHREF=, HREFLABELS=, and LHREF= options.

HREFLABELS='*label1*' ... '*labeln*'

HREFLABEL='*label1*' ... '*labeln*'

HREFLAB='*label1*' ... '*labeln*'

specifies labels for the lines requested by the HREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

HREFLABPOS=*n*

specifies the vertical position of labels for HREF= lines. The following table shows the valid values for *n* and the corresponding label placements.

<i>n</i>	Label Placement
1	Top
2	Staggered from top
3	Bottom
4	Staggered from bottom
5	Alternating from top
6	Alternating from bottom

INBORDER

requests a border around probability plots.

INTERTILE=*value*

specifies the distance between tiles.

ITPRINTEM

displays the iteration history for the Turnbull algorithm.

JITTER=*value*

specifies the amount to jitter overlaying plot symbols, in units of symbol width.

LFIT=*linetype*

specifies a line style for fitted curves and confidence limits. By default, fitted curves are drawn by connecting solid lines (*linetype* = 1), and confidence limits are drawn by connecting dashed lines (*linetype* = 3).

LGRID=*linetype*

specifies a line style for all grid lines; *linetype* is between 1 and 46. The default is 35.

LHREF=*linetype***LH=*linetype***

specifies the line type for lines requested by the HREF= option. The default is 2, which produces a dashed line.

LVREF=*linetype***LV=*linetype***

specifies the line type for lines requested by the VREF= option. The default is 2, which produces a dashed line.

MAXITEM=*n1* <, *n2*>

specifies the maximum number of iterations for the Turnbull algorithm. Iteration history will be displayed in increments of *n2* if requested with the ITPRINTEM option. See the section “[Arbitrarily Censored Data](#)” on page 3942 for details.

NAME=*'string'*

specifies a name for the plot, up to eight characters, that appears in the PROC GREPLAY master menu. The default is 'LIFEREG'.

NOCENPLOT

suppresses the plotting of censored data points.

NOCONF

suppresses the default confidence bands on the probability plot.

NODATA

suppresses plotting of the estimated empirical probability plot.

NOFIT

suppresses the fitted probability (percentile) line and confidence bands.

NOFRAME

suppresses the frame around plotting areas.

NOGRID

suppresses grid lines.

NOHLABEL

suppresses horizontal labels.

NOHTICK

suppresses horizontal tick marks.

NOPOLISH

suppresses setting small interval probabilities to zero in the Turnbull algorithm.

NOVLABEL

suppresses vertical labels.

NOVTICK

suppresses vertical tick marks.

NPINTERVALS=*interval type*

specifies one of the two kinds of confidence limits for the estimated cumulative probabilities, pointwise (NPINTERVALS=POINT) or simultaneous (NPINTERVALS=SIMUL), requested by the PPOUT option to be displayed in the tabular output.

PCTLIST=*value-list*

specifies the list of percentages for which to compute percentile estimates; *value-list* must be a list of values separated by blanks or commas. Each value in the list must be between 0 and 100.

PLOWER=*value*

specifies the lower limit on the probability axis scale. The PLOWER= option specifies *value* as the lower probability axis tick mark. The tick mark interval and the upper axis limit are determined automatically.

PRINTPROBS

displays intervals and associated probabilities for the Turnbull algorithm.

PUPPER=*value*

specifies the upper limit on the probability axis scale. The PUPPER= option specifies *value* as the upper probability axis tick mark. The tick mark interval and the lower axis limit are determined automatically.

PPOS=*character-list*

specifies the plotting position type. See the section “[Probability Plotting](#)” on page 3940 for details.

PPOS=	Method
EXPRANK	Expected ranks
MEDRANK	Median ranks
MEDRANK1	Median ranks (exact formula)
KM	Kaplan-Meier
MKM	Modified Kaplan-Meier (default)

PPOUT

specifies that a table of the cumulative probabilities plotted on the probability plot be displayed. Kaplan-Meier estimates of the cumulative probabilities are also displayed, along with standard errors and confidence limits. The confidence limits can be pointwise or simultaneous, as specified by the NPINTERVALS= option.

PROBLIST=*value-list*

specifies the list of initial values for the Turnbull algorithm.

ROTATE

requests probability plots with probability scale on the horizontal axis.

SQUARE

makes the layout of the probability plots square.

TOLLIKE=*value*

specifies the criterion for convergence in the Turnbull algorithm.

TOLPROB=*value*

specifies the criterion for setting the interval probability to zero in the Turnbull algorithm.

VAXISLABEL=*‘string’*

specifies a label for the vertical axis.

VREF<(INTERSECT)>=*value-list*

requests reference lines perpendicular to the vertical axis be drawn at vertical axis values in the *value-list*. If (INTERSECT) is specified, a second reference line perpendicular to the horizontal axis is drawn that intersects the fit line at the same point as the vertical axis reference line. If a vertical axis reference line label is specified with the VREFLABELS= option, the intersecting horizontal axis reference line is labeled with the horizontal axis value. See also the CVREF=, LVREF=, and VREFLABELS= options.

VREFLABELS='label1' ... 'labeln'

VREFLABEL='label1' ... 'labeln'

VREFLAB='label1' ... 'labeln'

specifies labels for the lines requested by the VREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

VREFLABPOS=*n*

specifies the horizontal position of labels for VREF= lines. The valid values for *n* and the corresponding label placements are shown in the following table.

<i>n</i>	Label Placement
1	Left
2	Right

WAXIS=*n*

specifies line thickness for axes and frame. The default value is 1.

WFIT=*n*

specifies line thickness for fitted curves. The default value is 1.

WGRID=*n*

specifies line thickness for grids. The default value is 1.

WREFL=*n*

specifies line thickness for reference lines. The default value is 1.

ODS Graphics

The following options are available if ODS Graphics is enabled.

HCL

computes and draws confidence limits for the predicted probabilities in the horizontal direction.

HLOWER=*value*

specifies the lower limit on the lifetime axis scale. The HLOWER= option specifies *value* as the lower lifetime axis tick mark. The tick mark interval and the upper axis limit are determined automatically.

HUPPER=*value*

specifies *value* as the upper lifetime axis tick mark. The tick mark interval and the lower axis limit are determined automatically.

HREF < (INTERSECT) > =*value-list*

requests reference lines perpendicular to the horizontal axis be drawn at horizontal axis values in the *value-list*. If (INTERSECT) is specified, a second reference line perpendicular to the vertical axis is drawn that intersects the fit line at the same point as the horizontal axis reference line. If a horizontal axis reference line label is specified with the HREFLABELS= option, the intersecting vertical axis reference line is labeled with the vertical axis value. See also the CHREF=, HREFLABELS=, and LHREF= options.

HREFLABELS=*'label1' ... 'labeln'*

HREFLABEL=*'label1' ... 'labeln'*

HREFLAB=*'label1' ... 'labeln'*

specifies labels for the lines requested by the HREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

ITPRINTM

displays the iteration history for the Turnbull algorithm.

MAXITEM=*n1 <,n2>*

specifies the maximum number of iterations for the Turnbull algorithm. Iteration history will be displayed in increments of *n2* if requested with the ITPRINTM option. See the section “[Arbitrarily Censored Data](#)” on page 3942 for details.

NOCENPLOT

suppresses the plotting of censored data points.

NOCONF

suppresses the default confidence bands on the probability plot.

NODATA

suppresses plotting of the estimated empirical probability plot.

NOFIT

suppresses the fitted probability (percentile) line and confidence bands.

NOFRAME

suppresses the frame around plotting areas.

NOGRID

suppresses grid lines.

NOPOLISH

suppresses setting small interval probabilities to zero in the Turnbull algorithm.

NPINTERVALS=*interval type*

specifies one of the two kinds of confidence limits for the estimated cumulative probabilities, pointwise (NPINTERVALS=POINT) or simultaneous (NPINTERVALS=SIMUL), requested by the PPOUT option to be displayed in the tabular output.

PCTLIST=*value-list*

specifies the list of percentages for which to compute percentile estimates; *value-list* must be a list of values separated by blanks or commas. Each value in the list must be between 0 and 100.

PLOWER=*value*

specifies the lower limit on the probability axis scale. The PLOWER= option specifies *value* as the lower probability axis tick mark. The tick mark interval and the upper axis limit are determined automatically.

PRINTPROBS

displays intervals and associated probabilities for the Turnbull algorithm.

PUPPER=*value*

specifies the upper limit on the probability axis scale. The PUPPER= option specifies *value* as the upper probability axis tick mark. The tick mark interval and the lower axis limit are determined automatically.

PPOS=*plotting-position-type*

specifies the plotting position type. See the section “[Probability Plotting](#)” on page 3940 for details.

PPOS=	Method
EXPRANK	Expected ranks
MEDRANK	Median ranks
MEDRANK1	Median ranks (exact formula)
KM	Kaplan-Meier
MKM	Modified Kaplan-Meier (default)

PPOUT

specifies that a table of the cumulative probabilities plotted on the probability plot be displayed. Kaplan-Meier estimates of the cumulative probabilities are also displayed, along with standard errors and confidence limits. The confidence limits can be pointwise or simultaneous, as specified by the NPINTERVALS= option.

PROBLIST=*value-list*

specifies the list of initial values for the Turnbull algorithm.

ROTATE

requests probability plots with probability scale on the horizontal axis.

SQUARE

makes the layout of the probability plots square.

TOLLIKE=*value*

specifies the criterion for convergence in the Turnbull algorithm.

TOLPROB=*value*

specifies the criterion for setting the interval probability to zero in the Turnbull algorithm.

VREF<(INTERSECT)>=*value-list*

requests reference lines perpendicular to the vertical axis be drawn at vertical axis values in the *value-list*. If (INTERSECT) is specified, a second reference line perpendicular to the horizontal axis is drawn that intersects the fit line at the same point as the vertical axis reference line. If a vertical axis reference line label is specified with the VREFLABELS= option, the intersecting horizontal axis reference line is labeled with the horizontal axis value. See also the CVREF=, LVREF=, and VREFLABELS= options.

VREFLABELS=*'label1' ... 'labeln'***VREFLABEL=***'label1' ... 'labeln'***VREFLAB=***'label1' ... 'labeln'*

specifies labels for the lines requested by the VREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

SLICE Statement

SLICE *model-effect* </ options> ;

The SLICE statement provides a general mechanism for performing a partitioned analysis of the LS-means for an interaction. This analysis is also known as an analysis of simple effects.

The SLICE statement uses the same options as the LSMEANS statement, which are summarized in [Table 19.21](#). For details about the syntax of the SLICE statement, see the section “[SLICE Statement](#)” on page 498 in Chapter 19, “[Shared Concepts and Topics](#).”

STORE Statement

STORE < **OUT=** > *item-store-name* </ **LABEL=** 'label' > ;

The STORE statement requests that the procedure save the context and results of the statistical analysis. The resulting item store has a binary file format that cannot be modified. The contents of the item store can be processed with the PLM procedure.

For details about the syntax of the STORE statement, see the section “[STORE Statement](#)” on page 501 in Chapter 19, “[Shared Concepts and Topics](#).”

TEST Statement

TEST < *model-effects* > </ options> ;

The TEST statement enables you to perform chi-square tests for model effects that test Type I, Type II, or Type III hypotheses. By default, the Type III tests are performed. For more information, see Chapter 19, “[Shared Concepts and Topics](#).”

WEIGHT Statement

WEIGHT *variable* ;

If you want to use weights for each observation in the input data set, place the weights in a variable in the data set and specify the name in a WEIGHT statement. The values of the WEIGHT variable can be nonintegral and are not truncated. Observations with nonpositive or missing values for the weight variable do not contribute to the fit of the model. The WEIGHT variable multiplies the contribution to the log likelihood for each observation.

Details: LIFEREG Procedure

Missing Values

Any observation with missing values for the dependent variable is not used in the model estimation unless it is one and only one of the values in an interval specification. Also, if one of the explanatory variables or the censoring variable is missing, the observation is not used. For any observation to be used in the estimation of a model, only the variables needed in that model have to be nonmissing. Predicted values are computed for all observations with no missing explanatory variable values. If the censoring variable is missing, the CENSORED= variable in the OUT= SAS data set is also missing.

Model Specification

Main effects as well as interaction terms are allowed in the model specification, similar to the GLM procedure. For numeric variables, a main effect is a linear term equal to the value of the variable unless the variable appears in the CLASS statement. For variables listed in the CLASS statement, PROC LIFEREG creates indicator variables (variables taking the values zero or one) for every level of the variable except the last level. If there is no intercept term, the first CLASS variable has indicator variables created for all levels including the last level. The levels are ordered according to the ORDER= option. Estimates of a main effect depend upon other effects in the model and, therefore, are adjusted for the presence of other effects in the model.

Computational Method

By default, the LIFEREG procedure computes initial values for the parameters by using ordinary least squares (OLS) and ignoring censoring. This might not be the best set of starting values for a given set of data. For example, if there are extreme values in your data, the OLS fit might be excessively influenced by the extreme observations, causing an overflow or convergence problems. See [Example 51.3](#) for one way to deal with convergence problems.

You can specify the INITIAL= option in the MODEL statement to override these starting values. You can also specify the INTERCEPT=, SCALE=, and SHAPE= options to set initial values of the intercept, scale, and shape parameters. For models with multilevel interaction effects, it is a little difficult to use the INITIAL= option to provide starting values for all parameters. In this case, you can use the INEST= data set. See the section “[INEST= Data Set](#)” on page 3945 for details. The INEST= data set overrides all previous specifications for starting values of parameters.

The rank of the design matrix \mathbf{X} is estimated before the model is fit. Columns of \mathbf{X} that are judged linearly dependent on other columns have the corresponding parameters set to zero. The test for linear dependence is controlled by the SINGULAR= option in the MODEL statement. Variables are included in the model in the order in which they are listed in the MODEL statement with the continuous variables included in the model before any classification variables.

The log-likelihood function is maximized by means of a ridge-stabilized Newton-Raphson algorithm. The maximized value of the log likelihood can take positive or negative values, depending on the specified model and the values of the maximum likelihood estimates of the model parameters.

If convergence of the maximum likelihood estimates is attained, a Type III chi-square test statistic is computed for each effect, testing whether there is any contribution from any of the levels of the effect. This statistic is computed as a quadratic form in the appropriate parameter estimates by using the corresponding submatrix of the asymptotic covariance matrix estimate. See Chapter 42, “[The GLM Procedure](#),” and Chapter 15, “[The Four Types of Estimable Functions](#),” for more information about Type III estimable functions. The asymptotic covariance matrix is computed as the inverse of the observed information matrix. Note that if the NOINT option is specified and CLASS variables are used, the first CLASS variable contains a contribution from an intercept term. The results are displayed in an ODS table named “Type3Analysis.” Chi-square tests for individual parameters are Wald tests based on the observed information matrix and the parameter estimates. If an effect has a single degree of freedom in the parameter estimates table, the chi-square test for this parameter is equivalent to the Type III test for this effect.

Before SAS 8.2, a multiple-degree-of-freedom statistic was computed for each effect to test for contribution from any level of the effect. In general, the Type III test statistic in a main-effect-only model (no interaction terms) will be equal to the previously computed effect statistic, unless there are collinearities among the effects. If there are collinearities, the Type III statistic will adjust for them, and the value of the Type III statistic and the number of degrees of freedom might not be equal to those of the previous effect statistic.

Suppose there are n observations from the model $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \sigma\boldsymbol{\epsilon}$ (or $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{O} + \sigma\boldsymbol{\epsilon}$ if there is an offset variable), where \mathbf{X} is an $n \times k$ matrix of covariate values (including the intercept), \mathbf{y} is a vector of responses, \mathbf{O} is a vector of offset variable values, and $\boldsymbol{\epsilon}$ is a vector of errors with survival function S , cumulative distribution function F , and probability density function f . That is, $S(t) = \Pr(\epsilon_i > t)$, $F(t) = \Pr(\epsilon_i \leq t)$, and $f(t) = dF(t)/dt$, where ϵ_i is a component of the error vector. Then, if all the responses are observed, the log likelihood, L , can be written as

$$L = \sum \log \left(\frac{f(u_i)}{\sigma} \right)$$

where $u_i = \frac{1}{\sigma}(y_i - \mathbf{x}_i' \boldsymbol{\beta})$.

If some of the responses are left, right, or interval censored, the log likelihood can be written as

$$L = \sum \log \left(\frac{f(u_i)}{\sigma} \right) + \sum \log (S(u_i)) + \sum \log (F(u_i)) + \sum \log (F(u_i) - F(v_i))$$

with the first sum over uncensored observations, the second sum over right-censored observations, the third sum over left-censored observations, the last sum over interval-censored observations, and

$$v_i = \frac{1}{\sigma}(z_i - \mathbf{x}_i' \boldsymbol{\beta})$$

where z_i is the lower end of a censoring interval.

If the response is specified in the binomial format, *events/trials*, then the log-likelihood function is

$$L = \sum r_i \log(P_i) + (n_i - r_i) \log(1 - P_i)$$

where r_i is the number of events and n_i is the number of trials for the i th observation. In this case, $P_i = 1 - F(-\mathbf{x}_i' \boldsymbol{\beta})$. For the symmetric distributions, logistic and normal, this is the same as $F(\mathbf{x}_i' \boldsymbol{\beta})$. Additional

information about censored and limited dependent variable models can be found in Kalbfleisch and Prentice (1980) and Maddala (1983).

The estimated covariance matrix of the parameter estimates is computed as the negative inverse of \mathbf{I} , which is the information matrix of second derivatives of L with respect to the parameters evaluated at the final parameter estimates. If \mathbf{I} is not positive definite, a positive-definite submatrix of \mathbf{I} is inverted, and the remaining rows and columns of the inverse are set to zero. If some of the parameters, such as the scale and intercept, are restricted, the corresponding elements of the estimated covariance matrix are set to zero. The standard error estimates for the parameter estimates are taken as the square roots of the corresponding diagonal elements.

For restrictions placed on the intercept, scale, and shape parameters, one-degree-of-freedom Lagrange multiplier test statistics are computed. These statistics are computed as

$$\chi^2 = \frac{g^2}{V}$$

where g is the derivative of the log likelihood with respect to the restricted parameter at the restricted maximum and

$$V = \mathbf{I}_{11} - \mathbf{I}_{12}\mathbf{I}_{22}^{-1}\mathbf{I}_{21}$$

where the 1 subscripts refer to the restricted parameter and the 2 subscripts refer to the unrestricted parameters. The information matrix is evaluated at the restricted maximum. These statistics are asymptotically distributed as chi-squares with one degree of freedom under the null hypothesis that the restrictions are valid, provided that some regularity conditions are satisfied. See Rao (1973, p. 418) for a more complete discussion. It is possible for these statistics to be missing if the observed information matrix is not positive definite. Higher-degree-of-freedom tests for multiple restrictions are not currently computed.

A Lagrange multiplier test statistic is computed to test this constraint. Notice that this test statistic is comparable to the Wald test statistic for testing that the scale is one. The Wald statistic is the result of squaring the difference of the estimate of the scale parameter from one and dividing this by the square of its estimated standard error.

Supported Distributions

For most distributions, the baseline survival function (S) and the probability density function (f) are listed for the additive random disturbance (y_0 or $\log(T_0)$) with location parameter μ and scale parameter σ . See the section “[Overview: LIFEREG Procedure](#)” on page 3878 for more information. These distributions apply when the log of the response is modeled (this is the default analysis). The corresponding survival function (G) and its density function (g) are given for the untransformed baseline distribution (T_0).

For the normal and logistic distributions, the response is not log transformed by PROC LIFEREG, and the survival functions and probability density functions listed apply to the untransformed response.

For example, for the WEIBULL distribution, $S(w)$ and $f(w)$ are the survival function and the probability density function for the extreme-value distribution (distribution of the log of the response), while $G(t)$ and $g(t)$ are the survival function and the probability density function of a Weibull distribution (using the untransformed response).

The chosen baseline functions define the meaning of the intercept, scale, and shape parameters. Only the gamma distribution has a free shape parameter in the following parameterizations. Notice that some of the

distributions do not have mean zero and that σ is not, in general, the standard deviation of the baseline distribution.

For the Weibull distribution, the accelerated failure time model is also a proportional-hazards model. However, the parameterization for the covariates differs by a multiple of the scale parameter from the parameterization commonly used for the proportional hazards model.

The distributions supported in the LIFEREG procedure follow. If there are no covariates in the model, $\mu = \text{Intercept}$ in the output; otherwise, $\mu = \mathbf{x}'\boldsymbol{\beta}$. $\sigma = \text{Scale}$ in the output.

Exponential

$$\begin{aligned} S(w) &= \exp(-\exp(w - \mu)) \\ f(w) &= \exp(w - \mu) \exp(-\exp(w - \mu)) \\ G(t) &= \exp(-\alpha t) \\ g(t) &= \alpha \exp(-\alpha t) \end{aligned}$$

where $\exp(-\mu) = \alpha$.

Generalized Gamma

$S(w) = S'(u)$, $f(w) = \sigma^{-1} f'(u)$, $G(t) = G'(v)$, $g(t) = \frac{v}{t\sigma} g'(v)$, $u = \frac{w - \mu}{\sigma}$, $v = \exp(\frac{\log(t) - \mu}{\sigma})$, and

$$\begin{aligned} S'(u) &= \begin{cases} 1 - \frac{\Gamma(\delta^{-2}, \delta^{-2} \exp(\delta u))}{\Gamma(\delta^{-2})} & \text{if } \delta > 0 \\ \frac{\Gamma(\delta^{-2}, \delta^{-2} \exp(\delta u))}{\Gamma(\delta^{-2})} & \text{if } \delta < 0 \end{cases} \\ f'(u) &= \frac{|\delta|}{\Gamma(\delta^{-2})} (\delta^{-2} \exp(\delta u))^{\delta^{-2}} \exp(-\exp(\delta u) \delta^{-2}) \\ G'(v) &= \begin{cases} 1 - \frac{\Gamma(\delta^{-2}, \delta^{-2} v^\delta)}{\Gamma(\delta^{-2})} & \text{if } \delta > 0 \\ \frac{\Gamma(\delta^{-2}, \delta^{-2} v^\delta)}{\Gamma(\delta^{-2})} & \text{if } \delta < 0 \end{cases} \\ g'(v) &= \frac{|\delta|}{v \Gamma(\delta^{-2})} (\delta^{-2} v^\delta)^{\delta^{-2}} \exp(-v^\delta \delta^{-2}) \end{aligned}$$

where $\Gamma(a)$ denotes the complete gamma function, $\Gamma(a, z)$ denotes the incomplete gamma function, and δ is a free shape parameter. The δ parameter is called Shape by PROC LIFEREG. See Lawless (2003, p. 240), and Klein and Moeschberger (1997, p. 386) for a description of the generalized gamma distribution.

Logistic

$$S(w) = \left(1 + \exp\left(\frac{w - \mu}{\sigma}\right)\right)^{-1}$$

$$f(w) = \frac{\exp\left(\frac{w - \mu}{\sigma}\right)}{\sigma \left(1 + \exp\left(\frac{w - \mu}{\sigma}\right)\right)^2}$$

Log-Logistic

$$S(w) = \left(1 + \exp\left(\frac{w - \mu}{\sigma}\right)\right)^{-1}$$

$$f(w) = \frac{\exp\left(\frac{w - \mu}{\sigma}\right)}{\sigma \left(1 + \exp\left(\frac{w - \mu}{\sigma}\right)\right)^2}$$

$$G(t) = \frac{1}{1 + \alpha t^\gamma}$$

$$g(t) = \frac{\alpha \gamma t^{\gamma-1}}{(1 + \alpha t^\gamma)^2}$$

where $\gamma = 1/\sigma$ and $\alpha = \exp(-\mu/\sigma)$.

Lognormal

$$S(w) = 1 - \Phi\left(\frac{w - \mu}{\sigma}\right)$$

$$f(w) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{1}{2}\left(\frac{w - \mu}{\sigma}\right)^2\right)$$

$$G(t) = 1 - \Phi\left(\frac{\log(t) - \mu}{\sigma}\right)$$

$$g(t) = \frac{1}{\sqrt{2\pi}\sigma t} \exp\left(-\frac{1}{2}\left(\frac{\log(t) - \mu}{\sigma}\right)^2\right)$$

where Φ is the cumulative distribution function for the normal distribution.

Normal

$$S(w) = 1 - \Phi\left(\frac{w - \mu}{\sigma}\right)$$

$$f(w) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{1}{2}\left(\frac{w - \mu}{\sigma}\right)^2\right)$$

where Φ is the cumulative distribution function for the normal distribution.

Weibull

$$S(w) = \exp\left(-\exp\left(\frac{w - \mu}{\sigma}\right)\right)$$

$$f(w) = \frac{1}{\sigma} \exp\left(\frac{w - \mu}{\sigma}\right) \exp\left(-\exp\left(\frac{w - \mu}{\sigma}\right)\right)$$

$$G(t) = \exp(-\alpha t^\gamma)$$

$$g(t) = \gamma \alpha t^{\gamma-1} \exp(-\alpha t^\gamma)$$

where $\sigma = 1/\gamma$ and $\alpha = \exp(-\mu/\sigma)$.

If your parameterization is different from the ones shown here, you can still use the procedure to fit your model. For example, a common parameterization for the Weibull distribution is

$$g(t; \lambda, \beta) = \left(\frac{\beta}{\lambda}\right) \left(\frac{t}{\lambda}\right)^{\beta-1} \exp\left(-\left(\frac{t}{\lambda}\right)^\beta\right)$$

$$G(t; \lambda, \beta) = \exp\left(-\left(\frac{t}{\lambda}\right)^\beta\right)$$

so that $\lambda = \exp(\mu)$ and $\beta = 1/\sigma$.

Again note that the expected value of the baseline log response is, in general, not zero and that the distributions are not symmetric in all cases. Thus, for a given set of covariates, \mathbf{x} , the expected value of the log response is not always $\mathbf{x}'\boldsymbol{\beta}$.

Some relations among the distributions are as follows:

- The gamma with Shape=1 is a Weibull distribution.
- The gamma with Shape=0 is a lognormal distribution.
- The Weibull with Scale=1 is an exponential distribution.

Predicted Values

For a given set of covariates, \mathbf{x} (including the intercept term), the p th quantile of the log response, y_p , is given by

$$y_p = \mathbf{x}'\boldsymbol{\beta} + \sigma u_p$$

if no offset variable has been specified, or

$$y_p = \mathbf{x}'\boldsymbol{\beta} + o + \sigma u_p$$

for a given value o of an offset variable, where u_p is the p th quantile of the baseline distribution. The estimated quantile is computed by replacing the unknown parameters with their estimates, including any shape parameters on which the baseline distribution might depend. The estimated quantile of the original response is obtained by taking the exponential of the estimated log quantile unless the NOLOG option is specified in the preceding MODEL statement.

The following table shows how u_p is computed from the baseline distribution $F(u)$:

Table 51.13 Baseline Probability Functions and u_p

Distribution	$F(u)$	u_p
Exponential	$1 - \exp(-\exp(u))$	$\log(-\log(1 - p))$
Generalized Gamma	$\begin{cases} \frac{\Gamma(\delta^{-2}, \delta^{-2} \exp(\delta u))}{\Gamma(\delta^{-2})} & \text{if } \delta > 0 \\ 1 - \frac{\Gamma(\delta^{-2}, \delta^{-2} \exp(\delta u))}{\Gamma(\delta^{-2})} & \text{if } \delta < 0 \end{cases}$	$F^{-1}(p)$
Logistic	$1 - (1 + \exp(u))^{-1}$	$\log(p/(1 - p))$
Log-logistic	$1 - (1 + \exp(u))^{-1}$	$\log(p/(1 - p))$
Lognormal	$\Phi(u)$	$\Phi^{-1}(p)$
Normal	$\Phi(u)$	$\Phi^{-1}(p)$
Weibull	$1 - \exp(-\exp(u))$	$\log(-\log(1 - p))$

For the generalized gamma distribution, u_p is computed numerically.

The standard errors of the quantile estimates are computed using the estimated covariance matrix of the parameter estimates and a Taylor series expansion of the quantile estimate. The standard error is computed as

$$\text{STD} = \sqrt{\mathbf{z}'\mathbf{V}\mathbf{z}}$$

where \mathbf{V} is the estimated covariance matrix of the parameter vector $(\boldsymbol{\beta}', \sigma, \delta)'$, and \mathbf{z} is the vector

$$\mathbf{z} = \begin{bmatrix} \mathbf{x} \\ \hat{u}_p \\ \hat{\sigma} \frac{\partial u_p}{\partial \delta} \end{bmatrix}$$

where δ is the vector of the shape parameters. Unless the NOLOG option is specified, this standard error estimate is converted into a standard error estimate for $\exp(y_p)$ as $\exp(\hat{y}_p)\text{STD}$. It might be more desirable

to compute confidence limits for the log response and convert them back to the original response variable than to use the standard error estimates for $\exp(y_p)$ directly. See [Example 51.1](#) for a 90% confidence interval of the response constructed by exponentiating a confidence interval for the log response.

The variable CDF is computed as

$$\text{CDF}_i = F(u_i)$$

where the residual is defined by

$$u_i = \left(\frac{y_i - \mathbf{x}_i' \mathbf{b}}{\hat{\sigma}} \right)$$

and F is the baseline cumulative distribution function. If the data are interval-censored, then the cumulative distribution function, $\text{CDF}_i = F(u_i)$, is evaluated at the lower interval endpoint.

Confidence Intervals

Confidence intervals are computed for all model parameters and are reported in the “Analysis of Parameter Estimates” table. The confidence coefficient can be specified with the ALPHA= α MODEL statement option, resulting in a $(1 - \alpha) \times 100\%$ two-sided confidence coefficient. The default confidence coefficient is 95%, corresponding to $\alpha = 0.05$.

Regression Parameters

A two-sided $(1 - \alpha) \times 100\%$ confidence interval $[\beta_{iL}, \beta_{iU}]$ for the regression parameter β_i is based on the asymptotic normality of the maximum likelihood estimator $\hat{\beta}_i$ and is computed by

$$\beta_{iL} = \hat{\beta}_i - z_{1-\alpha/2}(\text{SE}_{\hat{\beta}_i})$$

$$\beta_{iU} = \hat{\beta}_i + z_{1-\alpha/2}(\text{SE}_{\hat{\beta}_i})$$

where $\text{SE}_{\hat{\beta}_i}$ is the estimated standard error of $\hat{\beta}_i$, and z_p is the $p \times 100\%$ percentile of the standard normal distribution.

Scale Parameter

A two-sided $(1 - \alpha) \times 100\%$ confidence interval $[\sigma_L, \sigma_U]$ for the scale parameter σ in the location-scale model is based on the asymptotic normality of the logarithm of the maximum likelihood estimator $\log(\hat{\sigma})$, and is computed by

$$\sigma_L = \hat{\sigma} / \exp[z_{1-\alpha/2}(\text{SE}_{\hat{\sigma}})/\hat{\sigma}]$$

$$\sigma_U = \hat{\sigma} \exp[z_{1-\alpha/2}(\text{SE}_{\hat{\sigma}})/\hat{\sigma}]$$

See Meeker and Escobar (1998) for more information.

Weibull Scale and Shape Parameters

The Weibull distribution scale parameter η and shape parameter β are obtained by transforming the extreme-value location parameter μ and scale parameter σ :

$$\eta = \exp(\mu)$$

$$\beta = 1/\sigma$$

Consequently, two-sided $(1 - \alpha) \times 100\%$ confidence intervals for the Weibull scale and shape parameters are computed as

$$[\eta_L, \eta_U] = [\exp(\mu_L), \exp(\mu_U)]$$

$$[\beta_L, \beta_U] = [1/\sigma_U, 1/\sigma_L]$$

Gamma Shape Parameter

A two-sided $(1 - \alpha) \times 100\%$ confidence interval for the three-parameter gamma shape parameter δ is computed by

$$[\delta_L, \delta_U] = [\hat{\delta} - z_{1-\alpha/2}(\text{SE}_{\hat{\delta}}), \hat{\delta} + z_{1-\alpha/2}(\text{SE}_{\hat{\delta}})]$$

Fit Statistics

Suppose that the model contains p parameters and that n observations are used in model fitting. The fit criteria displayed by the LIFEREG procedure are calculated as follows:

- $-2 \log$ likelihood:

$$-2\log(L)$$

where L is the maximized likelihood for the model.

- Akaike's information criterion:

$$\text{AIC} = -2\log(L) + 2p$$

- corrected Akaike's information criterion:

$$\text{AICC} = \text{AIC} + \frac{2p(p+1)}{n-p-1}$$

- Bayesian information criterion:

$$\text{BIC} = -2\log(L) + p \log(n)$$

If you specify the Weibull, exponential, lognormal, log-logistic, or gamma distribution, then maximum likelihood estimates of model parameters are computed by maximizing the log likelihood of the distribution of the logarithm of the response. This is equivalent to computing maximum likelihood parameter estimates based on the response on the original, rather than log, scale. If you specify the Weibull, exponential, lognormal, log-logistic, or gamma distribution, then fit statistics based on the maximized log likelihood $\log(L)$ of the log of the response are reported in the “Fit Statistics” table. Fit criteria computed in this way cannot be meaningfully compared with fit criteria that are based on the log likelihood of the unlogged response. If you specify the normal or logistic distribution, or if you specify the NOLOG option in the MODEL statement, then the fit criteria reported in the “Fit Statistics” table are based on the response on the original, rather than log, scale.

In addition to the “Fit Statistics” table described previously, if you specify the Weibull, exponential, lognormal, log-logistic, or gamma distribution, fit criteria that are based on the distribution of the response on the original scale, rather than the log of the response, are reported in the “Fit Statistics (Unlogged Response)” table.

When comparing models, you should compare fit criteria based on the log likelihood that is computed by using the response on the same scale, either always based on the log of the response or always based on the response on the original scale.

See Akaike (1981, 1979) for details of AIC and BIC. See Simonoff (2003) for a discussion of using AIC, AICC, and BIC in statistical modeling.

Probability Plotting

Probability plots are useful tools for the display and analysis of lifetime data. Probability plots use an inverse distribution scale so that a cumulative distribution function (CDF) plots as a straight line. A nonparametric estimate of the CDF of the lifetime data will plot approximately as a straight line, thus providing a visual assessment of goodness of fit.

You can use the PROBLOT statement in PROC LIFEREG to create probability plots of data that are complete, right censored, interval censored, or a combination of censoring types (arbitrarily censored). A line representing the maximum likelihood fit from the MODEL statement and pointwise parametric confidence bands for the cumulative probabilities are also included in the plot.

A random variable Y belongs to a *location-scale* family of distributions if its CDF F is of the form

$$\Pr\{Y \leq y\} = F(y) = G\left(\frac{y - \mu}{\sigma}\right)$$

where μ is the location parameter and σ is the scale parameter. Here, G is a CDF that cannot depend on any unknown parameters, and G is the CDF of Y if $\mu = 0$ and $\sigma = 1$. For example, if Y is a normal random variable with mean μ and standard deviation σ ,

$$G(u) = \Phi(u) = \int_{-\infty}^u \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{u^2}{2}\right) du$$

and

$$F(y) = \Phi\left(\frac{y - \mu}{\sigma}\right)$$

The normal, extreme-value, and logistic distributions are location-scale models. The three-parameter gamma distribution is a location-scale model if the shape parameter δ is fixed. If T has a lognormal, Weibull, or log-logistic distribution, then $\log(T)$ has a distribution that is a location-scale model. These distributions are said to be of type log-location-scale. Probability plots are constructed for lognormal, Weibull, and log-logistic distributions by using $\log(T)$ instead of T in the plots.

Let $y_{(1)} \leq y_{(2)} \leq \dots \leq y_{(n)}$ be ordered observations of a random sample with distribution function $F(y)$. A probability plot is a plot of the points $y_{(i)}$ against $m_i = G^{-1}(a_i)$, where $a_i = \hat{F}(y_{(i)})$ is an estimate of the CDF $F(y_{(i)}) = G\left(\frac{y_{(i)} - \mu}{\sigma}\right)$. The nonparametric CDF estimates a_i are sometimes called *plotting positions*. The axis on which the points m_i are plotted is usually labeled with a probability scale (the scale of a_i).

If F is one of the location-scale distributions, then y is the lifetime; otherwise, the log of the lifetime is used to transform the distribution to a location-scale model.

If the data actually have the stated distribution, then $\hat{F} \approx F$,

$$m_i = G^{-1}(\hat{F}(y_{(i)})) \approx G^{-1}\left(G\left(\frac{y_{(i)} - \mu}{\sigma}\right)\right) = \frac{y_{(i)} - \mu}{\sigma}$$

and points $(y_{(i)}, m_i)$ should fall approximately in a straight line.

There are several ways to compute the nonparametric CDF estimates used in probability plots from lifetime data. These are discussed in the next two sections.

Complete and Right-Censored Data

The censoring times must be taken into account when you compute plotting positions for right-censored data. The modified Kaplan-Meier method described in the following section is the default method for computing nonparametric CDF estimates for display on probability plots. See Abernethy (1996), Meeker and Escobar (1998), and Nelson (1982) for discussions of the methods described in the following sections.

Expected Ranks, Kaplan-Meier, and Modified Kaplan-Meier Methods

Let $y_{(1)} \leq y_{(2)} \leq \dots \leq y_{(n)}$ be ordered observations of a random sample including failure times and censor times. Order the data in increasing order. Label all the data with reverse ranks r_i , with $r_1 = n, \dots, r_n = 1$. For the lifetime (not censoring time) corresponding to reverse rank r_i , compute the survival function estimate

$$S_i = \left[\frac{r_i}{r_i + 1} \right] S_{i-1}$$

with $S_0 = 1$. The expected rank plotting position is computed as $a_i = 1 - S_i$. The option PPOS=EXPRANK specifies the expected rank plotting position.

For the Kaplan-Meier method,

$$S_i = \left[\frac{r_i - 1}{r_i} \right] S_{i-1}$$

The Kaplan-Meier plotting position is then computed as $a'_i = 1 - S_i$. The option PPOS=KM specifies the Kaplan-Meier plotting position.

For the modified Kaplan-Meier method, use

$$S'_i = \frac{S_i + S_{i-1}}{2}$$

where S_i is computed from the Kaplan-Meier formula with $S_0 = 1$. The plotting position is then computed as $a_i'' = 1 - S_i'$. The option PPOS=MKM specifies the modified Kaplan-Meier plotting position. If the PPOS option is not specified, the modified Kaplan-Meier plotting position is used as the default method.

For complete samples, $a_i = i/(n + 1)$ for the expected rank method, $a_i' = i/n$ for the Kaplan-Meier method, and $a_i'' = (i - 0.5)/n$ for the modified Kaplan-Meier method. If the largest observation is a failure for the Kaplan-Meier estimator, then $F_n = 1$ and the point is not plotted.

Median Ranks

Let $y_{(1)} \leq y_{(2)} \leq \dots \leq y_{(n)}$ be ordered observations of a random sample including failure times and censor times. A failure order number j_i is assigned to the i th failure: $j_i = j_{i-1} + \Delta$, where $j_0 = 0$. The increment Δ is initially 1 and is modified when a censoring time is encountered in the ordered sample. The new increment is computed as

$$\Delta = \frac{(n + 1) - \text{previous failure order number}}{1 + \text{number of items beyond previous censored item}}$$

The plotting position is computed for the i th failure time as

$$a_i = \frac{j_i - 0.3}{n + 0.4}$$

For complete samples, the failure order number j_i is equal to i , the order of the failure in the sample. In this case, the preceding equation for a_i is an approximation of the median plotting position computed as the median of the i th-order statistic from the uniform distribution on (0, 1). In the censored case, j_i is not necessarily an integer, but the preceding equation still provides an approximation to the median plotting position. The PPOS=MEDRANK option specifies the median rank plotting position.

Arbitrarily Censored Data

The LIFEREG procedure can create probability plots for data that consist of combinations of exact, left-censored, right-censored, and interval-censored lifetimes—that is, arbitrarily censored data. The LIFEREG procedure uses an iterative algorithm developed by Turnbull (1976) to compute a nonparametric maximum likelihood estimate of the cumulative distribution function for the data. Since the technique is maximum likelihood, standard errors of the cumulative probability estimates are computed from the inverse of the associated Fisher information matrix. This algorithm is an example of the expectation-maximization (EM) algorithm. The default initial estimate assigns equal probabilities to each interval. You can specify different initial values with the PROBLIST= option. Convergence is determined if the change in the log likelihood between two successive iterations is less than delta, where the default value of delta is 10^{-8} . You can specify a different value for delta with the TOLLIKE= option. Iterations will be terminated if the algorithm does not converge after a fixed number of iterations. The default maximum number of iterations is 1000. Some data might require more iterations for convergence. You can specify the maximum allowed number of iterations with the MAXITEM= option in the PROBLOT statement. The iteration history of the log likelihood is displayed if you specify the ITPRINTEM option. The iteration history of the estimated interval probabilities are also displayed if you specify both options ITPRINTEM and PRINTPROBS.

If an interval probability is smaller than a tolerance (10^{-6} by default) after convergence, the probability is set to zero, the interval probabilities are renormalized so that they add to one, and iterations are restarted. Usually the algorithm converges in just a few more iterations. You can change the default value of the tolerance with the TOLPROB= option. You can specify the NOPOLISH option to avoid setting small probabilities to zero and restarting the algorithm.

If you specify the ITPRINTEM option, a table summarizing the Turnbull estimate of the interval probabilities is displayed. The columns labeled “Reduced Gradient” and “Lagrange Multiplier” are used in checking final convergence of the maximum likelihood estimate. The Lagrange multipliers must all be greater than or equal to zero, or the solution is not maximum likelihood. See Gentleman and Geyer (1994) for more details of the convergence checking. Also see Meeker and Escobar (1998, Chapter 3) for more information.

See [Example 51.6](#) for an illustration.

Nonparametric Confidence Intervals

You can use the PPOUT option in the PROBPLOT statement to create a table containing the nonparametric CDF estimates computed by the selected method, Kaplan-Meier CDF estimates, standard errors of the Kaplan-Meier estimator, and nonparametric confidence limits for the CDF. The confidence limits are either pointwise or simultaneous, depending on the value of the NPINTERVALS= option in the PROBPLOT statement. The method used in the LIFEREG procedure for computation of approximate pointwise and simultaneous confidence intervals for cumulative failure probabilities relies on the Kaplan-Meier estimator of the cumulative distribution function of failure time and approximate standard deviation of the Kaplan-Meier estimator. For the case of arbitrarily censored data, the Turnbull algorithm, discussed previously, provides an extension of the Kaplan-Meier estimator. Both the Kaplan-Meier and the Turnbull estimators provide an estimate of the standard error of the CDF estimator, $se_{\hat{F}}$, that is used in computing confidence intervals.

Pointwise Confidence Intervals

Approximate $(1 - \alpha)100\%$ pointwise confidence intervals are computed as in Meeker and Escobar (1998, Section 3.6) as

$$[F_L, F_U] = \left[\frac{\hat{F}}{\hat{F} + (1 - \hat{F})w}, \frac{\hat{F}}{\hat{F} + (1 - \hat{F})/w} \right]$$

where

$$w = \exp \left[\frac{z_{1-\alpha/2} se_{\hat{F}}}{(\hat{F}(1 - \hat{F}))} \right]$$

where z_p is the p th quantile of the standard normal distribution.

Simultaneous Confidence Intervals

Approximate $(1 - \alpha)100\%$ simultaneous confidence bands valid over the lifetime interval (t_a, t_b) are computed as the “Equal Precision” case of Nair (1984) and Meeker and Escobar (1998, Section 3.8) as

$$[F_L, F_U] = \left[\frac{\hat{F}}{\hat{F} + (1 - \hat{F})w}, \frac{\hat{F}}{\hat{F} + (1 - \hat{F})/w} \right]$$

where

$$w = \exp \left[\frac{e_{a,b,1-\alpha/2} \text{se } \hat{F}}{(\hat{F}(1 - \hat{F}))} \right]$$

where the factor $x = e_{a,b,1-\alpha/2}$ is the solution of

$$x \exp(-x^2/2) \log \left[\frac{(1-a)b}{(1-b)a} \right] / \sqrt{8\pi} = \alpha/2$$

The time interval (t_a, t_b) over which the bands are valid depends in a complicated way on the constants a and b defined in Nair (1984), $0 < a < b < 1$. The constants a and b are chosen by default so that the confidence bands are valid between the lowest and highest times corresponding to failures in the case of multiply censored data, or to the lowest and highest intervals for which probabilities are computed for arbitrarily censored data. You can optionally specify a and b directly with the NPINTERVALS=SIMULTANEOUS(a , b) option in the PROBLOT statement.

Parametric Confidence Intervals

Pointwise parametric confidence bands are displayed in a probability plot, unless you specify the NOCONF option in the PROBLOT statement. Two kinds of confidence intervals are available for display in a probability plot: confidence limits for the estimated cumulative distribution function (CDF) and confidence limits for estimated distribution percentiles.

Confidence Limits for the Estimated CDF

If the distribution is of type log-location-scale, let $y = \log(t)$ where t is the value of time at which the confidence limits are to be computed. If the distribution is of type location-scale, let y be the value at which you want to evaluate confidence limits for the estimated CDF $\hat{F}(y)$. Let

$$\hat{u} = \frac{y - \mathbf{x}'\hat{\boldsymbol{\beta}}}{\hat{\sigma}}$$

where the column vector \mathbf{x} of covariate values is determined by the rules summarized in the section “XDATA= Data Set” on page 3947. If an offset variable is specified, the mean of the offset variable values is included in $\mathbf{x}'\hat{\boldsymbol{\beta}}$.

The CDF estimate is given by

$$\hat{F}(y) = G(\hat{u})$$

where G is the baseline distribution. The approximate standard error of $\hat{F}(y)$ is computed as in Meeker and Escobar (1998, Section 8.4.3) as

$$\text{SE}_{\hat{F}} = \frac{g(\hat{u})}{\hat{\sigma}} \left[\text{Var}(\mathbf{x}'\hat{\boldsymbol{\beta}}) + 2\hat{u}\text{Cov}(\mathbf{x}'\hat{\boldsymbol{\beta}}, \hat{\sigma}) + \hat{u}^2 \text{Var}(\hat{\sigma}) \right]^{\frac{1}{2}}$$

where g is the probability density function corresponding to G . Two-sided $(1 - \alpha) \times 100\%$ confidence limits are given by

$$[F_L, F_U] = \left[\frac{\hat{F}}{\hat{F} + (1 - \hat{F}) \times w}, \frac{\hat{F}}{\hat{F} + (1 - \hat{F})/w} \right]$$

where

$$w = \exp \left[\frac{z_{1-\alpha/2} \text{SE}_{\hat{F}}}{\hat{F}(1 - \hat{F})} \right]$$

and z_p is the $p \times 100\%$ percentile of the standard normal distribution. The quantities $\text{Var}(\mathbf{x}'\hat{\boldsymbol{\beta}})$, $\text{Cov}(\mathbf{x}'\hat{\boldsymbol{\beta}}, \hat{\sigma})$, and $\text{Var}(\hat{\sigma})$ are computed based on the covariance matrix of the estimated parameter vector $(\hat{\boldsymbol{\beta}}, \hat{\sigma})$.

Confidence Limits for Percentiles

If the **HCL** option is specified in the **PROBPLOT** statement, confidence limits based on estimated distribution percentiles instead of the default CDF limits are displayed in the probability plot.

For location-scale distributions, the estimated $p \times 100\%$ percentile of the distribution F is given by

$$y_p = \mathbf{x}'\hat{\boldsymbol{\beta}} + G^{-1}(p)\hat{\sigma}$$

where G is the baseline distribution and the column vector \mathbf{x} of covariate values is determined by the rules summarized in the section “**XDATA= Data Set**” on page 3947. The standard error of y_p is estimated by $\text{SE}_y = \mathbf{z}'\Sigma\mathbf{z}$ where $\mathbf{z} = (\mathbf{x}', G^{-1}(p))'$ and Σ is the covariance matrix of the parameter estimates $(\hat{\boldsymbol{\beta}}, \hat{\sigma})'$. Two-sided $(1 - \alpha) \times 100\%$ confidence limits for y_p are given by

$$[y_L, y_U] = [y_p - z_{1-\alpha/2}\text{SE}_y, y_p + z_{1-\alpha/2}\text{SE}_y]$$

For distributions of type log-location-scale, the confidence limits are computed as

$$[t_L = \exp(y_L), t_U = \exp(y_U)]$$

For example, if T has the Weibull distribution, G is the standardized extreme value distribution, $[y_L, y_U]$ are confidence limits for the $p \times 100\%$ percentile of the extreme value distribution for $\log(T)$, and $[t_L = \exp(y_L), t_U = \exp(y_U)]$ are confidence limits for the $p \times 100\%$ percentile of the Weibull distribution for T .

INEST= Data Set

If specified, the **INEST=** data set specifies initial estimates for all the parameters in the model. The **INEST=** data set must contain the intercept variable (named **Intercept**) and all independent variables in the **MODEL** statement.

If **BY** processing is used, the **INEST=** data set should also include the **BY** variables, and there must be at least one observation for each **BY** group. If there is more than one observation in one **BY** group, the first observation read is used for that **BY** group.

If the **INEST=** data set also contains the **_TYPE_** variable, only observations with **_TYPE_** value 'PARMS' are used as starting values. Combining the **INEST=** data set and the **MAXITER=** option in the **MODEL**

statement, partial scoring can be done, such as predicting on a validation data set by using the model built from a training data set.

You can specify starting values for the iterative algorithm in the INEST= data set. This data set overwrites the INITIAL= option in the MODEL statement, which is a little difficult to use for models including multilevel interaction effects. The INEST= data set has the same structure as the OUTEST= data set but is not required to have all the variables or observations that appear in the OUTEST= data set. One simple use of the INEST= option is passing the previous OUTEST= data set directly to the next model as an INEST= data set, assuming that the two models have the same parameterization. See [Example 51.3](#) for an illustration.

OUTEST= Data Set

The OUTEST= data set contains parameter estimates and the log likelihood for the model. You can specify a label in the MODEL statement to distinguish between the estimates for different models fit with the LIFEREG procedure. If the COVOUT option is specified, the OUTEST= data set also contains the estimated covariance matrix of the parameter estimates. Note that, if the LIFEREG procedure does not converge, the parameter estimates are set to missing in the OUTEST data set.

The OUTEST= data set contains all variables specified in the MODEL statement and the BY statement. One observation consists of parameter values for the model with the dependent variable having the value -1. If the COVOUT option is specified, there are additional observations containing the rows of the estimated covariance matrix. For these observations, the dependent variable contains the parameter estimate for the corresponding row variable. The following variables are also added to the data set:

<code>_MODEL_</code>	a character variable containing the label of the MODEL statement, if present. Otherwise, the variable's value is blank.
<code>_NAME_</code>	a character variable containing the name of the dependent variable for the parameter estimates observations or the name of the row for the covariance matrix estimates
<code>_TYPE_</code>	a character variable containing the type of the observation, either PARMS for parameter estimates or COV for covariance estimates
<code>_DIST_</code>	a character variable containing the name of the distribution modeled
<code>_LNLIKE_</code>	a numeric variable containing the last computed value of the log likelihood
<code>INTERCEPT</code>	a numeric variable containing the intercept parameter estimates and covariances
<code>_SCALE_</code>	a numeric variable containing the scale parameter estimates and covariances
<code>_SHAPE1_</code>	a numeric variable containing the first shape parameter estimates and covariances if the specified distribution has additional shape parameters

Any BY variables specified are also added to the OUTEST= data set.

XDATA= Data Set

The XDATA= data set is used for plotting the predicted probability when there are covariates specified in a MODEL statement and a probability plot is specified with a PROBPLOT statement. See [Example 51.4](#) for an illustration.

The XDATA= data set is an input SAS data set that contains values for all the independent variables in the MODEL statement and variables in the CLASS statement. The XDATA= data set has the same structure as the DATA= data set but is not required to have all the variables or observations that appear in the DATA= data set.

The XDATA= data set must contain all the independent variables in the MODEL statement and variables in the CLASS statement. Even though variables in the CLASS statement might not be used, valid values are required for these variables in the XDATA= data set. Missing values are not allowed. Missing values are not allowed in the XDATA= data set for any of the independent variables, either. Missing values are allowed for the dependent variables and other variables if they are included in the XDATA= data set.

If BY processing is used, the XDATA= data set should also include the BY variables, and there must be at least one valid observation for each BY group. If there is more than one valid observation in a BY group, the last one read is used for that BY group.

If there is no XDATA= data set in the PROC LIFEREG statement, by default, the LIFEREG procedure will use the overall mean for effects containing a continuous variable (or variables) and the highest level of a single classification variable as reference level. The rules are summarized as follows:

- If the effect contains a continuous variable (or variables), the overall mean of this effect (not the variables) is used.
- If the effect is a single classification variable, the highest level of the variable is used.

Computational Resources

Let p be the number of parameters estimated in the model. The minimum working space (in bytes) needed is

$$16p^2 + 100p$$

However, if sufficient space is available, the input data set is also kept in memory; otherwise, the input data set is reread for each evaluation of the likelihood function and its derivatives, with the resulting execution time of the procedure substantially increased.

Let n be the number of observations used in the model estimation. Each evaluation of the likelihood function and its first and second derivatives requires $O(np^2)$ multiplications and additions, n individual function evaluations for the log density or log distribution function, and n evaluations of the first and second derivatives of the function. The calculation of each updating step from the gradient and Hessian requires $O(p^3)$ multiplications and additions. The $O(v)$ notation means that, for large values of the argument, v , $O(v)$ is approximately a constant times v .

Bayesian Analysis

Gibbs Sampling

This section provides details about Bayesian analysis by Gibbs sampling in the location-scale models for survival data available in PROC LIFEREG. See the section “[Gibbs Sampler](#)” on page 135 for a general discussion of Gibbs sampling. PROC LIFEREG fits parametric location-scale survival models. That is, the probability density of the response Y can be expressed in the general form

$$f(y) = g\left(\frac{y - \mu}{\sigma}\right)$$

where $Y = \log(T)$ for lifetimes T . The function g determines the specific distribution. The location parameter μ_i is modeled through regression parameters as $\mu_i = \mathbf{x}_i' \boldsymbol{\beta}$. The LIFEREG procedure can provide Bayesian estimates of the regression parameters and σ . The OUTPUT and PROBPLOT statements, if specified, are ignored. The PLOTS=PROBPLOT option in the PROC LIFEREG statement and the CORRB and COVB options in the MODEL statement are also ignored.

For the Weibull distribution, you can specify that Gibbs sampling be performed on the Weibull shape parameter $\beta = \sigma^{-1}$ instead of the scale parameter σ by specifying a prior distribution for the shape parameter with the WEIBULLSHAPEPRIOR= option. In addition, if there are no covariates in the model, you can specify Gibbs sampling on the Weibull scale parameter $\alpha = \exp(\mu)$, where μ is the intercept term, with the WEIBULLSCALEPRIOR= option.

In the case of the exponential distribution with no covariates, you can specify Gibbs sampling on the exponential scale parameter $\alpha = \exp(\mu)$, where μ is the intercept term, with the EXPSCALEPRIOR= option.

Let $\boldsymbol{\theta} = (\theta_1, \dots, \theta_k)'$ be the parameter vector. For location-scale models, the θ_i 's are the regression coefficients β_i 's and the scale parameter σ . In the case of the three-parameter gamma distribution, there is an additional gamma shape parameter τ . Let $L(D|\boldsymbol{\theta})$ be the likelihood function, where D is the observed data. Let $\pi(\boldsymbol{\theta})$ be the prior distribution. The full conditional distribution of $[\theta_i|\theta_j, i \neq j]$ is proportional to the joint distribution; that is,

$$\pi(\theta_i|\theta_j, i \neq j, D) \propto L(D|\boldsymbol{\theta})p(\boldsymbol{\theta})$$

For instance, the one-dimensional conditional distribution of θ_1 given $\theta_j = \theta_j^*, 2 \leq j \leq k$, is computed as

$$\pi(\theta_1|\theta_j = \theta_j^*, 2 \leq j \leq k, D) = L(D|(\boldsymbol{\theta} = (\theta_1, \theta_2^*, \dots, \theta_k^*)'))p(\boldsymbol{\theta} = (\theta_1, \theta_2^*, \dots, \theta_k^*)')$$

Suppose you have a set of arbitrary starting values $\{\theta_1^{(0)}, \dots, \theta_k^{(0)}\}$. Using the ARMS (adaptive rejection Metropolis sampling) algorithm of Gilks and Wild (1992) and Gilks, Best, and Tan (1995), you can do the following:

```
draw  $\theta_1^{(1)}$  from  $[\theta_1|\theta_2^{(0)}, \dots, \theta_k^{(0)}]$ 
draw  $\theta_2^{(1)}$  from  $[\theta_2|\theta_1^{(1)}, \theta_3^{(0)}, \dots, \theta_k^{(0)}]$ 
...
draw  $\theta_k^{(1)}$  from  $[\theta_k|\theta_1^{(1)}, \dots, \theta_{k-1}^{(1)}]$ 
```

This completes one iteration of the Gibbs sampler. After one iteration, you have $\{\theta_1^{(1)}, \dots, \theta_k^{(1)}\}$. After n iterations, you have $\{\theta_1^{(n)}, \dots, \theta_k^{(n)}\}$. PROC LIFEREG implements the ARMS algorithm based on a program provided by Gilks (2003) to draw a sample from a full conditional distribution. See the section “Assessing Markov Chain Convergence” on page 139 for information about assessing the convergence of the chain of posterior samples.

You can output these posterior samples into a SAS data set. The following option in the BAYES statement outputs the posterior samples into the SAS data set `Post`: `OUTPOST=Post`. The data set also includes the variables `LogPost` and `LogLike`, which represent the log of the posterior distribution and the log of the likelihood, respectively.

Priors for Model Parameters

The model parameters are the regression coefficients and the dispersion parameter (or the precision or scale), if the model has one. The priors for the dispersion parameter and the priors for the regression coefficients are assumed to be independent, while you can have a joint multivariate normal prior for the regression coefficients.

Scale and Shape Parameters

Gamma Prior The gamma distribution $G(a, b)$ has a PDF

$$f_{a,b}(u) = \frac{b(bu)^{a-1}e^{-bu}}{\Gamma(a)}, \quad u > 0$$

where a is the shape parameter and b is the inverse-scale parameter. The mean is $\frac{a}{b}$ and the variance is $\frac{a}{b^2}$.

Improper Prior The joint prior density is given by

$$p(u) \propto u^{-1}, \quad u > 0$$

Regression Coefficients

Let $\boldsymbol{\beta}$ be the regression coefficients.

Normal Prior Assume $\boldsymbol{\beta}$ has a multivariate normal prior with mean vector $\boldsymbol{\beta}_0$ and covariance matrix $\boldsymbol{\Sigma}_0$. The joint prior density is given by

$$p(\boldsymbol{\beta}) \propto e^{-\frac{1}{2}(\boldsymbol{\beta}-\boldsymbol{\beta}_0)'\boldsymbol{\Sigma}_0^{-1}(\boldsymbol{\beta}-\boldsymbol{\beta}_0)}$$

Uniform Prior The joint prior density is given by

$$p(\boldsymbol{\beta}) \propto 1$$

Posterior Distribution

Denote the observed data by D .

The posterior distribution is

$$\pi(\boldsymbol{\theta}|D) \propto L_P(D|\boldsymbol{\theta})p(\boldsymbol{\theta})$$

where $L_P(D|\boldsymbol{\theta})$ is the likelihood function with regression coefficients and any additional parameters, such as scale or shape, $\boldsymbol{\theta}$ as parameters; and $p(\boldsymbol{\theta})$ is the joint prior distribution of the parameters.

Deviance Information Criterion

Let θ_i be the model parameters at iteration i of the Gibbs sampler, and let $LL(\theta_i)$ be the corresponding model log likelihood. PROC LIFEREG computes the following fit statistics defined by Spiegelhalter et al. (2002):

- effective number of parameters:

$$p_D = \overline{LL(\theta)} - LL(\bar{\theta})$$

- deviance information criterion (DIC):

$$DIC = \overline{LL(\theta)} + p_D$$

where

$$\overline{LL(\theta)} = \frac{1}{n} \sum_{i=1}^n LL(\theta_i)$$

$$\bar{\theta} = \frac{1}{n} \sum_{i=1}^n \theta_i$$

and n is the number of Gibbs samples.

Starting Values of the Markov Chains

When the BAYES statement is specified, PROC LIFEREG generates one Markov chain containing the approximate posterior samples of the model parameters. Additional chains are produced when the Gelman-Rubin diagnostics are requested. Starting values (or initial values) can be specified in the INITIAL= data set in the BAYES statement. If INITIAL= option is not specified, PROC LIFEREG picks its own initial values for the chains.

Denote $[x]$ as the integral value of x . Denote $\hat{s}(X)$ as the estimated standard error of the estimator X .

Regression Coefficients and Gamma Shape Parameter

For the first chain that the summary statistics and regression diagnostics are based on, the default initial values are estimates of the mode of the posterior distribution. If the INITIALMLE option is specified, the initial values are the maximum likelihood estimates; that is,

$$\beta_i^{(0)} = \hat{\beta}_i$$

Initial values for the r th chain ($r \geq 2$) are given by

$$\beta_i^{(0)} = \hat{\beta}_i \pm \left(2 + \left\lceil \frac{r}{2} \right\rceil\right) \hat{s}(\hat{\beta}_i)$$

with the plus sign for odd r and minus sign for even r .

Scale, Exponential Scale, Weibull Scale, or Weibull Shape Parameter λ

Let λ be the parameter sampled.

For the first chain that the summary statistics and diagnostics are based on, the initial values are estimates of the mode of the posterior distribution; or the maximum likelihood estimates if the INITIALMLE option is specified; that is,

$$\lambda^{(0)} = \hat{\lambda}$$

The initial values of the r th chain ($r \geq 2$) are given by

$$\lambda^{(0)} = \hat{\lambda} e^{\pm \left(\left[\frac{r}{2} \right] + 2 \right) \hat{s}(\hat{\lambda})}$$

with the plus sign for odd r and minus sign for even r .

OUTPOST= Output Data Set

The OUTPOST= data set contains the generated posterior samples. There are $2+n$ variables, where n is the number of model parameters. The variable Iteration represents the iteration number and the variable LogPost contains the log posterior likelihood values. The other n variables represent the draws of the Markov chain for the model parameters.

Displayed Output for Classical Analysis

For each model, PROC LIFEREG displays the following.

Model Information

The “Model Information” table displays the two-level name of the input data set, the distribution name, and the name and label of the dependent variable; the name and label of the censor indicator variable, for right-censored data; if you specify the WEIGHT statement, the name and label of the weight variable; and the maximum value of the log likelihood.

Number of Observations

The “Number of Observations” table displays the number of observations read from the input data set, and the number of observations used in the analysis.

Class Level Information

The “Class Level Information” table displays the levels of classification variables if you specify a CLASS statement.

Fit Statistics

The “Fit Statistics” table displays the negative of twice the log likelihood, Akaike’s information criterion (AIC), the corrected Akaike’s information criterion (AICC), and the Bayesian information criterion (BIC). If the specified distribution is Weibull, lognormal, log-logistic, or gamma, the fit criteria are based on the log likelihood for the log of the response, rather than for the response on the original scale.

Fit Statistics (Unlogged Response)

If the specified distribution is Weibull, lognormal, log-logistic, or gamma, the “Fit Statistics (Unlogged Response)” table displays fit criteria that are based on the log likelihood for the response on the original, rather than log, scale. The negative of twice the log likelihood, Akaike’s information criterion (AIC), the corrected Akaike’s information criterion (AICC), and the Bayesian information criterion (BIC) are displayed.

Type III Analysis of Effects

The “Type III Analysis of Effects” table displays, for each effect in the model, the effect name, the degrees of freedom associated with the type III contrast for the effect, the chi-square statistic for the contrast, and the p -value for the statistic.

Analysis of Maximum Likelihood Parameter Estimates

The “Analysis of Maximum Likelihood Parameter Estimates” table displays the parameter name, the degrees of freedom for each parameter, the maximum likelihood estimate of each parameter, the estimated standard error of the parameter estimator, confidence limits for each parameter, a chi-square statistic for testing whether the parameter is zero, and the associated p -value for the statistic.

Lagrange Multiplier Statistics

If there are constrained parameters in the model, such as the scale or intercept, then the “Lagrange Multiplier Statistics” table displays a Lagrange multiplier test for the constraint.

Displayed Output for Bayesian Analysis

If a Bayesian analysis is requested with a BAYES statement, the displayed output includes the following.

Model Information

The “Model Information” table displays the two-level name of the input data set, the number of burn-in iterations, the number of iterations after the burn-in, the number of thinning iterations, the distribution name, and the name and label of the dependent variable; the name and label of the censor indicator variable, for right-censored data; if you specify the WEIGHT statement, the name and label of the weight variable; and the maximum value of the log likelihood.

Class Level Information

The “Class Level Information” table displays the levels of classification variables if you specify a CLASS statement.

Maximum Likelihood Estimates

The “Analysis of Maximum Likelihood Parameter Estimates” table displays the maximum likelihood estimate of each parameter, the estimated standard error of the parameter estimator, and confidence limits for each parameter.

Coefficient Prior

The “Coefficient Prior” table displays the prior distribution of the regression coefficients.

Independent Prior Distributions for Model Parameters

The “Independent Prior Distributions for Model Parameters” table displays the prior distributions of additional model parameters (scale, exponential scale, Weibull scale, Weibull shape, gamma shape).

Initial Values and Seeds

The “Initial Values and Seeds” table displays the initial values and random number generator seeds for the Gibbs chains.

Fit Statistics

The “Fit Statistics” table displays the deviance information criterion (DIC) and the effective number of parameters.

Posterior Summaries

The “Posterior Summaries” table contains the size of the sample, the mean, the standard deviation, and the quartiles for each model parameter.

Posterior Intervals

The “Posterior Intervals” table contains the HPD intervals and the credible intervals for each model parameter.

Correlation Matrix of the Posterior Samples

The “Correlation Matrix of the Posterior Samples” table is produced if you include the CORR suboption in the SUMMARY= option in the BAYES statement. This table displays the sample correlation of the posterior samples.

Covariance Matrix of the Posterior Samples

The “Covariance Matrix of the Posterior Samples” table is produced if you include the COV suboption in the SUMMARY= option in the BAYES statement. This table displays the sample covariance of the posterior samples.

Autocorrelations of the Posterior Samples

The “Autocorrelations of the Posterior Samples” table displays the lag1, lag5, lag10, and lag50 autocorrelations for each parameter.

Gelman and Rubin Diagnostics

The “Gelman and Rubin Diagnostics” table is produced if you include the GELMAN suboption in the DIAGNOSTIC= option in the BAYES statement. This table displays the estimate of the potential scale reduction factor and its 97.5% upper confidence limit for each parameter.

Geweke Diagnostics

The “Geweke Diagnostics” table displays the Geweke statistic and its p -value for each parameter.

Raftery and Lewis Diagnostics

The “Raftery Diagnostics” table is produced if you include the RAFTERY suboption in the DIAGNOSTIC= option in the BAYES statement. This table displays the Raftery and Lewis diagnostics for each variable.

Heidelberger and Welch Diagnostics

The “Heidelberger and Welch Diagnostics” table is displayed if you include the HEIDELBERGER suboption in the DIAGNOSTIC= option in the BAYES statement. This table shows the results of a stationary test and a halfwidth test for each parameter.

Effective Sample Size

The “Effective Sample Size” table displays, for each parameter, the effective sample size, the correlation time, and the efficiency.

Monte Carlo Standard Errors

The “Monte Carlo Standard Errors” table displays, for each parameter, the Monte Carlo standard error, the posterior sample standard deviation, and the ratio of the two.

ODS Table Names

PROC LIFEREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed separately in [Table 51.14](#) for a maximum likelihood analysis and in [Table 51.15](#) for a Bayesian analysis. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 51.14 ODS Tables Produced in PROC LIFEREG for a Classical Analysis

ODS Table Name	Description	Statement	Option

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

Some graphs are produced by default; other graphs are produced by using statements and options.

ODS Graph Names

PROC LIFEREG assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names of the graphs that PROC LIFEREG generates are listed in [Table 51.16](#), along with the required statements and options.

Table 51.16 Graphs Produced by PROC LIFEREG

ODS Graph Name	Description	Statement	Option
ADPanel	Autocorrelation function and density panel	BAYES	PLOTS =(AUTOCORR DENSITY)
AutocorrPanel	Autocorrelation function panel	BAYES	PLOTS = AUTOCORR
AutocorrPlot	Autocorrelation function plot	BAYES	PLOTS (UNPACK)=AUTOCORR
ProbPlot	Probability plot	PROBPLOT	Default
TAPanel	Trace and autocorrelation function panel	BAYES	PLOTS =(TRACE AUTOCORR)

TDPanel	Trace and density panel	BAYES	PLOTS =(TRACE DENSITY)
TracePanel	Trace panel	BAYES	PLOTS =TRACE
TracePlot	Trace plot	BAYES	PLOTS (UNPACK)=TRACE

Examples: LIFEREG Procedure

Example 51.1: Motorette Failure

This example fits a Weibull model and a lognormal model to the example given in Kalbfleisch and Prentice (1980, p. 5). An output data set called `models` is specified to contain the parameter estimates. By default, the natural log of the variable `time` is used by the procedure as the response. After this log transformation, the Weibull model is fit using the extreme-value baseline distribution, and the lognormal is fit using the normal baseline distribution.

Since the extreme-value and normal distributions do not contain any shape parameters, the variable `SHAPE1` is missing in the `models` data set. An additional output data set, `out`, is created that contains the predicted quantiles and their standard errors for values of the covariate corresponding to `temp=130` and `temp=150`. This is done with the control variable, which is set to 1 for only two observations.

Using the standard error estimates obtained from the output data set, approximate 90% confidence limits for the predicted quantities are then created in a subsequent `DATA` step for the log response. The logs of the predicted values are obtained because the values of the `P=` variable in the `OUT=` data set are in the same units as the original response variable, `time`. The standard errors of the quantiles of $\log(\text{time})$ are approximated (using a Taylor series approximation) by the standard deviation of `time` divided by the mean value of `time`. These confidence limits are then converted back to the original scale by the exponential function.

Define the censored random variable Y_i as

$$\begin{aligned} Y_i &= 0 \text{ if } Y_i^* \leq 0 \\ Y_i &= Y_i^* \text{ if } Y_i^* > 0 \end{aligned}$$

This is the Tobit model for left-censored normal data. Y_i^* is sometimes called the *latent variable*. PROC LIFEREG estimates parameters of the distribution of Y_i^* by maximum likelihood.

You can use the LIFEREG procedure to compute predicted values based on the mean functions of the latent and observed variables. The mean of the latent variable Y_i^* is $\mathbf{x}_i' \boldsymbol{\beta}$, and you can compute values of the mean for different settings of \mathbf{x}_i by specifying `XBETA=variable-name` in an `OUTPUT` statement. Estimates of $\mathbf{x}_i' \boldsymbol{\beta}$ for each observation will be written to the `OUT=` data set. Predicted values of the observed variable Y_i can be computed based on the mean

$$E(Y_i) = \Phi\left(\frac{\mathbf{x}_i' \boldsymbol{\beta}}{\sigma}\right) (\mathbf{x}_i' \boldsymbol{\beta} + \sigma \lambda_i)$$

where

$$\lambda_i = \frac{\phi(\mathbf{x}_i' \boldsymbol{\beta} / \sigma)}{\Phi(\mathbf{x}_i' \boldsymbol{\beta} / \sigma)}$$

ϕ and Φ represent the normal probability density and cumulative distribution functions.

Although the distribution of ϵ_i in the Tobit model is often assumed normal, you can use other distributions for the Tobit model in the LIFEREG procedure by specifying a distribution with the `DISTRIBUTION=` option in the `MODEL` statement. One distribution that should be mentioned is the logistic distribution. For this distribution, the MLE has bounded influence function with respect to the response variable, but not the design variables. If you believe your data have outliers in the response direction, you might try this distribution for some robust estimation of the Tobit model.

With the logistic distribution, the predicted values of the observed variable Y_i can be computed based on the mean of Y_i^* ,

$$E(Y_i) = \sigma \ln(1 + \exp(\mathbf{x}_i' \boldsymbol{\beta} / \sigma))$$

The following table shows a subset of the Mroz (1987) data set. In these data, `Hours` is the number of hours the wife worked outside the household in a given year, `Yrs_Ed` is the years of education, and `Yrs_Exp` is the years of work experience. A Tobit model will be fit to the hours worked with years of education and experience as covariates.

Hours	Yrs_Ed	Yrs_Exp
0	8	9
0	8	12
0	9	10
0	10	15
0	11	4
0	11	6
1000	12	1
1960	12	29
0	13	3
2100	13	36
3686	14	11
1920	14	38
0	15	14
1728	16	3
1568	16	19
1316	17	7
0	17	15

If the wife was not employed (worked 0 hours), her hours worked will be left censored at zero. In order to accommodate left censoring in PROC LIFEREG, you need two variables to indicate censoring status of observations. You can think of these variables as lower and upper endpoints of interval censoring. If there is no censoring, set both variables to the observed value of Hours. To indicate left censoring, set the lower endpoint to missing and the upper endpoint to the censored value, zero in this case.

The following statements create a SAS data set with the variables Hours, Yrs_Ed, and Yrs_Exp from the preceding data. A new variable, Lower, is created such that Lower=. if Hours=0 and Lower=Hours if Hours>0.

```
data subset;
  input Hours Yrs_Ed Yrs_Exp @@;
  if Hours eq 0
    then Lower=.;
    else Lower=Hours;
  datalines;
0 8 9 0 8 12 0 9 10 0 10 15 0 11 4 0 11 6
1000 12 1 1960 12 29 0 13 3 2100 13 36
3686 14 11 1920 14 38 0 15 14 1728 16 3
1568 16 19 1316 17 7 0 17 15
;
```

The following statements fit a normal regression model to the left-censored Hours data with Yrs_Ed and Yrs_Exp as covariates. You need the estimated standard deviation of the normal distribution to compute the predicted values of the censored distribution from the preceding formulas. The data set OUTEST contains the standard deviation estimate in a variable named `_SCALE_`. You also need estimates of $x_i'\beta$. These are contained in the data set OUT as the variable Xbeta.

```
proc lifereg data=subset outest=OUTEST(keep=_scale_);
  model (lower, hours) = yrs_ed yrs_exp / d=normal;
  output out=OUT xbeta=xbeta;
run;
```

Output 51.2.1 shows the results of the model fit. These tables show parameter estimates for the uncensored, or latent variable, distribution.

Output 51.2.1 Parameter Estimates from PROC LIFEREG

The LIFEREG Procedure

17	1	54	400.00
18	1	54	400.00

The following SAS statements request that a Weibull regression model be fit to the data:

```

title 'OLS (Default) Initial Values';
proc lifereg data=raw;
  model x*censor(1) = c1 / distribution = Weibull itprint;
run;

```

Convergence was not attained in 50 iterations for this model, as the following messages to the log indicate:

```

WARNING: Convergence was not attained in 50 iterations. You might want to
         increase the maximum number of iterations (MAXITER= option) or
         change the convergence criteria (CONVERGE = value) in the MODEL
         statement.
WARNING: The procedure is continuing in spite of the above warning. Results
         shown are based on the last maximum likelihood iteration. Validity
         of the model fit is questionable.

```

The first line (iter=0) of the iteration history table, shown in [Output 51.3.2](#), shows the default initial ordinary least squares (OLS) estimates of the parameters.

Output 51.3.2 Initial Least Squares

The log-logistic distribution is more robust to large values of the response than the Weibull distribution, so one approach to improving the convergence performance is to fit a log-logistic distribution, and if this converges, use the resulting parameter estimates as initial values in a subsequent fit of a model with the Weibull distribution.

The following statements fit a log-logistic distribution to the data:

```
proc lifereg data=raw;
  model x*censor(1) = c1 / distribution = llogistic;
run;
```

The algorithm converges, and the maximum likelihood estimates for the log-logistic distribution are shown in [Output 51.3.3](#)

Output 51.3.3 Estimates from the Log-Logistic Distribution

OLS (Default) Initial Values							
The LIFEREG Procedure							
Analysis of Maximum Likelihood Parameter Estimates							
Parameter	DF	Estimate	Standard Error	95% Confidence Limits		Chi-Square	Pr > ChiSq
Intercept	1	2.8983	0.0318	2.8360	2.9606	8309.43	<.0001
c1	1	0.1592	0.0133	0.1332	0.1852	143.85	<.0001
Scale	1	0.0498	0.0122	0.0308	0.0804		

The following statements refit the Weibull model by using the maximum likelihood estimates from the log-logistic fit as initial values:

```
proc lifereg data=raw outest=outest;
  model x*censor(1) = c1 / itprint distribution = weibull
                        intercept=2.898 initial=0.16 scale=0.05;
  output out=out xbeta=xbeta;
run;
```

Examination of the resulting output in [Output 51.3.4](#) shows that the convergence problem has been solved by specifying different initial values.

Output 51.3.4 Final Estimates from the Weibull Distribution

As an example of an alternative way of specifying initial values, the following invocation of PROC LIFEREG, using the INEST= data set to provide starting values for the three parameters, is equivalent to the previous invocation:

```
data in;
  input  intercept c1 scale;
  datalines;
2.898 0.16 0.05
;

proc lifereg data=raw inest=in outest=outest;
  model x*censor(1) = c1 / itprint distribution = weibull;
  output out=out xbeta=xbeta;
run;
```

Example 51.4: Analysis of Arbitrarily Censored Data with Interaction Effects

The artificial data in this example are from a study of the natural recovery time of mice after injection of a certain toxin. Twenty mice were grouped by sex (sex: 1 = Male, 2 = Female) with equal sizes. Their ages (in days) were recorded at the injection. Their recovery times (in minutes) were also recorded. Toxin density in blood was used to decide whether a mouse recovered. Mice were checked at two times for recovery. If a mouse had recovered at the first time, the observation is left censored, and no further measurement is made. The variable `time1` is set to missing and `time2` is set to the measurement time to indicate left censoring. If a mouse had not recovered at the first time, it was checked later at a second time. If it had recovered by the second measurement time, the observation is interval censored, and the variable `time1` is set to the first measurement time and `time2` is set to the second measurement time. If there was no recovery at the second measurement, the observation is right censored, and `time1` is set to the second measurement time and `time2` is set to missing to indicate right censoring.

The following statements create a SAS data set containing the data from the experiment:

```

title 'Natural Recovery Time';
data mice;
  input sex age time1 time2;
  datalines;

;

```

The following SAS statements create the SAS data sets xrow1 and xrow2:

```
data xrow1;
    input sex age time1 time2;
    datalines;
1  50  .  .
;

data xrow2;
    input sex age time1 time2;
    datalines;
2  60.6  .  .
;
```

The following SAS statements fit a Weibull model with age, sex, and an age-by-sex interaction term as covariates, and create a plot of predicted probabilities against recovery time for the fixed values of age and sex specified in the SAS data set xrow1:

```
ods graphics on;
proc lifereg data=mice xdata=xrow1;
    class sex;
    model (time1, time2) = age sex age*sex / dist=Weibull;

    probplot / nodata
        plower=.5
        vref(intersect) = 75
        vreflab = '75 Percent';
    inset;
run;
```

Standard output is shown in [Output 51.4.1](#). Tables containing general model information, Type III tests for the main effects and interaction terms, and parameter estimates are created.

Output 51.4.1 Parameter Estimates for the Interaction Model

The following two plots display the predicted probability against the recovery time for two different populations. [Output 51.4.2](#) is created with the PROBLOT statement with the option XDATA= xrow1, which specifies the population with sex = 1, age = 50. [Output 51.4.3](#) is created with the PROBLOT statement with the option XDATA= xrow2, which specifies the population with sex = 2, age = 60.6. These are the default values that the LIFEREG procedure would use for the probability plot if the XDATA= option had not been specified. Reference lines are used to display specified predicted probability points and their relative locations in the plot.

Output 51.4.2 Probability Plot for Recovery Time with sex = 1, age = 50

The following SAS statements fit a Weibull model with age, sex, and an age-by-sex interaction term as covariates, and create the plot of predicted probabilities against recovery time shown in [Output 51.4.3](#), for the fixed values of age and sex specified in the SAS data set xrow2:

```
proc lifereg data=mice xdata=xrow2;
  class sex;
  model (time1, time2) = age sex age*sex / dist=Weibull;

  probplot / nodata
    plower=.5
    vref(intersect) = 75
    vreflab = '75 Percent';
  inset;
run;
title;
ods graphics off;
```

Output 51.4.3 Probability Plot for Recovery Time with sex = 2, age = 60.6

Example 51.5: Probability Plotting—Right Censoring

The following statements create a SAS data set containing observed and right-censored lifetimes of 70 diesel engine fans (Nelson 1982):

```
data Fan;
  input Lifetime Censor@@;
  Lifetime = Lifetime / 1000;
  datalines;
  450 0    460 1    1150 0    1150 0    1560 1
  1600 0    1660 1    1850 1    1850 1    1850 1
  1850 1    1850 1    2030 1    2030 1    2030 1
  2070 0    2070 0    2080 0    2200 1    3000 1
  3000 1    3000 1    3000 1    3100 0    3200 1
  3450 0    3750 1    3750 1    4150 1    4150 1
  4150 1    4150 1    4300 1    4300 1    4300 1
  4300 1    4600 0    4850 1    4850 1    4850 1
  4850 1    5000 1    5000 1    5000 1    6100 1
  6100 0    6100 1    6100 1    6300 1    6450 1
  6450 1    6700 1    7450 1    7800 1    7800 1
  8100 1    8100 1    8200 1    8500 1    8500 1
  8500 1    8750 1    8750 0    8750 1    9400 1
  9900 1    10100 1    10100 1    10100 1    11500 1
;
```

Some of the fans had not failed at the time the data were collected, and the unfailed units have right-censored lifetimes. The variable LIFETIME represents either a failure time or a censoring time, in thousands of hours. The variable CENSOR is equal to 0 if the value of LIFETIME is a failure time, and it is equal to 1 if the value is a censoring time. The following statements use the LIFEREG procedure to produce the probability plot with an inset for the engine lifetimes:

```
ods graphics on;
proc lifereg data=Fan;
  model Lifetime*Censor( 1 ) = / d = Weibull;
  probplot
  ppout
  npintervals=simul;
  inset;
run;
ods graphics off;
```

The resulting graphical output is shown in [Output 51.5.1](#). The estimated CDF, a line representing the maximum likelihood fit, and pointwise parametric confidence bands are plotted in the body of [Output 51.5.1](#). The values of right-censored observations are plotted along the bottom of the graph. The “Cumulative Probability Estimates” table is also created in [Output 51.5.2](#).

Output 51.5.1 Probability Plot for the Fan Data**Output 51.5.2** CDF Estimates

Lifetime	Cumulative Probability Estimates				Kaplan- Meier Standard Error

Example 51.6: Probability Plotting—Arbitrary Censoring

Table 51.17 contains microprocessor failure data (Nelson 1990). Units were inspected at predetermined time intervals. The data consist of inspection interval endpoints (in hours) and the number of units failing in each interval. A missing (.) lower endpoint indicates left censoring, and a missing upper endpoint indicates right censoring. These can be thought of as semi-infinite intervals with a lower (upper) endpoint of negative (positive) infinity for left (right) censoring.

Table 51.17 Interval-Censored Data

Lower Endpoint	Upper Endpoint	Number Failed
.	6	6
6	12	2
24	48	2
24	.	1
48	168	1
48	.	839
168	500	1
168	.	150
500	1000	2
500	.	149
1000	2000	1
1000	.	147
2000	.	122

The following SAS statements create the SAS data set Micro:

```
data Micro;
  input t1 t2 f;
  datalines;
. 6 6
6 12 2
12 24 0
24 48 2
24 . 1
48 168 1
48 . 839
168 500 1
168 . 150
500 1000 2
500 . 149
1000 2000 1
1000 . 147
2000 . 122
;
```

The following SAS statements compute the nonparametric Turnbull estimate of the cumulative distribution function and create a lognormal probability plot:

```
ods graphics on;
proc lifereg data=Micro;
  model ( t1 t2 ) = / d=lognormal intercept=25 scale=5;
  weight f;
  probplot
  pupper = 10
  itprintem
  printprobs
  maxitem = (1000,25)
  ppout;
  inset;
run;
ods graphics off;
```

The two initial values INTERCEPT=25 and SCALE=5 in the MODEL statement are used to aid convergence in the model-fitting algorithm.

The following tables are created by the PROBPLOT statement in addition to the standard tabular output from the MODEL statement. [Output 51.6.1](#) shows the iteration history for the Turnbull estimate of the CDF for the microprocessor data. With both options ITPRINTEM and PRINTPROBS specified in the PROBPLOT statement, this table contains the log likelihoods and interval probabilities for every 25th iteration and the last iteration. It would contain only the log likelihoods if the option PRINTPROBS were not specified.

Output 51.6.1 Iteration History for the Turnbull Estimate

The LIFEREG Procedure					
Iteration History for the Turnbull Estimate of the CDF					
Iteration	Loglikelihood	(., 6)	(6, 12)	(24, 48)	(48, 168)

The table in [Output 51.6.2](#) summarizes the Turnbull estimates of the interval probabilities, the reduced gradients, and Lagrange multipliers as described in the section “[Arbitrarily Censored Data](#)” on page 3942.

Output 51.6.2 Summary for the Turnbull Algorithm

Lower Lifetime	Upper Lifetime	Probability	Reduced Gradient	Lagrange Multiplier
.	6	0.0042	0	0
6	12	0.0014	0	0
24	48	0.0014	0	0
48	168	0.0017	0	0
168	500	0.0023	0	0
500	1000	0.0073	-7.219342E-9	0
1000	2000	0.0080	-0.037063236	0
2000	.	0.9736	0.0003038877	0

[Output 51.6.3](#) shows the final estimate of the CDF, along with standard errors and nonparametric confidence limits. Two kinds of nonparametric confidence limits, pointwise or simultaneous, are available. The default is the pointwise nonparametric confidence limits. You can specify the simultaneous nonparametric confidence limits by using the NPINTERVALS=SIMUL option.

Output 51.6.3 Final CDF Estimates for Turnbull Algorithm

Cumulative Probability Estimates					
Pointwise 95% Confidence Limits					
Lower Lifetime	Upper Lifetime	Cumulative Probability	Limits		Standard Error
			Lower	Upper	
6	6	0.0042	0.0019	0.0094	0.0017

[Output 51.6.4](#) shows the CDF estimates, maximum likelihood fit, and pointwise parametric confidence limits plotted on a lognormal probability plot.

Output 51.6.4 Lognormal Probability Plot for the Microprocessor Data

Example 51.7: Bayesian Analysis of Clinical Trial Data

Consider the data on melanoma patients from a clinical trial described in Ibrahim, Chen, and Sinha (2001). A partial listing of the data is shown in [Output 51.7.1](#).

The survival time is modeled by a Weibull regression model with three covariates. An analysis of the right-censored survival data is performed with PROC LIFEREG to obtain Bayesian estimates of the regression coefficients by using the following SAS statements:

```
ods graphics on;
proc lifereg data=e1684;
  class Sex;
  model Survtime*Surv cens(1)=Age Sex Perform / dist=Weibull;
  bayes WeibullShapePrior=gamma seed=9999;
run;
ods graphics off;
```

Output 51.7.1 Clinical Trial Data

Obs	survtime	survcens	age	sex	perform

Example 51.8: Model Postfitting Analysis

PROC LIFEREG enables you to make model-based inferences. This example uses the larynx cancer data (Klein and Moeschberger 1997) to illustrate usage of the LSMEANS, LSMESTIMATE, and EFFECTPLOT statements for model postfitting analysis.

The survival time is modeled by a proportional odds model with two covariates: patient age and cancer stage (1, 2, 3, 4). The following statements use PROC LIFEREG to fit this model:

```
ods graphics on;

proc sort data=Larynx;
  by DESCENDING Stage;
run;

proc lifereg data=Larynx order=data;
  class Stage;
  model Time*Death(0) = Age Stage / dist = llogistic;
  lsmeans Stage / diff adjust=Sidak;
  effectplot / noobs;
run;
```

The LSMEANS statement compares pairwise differences in survival times among the four different cancer stages, while adjusting for age. The ADJUST=SIDAK option uses the Sidak method to control the overall Type I error rate of these comparisons. Results are displayed in [Output 51.8.1](#).

Output 51.8.1 LS-Means Differences between Disease Stages

The LIFEREG Procedure						
Differences of Stage Least Squares Means						
Adjustment for Multiple Comparisons: Sidak						
Stage	_Stage	Estimate	Standard Error	z Value	Pr > z	Adj P
4	3	-0.9604	0.4379	-2.19	0.0283	0.1581
4	2	-1.6404	0.4931	-3.33	0.0009	0.0053
4	1	-1.7661	0.4257	-4.15	<.0001	0.0002
3	2	-0.6800	0.4316	-1.58	0.1151	0.5199
3	1	-0.8057	0.3539	-2.28	0.0228	0.1292
2	1	-0.1257	0.4152	-0.30	0.7621	0.9998

All the LS-means differences and their significance are displayed by the mean-mean scatter plot in [Output 51.8.2](#).

Output 51.8.2 Plot of Pairwise LS-Means Differences

Suppose you want to jointly test whether the effects of stages 2, 3, and 4 are different from stage 1. The following LSMESTIMATE statement contrasts the LS-means of stages 2, 3, and 4 against the LS-means of stage 1:

```
proc lifereg data=Larynx order=data;
  class Stage year;
  model Time*Death(0) = Age Stage / dist = llogistic;
  lsmestimate Stage 'Stage 4 vs 1' 1 0 0 -1,
                 'Stage 3 vs 1' 0 1 0 -1,
                 'Stage 2 vs 1' 0 0 1 -1 / cl adjust=Sidak;
run;
```

The CL option produces 95% confidence limits, including both unadjusted ones and those adjusted for multiple comparisons according to the ADJUST= option. Results are displayed in [Output 51.8.3](#).

Output 51.8.3 Custom LS-Means Tests and Relative Odds

The LIFEREG Procedure							
Least Squares Means Estimates							
Adjustment for Multiplicity: Sidak							
Effect	Label	Standard		z Value	Pr > z	Adj P	Alpha
		Estimate	Error				
Stage	Stage 4 vs 1	-1.7661	0.4257	-4.15	<.0001	0.0001	0.05
Stage	Stage 3 vs 1	-0.8057	0.3539	-2.28	0.0228	0.0668	0.05
Stage	Stage 2 vs 1	-0.1257	0.4152	-0.30	0.7621	0.9865	0.05
Least Squares Means Estimates							
Adjustment for Multiplicity: Sidak							
Effect	Label			Adj		Adj	
		Lower	Upper	Lower	Upper	Lower	Upper
Stage	Stage 4 vs 1	-2.6004	-0.9319	-2.7825	-0.7498	-0.7498	-0.7498
Stage	Stage 3 vs 1	-1.4993	-0.1122	-1.6507	0.03921	0.03921	0.03921
Stage	Stage 2 vs 1	-0.9395	0.6881	-1.1171	0.8657	0.8657	0.8657

As displayed in [Output 51.8.4](#), the EFFECTPLOT statement generates a plot of age effects on survival time on a natural logarithm scale by four disease stages.

Output 51.8.4 Age Effects by Disease Stages

You can also perform the preceding analysis for a Bayesian model. The following statements generate posterior samples from a Bayesian model and request an LS-means analysis to compare the stage effects:

```
proc lifereg data=Larynx order=data;
  class Stage;
  model Time*Death(0) = Age Stage / dist = llogistic;
  bayes seed=100 nmc=500 nbi=500 diagnostic=none outpost=000;
  lsmeans Stage / diff exp;
  lsmestimate Stage 'Stage 4 vs 1' 1 0 0 -1,
                  'Stage 3 vs 1' 0 1 0 -1,
                  'Stage 2 vs 1' 0 0 1 -1
                  / cl plots=boxplot(orient=horizontal);
run;
```

Because no prior distributions for the regression coefficients were specified, the default uniform improper distributions shown in the “Uniform Prior for Regression Coefficients” table in [Output 51.8.5](#) are used. The specified gamma prior for the scale parameter is also shown in [Output 51.8.5](#).

Output 51.8.5 Model Parameter Priors

The LIFEREG Procedure					
Bayesian Analysis					
Uniform Prior for Regression Coefficients					
Parameter		Prior			
Intercept		Constant			
Age		Constant			
Stage4		Constant			
Stage3		Constant			
Stage2		Constant			
Independent Prior Distributions for Model Parameters					
Parameter	Prior Distribution	Hyperparameters			
Scale	Gamma	Shape	0.001	Inverse Scale	0.001

Under the Bayesian framework, the LS-means differences are treated as random variables for which posterior samples are readily available according to the linear relationship of LS-means and the regression coefficients. [Output 51.8.6](#) lists the sample mean, standard deviation, and percentiles for each LS-means difference.

Output 51.8.6 LS-Means Differences between Disease Stages

Sample Differences of Stage Least Squares Means

Overview: LIFETEST Procedure

A common feature of lifetime or survival data is the presence of right-censored observations due either to withdrawal of experimental units or to termination of the experiment. For such observations, you know only that the lifetime exceeded a given value; the exact lifetime remains unknown. Such data cannot be analyzed by ignoring the censored observations because, among other considerations, the longer-lived units are generally more likely to be censored. The analysis methodology must correctly use the censored observations in addition to the uncensored observations.

Texts that discuss the survival analysis methodology include Collett (1994), Cox and Oakes (1984); Kalbfleisch and Prentice (1980); Klein and Moeschberger (1997); Lawless (1982); Lee (1992). Users interested in the theory should consult Fleming and Harrington (1991); Andersen et al. (1992).

Usually, a first step in the analysis of survival data is the estimation of the distribution of the survival times. Survival times are often called *failure* times, and *event* times are uncensored survival times. The survival distribution function (SDF), also known as the survivor function, is used to describe the lifetimes of the population of interest. The SDF evaluated at t is the probability that an experimental unit from the population will have a lifetime that exceeds t —that is,

$$S(t) = \Pr(T > t)$$

where $S(t)$ denotes the survivor function and T is the lifetime of a randomly selected experimental unit. The LIFETEST procedure can be used to compute nonparametric estimates of the survivor function either by the product-limit method (also called the Kaplan-Meier method) or by the life-table method (also called the actuarial method). The life-table estimator is a grouped-data analog of the Kaplan-Meier estimator. The procedure can also compute the Breslow estimator or the Fleming-Harrington estimator, which are asymptotic equivalent alternatives to the Kaplan-Meier estimator.

Some functions closely related to the SDF are the cumulative distribution function (CDF), the probability density function (PDF), and the hazard function. The CDF, denoted $F(t)$, is defined as $1 - S(t)$ and is the probability that a lifetime does not exceed t . The PDF, denoted $f(t)$, is defined as the derivative of $F(t)$, and the hazard function, denoted $h(t)$, is defined as $f(t)/S(t)$. If the life-table method is chosen, the estimates of the probability density function can also be computed. Plots of these estimates can be produced by a graphical or line printer device, or based on the output delivery system (ODS).

An important task in the analysis of survival data is the comparison of survival curves. It is of interest to determine whether the underlying populations of k ($k \geq 2$) samples have identical survivor functions. PROC LIFETEST provides nonparametric k -sample tests based on weighted comparisons of the estimated hazard rate of the individual population under the null and alternative hypotheses. Corresponding to various weight functions, a variety of tests can be specified, which include the log-rank test, Wilcoxon test, Tarone-Ware test, Peto-Peto test, modified Peto-Peto test, and Fleming-Harrington G_ρ family of tests. PROC LIFETEST also provides corresponding trend tests to detect ordered alternatives. Stratified tests can be specified to adjust for prognostic factors that affect the events rates in the various populations. A likelihood ratio test, based on an underlying exponential model, is also included to compare the survival curves of the samples.

There are other prognostic variables, called covariates, that are thought to be related to the failure time. These covariates can also be used to construct statistics to test for association between the covariates and the lifetime variable. PROC LIFETEST can compute two such test statistics: censored data linear rank statistics based on the exponential scores and the Wilcoxon scores. The corresponding tests are known as the log-rank test and the Wilcoxon test, respectively. These tests are computed by pooling over any defined strata, thus adjusting for the stratum variables.

One change in SAS 9.2 and later is that the calculation of confidence limits for the quartiles of survival time is based on the transformation specified by the **CONFTYPE=** option. Another change is that the SURVIVAL statement in SAS 9.1 is folded into the PROC LIFETEST statement; that is, options that were in the SURVIVAL statement can now be specified in the PROC LIFETEST statement. The SURVIVAL statement is no longer needed and it is not documented.

Getting Started: LIFETEST Procedure

You can use the LIFETEST procedure to compute nonparametric estimates of the survivor functions, to compare survival curves, and to compute rank tests for association of the failure time variable with covariates.

For simple analyses, only the PROC LIFETEST and TIME statements are required. Consider a sample of survival data. Suppose that the time variable is T and the censoring variable is C with value 1 indicating censored observations. The following statements compute the product-limit estimate for the sample:

```
proc lifetest;
    time t*c(1);
run;
```

You can use the STRATA statement to divide the data into various strata. A separate survivor function is then estimated for each stratum, and tests of the homogeneity of strata are performed. However, if the GROUP= option is also specified in the STRATA statement, the GROUP= variable is used to identify the samples whose survivor functions are to be compared, and the STRATA variables are used to define the strata for the stratified tests. You can specify covariates (prognostic variables) in the TEST statement, and PROC LIFETEST computes linear rank statistics to test the effects of these covariates on survival.

For example, consider the results of a small randomized trial on rats. Suppose you randomize 40 rats that have been exposed to a carcinogen into two treatment groups (Drug X and Placebo). The event of interest is death from cancer induced by the carcinogen. The response is the time from randomization to death. Four rats died of other causes; their survival times are regarded as censored observations. Interest lies in whether the survival distributions differ between the two treatments.

The following DATA step creates the data set Exposed, which contains four variables: Days (survival time in days from treatment to death), Status (censoring indicator variable: 0 if censored and 1 if not censored), Treatment (treatment indicator), and Sex (gender: F if female and M if male).

```

proc format;
  value Rx 1='Drug X' 0='Placebo';
run;
data exposed;
  input Days  Status Treatment Sex $ @@;
  format Treatment Rx.;
  datalines;
179  1  1  F  378  0  1  M
256  1  1  F  355  1  1  M
262  1  1  M  319  1  1  M
256  1  1  F  256  1  1  M
255  1  1  M  171  1  1  F
224  0  1  F  325  1  1  M
225  1  1  F  325  1  1  M
287  1  1  M  217  1  1  F
319  1  1  M  255  1  1  F
264  1  1  M  256  1  1  F
237  0  0  F  291  1  0  M
156  1  0  F  323  1  0  M
270  1  0  M  253  1  0  M
257  1  0  M  206  1  0  F
242  1  0  M  206  1  0  F
157  1  0  F  237  1  0  M
249  1  0  M  211  1  0  F
180  1  0  F  229  1  0  F
226  1  0  F  234  1  0  F
268  0  0  M  209  1  0  F
;

```

PROC LIFETEST is invoked as follows to compute the product-limit estimate of the survivor function for each treatment and to compare the survivor functions between the two treatments:

```

ods graphics on;
proc lifetest data=Exposed plots=(survival(atrisk) logsurv);
  time Days*Status(0);
  strata Treatment;
run;
ods graphics off;

```

In the TIME statement, the survival time variable, Days, is crossed with the censoring variable, Status, with the value 0 indicating censoring. That is, the values of Days are considered censored if the corresponding values of Status are 0; otherwise, they are considered as event times. In the STRATA statement, the variable Treatment is specified, which indicates that the data are to be divided into strata based on the values of Treatment. ODS Graphics must be enabled before producing graphs. Two plots are requested through the PLOTS= option—a plot of the survival curves with at risk numbers and a plot of the negative log of the survival curves.

The results of the analysis are displayed in the following figures.

Figure 52.1 displays the product-limit survival estimate for the Drug X group (Treatment=1). The figure lists, for each observed time, the survival estimate, failure rate, standard error of the estimate, cumulative number of failures, and number of subjects remaining in the study.

Figure 52.1 Survivor Function Estimate for the Drug X-Treated Rats

The LIFETEST Procedure					
Stratum 1: Treatment = Drug X

325.000	0.1062	0.8938	0.0710	17	2
355.000	0.0531	0.9469	0.0517	18	1
378.000*	0.0531	.	.	18	0

NOTE: The marked survival times are censored observations.

Figure 52.2 displays summary statistics of survival times for the Drug X group. It contains estimates of the 25th, 50th, and 75th percentiles and the corresponding 95% confidence limits. The median survival time for rats in this treatment is 256 days. The mean and standard error are also displayed; however, these values are underestimated because the largest observed time is censored and the estimation is restricted to the largest event time.

Figure 52.2 Summary Statistics of Survival Times for Drug X-Treated Rats

Quartile Estimates				
Percent	Point Estimate	95% Confidence Interval Transform	[Lower	Upper)
75	319.000	LOGLOG	256.000	355.000
50	256.000	LOGLOG	255.000	319.000
25	255.000	LOGLOG	171.000	256.000

Figure 52.2 continued

Mean	Standard Error
271.131	11.877
NOTE: The mean survival time and its standard error were underestimated because the largest observation was censored and the estimation was restricted to the largest event time.	

Figure 52.3 and Figure 52.4 display the survival estimates and the summary statistics of the survival times for Placebo (Treatment=0). The median survival time for rats in this treatment is 235 days.

Figure 52.3 Survivor Function Estimate for Placebo-Treated Rats

The LIFETEST Procedure

NOTE: The marked survival times are censored observations.					

Figure 52.4 Summary Statistics of Survival Times for Placebo-Treated Rats

Quartile Estimates				
Percent	Point Estimate	95% Confidence Interval Transform	[Lower	Upper)
75	257.000	LOGLOG	237.000	323.000
50	235.500	LOGLOG	206.000	253.000
25	207.500	LOGLOG	156.000	229.000
Mean Standard Error				
235.156		10.211		

A summary of the number of censored and event observations is shown in [Figure 52.5](#). The figure lists, for each stratum, the number of event and censored observations, and the percentage of censored observations.

Figure 52.5 Number of Event and Censored Observations

Summary of the Number of Censored and Uncensored Values					
Stratum	Treatment	Total	Failed	Censored	Percent Censored
1	Drug X	20	18	2	10.00
2	Placebo	20	18	2	10.00

Total		40	36	4	10.00

[Figure 52.6](#) displays the graph of the product-limit survivor function estimates versus survival time. The two treatments differ primarily at larger survival times. Note the number of subjects at risk in the plot. You can display the number of subjects at risk at specific time points by using the [ATRISK=](#) option.

Figure 52.6 Plot of Estimated Survivor Functions

Figure 52.7 displays the graph of the log survivor function estimates versus survival time. Neither curve approximates a straight line through the origin—the exponential model is not appropriate for the survival data.

Note that these graphical displays are generated through ODS. For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS.”

Figure 52.7 Plot of Estimated Negative Log Survivor Functions

Results of the comparison of survival curves between the two treatments are shown in [Figure 52.8](#). The rank tests for homogeneity indicate a significant difference between the treatments ($p = 0.0175$ for the log-rank test and $p = 0.0249$ for the Wilcoxon test). Rats treated with Drug X live significantly longer than those treated with Placebo. Since the survival curves for the two treatments differ primarily at longer survival times, the Wilcoxon test, which places more weight on shorter survival times, becomes less significant than the log-rank test. As noted earlier, the exponential model is not appropriate for the given survival data; consequently, the result of the likelihood ratio test should be ignored.

Figure 52.8 Results of the Two-Sample Tests

Test of Equality over Strata			
Test	Chi-Square	DF	Pr > Chi-Square
Log-Rank	5.6485	1	0.0175
Wilcoxon	5.0312	1	0.0249
-2Log(LR)	0.1983	1	0.6561

Next, suppose male rats and female rats are thought to have different survival rates, and you want to assess the treatment effect while adjusting for the gender differences. By specifying the variable `Sex` in the `STRATA` statement as a stratifying variable and by specifying the variable `Treatment` in the `GROUP=` option, you can carry out a stratified test to test `Treatment` while adjusting for `Sex`. The test statistics are computed by pooling over the strata defined by the values of `Sex`, thus controlling for the effect of `Sex`. The `NOTABLE` option is added to the `PROC LIFETEST` statement as follows to avoid estimating a survival curve for each gender:

```
proc lifetest data=Exposed notable;
  time Days*Status(0);
  strata Sex / group=Treatment;
run;
```

Results of the stratified tests are shown in Figure 52.9. The treatment effect is statistically significant for both the log-rank test ($p = 0.0071$) and the Wilcoxon test ($p = 0.0150$). As compared to the results of the unstratified tests in Figure 52.8, the significance of the treatment effect has been sharpened by controlling for the effect of the gender of the subjects.

Figure 52.9 Results of the Stratified Two-Sample Tests

The LIFETEST Procedure			
Stratified Test of Equality over Group			
Test	Chi-Square	DF	Pr > Chi-Square
Log-Rank	7.2466	1	0.0071
Wilcoxon	5.9179	1	0.0150

Since `Treatment` is a binary variable, another way to study the effect of `Treatment` is to carry out a censored linear rank test with `Treatment` as an independent variable. This test is less popular than the two-sample test; nevertheless, in situations where the independent variables are continuous and are difficult to discretize, it might be infeasible to perform a k -sample test. To compute the censored linear rank statistics to test the `Treatment` effect, `Treatment` is specified in the `TEST` statement as follows:

```
proc lifetest data=Exposed notable;
  time Days*Status(0);
  test Treatment;
run;
```

Results of the linear rank tests are shown Figure 52.10. The p -values are very similar to those of the two-sample tests in Figure 52.8.

Figure 52.10 Results of Linear Rank Tests of Treatment

The LIFETEST Procedure				
Univariate Chi-Squares for the Wilcoxon Test				
Variable	Test Statistic	Standard Error	Chi-Square	Pr > Chi-Square
Treatment	3.9525	1.7524	5.0875	0.0241
Univariate Chi-Squares for the Log-Rank Test				
Variable	Test Statistic	Standard Error	Chi-Square	Pr > Chi-Square
Treatment	6.2708	2.6793	5.4779	0.0193

With Sex as a prognostic factor that you want to control, you can compute a stratified linear rank statistic to test the effect of Treatment by specifying Sex in the STRATA statement and Treatment in the TEST statement as in the following program. The TEST=NONE option is specified in the STRATA statement to suppress the two-sample tests for Sex.

```
proc lifetest data=Exposed notable;
  time Days*Status(0);
  strata Sex / test=none;
  test Treatment;
run;
```

Results of the stratified linear rank tests are shown in [Figure 52.11](#). The p -values are very similar to those of the stratified tests in [Figure 52.9](#).

Figure 52.11 Results of Stratified Linear Rank Tests of Treatment

The LIFETEST Procedure				
Univariate Chi-Squares for the Wilcoxon Test				
Variable	Test Statistic	Standard Error	Chi-Square	Pr > Chi-Square
Treatment	4.2372	1.7371	5.9503	0.0147
Univariate Chi-Squares for the Log-Rank Test				
Variable	Test Statistic	Standard Error	Chi-Square	Pr > Chi-Square
Treatment	6.8021	2.5419	7.1609	0.0075

Syntax: LIFETEST Procedure

The following statements are available in the LIFETEST procedure:

```
PROC LIFETEST < options > ;
    BY variables ;
    FREQ variable ;
    ID variables ;
    STRATA variable < (list) > < . . . variable < (list) > > < / options > ;
    TEST variables ;
    TIME variable < * censor(list) > ;
    WEIGHT variable ;
```

The simplest use of PROC LIFETEST is to request the nonparametric estimates of the survivor function for a sample of survival times. In such a case, only the PROC LIFETEST statement and the TIME statement are required. You can use the STRATA statement to divide the data into various strata. A separate survivor function is then estimated for each stratum, and tests of the homogeneity of strata are performed. However, if the GROUP= option is also specified in the STRATA statement, stratified tests are carried out to test the k samples defined by the GROUP= variable while controlling for the effect of the STRATA variables. You can specify covariates in the TEST statement. PROC LIFETEST computes linear rank statistics to test the effects of these covariates on survival.

The PROC LIFETEST statement invokes the procedure. All statements except the TIME statement are optional, and there is no required order for the statements that follow the PROC LIFETEST statement. The TIME statement is used to specify the variables that define the survival time and censoring indicator. The STRATA statement specifies a variable or set of variables that define the strata for the analysis. The TEST statement specifies a list of numeric covariates to be tested for their association with the response survival time. Each variable is tested individually, and a joint test statistic is also computed. The ID statement provides a list of variables whose values are used to identify observations in the product-limit, Breslow, or Fleming-Harrington estimates. When only the TIME statement appears, no strata are defined and no tests of homogeneity are performed.

PROC LIFETEST Statement

```
PROC LIFETEST < options > ;
```

The PROC LIFETEST statement invokes the LIFETEST procedure. Optionally, this statement identifies an input and an OUTSURV= data set, and specifies the computation details of the survivor function estimation. Table 52.1 summarizes the options available in the PROC LIFETEST statement. These options are described in alphabetic order. If no options are requested, PROC LIFETEST computes and displays the product-limit estimate of the survivor function; and if ODS Graphics is enabled, a plot of the estimated survivor function is also displayed.

Table 52.1 Options Available in the PROC LIFETEST Statement

Option	Description
Input and Output Data Sets	
DATA=	Specifies the input SAS data set
OUTSURV=	Names an output data set to contain survival estimates and confidence limits
OUTTEST=	Names an output data set to contain rank test statistics for association of survival time with covariates
Nonparametric Estimation	
INTERVALS=	Specifies interval endpoints for life-table estimates
NELSON	Adds the Nelson-Aalen estimates
METHOD=	Specifies the method to compute survivor function
NINTERVAL=	Specifies the number of intervals for life-table estimates
WIDTH=	Specifies the width of intervals for life-table estimates
Confidence Limits for Survivorship	
ALPHA=	Sets the confidence level for interval estimation estimates
BANDMAXTIME=	Specifies the maximum time for confidence band
BANDMINTIME=	Specifies the minimum time for confidence band
CONFBAND=	Specifies the type of confidence band in the OUTSURV= data set
CONFTYPE=	Specifies the transformation applied to the survivor function to obtain confidence limits
Line Printer Plots	
FORMCHAR(1,2,7,9)=	Defines the characters used for line printer plot axes
LINEPRINTER	Specifies that plots be produced by a line printer
MAXTIME=	Specifies the maximum time value for plotting
NOCENSLOT	Suppresses the plot of censored observations
PLOTS=	Specifies the plots to display
ODS Graphics	
MAXTIME=	Specifies the maximum time value for plotting
PLOTS=	Specifies plots to display
Traditional Graphics	
ANNOTATE=	Specifies an Annotate data set that adds features to plots
CENSORED SYMBOL=	Defines the symbol used for censored observations in plots
DESCRIPTION=	Specifies the string that appears in the description field of the PROC GREPLAY master menu for the plots
EVENTSYMBOL=	Specifies the symbol used for event observations in plots
GOUT=	Specifies the graphics catalog name for saving graphics output
LANNOTATE=	Specifies an input data set that contains variables for local annotation
MAXTIME=	Specifies the maximum time value for plotting
PLOTS=	Specifies the plots to display
Control Output	
ATRISK	Adds the number of subjects at risk to the survival estimate table

Table 52.1 *continued*

Option	Description
NOPRINT	Suppresses the display of printed output
NOTABLE	Suppresses the display of survival function estimates
INTERVALS=	Displays only the estimate for the smallest time in each interval
NOLEFT	Suppresses the Number Left column in the survival estimate table
TIMELIST=	Specifies a list of time points to display the survival estimate
REDUCEOUT	Specifies that only INTERVAL= or TIMELIST= observations be listed in the OUTSURV= data set
Miscellaneous	
ALPHAQT=	Sets the confidence level for survival time quartiles
MISSING	Allows missing values to be a stratum level
SINGULAR=	Sets the tolerance for testing singularity of covariance matrix of rank statistics
STDERR	Outputs the standard error for the survival estimators to the OUTSURV= data set
TIMELIM=	Specifies the time limit used to estimate the mean survival time and its standard error

The PLOTS= option in the PROC LIFETEST statement specifies the plots to display. You can select one of the following three types of graphics in PROC LIFETEST: line printer, traditional, and ODS. If you specify the [LINEPRINTER](#) option, line printer plots are produced; otherwise traditional graphics are produced if ODS Graphics is not enabled, or ODS Graphics plots are produced if the ODS Graphics is enabled.

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

Table 52.2 shows whether graphics are produced, and the type of graphics, for all possible combinations:

Table 52.2 Ways of Displaying Graphics

ODS Graphics	PLOTS= Option	LINEPRINTER Option	Graphics Results
Disabled	No	No	No graphics
Disabled	No	Yes	No graphics
Disabled	Yes	No	Traditional graphics
Disabled	Yes	Yes	Line printer plot
Enabled	No	No	ODS Graphics survival plot
Enabled	No	Yes	No graphics
Enabled	Yes	No	ODS Graphics
Enabled	Yes	Yes	Line printer plot

ODS Graphics is the preferred method of creating graphs. Many new features have been added to the ODS Graphics plots in PROC LIFETEST. For example, you can display the number of subjects at risk in a survival plot through ODS Graphics, but such a feature is not available in traditional graphics or line printer plots. The PLOTS= option syntax is documented separately for each type of graphics and is preceded by a heading that indicates the graphics type.

ALPHA= α

specifies the level of significance α for the $100(1 - \alpha)\%$ confidence intervals for the survivor, hazard, and density functions. For example, the option ALPHA=0.05 requests the 95% confidence limits for the survivor function. The default value is 0.05.

ALPHAQT= α

specifies the significance level α for the $100(1 - \alpha)\%$ confidence intervals for the quartiles of the survival time. For example, the option ALPHAQT=0.05 requests a 95% confidence interval for the quartiles of the survival time. The default value is 0.05.

ANNOTATE=SAS-data-set**ANNO=SAS-data-set**

specifies an input data set that contains appropriate variables for annotation of the traditional graphics. The ANNOTATE= option enables you to add features (for example, labels that explain extreme observations) to plots produced on graphics devices. The ANNOTATE= option cannot be used if the [LINEPRINTER](#) option is specified or if ODS Graphics is enabled. The data set specified must be an ANNOTATE= type data set, as described in *SAS/GRAPH: Reference*.

The data set specified with the ANNOTATE= option in the PROC LIFETEST statement is “global” in the sense that the information in this data set is displayed in every plot produced by a single invocation of PROC LIFETEST.

ATRISK

adds a column that represents the number of subjects at risk to the survival estimate table. Also added is a column that represents the number of events at each observed time. This option has no effect for the life-table method.

BANDMAXTIME=value**BANDMAX=value**

specifies the maximum time for the confidence bands. The default is the largest observed event time. If the specified BANDMAX= time exceeds the largest observed event time, it is truncated to the largest observed event time.

BANDMINTIME=value**BANDMIN=value**

specifies the minimum time for the confidence bands. The default is the smallest observed event time. For the equal-precision band, if the BANDMIN= value is less than the smallest observed event time, it is defaulted to the smallest observed event time.

CENSORED SYMBOL=name | 'string'**CS=name | 'string'**

specifies the symbol value for the censored observations in traditional graphics. The value, *name* or 'string', is the symbol value specification allowed in SAS/GRAPH software. The default is CS=CIRCLE. If you want to omit plotting the censored observations, specify CS=NONE. The CENSORED SYMBOL= option cannot be used if the [LINEPRINTER](#) option is specified or if ODS Graphics is enabled.

CONFBAND=keyword

specifies the confidence bands to be output to the OUTSURV= data set. Confidence bands are available for METHOD=KM, METHOD=BRESLOW, or METHOD=FH. You can use the following *keywords*:

ALL	outputs both the Hall-Wellner and the equal-precision confidence bands.
EP	outputs the equal-precision confidence bands.
HW	outputs the Hall-Wellner confidence bands.

CONFTYPE=keyword

specifies the transformation applied to $S(t)$ to obtain the pointwise confidence intervals and the confidence bands for the survivor function in addition to the confidence intervals for the quartiles of the survival times. The following *keywords* can be used; the default is CONFTYPE=LOGLOG.

ASINSQRT the arcsine-square root transformation,

$$g(x) = \sin^{-1}(\sqrt{x})$$

LOGLOG the log-log transformation,

$$g(x) = \log(-\log(x))$$

This is also referred to as the log cumulative hazard transformation since it applies the logarithmic function to the cumulative hazard function. Collett (1994) and Lachin (2000) refer to it as the complementary log-log transformation.

LINEAR the identity transformation,

$$g(x) = x$$

LOG the logarithmic transformation,

$$g(x) = \log(x)$$

LOGIT the logit transformation,

$$g(x) = \log\left(\frac{x}{1-x}\right)$$

DATA=SAS-data-set

names the SAS data set used by PROC LIFETEST. By default, the most recently created SAS data set is used.

DESCRIPTION='string'**DES='string'**

specifies a descriptive string of up to 256 characters that appears in the “Description” field of the traditional graphics catalog. The description does not appear in the plots. By default, PROC LIFETEST assigns a description of the form PLOT OF *vname* versus *hname*, where *vname* and *hname* are the names of the *y* variable and the *x* variable, respectively. The DESCRIPTION= option cannot be used if the [LINEPRINTER](#) option is specified or if ODS Graphics is enabled.

EVENTSYMBOL=*name* | '*string*'

ES=*name* | '*string*'

specifies the symbol value for the event observations in traditional graphics. The value, *name* or '*string*', is the symbol value specification allowed in SAS/GRAPH software. The default is ES=NONE. The EVENTSYMBOL= option cannot be used if the [LINEPRINTER](#) option is specified or if ODS Graphics is enabled.

FORMCHAR(1,2,7,9)='*string*'

defines the characters used for constructing the vertical and horizontal axes of the line printer plots. The string should be four characters. The first and second characters define the vertical and horizontal bars, respectively, which are also used in drawing the steps of the Kaplan-Meier, Breslow, or Fleming-Harrington survival curve. The third character defines the tick mark for the axes, and the fourth character defines the lower left corner of the plot. The default is FORMCHAR(1,2,7,9)='|+-'. Any character or hexadecimal string can be used to customize the plot appearance. If you use hexadecimal, you must put an x after the closing quote. For example, to send the plot output to a printer with the IBM graphics character set (1 or 2), specify the following:

```
formchar (1, 2, 7, 9) = 'B3C4C5C0' x
```

See the chapter titled “The PLOT Procedure” in the *Base SAS Procedures Guide* for further information.

GOUT=*graphics-catalog*

specifies the graphics catalog for saving traditional graphics output from PROC LIFETEST. The default is Work.Gseg. The GOUT= option cannot be used if the [LINEPRINTER](#) option is specified or if ODS Graphics is enabled. For more information, see the chapter titled “The GREPLAY Procedure” in *SAS/GRAPH: Reference*.

INTERVALS=*values*

specifies a list of interval endpoints for the life-table method. These endpoints must all be nonnegative numbers. The initial interval is assumed to start at zero whether or not zero is specified in the list. Each interval contains its lower endpoint but does not contain its upper endpoint. When this option is used with METHOD=KM, METHOD=BRESLOW, or METHOD=FH, it reduces the number of survival estimates displayed by showing only the estimates for the smallest time within each specified interval. The INTERVALS= option can be specified in any of the following ways:

- A list separated by blanks **INTERVALS=1 3 5 7**
- A list separated by commas **INTERVALS=1, 3, 5, 7**
- *x* to *y* **INTERVALS=1 to 7**
- *x* to *y* BY *z* **INTERVALS=1 to 7 by 1**
- A combination of the above **INTERVALS=1, 3 to 5, 7**

For example, the specification

```
intervals=5,10 to 30 by 10
```

produces the set of intervals

```
{[0, 5), [5, 10), [10, 20), [20, 30), [30, ∞)}
```

LANNOTATE=SAS-data-set**LANN=SAS-data-set**

specifies an input data set that contains variables for local annotation of traditional graphics. You can use the LANNOTATE= option to specify a different annotation for each BY group, in which case the BY variables must be included in the LANNOTATE= data set. The LANNOTATE= option cannot be used if the [LINEPRINTER](#) option is specified or if ODS Graphics is enabled. The data set specified must be an [ANNOTATE=](#) type data set, as described in *SAS/GRAPH: Reference*.

If there is no BY-group processing, the [ANNOTATE=](#) and LANNOTATE= options have the same effects.

LINEPRINTER**LS**

specifies that plots are produced by a line printer instead of by a graphical device.

MAXTIME=value

specifies the maximum value of the time variable allowed on the plots so that outlying points do not determine the scale of the time axis of the plots. This option affects only the displayed plots and has no effect on any calculations.

METHOD=type

specifies the method to be used to compute the survival function estimates. Valid values for *type* are as follows:

BRESLOW

specifies that the Breslow estimates be computed. The Breslow estimator is the exponentiation of the negative Nelson-Aalen estimator of the cumulative hazard function.

FH

specifies that the Fleming-Harrington (FH) estimates be computed. The FH estimator is a tie-breaking modification of the Breslow estimator. If there are no tied event times, this estimator is the same as the Breslow estimator.

KM**PL**

specifies that Kaplan-Meier estimates (also known as the product-limit estimates) be computed.

ACT**LIFE****LT**

specifies that life-table estimates (also known as actuarial estimates) be computed.

By default, METHOD=KM.

MISSING

allows missing values for numeric variables and blank values for character variables as valid stratum levels. See the section “[Missing Values](#)” on page 4031 for details.

By default, PROC LIFETEST does not use observations with missing values for any stratum variables.

NELSON**AALEN**

produces the Nelson-Aalen estimates of the cumulative hazards and the corresponding standard errors. This option is ignored if METHOD=LT is specified.

NINTERVAL=*value*

specifies the number of intervals used to compute the life-table estimates of the survivor function. This parameter is overridden by the **WIDTH=** option or the **INTERVALS=** option. When you specify the **NINTERVAL=** option, PROC LIFETEST tries to find an interval that results in round numbers for the endpoints. Consequently, the number of intervals can be different from the number requested. Use the **INTERVALS=** option to control the interval endpoints. The default is NINTERVAL=10.

NOCENS PLOT**NOCENS**

requests that the plot of censored observations be suppressed when the **LINEPRINTER** and **PLOTS=** options are specified. This option is not needed when the life-table method is used to compute the survival estimates, because the plot of censored observations is not produced.

NOLEFT

suppresses the Number Left and Number Event columns in the survival estimate table. This option has no effect for the life-table estimate.

NOPRINT

suppresses the display of output. This option is useful when only an output data set is needed. It temporarily disables the Output Delivery System (ODS); see Chapter 20, “[Using the Output Delivery System](#)” for more information.

NOTABLE

suppresses the display of survival function estimates. Only the number of censored and event times, plots, and test results is displayed.

OUTSURV=*SAS-data-set***OUTS=***SAS-data-set*

creates an output SAS data set to contain the estimates of the survival function and corresponding confidence limits for all strata. See the section “[OUTSURV= Data Set](#)” on page 4049 for more information about the contents of the OUTSURV= data set.

OUTTEST=*SAS-data-set***OUTT=***SAS-data-set*

creates an output SAS data set to contain the overall chi-square test statistic for association with failure time for the variables in the TEST statement, the values of the univariate rank test statistics for each variable in the TEST statement, and the estimated covariance matrix of the univariate rank test statistics. See the section “[OUTTEST= Data Set](#)” on page 4051 for more information about the contents of the OUTTEST= data set.

Line Printer PLOTS= Option**PLOTS=***plot-request***PLOTS=**(*plot-requests*)

controls the line printer plots produced. You must also specify the [LINEPRINTER](#) option to obtain line printer plots. When you specify only one *plot-request*, you can omit the parentheses around the *plot-request*. Here are some examples:

```
plots=s
plots=(s ls lls)
```

The *plot-requests* include the following:

CENSORED**C**

specifies a plot of censored observations. This option is available for METHOD=KM, METHOD=BRESLOW, or METHOD=FH only.

SURVIVAL**S**

specifies a plot of the estimated SDF versus time.

LOGSURV**LS**

specifies a plot of the negative log of the estimated SDF versus time.

LOGLOGS**LLS**

specifies a plot of the log of the negative log of the estimated SDF versus the log of time.

HAZARD**H**

specifies a plot of the estimated hazard function versus time (life-table method only).

PDF**P**

specifies a plot of the estimated probability density function versus time (life-table method only).

ODS Graphics PLOTS= Option**PLOTS**< (*global-plot-option*) > = *plot-request* < (*options*) >**PLOTS**< (*global-plot-option*) > = (*plot-request* < (*options*) > < ... *plot-request* < (*options*) > >)

controls the plots produced using ODS Graphics. When you specify only one *plot-request*, you can omit the parentheses around the *plot-request*. Here are some examples:

```
plots=none
plots=(survival(atrisk=100 to 350 by 50) logsurv)
plots(only)=hazard
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;

proc lifetest plots=survival(atrisk);
    time T*Status(0);
run;

ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

If ODS Graphics is enabled but you do not specify the PLOTS= option, then PROC LIFETEST produces a plot of the estimated survivor functions by default.

The only *global-plot-option* follows:

ONLY

specifies that only the specified plots in the list be produced; otherwise, the default survivor function plot is also displayed.

The *plot-requests* and *plot-request options* include the following.

ALL

produces all appropriate plots. For METHOD=KM, METHOD=BRESLOW, or METHOD=FH, specifying PLOTS=ALL is equivalent to specifying PLOTS=(SURVIVAL LOGSURV LOGLOGLS HAZARD); for the life-table method, PLOTS=ALL is equivalent to specifying PLOTS=(SURVIVAL LOGSURV LOGLOGS DENSITY HAZARD).

HAZARD <(hazard-options)>

H <hazard-options>

plots the estimated hazard functions. Kernel-smoothed estimates are produced for METHOD=KM, METHOD=BRESLOW, or METHOD=FH. You can specify the following *hazard-options*, but only the CL option can be used for the life-table method:

BANDWIDTH=*bandwidth-option*

BW=*bandwidth-option*

specifies what bandwidth is chosen for the kernel-smoothing and how it is chosen. You can specify one of the following *bandwidth-options*.

value

sets the bandwidth to the given *value*.

numeric-list

selects the bandwidth from the given *numeric-list* that minimizes the mean integrated squared error.

RANGE(*lower,upper*)

selects the bandwidth from the interval (*lower, upper*) that minimizes the mean integrated squared error. PROC LIFETEST uses the golden section search algorithm to find the minimum. If there is more than one local minimum in the interval, there is no guarantee that the local minimum found is also the global minimum.

See the section “[Optimal Bandwidth](#)” on page 4042 for details about the mean integrated squared error. If the BANDWIDTH= option is not specified, the default is BANDWIDTH=RANGE(0.2*b*,20*b*), where $b = \frac{g_u - g_l}{8n^{.2}}$, g_l and g_u are the values of the GRIDL= and GRIDU= options, respectively, and n is the total number of noncensored observations.

GRIDL=number

specifies the lower grid limit for the kernel-smoothed estimate. The default value is the time origin.

GRIDU=number

specifies the upper grid limit for the kernel-smoothed estimate. The default value equals the maximum event time.

KERNEL=kernel-option

specifies the kernel used. The choices are as follows:

BIWEIGHT

BW

$$K_{BW}(x) = \frac{15}{16}(1 - x^2)^2, \quad -1 \leq x \leq 1$$

EPANECHNIKOV

E

$$K_E(x) = \frac{3}{4}(1 - x^2), \quad -1 \leq x \leq 1$$

UNIFORM

U

$$K_U(x) = \frac{1}{2}, \quad -1 \leq x \leq 1$$

The default is KERNEL=EPANECHNIKOV.

NMINGRID=number

specifies the number of grid points in determining the mean integrated square error (MISE). The default value is 51.

NGRID=number

specifies the number of grid points. The default is 101.

CL

displays the pointwise confidence limits for the smoothed hazard.

LOGLOGS

LLS

plots the log of negative log of estimated survivor functions versus the log of time.

LOGSURV**LS**

plots the negative log of estimated survivor functions versus time.

NONE

suppresses all plots.

PDF <(CL)>**P <(CL)>**

plots the estimated probability density functions (life-table method only). Pointwise confidence limits are displayed optionally by specifying the CL option.

SURVIVAL <(survival-options)>**S <(survival-options)>**

plots the estimated survivor functions. Censored times are plotted as a plus sign on the Kaplan-Meier, Breslow, or Fleming-Harrington survival curves unless the NOCENSOR option is specified. You can customize the display by using the following *survival-options*. If these options are not sufficient for your purposes, you can customize the survival plot by modifying its graphical template (see the section “[Modifying the ODS Template for Survival Plots](#)” on page 4061 for more information).

ATRISK <(options)> <=number-list>

displays the numbers of subjects at risk at the given times. The following *options* can be specified:

ATRISKTICK**ATRISKLABEL**

shows the time values at which the numbers of subjects at risk are displayed.

MAXLEN=*n*

specifies the number of characters *n* that are allowed for displaying the stratum labels. If *n* is greater than or equal to the maximum length of the stratum labels, the stratum labels are used in the at-risk display; otherwise, the stratum numbers are used. The default is MAXLEN=12.

OUTSIDE<(p)>

specifies that the at-risk table be drawn outside the plot area. PROC LIFETEST uses an ODS graphical template with a two-row lattice layout. The upper cell displays the survival plot, and the bottom cell displays the at-risk table. You can specify an optional number *p* that represents the fractional proportion of the at-risk table height relative to the overall grid height. By default, *p* is set to 0.035 times the number of strata, with a maximum value of 0.5.

The *number-list* identifies the times at which the numbers at risk are displayed. If the *number-list* is not specified, PROC LIFETEST uses the default list $\{0, a, 2a, \dots, n \times a\}$, where *a* and *n* are computed by the following algorithm. Let *m* be the MAXTIME= value or the largest observed time if the MAXTIME= option is not specified; let *b* =

$10^{\text{ceil}(\log_{10}(m)-1)}$, where $\text{ceil}()$ is the ceiling function.

$$a = \begin{cases} \frac{b}{2} & \text{if } m < 0.25b \\ 2b & \text{if } m > 0.75b \\ b & \text{otherwise} \end{cases}$$

$$n = \text{integral value of } m/a$$

CB <=*keyword*>

displays the confidence bands (that is, simultaneous confidence intervals) for the survivor functions. You can specify one of the following *keywords*. The default is CB=HW.

ALL

displays both the equal-precision and the Hall-Wellner bands.

EP

displays the equal-precision band.

HW

displays the Hall-Wellner confidence band.

CL

displays the pointwise confidence limits for the survivor functions.

FAILURE

F

changes all the displays for survivor functions to those for the failure functions. For example, if both the FAILURE and CL options are specified, the plot displays the failure curves in addition to the pointwise confidence limits for the failure functions.

NOCENSOR

suppresses the plotting of the censored times on a Kaplan-Meier, Breslow, or Fleming-Harrington survival curve.

STRATA=*strata-option*

specifies how to display the survival/failure curves for multiple strata. This option has no effect if there is only one stratum. You can choose one of the following *strata options*:

INDIVIDUAL

UNPACK

specifies that a separate plot be displayed for each stratum.

OVERLAY

specifies that the survival/failure curves for the strata be overlaid in one plot.

PANEL

specifies that separate plots for the strata be organized into panels of two or four plots, depending on the number of strata.

The default is STRATA=OVERLAY.

TEST

displays the p -value of a homogeneity test specified in the STRATA statement. If more than one test is produced, the test is chosen in the following order: LOGRANK, WILCOXON, TARONE, PETO, MODPETO, FLEMING, and LR.

Traditional Graphics PLOTS= Option

PLOTS=*plot-request* < (**NAME=***name* | '*string*') >

PLOTS=(*plot-request* < (**NAME=***name* | '*string*') > <, ..., *plot-request* < (**NAME=***name* | '*string*') > >)

controls plots produced in traditional graphics. To obtain traditional graphics, you must neither enable ODS Graphics nor specify the [LINEPRINTER](#) option. For each *plot-request*, you can use the **NAME=** option to specify a name to identify the plot. The name can be specified as a SAS name or as a quoted string of up to 256 characters. Only the first eight characters are used as the entry name in the **GOUT=** catalog. The *plot-requests* include the following:

SURVIVAL**S**

plots the estimated survivor functions versus time.

LOGSURV**LS**

plots the negative log of estimated survivor functions versus time.

LOGLOGS**LLS**

plots the log of negative log of estimated survivor functions versus the log of time.

HAZARD**H**

plots estimated hazard function versus time (life-table method only).

PDF**P**

plots the estimated probability density function versus time (life-table method only).

When you specify only one *plot-request*, you can omit the parentheses around the *plot-request*. Here are some examples:

```
plots=s
plots=(s(name=Surv2), h(name=Haz2))
```

The latter requests a plot of the estimated survivor function versus time and a plot of the estimated hazard function versus time, with Surv2 and Haz2 as their names in the **GOUT=** catalog, respectively.

REDUCEOUT

specifies that the **OUTSURV=** data set contain only those observations that are included in the **INTERVALS=** or **TIMELIST=** option. This option has no effect if the **OUTSURV=** option is not specified. It also has no effect if neither the **INTERVALS=** option nor the **TIMELIST=** option is specified.

SINGULAR=*value*

specifies the tolerance for testing singularity of the covariance matrix for the rank test statistics. The test requires that a pivot for sweeping a covariance matrix be at least this number times a norm of the matrix. The default value is 1E-12.

STDERR

specifies that the standard error of the survivor function (SDF_STDERR) be output to the OUT-SURV= data set. If the life-table method is used, the standard error of the density function (PDF_STDERR) and the standard error of the hazard function (HAZ_STDERR) are also output.

TIMELIM=*time-limit*

specifies the time limit used in the estimation of the mean survival time and its standard error. The mean survival time can be shown to be the area under the Kaplan-Meier survival curve. However, if the largest observed time in the data is censored, the area under the survival curve is not a closed area. In such a situation, you can choose a time limit L and estimate the mean survival curve limited to a time L (Lee 1992, pp. 72–76). This option is ignored if the largest observed time is an event time. Valid *time-limit* values are as follows:

EVENT**LET**

specifies that the time limit L be the largest event time in the data. TIMELIM=EVENT is the default.

OBSERVED**LOT**

specifies that the time limit L be the largest observed time in the data.

number

specifies that the time limit L be the given *number*. The *number* must be positive and at least as large as the largest event time in the data.

TIMELIST=*number-list*

specifies a list of time points at which the Kaplan-Meier estimates are displayed. The time points are listed in the column labeled Timelist. Since the Kaplan-Meier survival curve is a decreasing step function, each given time point falls in an interval that has a constant survival estimate. The event time that corresponds to the beginning of the time interval is displayed along with its survival estimate.

WIDTH=*value*

sets the width of the intervals used in the life-table calculation of the survival function. This parameter is overridden by the **INTERVALS=** option.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC LIFETEST to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the LIFETEST procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

The BY statement is more efficient than the STRATA statement for defining strata in large data sets. However, if you use the BY statement to define strata, PROC LIFETEST does not pool over strata for testing the association of survival time with covariates, nor does it test for homogeneity across the BY groups.

When the life-table method is used to estimate survivor functions, each BY group might have a different set of intervals. To make intervals the same across BY groups, use the INTERVALS= or WIDTH= option in the PROC LIFETEST statement.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FREQ Statement

FREQ *variable* < / *option* > ;

The FREQ statement identifies a *variable* that contains the frequency of occurrence of each observation. PROC LIFETEST treats each observation as if it appeared n times, where n is the value of the FREQ variable for the observation. The FREQ statement is useful for producing life tables when the data are already in the form of a summary data set. If it is not an integer, it is truncated to an integer unless the NOTRUNCATE option is specified. If it is missing or less than or equal zero, the observation is not used.

The following *option* can be specified in the FREQ statement after a slash (/):

NOTRUNCATE

NOTRUNC

specifies that the frequency values are not truncated to integers. This option does not apply to the Fleming-Harrington estimator (METHOD=FH).

ID Statement

ID *variables* ;

The ID statement identifies *variables* whose values are used to label the observations of the Kaplan-Meier, Breslow, or Fleming-Harrington survivor function estimates. SAS format statements can be used to format the values of the ID variables.

STRATA Statement

STRATA *variable* <(list)> <... *variable* <(list)>> </ options> ;

The STRATA statement identifies the variables that determine the strata levels. Strata are formed according to the nonmissing values of these variables. The MISSING option can be used to allow missing values as a valid stratum level. Other options enable you to specify various *k*-sample tests, stratified tests, or trend tests and to make multiple-comparison adjustments for paired differences.

In the preceding syntax, *variable* is a variable whose values determine the stratum levels, and *list* is a list of endpoints for a numeric variable. The values for *variable* can be formatted or unformatted. If *variable* is a character variable, or if *variable* is numeric and no list appears, then the strata are defined by the unique values of the STRATA *variable*. More than one *variable* can be specified in the STRATA statement, and each numeric variable can be followed by a list. Each interval contains its lower endpoint but not its upper endpoint. The corresponding strata are formed by the combination of levels. If a variable is numeric and is followed by a list, then the levels for that variable correspond to the intervals defined by the list. The initial interval is assumed to start at $-\infty$, and the final interval is assumed to end at ∞ .

The specification of a STRATA *variable* can have any of the following forms:

- A list separated by blanks **Age (5 10 20 30)**
- A list separated by commas **Age (5, 10, 20, 30)**
- *x* to *y* **Age (5 to 10)**
- *x* to *y* by *z* **Age (5 to 30 by 10)**
- A combination of the above **Age (5, 10 to 50 by 10)**

For example, the specification

```
strata Age(5,20 to 50 by 10) Sex;
```

indicates the following levels for the Age variable:

$\{(-\infty, 5), [5, 20), [20, 30), [30, 40), [40, 50), [50, \infty)\}$

This statement also specifies that the Age strata be further subdivided by values of the variable Sex. In this example, there are six age groups by two sex groups, forming a total of 12 strata.

The specification of several STRATA *variables*, such as

```
strata A B C;
```

is equivalent to the A*B*C syntax of the TABLES statement in the FREQ procedure. The number of strata levels usually grows very rapidly with the number of STRATA variables, so you must be cautious when specifying the list of STRATA variables.

When comparing more than two survival curves, a *k*-sample test tells you whether the curves are significantly different from each other, but it does not identify which pairs of curves are different. A multiple-comparison adjustment of the *p*-values for the paired comparisons retains the same overall false positives as the *k*-sample test. Two types of paired comparisons can be made: comparisons between all pairs of curves and comparisons between a control curve and all other curves. You use the DIFF= option to specify the comparison type, and you use the ADJUST= option to select a method of multiple-comparison adjustments.

Table 52.3 summarizes the options available in the STRATA statement.

Table 52.3 Options Available in the STRATA Statement

Option	Description
Homogeneity Tests	
GROUP=	Specifies the group variable for stratified tests
NODETAIL	Suppresses printing the test statistic and covariance matrix
NOTEST	Suppresses any tests
TEST=	Specifies tests corresponding to various weight functions
TREND	Requests a trend test
Multiple Comparisons	
ADJUST=	Requests a multiple-comparison adjustment
DIFF=	Specifies the type of differences to consider
Missing Strata Value	
MISSING	Allows missing values as valid stratum values
Display Option	
NOLABEL	Uses the names of the STRATA variables in the display

You can specify the following *options* in the STRATA statement after a slash (“/”).

ADJUST=method

specifies the multiple-comparison method for adjusting the p -values of the paired tests. See the section “[Multiple-Comparison Adjustments](#)” on page 4045 for mathematical details; also see Westfall et al. (1999). The adjustment methods include the following:

BONFERRONI

BON

applies the Bonferroni correction to the raw p -values.

DUNNETT

performs Dunnett’s two-tailed comparisons of the control group with all other groups. PROC LIFETEST uses the factor-analytic covariance approximation described in Hsu (1992) and identifies the adjustment in the results as “Dunnett-Hsu.” Note that ADJUST=DUNNETT is incompatible with DIFF=ALL.

SCHEFFE

performs Scheffé’s multiple-comparison adjustment.

SIDAK

applies the Šidák correction to the raw p -values.

SMM

GTE

performs the paired comparisons based on the studentized maximum modulus test.

TUKEY

performs the paired comparisons based on Tukey’s studentized range test. PROC LIFETEST uses the approximation described in Kramer (1956) and identifies the adjustment as “Tukey-Kramer” in the results. Note that ADJUST=TUKEY is incompatible with DIFF=CONTROL.

SIMULATE <(simulate-options)>

computes the adjusted p -values from the simulated distribution of the maximum or maximum absolute value of a multivariate normal random vector. The simulation estimates q , the true $(1 - \alpha)$ quantile, where α is the value of the ALPHA= *simulate-option*.

The number of samples for the SIMULATE adjustment is set so that the tail area for the simulated q is within a certain accuracy radius γ of $1 - \alpha$ with an accuracy confidence of $100(1 - \epsilon)\%$. In equation form,

$$\Pr(|F(\hat{q}) - (1 - \alpha)| \leq \gamma) = 1 - \epsilon$$

where \hat{q} is the simulated q and F is the true distribution function of the maximum; see Edwards and Berry (1987) for details. By default, $\gamma = 0.005$ and $\epsilon = 0.01$ so that the tail area of \hat{q} is within 0.005 of 0.95 with 99% confidence.

The *simulate-options* include the following:

ACC=*value*

specifies the target accuracy radius γ of a $100(1 - \epsilon)\%$ confidence interval for the true probability content of the estimated $(1 - \alpha)$ quantile. The default value is ACC=0.005.

ALPHA=*value*

specifies the value α for estimating the $(1 - \alpha)$ quantile. The default value is the ALPHA= value in the PROC LIFETEST statement, or 0.05 if that option is not specified.

EPS=*value*

specifies the value ϵ for a $100(1 - \epsilon)\%$ confidence interval for the true probability content of the estimated $(1 - \alpha)$ quantile. The default value for the accuracy confidence is 99%, corresponding to EPS=0.01.

NSAMP=*n*

specifies the sample size for the simulation. By default, n is set based on the values of the target accuracy radius γ and accuracy confidence $100(1 - \epsilon)\%$ for an interval for the true probability content of the estimated $(1 - \alpha)$ quantile. With the default values for γ , ϵ , and α (0.005, 0.01, and 0.05, respectively), NSAMP=12604 by default.

REPORT

specifies that a report on the simulation should be displayed, including a listing of the parameters, such as γ , ϵ , and α , in addition to an analysis of various methods for estimating or approximating the quantile.

SEED=*number*

specifies an integer used to start the pseudorandom number generator for the simulation. If you do not specify a seed, or if you specify a value less than or equal to zero, the seed is generated by default from reading the time of day from the computer's clock.

DIFF=ALL | CONTROL<('string' <... , 'string'>)>

specifies which pairs of survival curves are considered for the multiple comparisons.

DIFF=ALL

requests all paired comparisons

DIFF=CONTROL <('string' <... 'string'>)>

requests comparisons of the control curve with all other curves. To specify the control curve, you specify the quotes strings of formatted values that represent the curve in parentheses. For example, if Cell='large' identifies the control group, you specify

```
DIFF=CONTROL('large')
```

If more than one variable is used to identify the curves (for example, if Cell='large' and Sex='F' represent the control), you specify

```
DIFF=CONTROL('large' 'F')
```

The order of the quoted strings should correspond to the order of the stratum variables. If no specific curve is specified as the control, the first stratum or group value is used.

By default, DIFF=ALL unless you specify **ADJUST=** DUNNETT, in which case DIFF=CONTROL.

GROUP=*variable*

specifies the variable whose formatted values identify the various samples whose underlying survival curves are to be compared. The tests are stratified on the levels of the STRATA variables. For example, in a multicenter trial in which two forms of therapy are to be compared, you specify the variable that identifies therapies as the **GROUP=** *variable* and the variable that identifies centers as the STRATA variable, in order to perform a stratified test to compare the therapies while controlling the effect of the centers.

MISSING

allows missing values to be a stratum level or a valid value of the **GROUP=** variable.

NODETAIL

suppresses the display of the rank statistics and the corresponding covariance matrices for various strata. If you specified the TREND option, the display of the scores for computing the trend tests is suppressed.

NOLABEL

specifies that the names instead of the labels of the STRATA variables be used in the display of the survival estimate table and in the legend of the survival plot.

NOTEST

suppresses the *k*-sample tests, stratified tests, and trend tests.

ORDER=FORMATTED | INTERNAL

specifies the sorting order of the values of the STRATA variables. The strata are presented in the specified order in the analysis results. You can use this option, for example, to display the curve labels in your preferred order in the survival plot legend (see [Example 52.2](#) for an illustration). The default is ORDER=FORMATTED, which sorts the strata according to their external formatted values, except for numeric variable with no explicit format, which are sorted by the unformatted (internal) values. ORDER=INTERNAL sorts the strata by their internal values. The ORDER= option has no effect on a stratum variable with cutpoints specified.

TREND

computes the trend tests for testing the null hypothesis that the k population hazards rate are the same versus an ordered alternatives. If there is only one STRATA variable and the variable is numeric, the unformatted values of the variable are used as the scores; otherwise, the scores are 1, 2, ..., in the given order of the strata.

TEST=*test-request*

TEST=(*test-request* <... *test-request* >)

controls the tests produced. Each test corresponds to a different weight function (see the section “Nonparametric Tests” on page 4043 for the weight functions). The *test-requests* include the following:

ALL	specifies all the nonparametric tests with $\rho_1=1$ and $\rho_2=0$ for the Fleming and Harrington test—FLEMING(1,0).
FLEMING(ρ_1, ρ_2)	specifies the family of tests in Harrington and Fleming (1982), where ρ_1 and ρ_2 are nonnegative numbers. FLEMING(ρ_1, ρ_2) reduces to the Fleming-Harrington G^{ρ} family (Fleming and Harrington 1981) when $\rho_2=0$, which you can specify as FLEMING(ρ) with one argument. When $\rho=0$, the test becomes the log-rank test. When $\rho=1$, the test should be very close to the Peto-Peto test.
LOGRANK	specifies the log-rank test.
NONE	suppresses all comparison tests. Specifying TEST=NONE is equivalent to specify NOTEST.
LR	specifies the likelihood ratio test based on the exponential model.
MODPETO	specifies the modified Peto-Peto test.
PETO	specifies the Peto-Peto test. The test is also referred to as the Peto-Peto-Prentice test.
WILCOXON	specifies the Wilcoxon test. The test is also referred to as the Gehan test or the Breslow test.
TARONE	specifies the Tarone-Ware test.

By default, TEST=(LOGRANK WILCOXON LR) for the k -sample tests, and TEST=(LOGRANK WILCOXON) for stratified and trend tests.

TEST Statement

TEST *variables* ;

The TEST statement specifies a list of numeric covariates (prognostic variables) that you want tested for association with the failure time.

Two sets of rank statistics are computed. These rank statistics and their variances are pooled over all strata. Univariate (marginal) test statistics are displayed for each of the covariates.

Additionally, a sequence of test statistics for joint effects of covariates is displayed. The first element of the sequence is the largest univariate test statistic. Other variables are then added on the basis of the largest

increase in the joint test statistic. The process continues until all the variables have been added or until the remaining variables are linearly dependent on the previously added variables.

See the section “Rank Tests for the Association of Survival Time with Covariates” on page 4047 for more information.

TIME Statement

TIME *variable* < * *censor(list)* > ;

The TIME statement is required. It is used to indicate the failure time variable, where *variable* is the name of the failure time variable that can be optionally followed by an asterisk, the name of the censoring variable, and a parenthetical list of values that correspond to right censoring. The censoring values should be numeric, nonmissing values. For example, the statement

```
time T*Flag(1,2);
```

identifies the variable T as containing the observed failure times (event or censored). If the variable Flag has the value 1 or 2, the corresponding value of T is a right-censored value.

WEIGHT Statement

WEIGHT *variable* ;

The *variable* in the WEIGHT statement identifies the variable in the input data set that contains the weights of the subjects. Values of the WEIGHT *variable* can be nonintegral and are not truncated. Observations with negative, zero, or missing values for the WEIGHT *variable* are not used in the computation.

The implementation of weights in PROC LIFETEST is based on Xie and Liu (2005, 2011), who use inverse probability of treatment weights to reduce confounding effects. A weight is assigned to each subject as the inverse probability of being in a certain group. If a subject has a higher probability of being in a group, it is considered as overrepresented and is therefore assigned a lower weight; on the other hand, if the subject has a smaller probability of being in a group, it is considered as underrepresented and is assigned a higher weight.

Details: LIFETEST Procedure

Missing Values

Observations with a missing value for either the failure time or the censoring variable are not used in the analysis. If a stratum variable value is missing, the observation is not used; however, the MISSING option can be used to request that missing values be treated as valid stratum values. If any variable specified in the TEST statement has a missing value, that observation is not used in the calculation of the rank statistics.

Computational Formulas

Breslow, Fleming-Harrington, and Kaplan-Meier Methods

Let $t_1 < t_2 < \dots < t_D$ represent the distinct event times. For each $i = 1, \dots, D$, let Y_i be the number of surviving units (the size of the risk set) just prior to t_i and let d_i be the number of units that fail at t_i . If the NOTRUNCATE option is specified in the FREQ statement, Y_i and d_i can be nonintegers.

The Breslow estimate of the survivor function is

$$\hat{S}(t_i) = \exp\left(-\sum_{j=1}^i \frac{d_j}{Y_j}\right)$$

Note that the Breslow estimate is the exponentiation of the negative Nelson-Aalen estimate of the cumulative hazard function.

The Fleming-Harrington estimate (Fleming and Harrington 1984) of the survivor function is

$$\hat{S}(t_i) = \exp\left(-\sum_{k=1}^i \sum_{j=0}^{d_k-1} \frac{1}{Y_k - j}\right)$$

If the frequency values are not integers, the Fleming-Harrington estimate cannot be computed.

The Kaplan-Meier (product-limit) estimate of the survivor function at t_i is the cumulative product

$$\hat{S}(t_i) = \prod_{j=1}^i \left(1 - \frac{d_j}{Y_j}\right)$$

Notice that all the estimators are defined to be right continuous; that is, the events at t_i are included in the estimate of $S(t_i)$. The corresponding estimate of the standard error is computed using Greenwood's formula (Kalbfleisch and Prentice 1980) as

$$\hat{\sigma}(\hat{S}(t_i)) = \hat{S}(t_i) \sqrt{\sum_{j=1}^i \frac{d_j}{Y_j(Y_j - d_j)}}$$

The first quartile (or the 25th percentile) of the survival time is the time beyond which 75% of the subjects in the population under study are expected to survive. It is estimated by

$$q_{.25} = \min\{t_j | \hat{S}(t_j) < 0.75\}$$

If $\hat{S}(t)$ is exactly equal to 0.75 from t_j to t_{j+1} , the first quartile is taken to be $(t_j + t_{j+1})/2$. If it happens that $\hat{S}(t)$ is greater than 0.75 for all values of t , the first quartile cannot be estimated and is represented by a missing value in the printed output.

The general formula for estimating the 100 p percentile point is

$$q_p = \min\{t_j | \hat{S}(t_j) < 1 - p\}$$

The second quartile (the median) and the third quartile of survival times correspond to $p = 0.5$ and $p = 0.75$, respectively.

Brookmeyer and Crowley (1982) have constructed the confidence interval for the median survival time based on the confidence interval for the $S(t)$. The methodology is generalized to construct the confidence interval for the $100p$ percentile based on a g -transformed confidence interval for $S(t)$ (Klein and Moeschberger 1997). You can use the CONFTYPE= option to specify the g -transformation. The $100(1 - \alpha)\%$ confidence interval for the first quantile survival time is the set of all points t that satisfy

$$\left| \frac{g(\hat{S}(t)) - g(1 - 0.25)}{g'(\hat{S}(t))\hat{\sigma}(\hat{S}(t))} \right| \leq z_{1-\frac{\alpha}{2}}$$

where $g'(x)$ is the first derivative of $g(x)$ and $z_{1-\frac{\alpha}{2}}$ is the $100(1 - \frac{\alpha}{2})$ percentile of the standard normal distribution.

Consider the bone marrow transplant data described in [Example 52.2](#). The following table illustrates the construction of the confidence limits for the first quartile in the ALL group. Values of $\frac{g(\hat{S}(t)) - g(1 - 0.25)}{g'(\hat{S}(t))\hat{\sigma}(\hat{S}(t))}$ that lie between $\pm z_{1-\frac{0.05}{2}} = \pm 1.965$ are highlighted.

Constructing 95% Confidence Limits for the 25th Percentile							
			$\frac{g(\hat{S}(t)) - g(1 - 0.25)}{g'(\hat{S}(t))\hat{\sigma}(\hat{S}(t))}$				
t	$\hat{S}(t)$	$\hat{\sigma}(\hat{S}(t))$	LINEAR	LOGLOG	LOG	ASINSQRT	LOGIT

Consider the LINEAR transformation where $g(x) = x$. The event times that satisfy $\left| \frac{g(\hat{S}(t)) - g(1 - p)}{g'(\hat{S}(t))\sqrt{\hat{V}(\hat{S}(t))}} \right| \leq 1.9599$ include 107, 109, 110, 122, 129, 172, 192, 194, and 230. The confidence of the interval [107, 230] is less than 95%. Brookmeyer and Crowley (1982) suggest extending the confidence interval to but not

including the next event time. As such the 95% confidence interval for the first quartile based on the linear transform is [107, 276). The following table lists the confidence intervals for the various transforms.

95% CI's for the 25th Percentile		
CONFTYPE	[Lower	Upper)
LINEAR	107	276
LOGLOG	86	230
LOG	107	332
ASINSQRT	104	276
LOGIT	104	230

Sometimes, the confidence limits for the quartiles cannot be estimated. For convenience of explanation, consider the linear transform $g(x) = x$. If the curve that represents the upper confidence limits for the survivor function lies above 0.75, the upper confidence limit for first quartile cannot be estimated. On the other hand, if the curve that represents the lower confidence limits for the survivor function lies above 0.75, the lower confidence limit for the quartile cannot be estimated.

The estimated mean survival time is

$$\hat{\mu} = \sum_{i=1}^D \hat{S}(t_{i-1})(t_i - t_{i-1})$$

where t_0 is defined to be zero. When the largest observed time is censored, this sum underestimates the mean. The standard error of $\hat{\mu}$ is estimated as

$$\hat{\sigma}(\hat{\mu}) = \sqrt{\frac{m}{m-1} \sum_{i=1}^{D-1} \frac{A_i^2}{Y_i(Y_i - d_i)}}$$

where

$$A_i = \sum_{j=i}^{D-1} \hat{S}(t_j)(t_{j+1} - t_j)$$

$$m = \sum_{j=1}^D d_j$$

If the largest observed time is not an event, you can use the TIMELIM= option to specify a time limit L and estimate the mean survival time limited to the time L and its standard error by replacing k by $k + 1$ with $t_{k+1} = L$.

Nelson-Aalen Estimate of the Cumulative Hazard Function

The Nelson-Aalen cumulative hazard estimator, defined up to the largest observed time on study, is

$$\tilde{H}(t) = \sum_{t_i \leq t} \frac{d_i}{Y_i}$$

and its estimated variance is

$$\hat{\sigma}^2(\tilde{H}(t)) = \sum_{t_i \leq t} \frac{d_i}{Y_i^2}$$

Adjusted Kaplan-Meier Estimate

PROC LIFETEST computes the adjusted Kaplan-Meier estimate (AKME) of the survivor function if you specify both METHOD=KM and the WEIGHT statement. Let (T_i, δ_i, w_i) , $i = 1, \dots, n$, denote an independent sample of right-censored survival data, where T_i is the possibly right-censored time, δ_i is the censoring indicator ($\delta_i = 0$ if T_i is censored and $\delta_i = 1$ if T_i is an event time), and w_i is the weight (from the WEIGHT statement). Let $t_1 < t_2, \dots, t_D$ be the D distinct event times in the sample. At time t_j , $j = 1, \dots, D$, there are $d_j = \sum_i \delta_i I(T_i = t_j)$ events out of $Y_j = \sum_i I(T_i \geq t_j)$ subjects. The weighted number of events and the weighted number at risk are $d_j^w = \sum_i w_i \delta_i I(T_i = t_j)$ and $Y_j^w = \sum_i w_i I(T_i \geq t_j)$, respectively. The AKME (Xie and Liu 2005) is

$$\hat{S}(t) = \begin{cases} 1 & \text{if } t < t_1 \\ \prod_{t_j \leq t} \left[1 - \frac{d_j^w}{Y_j^w} \right] & \text{if } t \geq t_1 \end{cases}$$

The estimated variance of $\hat{S}(t)$ is

$$\hat{\sigma}^2(\hat{S}(t)) = (\hat{S}(t))^2 \sum_{j: t_j \leq t} \frac{d_j^w / Y_j^w}{M_j (1 - d_j^w / Y_j^w)}$$

where

$$M_j = \frac{\left(\sum_{i: T_i \geq t_j} w_i \right)^2}{\sum_{i: T_i \geq t_j} w_i^2}$$

Life-Table Method

The life-table estimates are computed by counting the numbers of censored and uncensored observations that fall into each of the time intervals $[t_{i-1}, t_i)$, $i = 1, 2, \dots, k+1$, where $t_0 = 0$ and $t_{k+1} = \infty$. Let n_i be the number of units that enter the interval $[t_{i-1}, t_i)$, and let d_i be the number of events that occur in the interval. Let $b_i = t_i - t_{i-1}$, and let $n'_i = n_i - w_i/2$, where w_i is the number of units censored in the interval. The effective sample size of the interval $[t_{i-1}, t_i)$ is denoted by n'_i . Let t_{mi} denote the midpoint of $[t_{i-1}, t_i)$.

The conditional probability of an event in $[t_{i-1}, t_i)$ is estimated by

$$\hat{q}_i = \frac{d_i}{n'_i}$$

and its estimated standard error is

$$\hat{\sigma}(\hat{q}_i) = \sqrt{\frac{\hat{q}_i \hat{p}_i}{n'_i}}$$

where $\hat{p}_i = 1 - \hat{q}_i$.

The estimate of the survival function at t_i is

$$\hat{S}(t_i) = \begin{cases} 1 & i = 0 \\ \hat{S}(t_{i-1})p_{i-1} & i > 0 \end{cases}$$

and its estimated standard error is

$$\hat{\sigma}(\hat{S}(t_i)) = \hat{S}(t_i) \sqrt{\sum_{j=1}^{i-1} \frac{\hat{q}_j}{n'_j \hat{p}_j}}$$

The density function at t_{mi} is estimated by

$$\hat{f}(t_{mi}) = \frac{\hat{S}(t_i)\hat{q}_i}{b_i}$$

and its estimated standard error is

$$\hat{\sigma}(\hat{f}(t_{mi})) = \hat{f}(t_{mi}) \sqrt{\sum_{j=1}^{i-1} \frac{\hat{q}_j}{n'_j \hat{p}_j} + \frac{\hat{p}_i}{n'_i \hat{q}_i}}$$

The estimated hazard function at t_{mi} is

$$\hat{h}(t_{mi}) = \frac{2\hat{q}_i}{b_i(1 + \hat{p}_i)}$$

and its estimated standard error is

$$\hat{\sigma}(\hat{h}(t_{mi})) = \hat{h}(t_{mi}) \sqrt{\frac{1 - (b_i \hat{h}(t_{mi})/2)^2}{n'_i \hat{q}_i}}$$

Let $[t_{j-1}, t_j)$ be the interval in which $\hat{S}(t_{j-1}) \geq \hat{S}(t_i)/2 > \hat{S}(t_j)$. The median residual lifetime at t_i is estimated by

$$\hat{M}_i = t_{j-1} - t_i + b_j \frac{\hat{S}(t_{j-1}) - \hat{S}(t_i)/2}{\hat{S}(t_{j-1}) - \hat{S}(t_j)}$$

and the corresponding standard error is estimated by

$$\hat{\sigma}(\hat{M}_i) = \frac{\hat{S}(t_i)}{2\hat{f}(t_{mj})\sqrt{n'_i}}$$

Interval Determination

If you want to determine the intervals exactly, use the INTERVALS= option in the PROC LIFETEST statement to specify the interval endpoints. Use the WIDTH= option to specify the width of the intervals, thus indirectly determining the number of intervals. If neither the INTERVALS= option nor the WIDTH= option is specified in the life-table estimation, the number of intervals is determined by the NINTERVAL= option. The width of the time intervals is 2, 5, or 10 times an integer (possibly a negative integer) power of 10. Let

$c = \log_{10}(\text{maximum observed time/number of intervals})$, and let b be the largest integer not exceeding c . Let $d = 10^{c-b}$ and let

$$a = 2 \times I(d \leq 2) + 5 \times I(2 < d \leq 5) + 10 \times I(d > 5)$$

with I being the indicator function. The width is then given by

$$\text{width} = a \times 10^b$$

By default, NINTERVAL=10.

Pointwise Confidence Limits in the OUTSURV= Data Set

Pointwise confidence limits are computed for the survivor function, and for the density function and hazard function when the life-table method is used. Let α be specified by the ALPHA= option. Let $z_{\alpha/2}$ be the critical value for the standard normal distribution. That is, $\Phi(-z_{\alpha/2}) = \alpha/2$, where Φ is the cumulative distribution function of the standard normal random variable.

Survivor Function

When the computation of confidence limits for the survivor function $S(t)$ is based on the asymptotic normality of the survival estimator $\hat{S}(t)$, the approximate confidence interval might include impossible values outside the range $[0,1]$ at extreme values of t . This problem can be avoided by applying the asymptotic normality to a transformation of $S(t)$ for which the range is unrestricted. In addition, certain transformed confidence intervals for $S(t)$ perform better than the usual linear confidence intervals (Borgan and Liestøl 1990). The CONFTYPE= option enables you to pick one of the following transformations: the log-log function (Kalbfleisch and Prentice 1980), the arcsine-square root function (Nair 1984), the logit function (Meeker and Escobar 1998), the log function, and the linear function.

Let g be the transformation that is being applied to the survivor function $S(t)$. By the delta method, the standard error of $g(\hat{S}(t))$ is estimated by

$$\tau(t) = \hat{\sigma} \left[g(\hat{S}(t)) \right] = g'(\hat{S}(t)) \hat{\sigma}[\hat{S}(t)]$$

where g' is the first derivative of the function g . The $100(1-\alpha)\%$ confidence interval for $S(t)$ is given by

$$g^{-1} \left\{ g[\hat{S}(t)] \pm z_{\alpha/2} g'[\hat{S}(t)] \hat{\sigma}[\hat{S}(t)] \right\}$$

where g^{-1} is the inverse function of g . That choices of the transformation g are as follows:

- arcsine-square root transformation: The estimated variance of $\sin^{-1}(\sqrt{\hat{S}(t)})$ is $\hat{\tau}^2(t) = \frac{\hat{\sigma}^2[\hat{S}(t)]}{4\hat{S}(t)[1-\hat{S}(t)]}$. The $100(1-\alpha)\%$ confidence interval for $S(t)$ is given by

$$\sin^2 \left\{ \max \left[0, \sin^{-1}(\sqrt{\hat{S}(t)}) - z_{\alpha/2} \hat{\tau}(t) \right] \right\} \leq S(t) \leq \sin^2 \left\{ \min \left[\frac{\pi}{2}, \sin^{-1}(\sqrt{\hat{S}(t)}) + z_{\alpha/2} \hat{\tau}(t) \right] \right\}$$

- linear transformation: This is the same as having no transformation in which g is the identity. The $100(1-\alpha)\%$ confidence interval for $S(t)$ is given by

$$\hat{S}(t) - z_{\alpha/2} \hat{\sigma}[\hat{S}(t)] \leq S(t) \leq \hat{S}(t) + z_{\alpha/2} \hat{\sigma}[\hat{S}(t)]$$

- log transformation: The estimated variance of $\log(\hat{S}(t))$ is $\hat{\tau}^2(t) = \frac{\hat{\sigma}^2(\hat{S}(t))}{\hat{S}^2(t)}$. The $100(1-\alpha)\%$ confidence interval for $S(t)$ is given by

$$\hat{S}(t) \exp\left(-z_{\frac{\alpha}{2}} \hat{\tau}(t)\right) \leq S(t) \leq \hat{S}(t) \exp\left(z_{\frac{\alpha}{2}} \hat{\tau}(t)\right)$$

- log-log transformation: The estimated variance of $\log(-\log(\hat{S}(t)))$ is $\hat{\tau}^2(t) = \frac{\hat{\sigma}^2[\hat{S}(t)]}{[\hat{S}(t) \log(\hat{S}(t))]^2}$. The $100(1-\alpha)\%$ confidence interval for $S(t)$ is given by

$$\left[\hat{S}(t)\right]^{\exp\left(z_{\frac{\alpha}{2}} \hat{\tau}(t)\right)} \leq S(t) \leq \left[\hat{S}(t)\right]^{\exp\left(-z_{\frac{\alpha}{2}} \hat{\tau}(t)\right)}$$

- logit transformation: The estimated variance of $\log\left(\frac{\hat{S}(t)}{1-\hat{S}(t)}\right)$ is

$$\hat{\tau}^2(t) = \frac{\hat{\sigma}^2(\hat{S}(t))}{\hat{S}^2(t)[1-\hat{S}(t)]^2}.$$

The $100(1-\alpha)\%$ confidence limits for $S(t)$ are given by

$$\frac{\hat{S}(t)}{\hat{S}(t) + \left[1 - \hat{S}(t)\right] \exp\left(z_{\frac{\alpha}{2}} \hat{\tau}(t)\right)} \leq S(t) \leq \frac{\hat{S}(t)}{\hat{S}(t) + \left[1 - \hat{S}(t)\right] \exp\left(-z_{\frac{\alpha}{2}} \hat{\tau}(t)\right)}$$

Density and Hazard Functions

For the life-table method, a $100(1-\alpha)\%$ confidence interval for hazard function or density function at time t is computed as

$$\hat{g}(t) \pm z_{\alpha/2} \hat{\sigma}[\hat{g}(t)]$$

where $\hat{g}(t)$ is the estimate of either the hazard function or the density function at time t , and $\hat{\sigma}[\hat{g}(t)]$ is the corresponding standard error estimate.

Simultaneous Confidence Intervals for Kaplan-Meier Curves

The pointwise confidence interval for the survivor function $S(t)$ is valid for a single fixed time at which the inference is to be made. In some applications, it is of interest to find the upper and lower confidence bands that guarantee, with a given confidence level, that the survivor function falls within the band for all t in some interval. Hall and Wellner (1980) and Nair (1984) provide two different approaches for deriving the confidence bands. An excellent review can be found in Klein and Moeschberger (1997). You can use the CONF BAND= option in the SURVIVAL statement to select the confidence bands. The EP confidence band provides confidence bounds that are proportional to the pointwise confidence interval, while those of the HW band are not proportional to the pointwise confidence bounds. The maximum time, t_U , for the bands can be specified by the BANDMAX= option; the minimum time, t_L , can be specified by the BANDMIN= option. Transformations that are used to improve the pointwise confidence intervals can be applied to improve the confidence bands. It might turn out that the upper and lower bounds of the confidence bands are not decreasing in $t_L < t < t_U$, which is contrary to the nonincreasing characteristic of survivor function. Meeker and Escobar (1998) suggest making an adjustment so that the bounds do not increase: if the upper bound is increasing on the right, it is made flat from the minimum to t_U ; if the lower bound is

increasing from the right, it is made flat from t_L to the maximum. PROC LIFETEST does not make any adjustment for the nondecreasing behavior of the confidence bands in the OUTSURV= data set. However, the adjustment was made in the display of the confidence bands by using ODS Graphics.

For Kaplan-Meier estimation, let $t_1 < t_2 < \dots < t_D$ be the D distinct events times, and at time t_i , there are d_i events. Let Y_i be the number of individuals who are at risk at time t_i . The variance of $\hat{S}(t)$, given by the Greenwood formula, is $\hat{\sigma}^2[\hat{S}(t)] = \sigma_S^2(t)\hat{S}^2(t)$, where

$$\sigma_S^2(t) = \sum_{t_i \leq t} \frac{d_i}{Y_i(Y_i - d_i)}$$

Let $t_L < t_U$ be the time range for the confidence band so that t_U is less than or equal to the largest event time. For the Hall-Wellner band, t_L can be zero, but for the equal-precision band, t_L is greater than or equal to the smallest event time. Let

$$a_L = \frac{n\sigma_S^2(t_L)}{1 + n\sigma_S^2(t_L)} \text{ and } a_U = \frac{n\sigma_S^2(t_U)}{1 + n\sigma_S^2(t_U)}$$

Let $\{W^0(u), 0 \leq u \leq 1\}$ be a Brownian bridge.

Hall-Wellner Band

The 100(1- α)% HW band of Hall and Wellner (1980) is

$$\hat{S}(t) - h_\alpha(a_L, a_U)n^{-\frac{1}{2}}[1 + n\sigma_S^2(t)]\hat{S}(t) \leq S(t) \leq \hat{S}(t) + h_\alpha(a_L, a_U)n^{-\frac{1}{2}}[1 + n\sigma_S^2(t)]\hat{S}(t)$$

for all $t_L \leq t \leq t_U$, where the critical value $h_\alpha(a_L, a_U)$ is given by

$$\alpha = \Pr\left\{\sup_{a_L \leq u \leq a_U} |W^0(u)| > h_\alpha(a_L, a_U)\right\}$$

The critical values are computed from the results in Chung (1986).

Note that the given confidence band has a formula similar to that of the (linear) pointwise confidence interval, where $h_\alpha(a_L, a_U)$ and $n^{-\frac{1}{2}}[1 + n\sigma_S^2(t)]\hat{S}(t)$ in the former correspond to $z_{\frac{\alpha}{2}}$ and $\hat{\sigma}(\hat{S}(t))$ in the latter, respectively. You can obtain the other transformations (arcsine-square root, log-log, log, and logit) for the confidence bands by replacing $z_{\frac{\alpha}{2}}$ and $\hat{\tau}(t)$ in the corresponding pointwise confidence interval formula by $h_\alpha(a_L, a_U)$ and the following $\hat{\tau}(t)$, respectively:

- arcsine-square root transformation:

$$\hat{\tau}(t) = \frac{1 + n\sigma_S^2(t)}{2} \sqrt{\frac{S(t)}{n[1 - S(t)]}}$$

- log transformation:

$$\hat{\tau}(t) = \frac{1 + n\sigma_S^2(t)}{\sqrt{n}}$$

- log-log transformation:

$$\hat{\tau}(t) = \frac{1 + n\sigma_S^2(t)}{\sqrt{n}|\log[\hat{S}(t)]|}$$

- logit transformation:

$$\hat{\tau}(t) = \frac{1 + n\sigma_S^2(t)}{\sqrt{n}[1 - \hat{S}(t)]}$$

Equal-Precision Band

The 100(1- α)% EP band of Nair (1984) is

$$\hat{S}(t) - e_\alpha(a_L, a_U)\hat{S}(t)\sigma_S(t) \leq S(t) \leq \hat{S}(t) + e_\alpha(a_L, a_U)\hat{S}(t)\sigma_S(t)$$

for all $t_L \leq t \leq t_U$, where $e_\alpha(a_L, a_U)$ is given by

$$\alpha = \Pr\left\{\sup_{a_L \leq u \leq a_U} \frac{|W^0(u)|}{[u(1-u)]^{\frac{1}{2}}} > e_\alpha(a_L, a_U)\right\}$$

PROC LIFETEST uses the approximation of Miller and Siegmund (1982, Equation 8) to approximate the tail probability in which $e_\alpha(a_L, a_U)$ is obtained by solving x in

$$\frac{4x\phi(x)}{x} + \phi(x) \left(x - \frac{1}{x}\right) \log \left[\frac{a_U(1-a_L)}{a_L(1-a_U)}\right] = \alpha$$

where $\phi(x)$ is the standard normal density function evaluated at x . Note that the confidence bounds given are proportional to the pointwise confidence intervals. As a matter of fact, this confidence band and the (linear) pointwise confidence interval have the same formula except for the critical values ($z_{\frac{\alpha}{2}}$ for the pointwise confidence interval and $e_\alpha(a_L, a_U)$ for the band). You can obtain the other transformations (arcsine-square root, log-log, log, and logit) for the confidence bands by replacing $z_{\frac{\alpha}{2}}$ by $e_\alpha(a_L, a_U)$ in the formula of the pointwise confidence intervals.

Kernel-Smoothed Hazard Estimate

Kernel-smoothed estimators of the hazard function $h(t)$ are based on the Nelson-Aalen estimator $\tilde{H}(t)$ and its variance $\hat{V}(\tilde{H}(t))$. Consider the jumps of $\tilde{H}(t)$ and $\hat{V}(\tilde{H}(t))$ at the event times $t_1 < t_2 < \dots < t_D$ as follows:

$$\begin{aligned}\Delta\tilde{H}(t_i) &= \tilde{H}(t_i) - \tilde{H}(t_{i-1}) \\ \hat{V}(\tilde{H}(t_i)) &= \hat{V}(\tilde{H}(t_i)) - \hat{V}(\tilde{H}(t_{i-1}))\end{aligned}$$

where $t_0=0$.

The kernel-smoothed estimator of $h(t)$ is a weighted average of $\Delta\tilde{H}(t)$ over event times that are within a bandwidth distance b of t . The weights are controlled by the choice of kernel function, $K()$, defined on the interval $[-1,1]$. The choices are as follows:

- uniform kernel:

$$K_U(x) = \frac{1}{2}, \quad -1 \leq x \leq 1$$

- Epanechnikov kernel:

$$K_E(x) = \frac{3}{4}(1 - x^2), \quad -1 \leq x \leq 1$$

- biweight kernel:

$$K_{BW}(x) = \frac{15}{16}(1 - x^2)^2, \quad -1 \leq x \leq 1$$

The kernel-smoothed hazard rate estimator is defined for all time points on $(0, t_D)$. For time points t for which $b \leq t \leq t_D - b$, the kernel-smoothed estimated of $h(t)$ based on the kernel $K()$ is given by

$$\hat{h}(t) = \frac{1}{b} \sum_{i=1}^D K\left(\frac{t - t_i}{b}\right) \Delta \tilde{H}(t_i)$$

The variance of $\hat{h}(t)$ is estimated by

$$\hat{\sigma}^2(\hat{h}(t)) = \frac{1}{b^2} \sum_{i=1}^D K\left(\frac{t - t_i}{b}\right)^2 \Delta \hat{V}(\tilde{H}(t_i))$$

For $t < b$, the symmetric kernels $K()$ are replaced by the corresponding asymmetric kernels of Gasser and Müller (1979). Let $q = \frac{t}{b}$. The modified kernels are as follows:

- uniform kernel:

$$K_{U,q}(x) = \frac{4(1 + q^3)}{(1 + q)^4} + \frac{6(1 - q)}{(1 + q)^3}x, \quad -1 \leq x \leq q$$

- Epanechnikov kernel:

$$K_{E,q}(x) = K_E(x) \frac{64(2 - 4q + 6q^2 - 3q^3) + 240(1 - q)^2x}{(1 + q)^4(19 - 18q + 3q^2)}, \quad -1 \leq x \leq q$$

- biweight kernel:

$$K_{BW,q}(x) = K_{BW}(x) \frac{64(8 - 24q + 48q^2 - 45q^3 + 15q^4) + 1120(1 - q)^3x}{(1 + q)^5(81 - 168q + 126q^2 - 40q^3 + 5q^4)}, \quad -1 \leq x \leq q$$

For $t_D - b \leq t \leq t_D$, let $q = \frac{t_D - t}{b}$. The asymmetric kernels for $t < b$ are used with x replaced by $-x$.

Using the log transform on the smoothed hazard rate, the $100(1-\alpha)\%$ pointwise confidence interval for the smoothed hazard rate $h(t)$ is given by

$$\hat{h}(t) = \hat{h}(t) \exp \left[\pm \frac{z_{1-\alpha/2} \hat{\sigma}(\hat{h}(t))}{\hat{h}(t)} \right]$$

where $z_{1-\frac{\alpha}{2}}$ is the $100(1-\frac{\alpha}{2})$ th percentile of the standard normal distribution.

Optimal Bandwidth

The following mean integrated squared error (MISE) over the range τ_L and τ_U is used as a measure of the global performance of the kernel function estimator:

$$\begin{aligned}\text{MISE}(b) &= E \int_{\tau_L}^{\tau_U} (\hat{h}(u) - h(u))^2 du \\ &= E \int_{\tau_L}^{\tau_U} \hat{h}^2(u) du - 2E \int_{\tau_L}^{\tau_U} \hat{h}(u)h(u) du + E \int_{\tau_L}^{\tau_U} h^2(u) du\end{aligned}$$

The last term is independent of the choice of the kernel and bandwidth and can be ignored when you are looking for the best value of b . The first integral can be approximated by using the trapezoid rule by evaluating $\hat{h}(t)$ at a grid of points $\tau_L = u_1 < \dots < u_M = \tau_U$. You can specify τ_L , τ_R , and M by using the options GRIDL=, GRIDU=, and NMINGRID=, respectively, of the HAZARD plot. The second integral can be estimated by the Ramlau-Hansen (1983a, b) cross-validation estimate:

$$\frac{1}{b} \sum_{i \neq j} K\left(\frac{t_i - t_j}{b}\right) \Delta \hat{H}(t_i) \Delta \hat{H}(t_j)$$

Therefore, for a fixed kernel, the optimal bandwidth is the quantity b that minimizes

$$g(b) = \sum_{i=1}^{M-1} \left[\frac{u_{i+1} - u_i}{2} \left(\hat{h}^2(u_i) + \hat{h}^2(u_{i+1}) \right) \right] - \frac{2}{b} \sum_{i \neq j} K\left(\frac{t_i - t_j}{b}\right) \Delta \hat{H}(t_i) \Delta \hat{H}(t_j)$$

The minimization is carried out by the golden section search algorithm.

Comparison of Two or More Groups of Survival Data

Let K be the number of groups. Let $S_k(t)$ be the underlying survivor function of the k th group, $k = 1, \dots, K$. The null and alternative hypotheses to be tested are

$$H_0 : S_1(t) = S_2(t) = \dots = S_K(t) \text{ for all } t \leq \tau$$

versus

$$H_1 : \text{at least one of the } S_k(t) \text{'s is different for some } t \leq \tau$$

respectively, where τ is the largest observed time.

Likelihood Ratio Test

The likelihood ratio test statistic (Lawless 1982) for test H_0 versus H_1 assumes that the data in the various samples are exponentially distributed and tests that the scale parameters are equal. The test statistic is computed as

$$\chi^2 = 2N \log \left(\frac{T}{N} \right) - 2 \sum_{k=1}^K N_k \log \left(\frac{T_k}{N_k} \right)$$

where N_k is the total number of events in the k th group, $N = \sum_{k=1}^K N_k$, T_k is the total time on test in the k th stratum, and $T = \sum_{k=1}^K T_k$. The approximate probability value is computed by treating χ^2 as having a chi-square distribution with $K - 1$ degrees of freedom.

Nonparametric Tests

Let $(T_i, \delta_i, X_i), i = 1, \dots, n$, denote an independent sample of right-censored survival data, where T_i is the possibly right-censored time, δ_i is the censoring indicator ($\delta_i=0$ if T_i is censored and $\delta_i=1$ if T_i is an event time), and $X_i = 1, \dots, K$ for K different groups. Let $t_1 < t_2 < \dots < t_D$ be the distinct event times in the sample. At time $t_j, j = 1, \dots, D$, let $W(t_j)$ be a positive weight function, and let $Y_{jk} = \sum_{i:T_i \geq t_j} I(X_i = k)$ and $d_{jk} = \sum_{i:T_i = t_j} \delta_i I(X_i = k)$ be the size of the risk set and the number of events in the k th group, respectively. Let $Y_j = \sum_{k=1}^K Y_{jk}, d_j = \sum_{k=1}^K d_{jk}$.

The choices of the weight function $W(t_j)$ are given in Table 52.4.

Table 52.4 Weight Functions for Various Tests

Test	$W(t_i)$
Log-rank	1.0
Wilcoxon	Y_j
Tarone-Ware	$\sqrt{Y_j}$
Peto-Peto	$\hat{S}(t_j)$
Modified Peto-Peto	$\hat{S}(t_j) \frac{Y_j}{Y_j + 1}$
Harrington-Fleming (p, q)	$[\hat{S}(t_j)]^p [1 - \hat{S}(t_j)]^q, p \geq 0, q \geq 0$

In Table 52.4, $\hat{S}(t)$ is the product-limit estimate at t for the pooled sample, and $\tilde{S}(t)$ is a survivor function estimate close to $\hat{S}(t)$ given by

$$\tilde{S}(t) = \prod_{t_j \leq t} \left(1 - \frac{d_j}{Y_j + 1}\right)$$

Unstratified Tests The rank statistics (Klein and Moeschberger 1997, Section 7.3) for testing H_0 versus H_1 have the form of a K -vector $\mathbf{v} = (v_1, v_2, \dots, v_K)'$ with

$$v_k = \sum_{j=1}^D \left[W(t_j) \left(d_{jk} - Y_{jk} \frac{d_j}{Y_j} \right) \right]$$

and the variance of v_k and the covariance of v_k and v_h are, respectively,

$$V_{kk} = \sum_{j=1}^D \left[W^2(t_j) \frac{d_j(Y_j - d_j)Y_{jk}(Y_j - Y_{jk})}{Y_j^2(Y_j - 1)} \right], \quad 1 \leq k \leq K$$

$$V_{kh} = - \sum_{j=1}^D \left[W^2(t_j) \frac{d_j(Y_j - d_j)Y_{jk}Y_{jh}}{Y_j^2(Y_j - 1)} \right], \quad 1 \leq k \neq h \leq K$$

The statistic v_k can be interpreted as a weighted sum of observed minus expected numbers of failure for the k th group under the null hypothesis of identical survival curves. Let $\mathbf{V} = (V_{kh})$. The overall test statistic for homogeneity is $\mathbf{v}'\mathbf{V}^-\mathbf{v}$, where \mathbf{V}^- denotes a generalized inverse of \mathbf{V} . This statistic is treated as having a chi-square distribution with degrees of freedom equal to the rank of \mathbf{V} for the purposes of computing an approximate probability level.

Adjusted Log-Rank Test PROC LIFETEST computes the weighted log-rank test (Xie and Liu 2005, 2011) if you specify the WEIGHT statement. Let $(T_i, \delta_i, X_i, w_i), i = 1, \dots, n$, denote an independent sample of right-censored survival data, where T_i is the possibly right-censored time, δ_i is the censoring indicator ($\delta_i=0$ if T_i is censored and $\delta_i=1$ if T_i is an event time), $X_i = 1, \dots, K$ for K different groups, and w_i is the weight from the WEIGHT statement. Let $t_1 < t_2 < \dots < t_D$ be the distinct event times in the sample. At each $t_j, j = 1, \dots, D$, and for each $1 \leq k \leq K$, let

$$d_{jk} = \sum_{i:T_i=t_j} I(X_i = k) \quad d_{jk}^w = \sum_{i:T_i=t_j} w_i I(X_i = k)$$

$$Y_{jk} = \sum_{i:T_i \geq t_j} I(X_i = k) \quad Y_{jk}^w = \sum_{i:T_i \geq t_j} w_i I(X_i = k)$$

Let $d_j = \sum_{k=1}^K d_{jk}$ and $Y_j = \sum_{k=1}^K Y_{jk}$ denote the number of events and the number at risk, respectively, in the combined sample at time t_j . Similarly, let $d_j^w = \sum_{k=1}^K d_{jk}^w$ and $Y_j^w = \sum_{k=1}^K Y_{jk}^w$ denote the weighted number of events and the weighted number at risk, respectively, in the combined sample at time t_j . The test statistic is

$$v_k = \sum_{j=1}^D \left(d_{jk}^w - Y_{jk}^w \frac{d_j^w}{Y_j^w} \right) \quad k = 1, \dots, K$$

and the variance of v_k and the covariance of v_k and v_h are, respectively,

$$V_{kk} = \sum_{j=1}^D \left\{ \frac{d_j(Y_j - d_j)}{Y_j(Y_j - 1)} \sum_{i=1}^{Y_j} \left[\left(\frac{Y_{jk}^w}{Y_j^w} \right)^2 w_i^2 I\{X_i \neq k\} + \left(\frac{Y_j^w - Y_{jk}^w}{Y_j^w} \right)^2 w_i^2 I\{X_i = k\} \right] \right\}, \quad 1 \leq k \leq K$$

$$V_{kh} = \sum_{j=1}^D \left\{ \frac{d_j(Y_j - d_j)}{Y_j(Y_j - 1)} \sum_{i=1}^{Y_j} \left[\frac{Y_{jk}^w Y_{jh}^w}{(Y_j^w)^2} w_i^2 I\{X_i \neq k, h\} - \frac{(Y_j^w - Y_{jk}^w) Y_{jh}^w}{(Y_j^w)^2} w_i^2 I\{X_i = k\} \right. \right. \\ \left. \left. - \frac{(Y_j^w - Y_{jh}^w) Y_{jk}^w}{(Y_j^w)^2} w_i^2 I\{X_i = h\} \right] \right\}, \quad 1 \leq k \neq h \leq K$$

Let $V = (V_{kh})$. Under H_0 , the weighted K -sample test has a χ^2 statistic given by

$$\chi^2 = (v_1, \dots, v_K) \mathbf{V}^{-1} (v_1, \dots, v_K)'$$

with $K - 1$ degrees of freedom.

Stratified Tests Suppose the test is to be stratified on M levels of a set of STRATA variables. Based only on the data of the s th stratum ($s = 1 \dots M$), let \mathbf{v}_s be the test statistic (Klein and Moeschberger 1997, Section 7.5) for the s th stratum, and let \mathbf{V}_s be its covariance matrix. Let

$$\mathbf{v} = \sum_{s=1}^M \mathbf{v}_s$$

$$\mathbf{V} = \sum_{s=1}^M \mathbf{V}_s$$

A global test statistic is constructed as

$$\chi^2 = \mathbf{v}'\mathbf{V}^{-1}\mathbf{v}$$

Under the null hypothesis, the test statistic has a χ^2 distribution with the same degrees of freedom as the individual test for each stratum.

Multiple-Comparison Adjustments Let χ_r^2 denote a chi-square random variable with r degrees of freedom. Denote ϕ and Φ as the density function and the cumulative distribution function of a standard normal distribution, respectively. Let m be the number of comparisons; that is,

$$m = \begin{cases} \frac{k(k-1)}{2} & \text{DIFF} = \text{ALL} \\ k-1 & \text{DIFF} = \text{CONTROL} \end{cases}$$

For a two-sided test that compares the survival of the j th group with that of l th group, $1 \leq j \neq l \leq r$, the test statistic is

$$z_{jl}^2 = \frac{(v_j - v_l)^2}{V_{jj} + V_{ll} - 2V_{jl}}$$

and the raw p -value is

$$p = \Pr(\chi_1^2 > z_{jl}^2)$$

Adjusted p -values for various multiple-comparison adjustments are computed as follows:

- Bonferroni adjustment:

$$p = \min\{1, m\Pr(\chi_1^2 > z_{jl}^2)\}$$

- Dunnett-Hsu adjustment: With the first group being the control, let $\mathbf{C} = (c_{ij})$ be the $(r-1) \times r$ matrix of contrasts; that is,

$$c_{ij} = \begin{cases} 1 & i = 1, \dots, r-1, j = 2, \dots, r \\ -1 & j = i+1, i = 2, \dots, r \\ 0 & \text{otherwise} \end{cases}$$

Let $\mathbf{\Sigma} \equiv (\sigma_{ij})$ and $\mathbf{R} \equiv (r_{ij})$ be covariance and correlation matrices of $\mathbf{C}\mathbf{v}$, respectively; that is,

$$\mathbf{\Sigma} = \mathbf{C}\mathbf{V}\mathbf{C}'$$

and

$$r_{ij} = \frac{\sigma_{ij}}{\sqrt{\sigma_{ii}\sigma_{jj}}}$$

The factor-analytic covariance approximation of Hsu (1992) is to find $\lambda_1, \dots, \lambda_{r-1}$ such that

$$\mathbf{R} = \mathbf{D} + \boldsymbol{\lambda}\boldsymbol{\lambda}'$$

where \mathbf{D} is a diagonal matrix with the j th diagonal element being $1 - \lambda_j$ and $\boldsymbol{\lambda} = (\lambda_1, \dots, \lambda_{r-1})'$. The adjusted p -value is

$$p = 1 - \int_{-\infty}^{\infty} \phi(y) \prod_{i=1}^{r-1} \left[\Phi\left(\frac{\lambda_i y + z_{jl}}{\sqrt{1 - \lambda_i^2}}\right) - \Phi\left(\frac{\lambda_i y - z_{jl}}{\sqrt{1 - \lambda_i^2}}\right) \right] dy$$

which can be obtained in a DATA step as

$$p = \text{PROBMC}(\text{"DUNNETT2"}, z_{ij}, \dots, r-1, \lambda_1, \dots, \lambda_{r-1}).$$

- Scheffé adjustment:

$$p = \Pr(\chi_{r-1}^2 > z_{jl}^2)$$

- Šidák adjustment:

$$p = 1 - \{1 - \Pr(\chi_1^2 > z_{jl}^2)\}^m$$

- SMM adjustment:

$$p = 1 - [2\Phi(z_{jl}) - 1]^m$$

which can also be evaluated in a DATA step as

$$p = 1 - \text{PROBMC}(\text{"MAXMOD"}, z_{jl}, \dots, m).$$

- Tukey adjustment:

$$p = 1 - \int_{-\infty}^{\infty} r\phi(y) [\Phi(y) - \Phi(y - \sqrt{2}z_{jl})]^{r-1} dy$$

which can also be evaluated in a DATA step as

$$p = 1 - \text{PROBMC}(\text{"RANGE"}, \sqrt{2}z_{jl}, \dots, r).$$

Trend Tests Trend tests (Klein and Moeschberger 1997, Section 7.4) have more power to detect ordered alternatives as

$$H_2 : S_1(t) \geq S_2(t) \geq \dots \geq S_k(t), t \leq \tau, \text{ with at least one inequality}$$

or

$$H_2 : S_1(t) \leq S_2(t) \leq \dots \leq S_k(t), t \leq \tau, \text{ with at least one inequality}$$

Let $a_1 < a_2 < \dots < a_k$ be a sequence of scores associated with the k samples. The test statistic and its standard error are given by $\sum_{j=1}^k a_j v_j$ and $\sum_{j=1}^k \sum_{l=1}^k a_j a_l V_{jl}$, respectively. Under H_0 , the z -score

$$Z = \frac{\sum_{j=1}^k a_j v_j}{\sqrt{\sum_{j=1}^k \sum_{l=1}^k a_j a_l V_{jl}}}$$

has, asymptotically, a standard normal distribution. PROC LIFETEST provides both one-tail and two-tail p -values for the test.

Rank Tests for the Association of Survival Time with Covariates

The rank tests for the association of covariates (Kalbfleisch and Prentice 1980, Chapter 6) are more general cases of the rank tests for homogeneity. In this section, the index α is used to label all observations, $\alpha = 1, 2, \dots, n$, and the indices i, j range only over the observations that correspond to events, $i, j = 1, 2, \dots, k$. The ordered event times are denoted as $t_{(i)}$, the corresponding vectors of covariates are denoted as $\mathbf{z}_{(i)}$, and the ordered times, both censored and event times, are denoted as t_α .

The rank test statistics have the form

$$\mathbf{v} = \sum_{\alpha=1}^n c_{\alpha, \delta_\alpha} \mathbf{z}_\alpha$$

where n is the total number of observations, $c_{\alpha, \delta_\alpha}$ are rank scores, which can be either log-rank or Wilcoxon rank scores, δ_α is 1 if the observation is an event and 0 if the observation is censored, and \mathbf{z}_α is the vector of covariates in the TEST statement for the α th observation. Notice that the scores, $c_{\alpha, \delta_\alpha}$, depend on the censoring pattern and that the terms are summed up over all observations.

The log-rank scores are

$$c_{\alpha, \delta_\alpha} = \sum_{(j: t_{(j)} \leq t_\alpha)} \left(\frac{1}{n_j} - \delta_\alpha \right)$$

and the Wilcoxon scores are

$$c_{\alpha, \delta_\alpha} = 1 - (1 + \delta_\alpha) \prod_{(j: t_{(j)} \leq t_\alpha)} \frac{n_j}{n_j + 1}$$

where n_j is the number at risk just prior to $t_{(j)}$.

The estimates used for the covariance matrix of the log-rank statistics are

$$\mathbf{V} = \sum_{i=1}^k \frac{\mathbf{V}_i}{n_i}$$

where \mathbf{V}_i is the corrected sum of squares and crossproducts matrix for the risk set at time $t_{(i)}$; that is,

$$\mathbf{V}_i = \sum_{(\alpha: t_\alpha \geq t_{(i)})} (\mathbf{z}_\alpha - \bar{\mathbf{z}}_i)' (\mathbf{z}_\alpha - \bar{\mathbf{z}}_i)$$

where

$$\bar{\mathbf{z}}_i = \sum_{(\alpha: t_\alpha \geq t_{(i)})} \frac{\mathbf{z}_\alpha}{n_i}$$

The estimate used for the covariance matrix of the Wilcoxon statistics is

$$\mathbf{V} = \sum_{i=1}^k \left[a_i (1 - a_i^*) (2\mathbf{z}_{(i)} \mathbf{z}_{(i)}' + \mathbf{S}_i) - (a_i^* - a_i) \left(a_i \mathbf{x}_i \mathbf{x}_i' + \sum_{j=i+1}^k a_j (\mathbf{x}_i \mathbf{x}_j' + \mathbf{x}_j \mathbf{x}_i') \right) \right]$$

where

$$a_i = \prod_{j=1}^i \frac{n_j}{n_j + 1}$$

$$a_i^* = \prod_{j=1}^i \frac{n_j + 1}{n_j + 2}$$

$$\mathbf{S}_i = \sum_{(\alpha: t_{(i+1)} > t_\alpha > t_{(i)})} \mathbf{z}_\alpha \mathbf{z}'_\alpha$$

$$\mathbf{x}_i = 2\mathbf{z}_{(i)} + \sum_{(\alpha: t_{(i+1)} > t_\alpha > t_{(i)})} \mathbf{z}_\alpha$$

In the case of tied failure times, the statistics \mathbf{v} are averaged over the possible orderings of the tied failure times. The covariance matrices are also averaged over the tied failure times. Averaging the covariance matrices over the tied orderings produces functions with appropriate symmetries for the tied observations; however, the actual variances of the \mathbf{v} statistics would be smaller than the preceding estimates. Unless the proportion of ties is large, it is unlikely that this will be a problem.

The univariate tests for each covariate are formed from each component of \mathbf{v} and the corresponding diagonal element of \mathbf{V} as v_i^2 / V_{ii} . These statistics are treated as coming from a chi-square distribution for calculation of probability values.

The statistic $\mathbf{v}'\mathbf{V}^{-1}\mathbf{v}$ is computed by sweeping each pivot of the \mathbf{V} matrix in the order of greatest increase to the statistic. The corresponding sequence of partial statistics is tabulated. Sequential increments for including a given covariate and the corresponding probabilities are also included in the same table. These probabilities are calculated as the tail probabilities of a chi-square distribution with one degree of freedom. Because of the selection process, these probabilities should not be interpreted as p -values.

If desired for data screening purposes, the output data set requested by the OUTTEST= option can be treated as a sum of squares and crossproducts matrix and processed by the REG procedure by using the option METHOD=RSQUARE. Then the sets of variables of a given size can be found that give the largest test statistics. [Output 52.1](#) illustrates this process.

Computer Resources

The data are first read and sorted into strata. If the data are originally sorted by failure time and censoring state, with smaller failure times coming first and event values preceding censored values in cases of ties, the data can be processed by strata without additional sorting. Otherwise, the data are read into memory by strata and sorted.

Memory Requirements

For a given BY group, define the following:

N	the total number of observations
V	the number of STRATA variables
C	the number of covariates listed in the TEST statement
L	total length of the ID variables in bytes
S	number of strata
n	maximum number of observations within strata
b	$12 + 8C + L$
$m1$	$(112 + 16V) \times S$
$m2$	$50 \times b \times S$
$m3$	$(50 + n) \times (b + 4)$
$m4$	$8(C + 4)^2$
$m5$	$20N + 8S \times (S + 4)$

The memory, in bytes, required to process the BY group is at least

$$m1 + \max(m2, m3) + m4$$

The test of equality of survival functions across strata requires additional memory ($m5$ bytes). However, if this additional memory is not available, PROC LIFETEST skips the test for equality of survival functions and finishes the other computations. Additional memory is required for the PLOTS= option. Temporary storage of $16n$ bytes is required to store the product-limit estimates for plotting.

Output Data Sets

OUTSURV= Data Set

You can specify the OUTSURV= option in the PROC LIFETEST statement to create an output data set that contains the following columns:

- any specified BY variables
- any specified STRATA variables, their values coming from either their original values or the midpoints of the stratum intervals if endpoints are used to define strata (semi-infinite intervals are labeled by their finite endpoint)
- STRATUM, a numeric variable that numbers the strata

- the time variable as given in the TIME statement. For METHOD=KM, METHOD=BRESLOW, or METHOD=FM, it contains the observed failure or censored times. For the life-table estimates, it contains the lower endpoints of the time intervals.
- SURVIVAL, a variable that contains the survivor function estimates
- CONFTYPE, a variable that contains the name of the transformation applied to the survival time in the computation of confidence intervals (if the OUT= option is specified in the SURVIVAL statement)
- SDF_LCL, a variable that contains the lower limits of the pointwise confidence intervals for the survivor function
- SDF_UCL, a variable that contains the upper limits of the pointwise confidence intervals for the survivor function

If the estimation uses the product-limit, Breslow, or Fleming-Harrington method, then the data set also contains the following:

- _CENSOR_, an indicator variable that has a value 1 for a censored observation and a value 0 for an event observation
- SDF_STDERR, a variable that contains the standard error of the survivor function estimator (if the STDERR option is specified in the PROC LIFETEST statement)
- HW_LCL, a variable that contains the lower limits of the Hall-Wellner confidence bands (if the CONFBAND=HW option or the CONFBAND=ALL option is specified in the PROC LIFETEST statement)
- HW_UCL, a variable that contains the upper limits of the Hall-Wellner confidence bands (if the CONFBAND=HW option or the CONFBAND=ALL option is specified in the PROC LIFETEST statement)
- EP_LCL, a variable that contains the lower limits of the equal-precision confidence bands (if the CONFBAND=EP option or the CONFBAND=ALL option is specified in the PROC LIFETEST statement)
- EP_UCL, a variable that contains the upper limits of the equal-precision confidence bands (if the CONFBAND=EP option or the CONFBAND=ALL option is specified in the PROC LIFETEST statement)

If the estimation uses the life-table method, then the data set also contains the following:

- MIDPOINT, a variable that contains the value of the midpoint of the time interval
- PDF, a variable that contains the density function estimates
- PDF_LCL, a variable that contains the lower endpoints of the PDF confidence intervals
- PDF_UCL, a variable that contains the upper endpoints of the PDF confidence intervals
- HAZARD, a variable that contains the hazard estimates
- HAZ_LCL, a variable that contains the lower endpoints of the hazard confidence intervals

- HAZ_UCL, a variable that contains the upper endpoints of the hazard confidence intervals

Each survival function contains an initial observation with the value 1 for the SDF and the value 0 for the time. The output data set contains an observation for each distinct failure time if the product-limit, Breslow, or Fleming-Harrington method is used, or it contains an observation for each time interval if the life-table method is used. The product-limit, Breslow, or Fleming-Harrington survival estimates are defined to be right continuous; that is, the estimates at a given time include the factor for the failure events that occur at that time.

Labels are assigned to all the variables in the output data set except the BY variable and the STRATA variable.

OUTTEST= Data Set

The OUTTEST= option in the LIFETEST statement creates an output data set that contains the rank statistics for testing the association of failure time with covariates. It contains the following:

- any specified BY variables
- _TYPE_, a character variable of length 8 that labels the type of rank test, either “LOG-RANK” or “WILCOXON”
- _NAME_, a character variable of length 8 that labels the rows of the covariance matrix and the test statistics
- the TIME variable, containing the overall test statistic in the observation that has _NAME_ equal to the name of the time variable and the univariate test statistics under their respective covariates.
- all variables listed in the TEST statement

The output is in the form of a symmetric matrix formed by the covariance matrix of the rank statistics bordered by the rank statistics and the overall chi-square statistic. If the value of _NAME_ is the name of a variable in the TEST statement, the observation contains a row of the covariance matrix and the value of the rank statistic in the time variable. If the value of _NAME_ is the name of the TIME variable, the observation contains the values of the rank statistics in the variables from the TEST list and the value of the overall chi-square test statistic in the TIME variable.

Two complete sets of statistics labeled by the _TYPE_ variable are produced, one for the log-rank test and one for the Wilcoxon test.

Displayed Output

If you use the NOPRINT option in the PROC LIFETEST statement, the procedure does not display any output.

Product-Limit Survival Estimates

The “Product-Limit Survival Estimates” table is displayed if you request the product-limit method of estimation. The table displays the following:

- the observed (event or censored) time
- the number of units at risk (if you specify the ATRISK option in the PROC LIFETEST statement)
- the number of events (if you specify the ATRISK option in the PROC LIFETEST statement)
- the product-limit estimate of the survivor function
- the corresponding estimate of the cumulative distribution function of the failure time
- the standard error estimate of the survivor function estimator
- the Nelson-Aalen cumulative hazard function estimate (if the NELSON option is specified in the PROC LIFETEST statement)
- the standard error of the Nelson-Aalen estimator (if the NELSON option is specified in the PROC LIFETEST statement)
- the number of event times that have been observed
- the number of event or censored times that remain to be observed
- the frequency of the observed times (if you specify the FREQ statement)
- values of the ID variables (if you specify the ID statement)

The ODS name of this table is ProductLimitEstimates.

Breslow Survival Estimates

The “Breslow Survival Estimates” table is displayed if you request the Breslow method of estimation. The table displays the following:

- the observed (event or censored) time
- the number of units at risk (if you specify the ATRISK option in the PROC LIFETEST statement)
- the number of events (if you specify the ATRISK option in the PROC LIFETEST statement)
- the Breslow estimate of the survivor function
- the corresponding estimate of the cumulative distribution function of the failure time
- the standard error estimate of the survivor function estimator
- the Nelson-Aalen cumulative hazard function estimate (if the NELSON option is specified in the PROC LIFETEST statement)
- the standard error of the Nelson-Aalen estimator (if the NELSON option is specified in the PROC LIFETEST statement)

- the number of event times that have been observed
- the number of event or censored times that remain to be observed
- the frequency of the observed times (if you specify the FREQ statement)
- values of the ID variables (if you specify the ID statement)

The ODS name of this table is BreslowEstimates.

Fleming-Harrington Survival Estimates

The “Fleming-Harrington Survival Estimates” table is displayed if you request the Fleming-Harrington method of estimation. The table displays the following:

- the observed (event or censored) time
- the number of units at risk (if you specify the ATRISK option in the PROC LIFETEST statement)
- the number of events (if you specify the ATRISK option in the PROC LIFETEST statement)
- the Fleming-Harrington estimate of the survivor function
- the corresponding estimate of the cumulative distribution function of the failure time
- the standard error estimate of the survivor function estimator
- the Nelson-Aalen cumulative hazard function estimate (if the NELSON option is specified in the PROC LIFETEST statement)
- the standard error of the Nelson-Aalen estimator (if the NELSON option is specified in the PROC LIFETEST statement)
- the number of event times that have been observed
- the number of event or censored times that remain to be observed
- the frequency of the observed times (if you specify the FREQ statement)
- values of the ID variables (if you specify the ID statement)

The ODS name of this table is FlemingEstimates.

Quartile Estimates

The “Quartiles Estimates” table is displayed if you request the product-limit, Breslow, or Fleming-Harrington method of estimation. The table displays the following:

- point estimates of the quartiles of the survival times
- the lower and upper confidence limits for the quartiles

For ODS purposes, the name of this table is “Quartiles.”

Mean Estimate

The “Mean Estimate” table is displayed if you request the product-limit, Breslow, or Fleming-Harrington method of estimation. The table displays the following:

- the estimated mean survival time
- the estimated standard error of the mean estimator

The ODS name of this table is Means.

Life-Table Survival Estimates

The “Life-Table Survival Estimates” table is displayed if you request the life-table method of estimation. The table displays the following:

- the time intervals into which the failure and censored times are distributed. Each interval is from the lower limit, up to but not including the upper limit; if the upper limit is infinity, the missing value is printed.
- the number of events that occur in the interval
- the number of censored observations that fall into the interval
- the effective sample size for the interval
- the estimate of conditional probability of events (failures) in the interval
- the standard error of the conditional probability estimator
- the estimate of the survival function at the beginning of the interval
- the estimate of the cumulative distribution function of the failure time at the beginning of the interval
- the standard error estimate of the survivor function estimator
- the estimate of the median residual lifetime, which is the amount of time elapsed before reducing the number of at-risk units to one-half. This is also known as the *median future lifetime* in Elandt-Johnson and Johnson (1980)).
- the estimated standard error of the median residual lifetime estimator
- the density function estimated at the midpoint of the interval
- the standard error estimate of the density estimator
- the hazard rate estimated at the midpoint of the interval
- the standard error estimate of the hazard estimator

The ODS name of this table is LifetableEstimates.

Summary of the Number of Censored and Uncensored Values

The “Summary of the Number of Censored and Uncensored Values” table displays following:

- the stratum identification (if the STRATA statement is specified)
- the total number of observations
- the number of event observations
- the number of censored observations
- the percentage of censored observations

The ODS name of this table is CensoredSummary.

Rank Statistics

The “Rank Statistics” table contains the test statistics of the nonparametric k -sample tests. The ODS name of this table is HomStats.

Covariance Matrix for the Log-Rank Statistics

The “Covariance Matrix for the Log-Rank Statistics” table is displayed if the log-rank k -sample test is requested. The ODS name of this table is LogrankHomCov.

Covariance Matrix for the Wilcoxon Statistics

The “Covariance Matrix for the Wilcoxon Statistics” table is displayed if the Wilcoxon k -sample test is requested. The ODS name of this table is WilHomCov.

Covariance Matrix for the Tarone Statistics

The “Covariance Matrix for the Tarone Statistics” table is displayed if the Tarone-Ware k -sample test is requested. The ODS name of this table is TaroneHomCov.

Covariance Matrix for the Peto Statistics

The “Covariance Matrix for the Peto Statistics” table is displayed if the Peto-Peto k -sample test is requested. The ODS name of this table is PetoHomCov.

Covariance Matrix for the ModPeto Statistics

The “Covariance Matrix for the ModPeto Statistics” table is displayed if the modified Peto-Peto k -sample test is requested. The ODS name of this table is ModPetoHomCov.

Covariance Matrix for the Fleming Statistics

The “Covariance Matrix for the Fleming Statistics” table is displayed if the Fleming-Harrington k -sample test is requested. The ODS name of this table is FlemingHomCov.

Test of Equality over Strata

The “Test of Equality over Strata” table is displayed if an unstratified k -sample test is carried out. The table contains the chi-square statistics, degrees of freedom, and p -values of the nonparametric tests and the likelihood ratio test (which is based on the exponential distribution). The ODS name of this table is HomTests.

Stratified Test of Equality over Group

The “Stratified Test of Equality over Group” table is displayed if a stratified test is carried out. The table contains the chi-square statistics, degrees of freedom, and p -values of the stratified tests. The ODS name of this table is HomTests.

Scores for Trend Test

The “Scores for Trend Test” table is displayed if the TREND option is specified in the STRATA statement. The table contains the set of scores used to construct the trend tests. For ODS purposes, the name of this table is “TrendScores.”

Trend Tests

The “Trend Tests” table is displayed if the TREND option is specified in the STRATA statement. The table contains the results of the trend tests. The ODS name of this table is TrendTests.

Adjustment for Multiple Comparisons for the Log-Rank Test

The “Adjustment for Multiple Comparisons for the Log-Rank Test” table is displayed if the log-rank test and a multiple-comparison adjustment method are specified. The table contains the chi-square statistics and the raw and adjusted p -values of the paired comparisons. The ODS name of this table is SurvDiff.

Adjustment for Multiple Comparisons for the Wilcoxon Test

The “Adjustment for Multiple Comparisons for the Wilcoxon Test” table is displayed if the Wilcoxon test and a multiple-comparison method are specified. The table contains the chi-square statistics and the raw and adjusted p -values of the paired comparisons. The ODS name of this table is SurvDiff.

Adjustment for Multiple Comparisons for the Tarone Test

The “Adjustment for Multiple Comparisons for the Tarone Test” table is displayed if the Tarone-Ware test and a multiple-comparison method are specified. The table contains the chi-square statistics and the raw and adjusted p -values of the paired comparisons. The ODS name of this table is SurvDiff.

Adjustment for Multiple Comparisons for the Peto Test

The “Adjustment for Multiple Comparisons for the Peto Test” table is displayed if the Peto-Peto test and a multiple-comparison method are specified. The table contains the chi-square statistics and the raw and adjusted p -values of the paired comparisons. The ODS name of this table is SurvDiff.

Adjustment for Multiple Comparisons for the ModPeto Test

The “Adjustment for Multiple Comparisons for the ModPeto Test” table is displayed if the modified Peto-Peto test and a multiple-comparison method are specified. The table contains the chi-square statistics and the raw and adjusted p -values of the paired comparisons. The ODS name of this table is SurvDiff.

Adjustment for Multiple Comparisons for the Fleming Test

The “Adjustment for Multiple Comparisons for the Fleming Test” table is displayed if the Fleming-Harrington test and a multiple-comparison method are specified. The table contains the chi-square statistics and the raw and adjusted p -values of the paired comparisons. The ODS name of this table is SurvDiff.

Univariate Chi-Squares for the Log-Rank Test

The “Univariate Chi-Squares for the Log-Rank Test” table is displayed if the TEST statement is specified. The table displays the log-rank test results for individual variables in the TEST statement. The ODS name of this table is LogUniChiSq.

Covariance Matrix of the Log-Rank Statistics

The “Covariance Matrix of the Log-Rank Statistics” table is displayed if the TEST statement is specified. The table displays the estimated covariance matrix of the log-rank statistics for association. The ODS name of this table is LogTestCov.

Forward Stepwise Sequence of Chi-Squares for the Log-Rank Test

The “Forward Stepwise Sequence of Chi-Squares for the Log-Rank Test” table is displayed if the TEST statement is specified. The table contains the sequence of partial chi-square statistics for the log-rank test in the order of the greatest increase to the overall test statistic, the degrees of freedom of the partial chi-square statistics, the approximate probability values of the partial chi-square statistics, the chi-square increments for including the given variables, and the probability values of the chi-square increments. The ODS name of this table is LogForStepSeq.

Univariate Chi-Squares for the Wilcoxon Test

The “Univariate Chi-Squares for the Wilcoxon Test” table displays the Wilcoxon test results for individual variables in the TEST statement. The ODS name of this table is WilUniChiSq.

Covariance Matrix of the Wilcoxon Statistics

The “Covariance Matrix of the Wilcoxon Statistics” table is displayed if the TEST statement is specified. The table displays the estimated covariance matrix of the Wilcoxon statistics for association. The ODS name of this table is WilTestCov.

Forward Stepwise Sequence of Chi-Squares for the Wilcoxon Test

The “Forward Stepwise Sequence of Chi-Squares for the Wilcoxon Test” table is displayed if the TEST statement is specified. The table contains the sequence of partial chi-square statistics for the Wilcoxon test in the order of the greatest increase to the overall test statistic, the degrees of freedom of the partial chi-square statistics, the approximate probability values of the partial chi-square statistics, the chi-square

increments for including the given variables, and the probability values of the chi-square increments. The ODS name of this table is WilForStepSeq.

ODS Table Names

PROC LIFETEST assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 52.5. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 52.5 ODS Tables Produced by PROC LIFETEST

ODS Table Name	Description	Statement / Option
BreslowEstimates	Breslow estimates	PROC LIFETEST METHOD=B
CensoredSummary	Number of event and censored observations	PROC LIFETEST METHOD=PL B FH
FlemingEstimates	Fleming-Harrington estimates	PROC LIFETEST METHOD=FH
FlemingHomCov	Covariance matrix for k -sample FLEMING statistics	STRATA / TEST=FLEMING
HomStats	Test statistics for k -sample tests	STRATA / TEST=
HomTests	Results of k -sample tests	STRATA / TEST=
LifetableEstimates	Life-table survival estimates	PROC LIFETEST METHOD=LT
LogForStepSeq	Forward stepwise sequence for the log-rank statistics for association	TEST
LogrankHomCov	Covariance matrix for k -sample LOGRANK statistics	STRATA / TEST=LOGRANK
LogTestCov	Covariance matrix for log-rank statistics for association	TEST
LogUniChisq	Univariate chi-squares for log-rank statistics for association	TEST
Means	Mean and standard error of survival times	PROC LIFETEST METHOD=PL
ModPetoHomCov	Covariance matrix for k -sample MODPETO statistics	STRATA / TEST=MODPETO
PetoHomCov	Covariance matrix for k -sample PETO statistics	STRATA / TEST=PETO
ProductLimitEstimates	Product-limit survival estimates	PROC LIFETEST METHOD=PL
Quartiles	Quartiles of the survival times	PROC LIFETEST METHOD=PL B FH
SurvDiff	Adjustments for multiple comparisons	STRATA / ADJUST= and DIFF=
TaroneHomCov	Covariance matrix for k -sample TARONE statistics	STRATA / TEST=TARONE

Table 52.5 *continued*

ODS Table Name	Description	Statement / Option
TrendScores	Scores used to construct trend tests	STRATA / TREND
TrendTests	Results of trend tests	STRATA / TREND
WilForStepSeq	Forward stepwise sequence for the log-rank statistics for association	TEST
WilcoxonHomCov	Covariance matrix for k -sample WILCOXON statistics	STRATA / TEST=WILCOXON
WilTestCov	Covariance matrix for log-rank statistics for association	TEST
WilUniChiSq	Univariate chi-squares for Wilcoxon statistics for association	TEST

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The survival plot is produced by default; other graphs are produced by using the PLOTS= option in the PROC LIFETEST statement. You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC LIFETEST generates are listed in [Table 52.6](#), along with the required keywords for the PLOTS= option.

Table 52.6 Graphs Produced by PROC LIFETEST

ODS Graph Name	Plot Description	PLOTS=Option
DensityPlot	Estimated density for life-table method	PDF
FailurePlot	Estimated failure function	SURVIVAL(FAILURE)
HazardPlot	Estimated hazard function for life-table method or smoothed hazard for product-limit, Breslow, or Fleming-Harrington method	HAZARD
LogNegLogSurvivalPlot	Log of negative log of the estimated survivor function	LOGLOGS

Table 52.6 *continued*

ODS Graph Name	Plot Description	PLOTS=Option
NegLogSurvivalPlot	Negative log of the estimated survivor function	LOGSURV
SurvivalPlot	Estimated survivor function	SURVIVAL
SurvivalPlot	Estimated survivor function with number of subjects at risk	SURVIVAL(ATRISK=)
SurvivalPlot	Estimated survivor function with point-wise confidence limits	SURVIVAL(CL)
SurvivalPlot	Estimated survivor function with equal-precision band	SURVIVAL(CB=EP)
SurvivalPlot	Estimated survivor function with Hall-Wellner band	SURVIVAL(CB=HW)
SurvivalPlot	Estimated survivor function with homogeneity test <i>p</i> -value	SURVIVAL(TEST)

Additional Dynamic Variables for Survival Plots Using ODS Graphics

PROC LIFETEST passes a number of summary statistics as dynamic variables to the ODS Graphics for survival plots. Table 52.7 and Table 52.8 list these additional dynamic variables for the Kaplan-Meier curves and the life-table curves, respectively. These dynamic variables are not declared in the templates for the survival curves, but you can declare them and use them to enhance the default plots. The names of the dynamic variables depend on the STRATA= suboption of the PLOTS=SURVIVAL option: STRATA=INDIVIDUAL produces a separate plot for each stratum, and STRATA=OVERALL produces one plot with overlaid curves.

Table 52.7 Additional Dynamic Variables for `Stat.Graphics.ProductLimitSurvival`

STRATA=	Dynamic	Description
OVERLAY	StrVal j	Label for the j th stratum
	NObs j	Number of observations in the j th stratum
	NEvent j	Number of events in the j th stratum
	Median j	Median survival time of the j th stratum
	LowerMedian j	Lower median survival time of the j th stratum
	UpperMedian j	Upper median survival time of the j th stratum
INDIVIDUAL	PctMedianConfid	Confidence of the median intervals in percent
	NObs	Number of observations
	NEvent	Number of events
	Median	Median survival time
	LowerMedian	Lower median survival time
	UpperMedian	Upper median survival time
	PctMedianConfid	Confidence of the median interval in percent

Table 52.8 Additional Dynamic Variables for `Stat.Graphics.LifetableSurvival`

STRATA=	Dynamic	Description
OVERLAY	StrValj	Label for the <i>j</i> th stratum
	NObsj	Number of observations in the <i>j</i> th stratum
	NEventj	Number of events in the <i>j</i> th stratum
INDIVIDUAL	NObs	Number of observations
	NEvent	Number of events

See the section “The Graph Template Language” on page 707 in Chapter 22, “ODS Graphics Template Modification,” for the general use of dynamic variables. For the use of the particular dynamic variables shown in this section, see the sections “Modifying the Layout and Adding a New Inset Table” on page 766 and “Displaying Survival Summary Statistics” on page 784 in Chapter 22, “ODS Graphics Template Modification.”

Modifying the ODS Template for Survival Plots

PROC LIFETEST, like other statistical procedures, provides a PLOTS= option and other options for modifying its output without requiring template changes. Those options are sufficient for most purposes. When those options are not sufficient, you can change a graph by changing the graph template. “Example 22.3: Customizing Survival Plots” on page 748 in Chapter 22, “ODS Graphics Template Modification,” shows how to find the name of the template, display the template by using PROC TEMPLATE and the SOURCE statement, and make a series of template changes.

The example consists of the following parts:

- **Modifying the plot title:** This part identifies the template, displays it, explains its overall structure, and modifies the titles. See the section “Modifying the Plot Title” on page 749 in Chapter 22, “ODS Graphics Template Modification.”
- **Modifying the axes:** This part explains the options that control the X and Y axes, and shows how to modify the ticks and axis labels. See the section “Modifying the Axes” on page 753 in Chapter 22, “ODS Graphics Template Modification.”
- **Creating a template that is easy to modify:** This part shows how you can reorganize and modularize the entire template to make it easy to customize in various ways. See the section “Creating a Template That Is Easy to Modify” on page 756 in Chapter 22, “ODS Graphics Template Modification.”
- **Modifying the plot title in the revised template:** This part shows how to change the title by using the revised template. See the section “Modifying the Plot Title in the Revised Template” on page 762 in Chapter 22, “ODS Graphics Template Modification.”
- **Modifying the legend and inset table:** This part removes the small inset table and moves the legend inside the graph. The censoring information above the X axis is moved outside the graph. See the section “Modifying the Legend and Inset Table” on page 763 in Chapter 22, “ODS Graphics Template Modification.”

- **Modifying the layout and adding a new inset table:** This part moves the event and total information out of the graph and the legend in. It also moves the small inset table. See the section “[Modifying the Layout and Adding a New Inset Table](#)” on page 766 in Chapter 22, “[ODS Graphics Template Modification](#).”
- **Changing line styles:** This part shows how to modify a style template to change line colors and styles. See the section “[Changing Line Styles](#)” on page 773 in Chapter 22, “[ODS Graphics Template Modification](#).”
- **Changing fonts:** This part shows how to change the graph template and the style template to change some of the fonts that are used in the graph. See the section “[Changing Fonts](#)” on page 776 in Chapter 22, “[ODS Graphics Template Modification](#).”
- **Changing how censored data are displayed:** This part shows how to change or remove the plus marks that are used to display censored observations. See the section “[Changing How Censored Data Are Displayed](#)” on page 781 in Chapter 22, “[ODS Graphics Template Modification](#).”
- **Displaying survival summary statistics:** This part adds to the graph a table with event, censoring, and survival information. See the section “[Displaying Survival Summary Statistics](#)” on page 784 in Chapter 22, “[ODS Graphics Template Modification](#).”

Examples: LIFETEST Procedure

Example 52.1: Product-Limit Estimates and Tests of Association

The data presented in Appendix I of Kalbfleisch and Prentice (1980) are coded in the following DATA step. The response variable, `SurvTime`, is the survival time in days of a lung cancer patient. Negative values of `SurvTime` are censored values. The covariates are `Cell` (type of cancer cell), `Therapy` (type of therapy: standard or test), `Prior` (prior therapy: 0=no, 1=yes), `Age` (age in years), `DiagTime` (time in months from diagnosis to entry into the trial), and `Kps` (performance status). A censoring indicator variable `Censor` is created from the data, with the value 1 indicating a censored time and the value 0 indicating an event time. Since there are only two types of therapy, an indicator variable, `Treatment`, is constructed for therapy type, with value 0 for standard therapy and value 1 for test therapy.

```

In the following statements, PROC LIFETEST is invoked to compute the product-limit estimate of the survivor function for each type of cancer cell and to analyze the effects of the variables Age, Prior, DiagTime, Kps, and Treatment on the survival of the patients. These prognostic factors are specified in the TEST statement, and the variable Cell is specified in the STRATA statement. ODS Graphics must be enabled before producing graphs. Graphical displays of the product-limit estimates (S), the negative log estimates (LS), and the log of negative log estimates (LLS) are requested through the PLOTS= option in the PROC LIFETEST statement. Because of a few large survival times, a MAXTIME of 600 is used to set the scale of the time axis; that is, the time scale extends from 0 to a maximum of 600 days in the plots. The variable Therapy is specified in the ID statement to identify the type of therapy for each observation in the product-limit estimates. The OUTTEST option specifies the creation of an output data set named Test to contain the rank test matrices for the covariates.

```

ods graphics on;
proc lifetest data=VALung plots=(s,ls,lls) outtest=Test maxtime=600;
    time SurvTime*Censor(1);
    id Therapy;
    strata Cell;
    test Age Prior DiagTime Kps Treatment;
run;
ods graphics off;

```

Output 52.1.1 through Output 52.1.4 display the product-limit estimates of the survivor functions for the four cell types. Summary statistics of the survival times are also shown. The median survival times are 51 days, 156 days, 51 days, and 118 days for patients with adeno cells, large cells, small cells, and squamous cells, respectively.

Output 52.1.1 Estimation Results for Adeno Cells

NOTE: The marked survival times are censored observations.

The distribution of event and censored observations among the four cell types is summarized in [Output 52.1.5](#).

Output 52.1.5 Summary of Censored and Uncensored Values

Summary of the Number of Censored and Uncensored Values					
Stratum	Cell	Total	Failed	Censored	Percent Censored
1	adeno	27	26	1	3.70
2	large	27	26	1	3.70
3	small	48	45	3	6.25
4	squamous	35	31	4	11.43
<hr/>					
Total		137	128	9	6.57

The graph of the estimated survivor functions is shown in [Output 52.1.6](#). The adeno cell curve and the small cell curve are much closer to each other than they are to the large cell curve or the squamous cell curve. The survival rates of the adeno cell patients and the small cell patients decrease rapidly to approximately 29% in 90 days. Shapes of the large cell curve and the squamous cell curve are quite different, although both decrease less rapidly than those of the adeno and small cells. The squamous cell curve decreases more rapidly initially than the large cell curve, but the role is reversed in the later period.

Output 52.1.6 Graph of the Estimated Survivor Functions

The graph of the negative log of the estimated survivor functions is displayed in [Output 52.1.7](#). [Output 52.1.8](#) displays the log of the negative log of the estimated survivor functions against the log of time.

Output 52.1.7 Graph of Negative Log of the Estimated Survivor Functions

Output 52.1.8 Graph of Log of the Negative Log of the Estimated Survivor Functions

Results of the homogeneity tests across cell types are given in [Output 52.1.9](#). The log-rank and Wilcoxon statistics and their corresponding covariance matrices are displayed. Also given is a table that consists of the approximate chi-square statistics, degrees of freedom, and p -values for the log-rank, Wilcoxon, and likelihood ratio tests. All three tests indicate strong evidence of a significant difference among the survival curves for the four types of cancer cells ($p < 0.0001$).

Output 52.1.9 Homogeneity Tests across Cell Types

Rank Statistics		
Cell	Log-Rank	Wilcoxon
adeno	10.306	697.0
large	-8.549	-1085.0
small	14.898	1278.0
squamous	-16.655	-890.0

Output 52.1.9 *continued*

Covariance Matrix for the Log-Rank Statistics				
Cell	adeno	large	small	squamous
adeno	12.9662	-4.0701	-4.4087	-4.4873
large	-4.0701	24.1990	-7.8117	-12.3172
small	-4.4087	-7.8117	21.7543	-9.5339
squamous	-4.4873	-12.3172	-9.5339	26.3384

Covariance Matrix for the Wilcoxon Statistics

adeno	121188	-34718	-46639	-39831
large	-34718	151241	-59948	-56576
small	-46639	-59948	175590	-69002
squamous	-39831	-56576	-69002	165410

Test of Equality over Strata			
Test	Chi-Square	DF	Pr > Chi-Square
Log-Rank	25.4037	3	<.0001
Wilcoxon	19.4331	3	0.0002
-2Log (LR)	33.9343	3	<.0001

Results of the log-rank test of the prognostic variables are shown in [Output 52.1.10](#). The univariate test results correspond to testing each prognostic factor marginally. The joint covariance matrix of these univariate test statistics is also displayed. In computing the overall chi-square statistic, the partial chi-square statistics following a forward stepwise entry approach are tabulated.

Consider the log-rank test in [Output 52.1.10](#). Since the univariate test for Kps has the largest chi-square (43.4747) among all the covariates, Kps is entered first. At this stage, the partial chi-square and the chi-square increment for Kps are the same as the univariate chi-square. Among all the covariates not in the model (Age, Prior, DiagTime, Treatment), Treatment has the largest approximate chi-square increment (1.7261) and is entered next. The approximate chi-square for the model that contains Kps and Treatment is $43.4747 + 1.7261 = 45.2008$ with 2 degrees of freedom. The third covariate entered is Age. The fourth is Prior, and the fifth is DiagTime. The overall chi-square statistic in the last line of the output is the partial chi-square for including all the covariates. It has a value of 46.4200 with 5 degrees of freedom, which is highly significant ($p < 0.0001$).

Output 52.1.10 Log-Rank Test of the Prognostic Factors

Univariate Chi-Squares for the Log-Rank Test					
Variable	Test Statistic	Standard Error	Chi-Square	Pr > Chi-Square	Label
Age	-40.7383	105.7	0.1485	0.7000	Age in Years
Prior	-19.9435	46.9836	0.1802	0.6712	Prior Treatment?

Variable	Label
Kps	Karnofsky Index
Treatment	Treatment Indicator
Age	Age in Years
Prior	Prior Treatment?
DiagTime	Months till Randomization

You can establish this forward stepwise entry of prognostic factors by passing the matrix corresponding to the log-rank test to the RSQUARE method in the REG procedure, as follows. PROC REG finds the sets of variables that yield the largest chi-square statistics.

```
data RSq;
  set Test;
  if _type_='LOG RANK';
  _type_='cov';
run;
proc print data=RSq;
run;
proc reg data=RSq(type=COV);
  model SurvTime=Age Prior DiagTime Kps Treatment
    / selection=rsquare;
  title 'All Possible Subsets of Covariates for the log-rank Test';
run;
```

Output 52.1.11 displays the univariate statistics and their covariance matrix for the log-rank test.

Output 52.1.11 Log-Rank Statistics and Covariance Matrix

Obs	_TYPE_	_NAME_	SurvTime	Age	Prior	DiagTime	Kps	Treatment
1	cov	SurvTime	46.42	-40.74	-19.94	-115.86	1123.14	-4.208
2	cov	Age	-40.74	11175.44	-301.23	-892.24	-2948.45	119.297
3	cov	Prior	-19.94	-301.23	2207.46	2010.85	78.64	13.875
4	cov	DiagTime	-115.86	-892.24	2010.85	9578.69	-2295.32	21.859
5	cov	Kps	1123.14	-2948.45	78.64	-2295.32	29015.62	61.945
6	cov	Treatment	-4.21	119.30	13.87	21.86	61.95	25.409

Results of the best subset regression are shown in [Output 52.1.12](#). The variable Kps generates the largest univariate test statistic among all the covariates, the pair Kps and Age generate the largest test statistic among any other pairs of covariates, and so on. The entry order of covariates is identical to that of PROC LIFETEST.

Output 52.1.12 Best Subset Regression from the REG Procedure

Example 52.2: Enhanced Survival Plot and Multiple-Comparison Adjustments

This example highlights a number of features in the survival plot that uses ODS Graphics. Also shown in this example are comparisons of survival curves based on multiple comparison adjustments. Data of 137 bone marrow transplant patients extracted from Klein and Moeschberger (1997) have been saved in the data set BMT in the Sashelp library. At the time of transplant, each patient is classified into one of three risk categories: ALL (acute lymphoblastic leukemia), AML (acute myelocytic leukemia)-Low Risk, and AML-High Risk. The endpoint of interest is the disease-free survival time, which is the time to death or relapse or to the end of the study in days. In this data set, the variable Group represents the patient's risk category, the variable T represents the disease-free survival time, and the variable Status is the censoring indicator, with the value 1 indicating an event time and the value 0 a censored time.

The following step displays the first 10 observations of the BMT data set in [Output 52.2.1](#). The data set is available in the Sashelp library.

```
proc print data=Sashelp.BMT (obs=10);
run;
```

Output 52.2.1 A Subset of the Bone Marrow Transplant Data

Obs	Group	T	Status
1	ALL	2081	0
2	ALL	1602	0
3	ALL	1496	0
4	ALL	1462	0
5	ALL	1433	0
6	ALL	1377	0
7	ALL	1330	0
8	ALL	996	0
9	ALL	226	0
10	ALL	1199	0

In the following statements, PROC LIFETEST is invoked to compute the product-limit estimate of the survivor function for each risk category. Using ODS Graphics, you can display the number of subjects at risk in the survival plot. The **PLOTS=** option requests that the survival curves be plotted, and the **ATRISK=** suboption specifies the time points at which the at-risk numbers are displayed. In the STRATA statement, the **ADJUST=SIDAK** option requests the Šidák multiple-comparison adjustment, and by default, all paired comparisons are carried out.

```
ods graphics on;

proc lifetest data=sashelp.BMT plots=survival(atrisk=0 to 2500 by 500);
  time T * Status(0);
  strata Group / test=logrank adjust=sidak;
run;
```

[Output 52.2.2](#) displays the estimated disease-free survival for the three leukemia groups with the number of subjects at risk at 0, 500, 1,000, 1,500, 2,000, and 2,500 days. Patients in the AML-Low Risk group experience a longer disease-free survival than those in the ALL group, who in turn fare better than those in the AML-High Risk group.

Output 52.2.2 Estimated Disease-Free Survival for 137 Bone Marrow Transplant Patients

The log-rank test (Output 52.2.3) shows that the disease-free survival times for these three risk groups are significantly different ($p = 0.001$).

Output 52.2.3 Log-Rank Test of Disease Group Homogeneity

Test of Equality over Strata			
Test	Chi-Square	DF	Pr > Chi-Square
Log-Rank	13.8037	2	0.0010

The Šidák multiple-comparison results are shown in [Output 52.2.4](#). There is no significant difference in disease-free survivor functions between the ALL and AML-High Risk groups ($p = 0.2779$). The difference between the ALL and AML-Low Risk groups is marginal ($p = 0.0685$), but the AML-Low Risk and AML-High Risk groups have significantly different disease-free survivor functions ($p = 0.0006$).

Output 52.2.4 All Paired Comparisons

Adjustment for Multiple Comparisons for the Logrank Test				
Strata Comparison		Chi-Square	p-Values	
Group	Group		Raw	Sidak
ALL	AML-High Risk	2.6610	0.1028	0.2779
ALL	AML-Low Risk	5.1400	0.0234	0.0685
AML-High Risk	AML-Low Risk	13.8011	0.0002	0.0006

Suppose you consider the AML-Low Risk group as the reference group. You can use the `DIFF=` option in the `STRATA` statement to designate this risk group as the control and apply a multiple-comparison adjustment to the p -values for the paired comparison between the AML-Low Risk group with each of the other groups. Consider the Šidák correction again. You specify the `ADJUST=` and `DIFF=` options as in the following statements:

```
proc lifetest data=sashelp.BMT notable plots=none;
  time T * Status(0);
  strata Group / test=logrank adjust=sidak diff=control('AML-Low Risk');
run;
```

[Output 52.2.5](#) shows that although both the ALL and AML-High Risk groups differ from the AML-Low Risk group at the 0.05 level, the difference between the AML-High Risk and the AML-Low Risk group is highly significant ($p = 0.0004$).

Output 52.2.5 Comparisons with the Reference Group

The LIFETEST Procedure				
Adjustment for Multiple Comparisons for the Logrank Test				
Strata Comparison			p-Values	
Group	Group	Chi-Square	Raw	Sidak
ALL	AML-Low Risk	5.1400	0.0234	0.0462
AML-High Risk	AML-Low Risk	13.8011	0.0002	0.0004

The survival plot that is displayed in [Output 52.2.2](#) might be sufficient for many purposes, but you might have other preferences. Typical alternatives include displaying the number of subjects at risk outside the plot area, reordering the stratum labels in the survival plot legend, and displaying the strata in the at-risk table by using their full labels. PROC LIFETEST provides options that you can use to make these changes without requiring template changes. In the `sashelp.BMT` data set, the variable `Group` that represents the strata is a character variable with three values, namely (in alphabetical order), `ALL`, `AML-High Risk`, and `AML-Low Risk`. It might be desirable to present the strata in the order `ALL`, `AML-Low Risk`, and `AML-High Risk`. The `ORDER=INTERNAL` option in the `STRATA` statement enables you to order the strata by their internal values. In the following statements, the new dataset `Bmt2` is a copy of `sashelp.BMT` with the variable `Group` changed to a numeric variable with values 1, 2, and 3 representing `ALL`, `AML-Low Risk`, and `AML-High Risk`, respectively. The original character values of `Group` are kept as the formatted values, which are used to label the strata in the printed output.

```
proc format;
  invalue $bmtifmt 'ALL' = 1 'AML-Low Risk' = 2 'AML-High Risk' = 3;
  value bmtfmt 1 = 'ALL' 2 = 'AML-Low Risk' 3 = 'AML-High Risk';
run;

data Bmt2;
  set sashelp.BMT(rename=(Group=G));
  Group = input(input(G, $bmtifmt.), 1.);
  label Group = 'Disease Group';
  format Group bmtfmt.;
run;
```

The following statements produce a survival plot that has all the aforementioned modifications. The new data set `Bmt2` is used as the input data. The `OUTSIDE` and `MAXLEN=` options are specified in the `PLOTS=` option. The `OUTSIDE` option draws the at-risk table outside the plot area. Because the longest label of the strata has 13 characters, specifying `MAXLEN=13` is sufficient to display all the stratum labels in the at-risk table. The `ORDER=INTERNAL` option in the `STRATA` statement orders the strata by their numerical values 1, 2, and 3, which represent the order `ALL`, `AML-Low Risk`, and `AML-High Risk`, respectively.

```
proc LIFETEST data=Bmt2 plots=s(atrisk(outside maxlen=13)=0 to 2500 by 500);
  time T*Status(0);
  strata Group / order=internal;
run;
```

The modified survival plot is displayed in [Output 52.2.6](#). The most noticeable change from [Output 52.2.2](#) is that the number of subjects at risk is displayed below the time axis. Other changes include displaying the full labels of the strata in the at-risk table and presenting the strata in the order `ALL`, `AML-Low Risk`, and `AML-High Risk`.

Output 52.2.6 Modified Disease-Free Survival for Bone Marrow Transplant Patients

Klein and Moeschberger (1997, Section 4.4) describe in detail how to compute the Hall-Wellner (HW) and equal-precision (EP) confidence bands for the survivor function. You can output these simultaneous confidence intervals to a SAS data set by using the `CONFBAND=` and `OUTSURV=` options in the `PROC LIFETEST` statement. You can display survival curves with pointwise and simultaneous confidence limits through ODS Graphics. When the survival data are stratified, displaying all the survival curves and their confidence limits in the same plot can make the plot appear cluttered. In the following statements, the `PLOTS=` specification requests that the survivor functions be displayed along with their pointwise confidence limits (CL) and Hall-Wellner confidence bands (`CB=HW`). The `STRATA=``PANEL` specification requests that the survival curves be displayed in a panel of three plots, one for each risk group.

```
proc lifetest data=Bmt2 plots=survival(cl cb=hw strata=panel);
  time T * Status(0);
  strata Group/order=internal;
run;

ods graphics off;
```

The panel plot is shown in [Output 52.2.7](#).

Output 52.2.7 Estimated Disease-Free Survivor Functions with Confidence Limits

Example 52.3: Life-Table Estimates for Males with Angina Pectoris

The data in this example come from Lee (1992, p. 91) and represent the survival rates of males with angina pectoris. Survival time is measured as years from the time of diagnosis. In the following DATA step, the data are read as number of events and number of withdrawals in each one-year time interval for 16 intervals. Three variables are constructed from the data: Years (an artificial time variable with values that are the midpoints of the time intervals), Censored (a censoring indicator variable with the value 1 indicating censored observations and the value 0 indicating event observations), and Freq (the frequency variable). Two observations are created for each interval, one representing the event observations and the other representing the censored observations.

```

title 'Survival of Males with Angina Pectoris';
data Males;
    keep Freq Years Censored;
    retain Years -.5;
    input fail withdraw @@;
    Years + 1;

```

In the following statements, the ODS GRAPHICS ON specification enables ODS Graphics. PROC LIFETEST is invoked to compute the various life-table survival estimates, the median residual time, and their standard errors. The life-table method of computing estimates is requested by specifying METHOD=LT. The intervals are specified by the INTERVAL= option. Graphical displays of the life-table survivor function estimate, negative log of the estimate, log of negative log of the estimate, estimated density function, and estimated hazard function are requested by the PLOTS= option. No tests for homogeneity are carried out because the data are not stratified.

```

ods graphics on;
proc lifetest data=Males method=lt intervals=(0 to 15 by 1)
    plots=(s,ls,lls,h,p);
    time Years*Censored(1);
    freq Freq;
run;
ods graphics off;

```

Results of the life-table estimation are shown in [Output 52.3.1](#). The five-year survival rate is 0.5193 with a standard error of 0.0103. The estimated median residual lifetime, which is 5.33 years initially, reaches a maximum of 6.34 years at the beginning of the second year and decreases gradually to a value lower than the initial 5.33 years at the beginning of the seventh year.

Output 52.3.1 Life-Table Survivor Function Estimate

14	15	0.0207	0.00804	0.134831	0.054919	
15

The breakdown of event and censored observations in the data is shown in [Output 52.3.2](#). Note that 32.8% of the patients have withdrawn from the study.

Output 52.3.2 Summary of Censored and Event Observations

Summary of the Number of Censored and Uncensored Values				
Total	Failed	Censored	Percent Censored	
2418	1625	793	32.80	
NOTE: 2 observations with invalid time, censoring, or frequency values were deleted.				

Output 52.3.3 displays the graph of the life-table survivor function estimate. The median survival time, read from the survivor function curve, is 5.33 years, and the 25th and 75th percentiles are 1.04 and 11.13 years, respectively.

Output 52.3.3 Life-Table Survivor Function Estimate

An exponential model might be appropriate for the survival of these male patients with angina pectoris since the curve of the negative log of the survivor function estimate versus the survival time (Output 52.3.4) approximates a straight line through the origin. Note that the graph of the log of the negative log of the survivor function estimate versus the log of time (Output 52.3.5) is practically a straight line.

Output 52.3.4 Negative Log of Survivor Function Estimate

As discussed in Lee (1992), the graph of the estimated hazard function ([Output 52.3.6](#)) shows that the death rate is highest in the first year of diagnosis. From the end of the first year to the end of the tenth year, the death rate remains relatively constant, fluctuating between 0.09 and 0.12. The death rate is generally higher after the tenth year. This could indicate that a patient who has survived the first year has a better chance than a patient who has just been diagnosed. The profile of the median residual lifetimes also supports this interpretation.

Output 52.3.5 Log of Negative Log of Survivor Function Estimate

Output 52.3.6 Hazard Function Estimate

The density estimate is shown in (Output 52.3.7). Visually, it resembles the density function of an exponential distribution.

Output 52.3.7 Density Function Estimate

Overview: LOESS Procedure

The LOESS procedure implements a nonparametric method for estimating regression surfaces pioneered by Cleveland, Devlin, and Grosse (1988); Cleveland and Grosse (1991); Cleveland, Grosse, and Shyu (1992). The LOESS procedure allows great flexibility because no assumptions about the parametric form of the regression surface are needed.

The SAS System provides many regression procedures such as the GLM, REG, and NLIN procedures for situations in which you can specify a reasonable parametric model for the regression surface. You can use the LOESS procedure for situations in which you do not know a suitable parametric form of the regression surface. Furthermore, the LOESS procedure is suitable when there are outliers in the data and a robust fitting method is necessary.

The main features of the LOESS procedure are as follows:

- fits nonparametric models
- supports the use of multidimensional data
- supports multiple dependent variables
- supports both direct and interpolated fitting that uses k -d trees
- performs statistical inference
- performs automatic smoothing parameter selection
- performs iterative reweighting to provide robust fitting when there are outliers in the data
- produces graphs with ODS Graphics

Local Regression and the Loess Method

Assume that for $i = 1$ to n , the i th measurement y_i of the response y and the corresponding measurement x_i of the vector \mathbf{x} of p predictors are related by

$$y_i = g(x_i) + \epsilon_i$$

where g is the regression function and ϵ_i is a random error. The idea of local regression is that at a predictor \mathbf{x} , the regression function $g(\mathbf{x})$ can be locally approximated by the value of a function in some specified parametric class. Such a local approximation is obtained by fitting a regression surface to the data points within a chosen neighborhood of the point x_i .

In the loess method, weighted least squares is used to fit linear or quadratic functions of the predictors at the centers of neighborhoods. The radius of each neighborhood is chosen so that the neighborhood contains a specified percentage of the data points. The fraction of the data, called the *smoothing parameter*, in each local neighborhood controls the smoothness of the estimated surface. Data points in a given local neighborhood are weighted by a smooth decreasing function of their distance from the center of the neighborhood.

In a direct implementation, such fitting is done at each point at which the regression surface is to be estimated. A much faster computational procedure is to perform such local fitting at a selected sample of points in predictor space and then to blend these local polynomials to obtain a regression surface.

You can use the LOESS procedure to perform statistical inference provided that the error distribution satisfies some basic assumptions. In particular, such analysis is appropriate when the ϵ_i are iid normal random variables with mean 0. By using the iterative reweighting, the LOESS procedure can also provide statistical inference when the error distribution is symmetric but not necessarily normal. Furthermore, by doing iterative reweighting, you can use the LOESS procedure to perform robust fitting in the presence of outliers in the data.

While all output of the LOESS procedure can be optionally displayed, most often the LOESS procedure is used to produce output data sets that will be viewed and manipulated by other SAS procedures. PROC LOESS uses the Output Delivery System (ODS) to place results in output data sets. Alternatively, PROC LOESS also provides an OUTPUT statement to create SAS data sets from analysis results.

Getting Started: LOESS Procedure

Scatter Plot Smoothing

The following data from the Connecticut Tumor Registry presents age-adjusted numbers of melanoma incidences per 100,000 people for the 37 years from 1936 to 1972 (Houghton, Flannery, and Viola 1980).

```
data Melanoma;
  input Year Incidences @@;
  format Year d4.0;
  datalines;
1936 0.9 1937 0.8 1938 0.8 1939 1.3
1940 1.4 1941 1.2 1942 1.7 1943 1.8
1944 1.6 1945 1.5 1946 1.5 1947 2.0
1948 2.5 1949 2.7 1950 2.9 1951 2.5
1952 3.1 1953 2.4 1954 2.2 1955 2.9
1956 2.5 1957 2.6 1958 3.2 1959 3.8
1960 4.2 1961 3.9 1962 3.7 1963 3.3
1964 3.7 1965 3.9 1966 4.1 1967 3.8
1968 4.7 1969 4.4 1970 4.8 1971 4.8
1972 4.8
;
```

The following PROC SGPLOT statements produce the simple scatter plot of these data displayed in [Figure 53.1](#).

```
proc sgplot data=Melanoma;
  scatter y=Incidences x=Year;
run;
```

Figure 53.1 Scatter Plot of the Melanoma Data

Suppose that you want to smooth the response variable `Incidence`s as a function of the variable `Year`. The following PROC LOESS statements request this analysis with the default settings:

```
ods graphics on;

proc loess data=Melanoma;
  model Incidence=Year;
run;
```

You use the PROC LOESS statement to invoke the procedure and specify the data set. The MODEL statement names the dependent and independent variables.

Figure 53.2 Default Loess Fit for the Melanoma Data

When ODS Graphics is enabled, PROC LOESS produces several default plots. [Figure 53.2](#) shows the “Fit Plot” that overlays the loess fit on a scatter plot of the data. You can see that the loess fit captures the increasing trend in the data as well as the periodic pattern in the data, which is related to an 11-year sunspot activity cycle.

Figure 53.3 Fit Summary

The LOESS Procedure	
Selected Smoothing Parameter: 0.257	
Dependent Variable: Incidences	
Fit Summary	
Fit Method	kd Tree
Blending	Linear
Number of Observations	37
Number of Fitting Points	37
kd Tree Bucket Size	1
Degree of Local Polynomials	1
Smoothing Parameter	0.25676
Points in Local Neighborhood	9
Residual Sum of Squares	2.03105
Trace[L]	8.62243
GCV	0.00252
AICC	-1.17277

Figure 53.3 shows the “Fit Summary” table. This table details the settings used and provides statistics about the fit that is produced. You can see that smoothing parameter value for this loess fit is 0.257. This smoothing parameter determines the fraction of the data in each local neighborhood. In this example, there are 37 data points and so the smoothing parameter value of 0.257 yields local neighborhoods containing 9 observations.

Figure 53.4 Smoothing Parameter Selection

Optimal Smoothing Criterion	
AICC	Smoothing Parameter
-1.17277	0.25676

The “Smoothing Criterion” table provides information about how this smoothing parameter value is selected. The default method implemented in PROC LOESS chooses the smoothing parameter that minimizes the AICC criterion (Hurvich, Simonoff, and Tsai 1998) that strikes a balance between the residual sum of squares and the complexity of the fit.

You use options in the MODEL statement to change the default settings and request optionally displayed tables. For example, the following statements request that the “Model Summary” and “Output Statistics” tables be included in the displayed output. By default, these tables are not displayed.

```
proc loess data=Melanoma;
  model Incidences=Year / details(ModelSummary OutputStatistics);
run;
```

Figure 53.5 Model Summary Table

The LOESS Procedure				
Dependent Variable: Incidences				
Model Summary				
Smoothing Parameter	Local Points	Residual SS	GCV	AICC
0.41892	15	3.42229	0.00339	-0.96252
0.68919	25	4.05838	0.00359	-0.93459
0.31081	11	2.51054	0.00279	-1.12034
0.20270	7	1.58513	0.00239	-1.12221
0.17568	6	1.56896	0.00241	-1.09706
0.28378	10	2.50487	0.00282	-1.10402
0.20270	7	1.58513	0.00239	-1.12221
0.25676	9	2.03105	0.00252	-1.17277
0.22973	8	2.02965	0.00256	-1.15145
0.25676	9	2.03105	0.00252	-1.17277

The “Model Summary” table shown in [Figure 53.5](#) provides information about all the models that PROC LOESS evaluated in choosing the smoothing parameter value.

Figure 53.6 AICC Criterion by Smoothing Parameter

Figure 53.6 shows the “Criterion Plot” that provides a graphical display of the smoothing parameter selection process.

Figure 53.7 Output Statistics

The LOESS Procedure				
Selected Smoothing Parameter: 0.257				
Dependent Variable: Incidences				
Output Statistics				
Obs	Year	Incidences	Predicted Incidences	Residual
1	1936	0.90000	0.76235	0.13765
2	1937	0.80000	0.88992	-0.08992
3	1938	0.80000	1.01764	-0.21764
4	1939	1.30000	1.14303	0.15697
5	1940	1.40000	1.28654	0.11346
6	1941	1.20000	1.44528	-0.24528
7	1942	1.70000	1.53482	0.16518
8	1943	1.80000	1.57895	0.22105
9	1944	1.60000	1.62058	-0.02058
10	1945	1.50000	1.68627	-0.18627
11	1946	1.50000	1.82449	-0.32449
12	1947	2.00000	2.04976	-0.04976
13	1948	2.50000	2.30981	0.19019
14	1949	2.70000	2.53653	0.16347
15	1950	2.90000	2.68921	0.21079
16	1951	2.50000	2.70779	-0.20779
17	1952	3.10000	2.64837	0.45163
18	1953	2.40000	2.61468	-0.21468
19	1954	2.20000	2.58792	-0.38792
20	1955	2.90000	2.57877	0.32123
21	1956	2.50000	2.71078	-0.21078
22	1957	2.60000	2.96981	-0.36981
23	1958	3.20000	3.26005	-0.06005
24	1959	3.80000	3.54143	0.25857
25	1960	4.20000	3.73482	0.46518
26	1961	3.90000	3.78186	0.11814
27	1962	3.70000	3.74362	-0.04362
28	1963	3.30000	3.70904	-0.40904
29	1964	3.70000	3.72917	-0.02917
30	1965	3.90000	3.82382	0.07618
31	1966	4.10000	4.00515	0.09485
32	1967	3.80000	4.18573	-0.38573
33	1968	4.70000	4.35152	0.34848
34	1969	4.40000	4.50284	-0.10284
35	1970	4.80000	4.64413	0.15587
36	1971	4.80000	4.78291	0.01709
37	1972	4.80000	4.91602	-0.11602

Figure 53.7 show the “Output Statistics” table that contains the predicted loess fit value at each observation in the input data set.

Although the default method for selecting the smoothing parameter value is often satisfactory, it is often a good practice to examine how the loess fit varies with the smoothing parameter. In some cases, fits with different smoothing parameters might reveal important features of the data that cannot be discerned by looking at a fit with just a single “best” smoothing parameter. [Example 53.4](#) provides such an example.

You can produce the loess fits for a range of smoothing parameters by using the `SMOOTH=` option in the `MODEL` statement as follows:

```
proc loess data=Melanoma;
  model Incidences=Year/smooth=0.1 0.25 0.4 0.6 residual;
  ods output OutputStatistics=Results;
run;
```

The `RESIDUAL` option causes the residuals to be added to the “Output Statistics” table. Note that, even if you do not specify the `DETAILS` option in the `MODEL` statement to request the display of the “Output Statistics” table, you can use an `ODS OUTPUT` statement to output this and other optionally displayed tables as data sets.

`PROC PRINT` displays the first five observations of the Results data set:

```
proc print data=Results (obs=5);
  id obs;
run;
```

Figure 53.8 PROC PRINT Output of the Results Data Set

Obs	Smoothing Parameter	Year	Dep Var	Pred	Residual
1	0.1	1936	0.9	0.90000	0
2	0.1	1937	0.8	0.80000	0
3	0.1	1938	0.8	0.80000	0
4	0.1	1939	1.3	1.30000	0
5	0.1	1940	1.4	1.40000	0

Note that the fits for all the smoothing parameters are placed in single data set. A variable named `SmoothingParameter` that you use to distinguish each fit is included in this data set.

When you specify a list of smoothing parameters for a model and `ODS Graphics` is enabled, `PROC LOESS` produces a panel containing up to six plots that show the fit obtained for each value of the smoothing parameter that you specify. If you specify more than six smoothing values, then multiple panels are produced. For each regressor, `PROC LOESS` also produces panels of the residuals versus each regressor by the smoothing parameters that you specify.

Figure 53.9 Loess Fits for a Range of Smoothing Parameters

If you examine the plots in [Figure 53.9](#), you see that a visually reasonable fit is obtained with smoothing parameter values of 0.25. With smoothing parameter value 0.1, there is gross overfitting in the sense that the original data are exactly interpolated. When the smoothing parameter value is 0.4, you obtain an overly smooth fit where the contribution of the sunspot cycle has been mostly averaged away. At smoothing parameter value 0.6 the fit shows just the increasing trend in the data.

It is also instructive to look at scatter plots of the residuals for each of the fits. These are also produced by default by PROC LOESS when ODS Graphics is enabled.

Figure 53.10 Residuals of Loess Fits for a Range of Smoothing Parameters

Figure 53.10 shows a scatter plot of the residuals by year for each smoothing parameter value. One way to discern patterns in these residuals is to superimpose a loess fit on each plot in the panel. You request loess fits on the residual plots in this panel by specifying the `SMOOTH=` suboption of the `PLOTS=RESIDUALSBYSMOOTH` option in the `PROC LOESS` statement. Note that the loess fits that are displayed on each of the residual plots are obtained independently of the loess fit that produces these residuals. The following statements show how you do this for the Melanoma data.

```
proc loess data=Melanoma plots=ResidualsBySmooth(smooth);
  model Incidences=Year/smooth=0.1 0.25 0.4 0.6;
run;
```

Figure 53.11 Residuals with Superimposed Loess Fits

The loess fits shown on the plots in [Figure 53.11](#) help confirm the conclusions obtained when you look at [Figure 53.9](#). Note that residuals for smoothing parameter value 0.25 do not exhibit any pattern, confirming that at this value the loess fit of the melanoma data has successfully modeled the variation in this data. By contrast, the residuals for the fit with smoothing parameter 0.6 retain the variation caused by the sunspot cycle.

The examination of the fits and residuals obtained with a range of smoothing parameter values confirms that the value of 0.257 that PROC LOESS selects automatically is appropriate for these data. The next step in this analysis is to examine fit diagnostics and produce confidence limit for the fit. If ODS Graphics is enabled, then a panel of fit diagnostics is produced. Furthermore, you can request prediction confidence limits by adding the CLM option in the **MODEL** statement. By default 95% limits are produced, but you can use the ALPHA= option in the **MODEL** statement to change the significance level. The following statements request 90% confidence limits.

```
proc loess data=Melanoma;
  model Incidences=Year/clm alpha=0.1;
run;

ods graphics off;
```

Figure 53.12 Fit Diagnostics

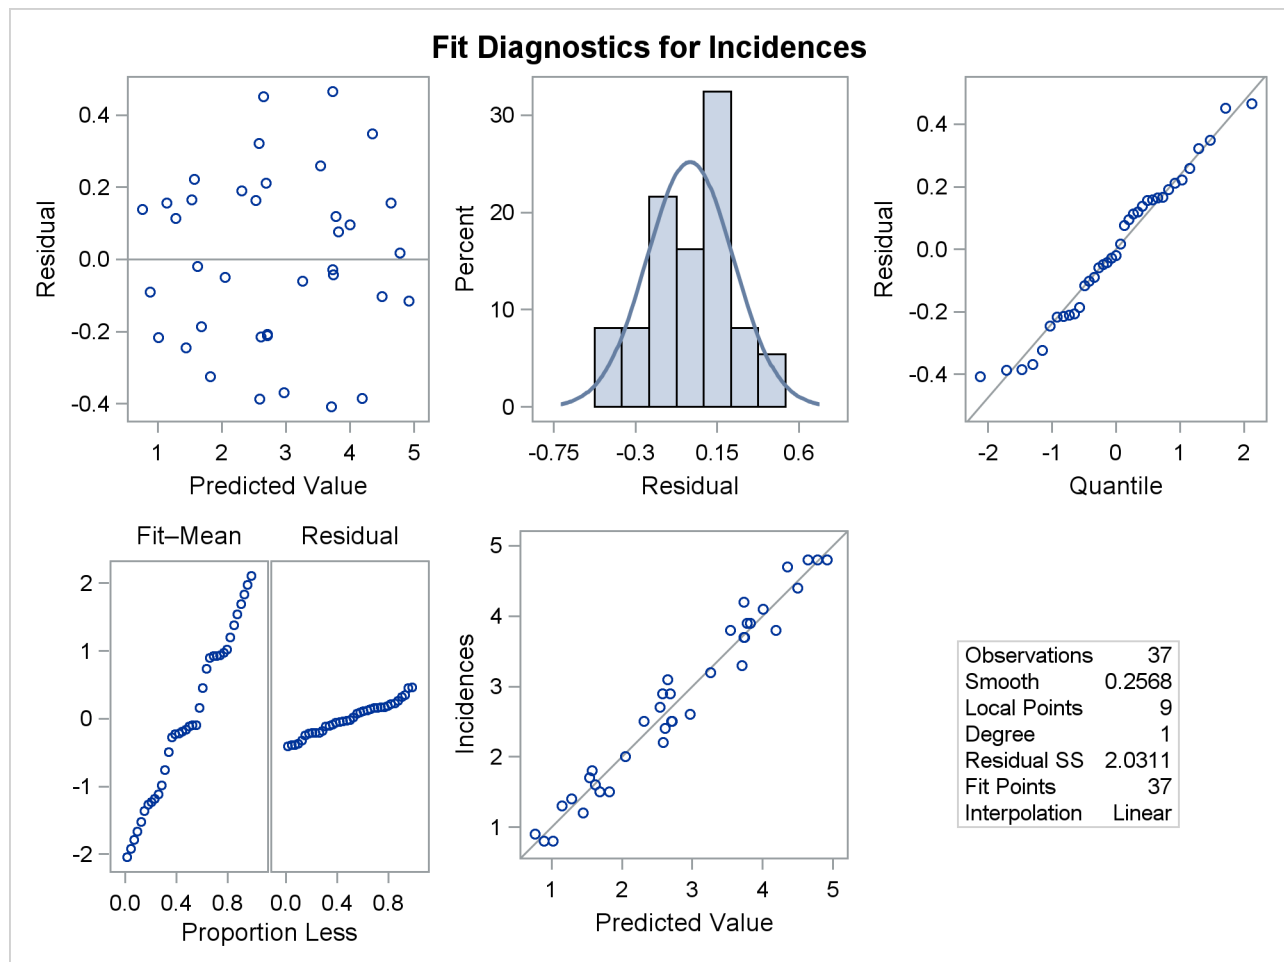

Figure 53.12 shows the fit diagnostics panel. The histogram of the residuals with overlaid normal density estimator and the normal quantile plot show that the residuals do exhibit some small departure from normality. The “Residual-Fit” spread plot shows that the spread in the centered fit is much wider than the spread in the residuals. This indicates that the fit has accounted for most of the variation in the incidences of melanoma in this data. This conclusion is supported by the absence of any clear pattern in the scatter plot of residuals by predicted values and the closeness of the points to the 45-degree reference line in the plot of observed by predicted values.

Figure 53.13 Loess Fit of Melanoma Data with 90% Confidence Limits

Finally, Figure 53.13 shows the selected loess fit with 90% confidence limits.

Syntax: LOESS Procedure

The following statements are available in the LOESS procedure:

```

PROC LOESS <DATA=SAS-data-set> ;
  MODEL dependents = regressors </ options> ;
  OUTPUT <OUT=SAS-data-set> <keyword <=name>> <... keyword <=name>> </ options> ;
  ID variables ;
  BY variables ;
  WEIGHT variable ;
  SCORE DATA=SAS-data-set <ID=(variable-list)> </ options> ;

```

The PROC LOESS and MODEL statements are required. The OUTPUT, BY, WEIGHT, and ID statements are optional. The SCORE statement is optional, and more than one SCORE statement can be used.

The statements used with the LOESS procedure, in addition to the PROC LOESS statement, are as follows.

BY	specifies variables to define subgroups for the analysis.
ID	names variables to identify observations in the displayed output.
MODEL	specifies the dependent and independent variables in the loess model, details and parameters for the computational algorithm, and the required output.
OUTPUT	creates an output data set containing predicted values, residuals, and results of statistical inference.
SCORE	specifies a data set containing observations to be scored.
WEIGHT	declares a variable to weight observations.

PROC LOESS Statement

PROC LOESS < options > ;

The PROC LOESS statement invokes the LOESS procedure. The PROC LOESS statement is required. You can specify the following options in the PROC LOESS statement:

DATA=SAS-data-set

names the SAS data set to be used by PROC LOESS. If the DATA= option is not specified, PROC LOESS uses the most recently created SAS data set.

PLOTS < (global-plot-options) > < = plot-request < (options) > >

PLOTS < (global-plot-options) > < = (plot-request < (options) > < ... plot-request < (options) > > >

controls the plots produced through ODS Graphics. When you specify only one plot request, you can omit the parentheses around the plot request. Here are some examples:

```
plots=none
plots=residuals(smooth)
plots(unpack)=diagnostics
plots(only)=(fit residualHistogram)
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;

proc loess;
    model y = x;
run;

ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

If ODS Graphics is enabled but you do not specify the PLOTS= option, then PROC LOESS produces a default set of plots. The following table lists the default set of plots produced.

Table 53.1 Default Graphs Produced

Plot	Conditional On
ContourFitPanel	SMOOTH= option specified in the MODEL statement
ContourFit	Model with two regressors
CriterionPlot	Smoothing parameter selection performed
DiagnosticsPanel	Unconditional
ResidualsBySmooth	SMOOTH= option specified in the MODEL statement
ResidualPanel	Unconditional
FitPanel	SMOOTH= option specified in the MODEL statement
FitPlot	Model with one regressor
ScorePlot	One or more SCORE statements and a model with one regressor

For models with multiple dependent variables, separate plots are produced for each dependent variable. For models where multiple smoothing parameters are requested with the SMOOTH= option in the [MODEL](#) statement and smoothing parameter value selection is not requested, separate plots are produced for each smoothing parameter. If smoothing parameter value selection is requested with the SELECT= option in the [MODEL](#) statement, then the plots are produced for the selected model only. However, if you specify the STEPS suboption of the SELECT= option, then plots are produced for all smoothing parameters examined in the selection process.

The *global-plot-options* apply to all relevant plots generated by the LOESS procedure, unless they are overridden with a *specific-plot-option*. The *global-plot-options* supported by the LOESS procedure follow.

Global Plot Options

MAXPOINTS=NONE | *number*

specifies that plots with elements that require processing more than *number* points are suppressed. The default is MAXPOINTS=5000. This cutoff is ignored if you specify MAXPOINTS=NONE.

ONLY

suppresses the default plots. Only the plots specifically requested are produced.

UNPACK

suppresses paneling. By default, multiple plots can appear in some output panels. Specify UNPACK to get each plot individually. You can specify PLOTS(UNPACK) to unpack the default plots. You can also specify UNPACK as a suboption with CONTOURFITPANEL, DIAGNOSTICS, FITPANEL, RESIDUALS and RESIDUALSBYSMOOTH.

Specific Plot Options

The following listing describes the specific plots and their options.

ALL

requests that all plots appropriate for the particular analysis be produced. You can specify other options with ALL; for example, to request all plots and unpack only the residuals, specify PLOTS=(ALL RESIDUALS(UNPACK)).

CONTOURFIT <(contour-options)>

produces a contour plot of the fitted surface overlaid with a scatter plot of the data for models with two regressors. Contour plots are not produced if you specify the **DIRECT** option in the **MODEL** statement. You can use the following *contour-options* to control how the observations are displayed:

OBS=GRADIENT

specifies that observations be displayed as circles colored by the observed response. The same color gradient is used to display the fitted surface and the observations. Observations where the predicted response is close to the observed response have similar colors—the greater the contrast between the color of an observation and the surface, the larger the residual is at that point. **OBS=GRADIENT** is the default if you do not specify any *contour-options*.

OBS=NONE

suppresses the observations.

OBS=OUTLINE

specifies that observations be displayed as circles with a border but with a completely transparent fill.

OBS=OUTLINEGRADIENT

is the same as **OBS=GRADIENT** except that a border is shown around each observation. This option is useful to identify the location of observations where the residuals are small, because at these points the color of the observations and the color of the surface are indistinguishable.

CONTOURFITPANEL <(UNPACK < contour-options >)>

produces panels of contour plots overlaid with a scatter plot of the data for each smoothing parameter specified in the **SMOOTH=** option in the **MODEL** statement, for models with two regressors. This plot is not produced if you specify the **DIRECT** option in the **MODEL** statement. If you do not specify the **SMOOTH=** option or if the model does not have two regressors, then this plot is not produced. If you specify the **SELECT=** option in addition to the **SMOOTH=** option in the **MODEL** statement, then you need to additionally specify the **STEPS** suboption of the **SELECT=** option to obtain this plot. Note that each panel contains at most six plots, and multiple panels are used in the case that there are more than six smoothing parameters in the **SMOOTH=** option in the **MODEL** statement. See the **CONTOURFIT** option for a description of the individual plots in this panel. The **UNPACK** option suppresses paneling, and the *contour-options* are the same as for the **CONTOURFIT** option.

CRITERIONPLOT | **CRITERION**

displays a scatter plot of the value of the **SELECTION=** criterion versus the smoothing parameter value for all smoothing parameter values examined in the selection process. This plot is not produced if smoothing parameter selection is not done.

DIAGNOSTICSPANEL | **DIAGNOSTICS** <(UNPACK)>

produces a summary panel of fit diagnostics consisting of the following:

- residuals versus the predicted values
- histogram of the residuals
- normal quantile plot of the residuals
- a “Residual-Fit” (or RF) plot consisting of side-by-side quantile plots of the centered fit and the residuals.

- dependent variable values versus the predicted values

You can request the five plots in this panel as individual plots by specifying the UNPACK option. You can also request individual plots in the panel by name without having to unpack the panel. Note that the fit diagnostics panel is produced by default whenever ODS Graphics is enabled.

FITPANEL <(UNPACK)>

produces panels of plots showing the fitted LOESS curve overlaid on a scatter plot of the input data for each smoothing parameter specified in the SMOOTH= option in the **MODEL** statement. If you do not specify the SMOOTH= option or the model has more than one regressor, then this plot is not produced. If you specify the SELECT= option in addition to the SMOOTH= option in the **MODEL** statement, then you need to additionally specify the STEPS suboption of the SELECT= option to obtain this plot. Note that each panel contains at most six plots, and multiple panels are used in the case that there are more than six smoothing parameters in the SMOOTH= option in the **MODEL** statement. If the CLM option is specified in the **MODEL** statement, then a confidence band at the significance level specified in the ALPHA= option is included in each plot in the panels. If you specify the UNPACK option, then all fit panels are unpacked.

FITPLOT | FIT

produces a scatter plot of the input data with the fitted LOESS curve overlaid for models with a single regressor. If the CLM option is specified in the **MODEL** statement, then a confidence band at the significance level specified in the ALPHA= option is included in the plot.

NONE

suppresses all plots.

OBSERVEDBYPREDICTED

produces a scatter plot of the dependent variable values by the predicted values.

QQPLOT | QQ

produces a normal quantile plot of the residuals.

RESIDUALSBYSMOOTH <(< UNPACK > < SMOOTH >)>

produces for each regressor panels of plots showing the residuals of the LOESS fit versus the regressor for each smoothing parameter specified in the SMOOTH= option in the **MODEL** statement. If you do not specify the SMOOTH= option, then this plot is not produced. If you specify the SELECT= option in addition to the SMOOTH= option in the **MODEL** statement, then you need to additionally specify the STEPS suboption of the SELECT= option to obtain this plot. Note that each panel contains at most six plots, and multiple panels are used in the case that there are more than six smoothing parameters in the SMOOTH= option in the **MODEL** statement. If you specify the UNPACK option, then all RESIDUALSBYSMOOTH panels are unpacked.

The SMOOTH option requests that a nonparametric fit line be shown in each plot in the panel. The type of nonparametric fit and the options used are controlled by the template that underlies this plot. In the standard template that is provided, the nonparametric smooth is specified to be a loess fit corresponding to the default options of PROC LOESS, except that the PRESEARCH suboption is always used. It is important to note that the loess fit that is shown in each of the residual plots is computed independently of the loess fit that is used to obtain the residuals.

RESIDUALBYPREDICTED

produces a scatter plot of the residuals by the predicted values.

RESIDUALHISTOGRAM

produces a histogram of the residuals.

RESIDUALPANEL | RESIDUALS *<(residual-options)>*

produces panels of the residuals versus the regressors in the model. Note that each panel contains at most six plots, and multiple panels are used when there are more than six regressors in the model.

The following *residual-options* are available:

SMOOTH

requests that a nonparametric fit line be shown in each plot in the panel. The type of nonparametric fit and the options used are controlled by the template that underlies this plot. In the standard template that is provided, the nonparametric smooth is specified to be a loess fit corresponding to the default options of PROC LOESS, except that the PRESEARCH suboption is always used. It is important to note that the loess fit that is shown in each of the residual plots is computed independently of the loess fit that is used to obtain the residuals.

UNPACK

suppresses paneling.

RFPLOT | RF

produces a “Residual-Fit” (or RF) plot consisting of side-by-side quantile plots of the centered fit and the residuals. This plot “shows how much variation in the data is explained by the fit and how much remains in the residuals” (Cleveland 1993).

SCOREPLOT | SCORE

produces a scatter plot of the scored values at the score points for each **SCORE** statement. **SCORE** plots are not produced for models with more than one regressor. If the CLM option is specified in the **MODEL** statement, then confidence bars at the significance level specified in the ALPHA= option are shown at score data points.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC LOESS to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the LOESS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.

- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

ID Statement

ID *variables* ;

The ID statement is optional, and more than one ID statement can be used. The variables listed in any of the ID statements are displayed in the “Output Statistics” table beside each observation. Any variables specified as a regressor or dependent variable in the **MODEL** statement already appear in the “Output Statistics” table and are not treated as ID variables, even if they appear in the variable list of an ID statement.

MODEL Statement

MODEL *dependents = regressors < / options >* ;

The MODEL statement names the dependent variables and the independent variables. Variables specified in the MODEL statement must be numeric variables in the data set being analyzed.

Table 53.2 summarizes the options available in the MODEL statement.

Table 53.2 Summary of MODEL Statement Options

Option	Description
Fit Options	
BUCKET=	specifies the number of points in k -d tree buckets
DEGREE=	specifies the degree of local polynomials (1 or 2)
DFMETHOD=	specifies the method of computing lookup degrees of freedom
DIRECT	specifies direct fitting at every data point
DROPSQUARE=	specifies the variables whose squares are to be dropped from local quadratic polynomials
INTERP=	specifies the interpolating polynomials (linear or cubic)
ITERATIONS=	specifies the number of reweighting iterations
SCALE=	specifies the method used to scale the regressor variables
SELECT=	specifies that automatic smoothing parameter selection be done
SMOOTH=	specifies the list of smoothing values
Output Statistics Table Options	
ALL	requests CLM , RESIDUAL , SCALEDINDEP , STD , and T options
CLM	displays confidence limits for mean predictions
RESIDUAL	displays residuals
SCALEDINDEP	displays scaled independent variable coordinates
STD	displays standard errors of the mean predicted values

Table 53.2 *continued*

Option	Description
T	displays t statistics
Other options	
ALPHA=	sets significance level for confidence intervals
DETAILS=	specifies which tables are to be displayed
TRACEL	displays the trace of the smoothing matrix

The following options are available in the MODEL statement after a slash (/).

ALL

requests all these options: CLM, RESIDUAL, SCALEDINDEP, STD, and T.

ALPHA=number

sets the significance level used for the construction of confidence intervals for the current MODEL statement. The value must be between 0 and 1; the default value of 0.05 results in 95% intervals.

BUCKET=number

specifies the maximum number of points in the leaf nodes of the k -d tree. The default value used is $s * n/5$, where s is a smoothing parameter value specified using the SMOOTH= option and n is the number of observations being used in the current BY group. The BUCKET= option is ignored if the DIRECT option is specified.

CLM

requests that $100(1 - \alpha)\%$ confidence limits on the mean predicted value be added to the “Output Statistics” table. By default, 95% limits are computed; the ALPHA= option in the MODEL statement can be used to change the significance level. The use of this option implicitly selects the model option DFMETHOD=EXACT if the DFMETHOD= option has not been explicitly used.

DEGREE=1 | 2

sets the degree of the local polynomials to use for each local regression. The valid values are 1 for local linear fitting and 2 for local quadratic fitting, with 1 being the default.

DETAILS <(tables)>

selects which tables to display, where *tables* is one or more of the specifications KDTREE, MODEL-SUMMARY, OUTPUTSTATISTICS, and PREDATVERTICES:

- KDTREE displays the k -d tree structure.
- MODELSUMMARY displays the fit criteria for all smoothing parameter values that are specified in the SMOOTH= option in the MODEL statement, or that are fit with automatic smoothing parameter selection.
- OUTPUTSTATISTICS displays the predicted values and other requested statistics at the points in the input data set.
- PREDATVERTICES displays fitted values and coordinates of the k -d tree vertices where the local least squares fitting is done.

The KDTREE and PREDATVERTICES specifications are ignored if the DIRECT option is specified in the MODEL statement. Specifying the option DETAILS with no qualifying list outputs all tables.

DFMETHOD=NONE | EXACT | APPROX <(approx-options)>

specifies the method used to calculate the lookup degrees of freedom used in performing statistical inference. The default is DFMETHOD=NONE, unless you specify any of the MODEL statement options ALL, CLM, STD, and T, or any SCORE statement CLM option, in which case the default is DFMETHOD=EXACT.

You can specify the following *approx-options* in parentheses after the DFMETHOD=APPROX option:

QUANTILE=number

specifies that the smallest 100(*number*)% of the nonzero coefficients in the smoothing matrix be set to zero in computing the approximate lookup degrees of freedom. The default value is QUANTILE=0.9.

CUTOFF=number

specifies that coefficients in the smoothing matrix whose magnitude is less than the specified value be set to zero in computing the approximate lookup degrees of freedom. Using the CUTOFF= option overrides the QUANTILE= option.

See the section “[Sparse and Approximate Degrees of Freedom Computation](#)” on page 4130 for a description of the method used when the DFMETHOD=APPROX option is specified.

DIRECT

specifies that local least squares fits are to be done at every point in the input data set. When the direct option is not specified, a computationally faster method is used. This faster method performs local fitting at vertices of a k -d tree decomposition of the predictor space followed by blending of the local polynomials to obtain a regression surface.

DROPSQUARE=(variables)

specifies the quadratic monomials to exclude from the local quadratic fits. This option is ignored unless the DEGREE=2 option has been specified.

For example,

```
model z=x y / degree=2 dropsquare=(y)
```

uses the monomials 1, x , y , x^2 , and xy in performing the local fitting.

INTERP=LINEAR | CUBIC

specifies the degree of the interpolating polynomials used for blending local polynomial fits at the k -d tree vertices. This option is ignored if the DIRECT option is specified in the model statement. INTERP=CUBIC is not supported for models with more than two regressors. The default is INTERP=LINEAR.

ITERATIONS=number

specifies the total number of iterations to be done. The first iteration performs an initial LOESS fit. Subsequent iterations perform iterative reweighting. Such iterations are appropriate when there are outliers in the data or when the error distribution is a symmetric long-tailed distribution. The default number of iterations is 1.

RESIDUAL | R

specifies that residuals be included in the “Output Statistics” table.

SCALE=NONE | SD < (number) >

specifies the scaling method to be applied to scale the regressors. The default is NONE, in which case no scaling is applied. A specification of SD(*number*) indicates that a trimmed standard deviation is to be used as a measure of scale, where *number* is the trimming fraction. A specification of SD with no qualification defaults to 10% trimmed standard deviation.

SCALEDINDEP

specifies that scaled regressor coordinates be included in the output tables. This option is ignored if the SCALE= model option is not used or if SCALE=NONE is specified.

SELECT=criterion < (<GLOBAL> <PRESEARCH> <STEPS> <RANGE(lower,upper)>) >

SELECT=DFCriterion < (target <GLOBAL> <PRESEARCH> <STEPS> <RANGE(lower,upper)>) >

specifies that automatic smoothing parameter selection be done using the named *criterion* or *DFCriterion*. Valid values for the *criterion* are as follows:

- AICC specifies the AIC_C criterion (Hurvich, Simonoff, and Tsai 1998).
- AICC1 specifies the AIC_{C1} criterion (Hurvich, Simonoff, and Tsai 1998).
- GCV specifies the generalized cross validation criterion (Craven and Wahba 1979).

The *DFCriterion* specifies the measure used to estimate the model degrees of freedom. The measures implemented in PROC LOESS all depend on prediction matrix **L** relating the observed and predicted values of the dependent variable. Valid values for the *DFCriterion* are as follows:

- DF1 specifies Trace(**L**).
- DF2 specifies Trace(**L'****L**).
- DF3 specifies $2\text{Trace}(\mathbf{L}) - \text{Trace}(\mathbf{L}'\mathbf{L})$.

For both types of selection, the smoothing parameter value is selected to yield a minimum of an optimization criterion. If you specify *criterion* as one of AICC, AICC1, or GCV, the optimization criterion is the specified *criterion*. If you specify *DFCriterion* as one of DF1, DF2, or DF3, the optimization criterion is $|DFCriterion - target|$, where *target* is a specified target degree of freedom value. Note that if you specify a *DFCriterion*, then you must also specify a target value. See the section “[Automatic Smoothing Parameter Selection](#)” on page 4127 for definitions and properties of the selection criteria.

The selection is done as follows:

- If you specify the SMOOTH=*value-list* option, then PROC LOESS selects the largest value in this list that yields the global minimum of the specified optimization criterion.
- If you do not specify the SMOOTH= option, then PROC LOESS finds a local minimum of the specified optimization criterion by using a golden section search of values less than or equal to one.

You can specify the following suboptions in parentheses after the specified criterion to alter the behavior of the SELECT= option:

GLOBAL

specifies that a global minimum be found within the range of smoothing parameter values examined. This suboption has no effect if you also specify the SMOOTH= option in the MODEL statement.

PRESEARCH

requests an initial grid search to find a smoothing parameter range within which the subsequent golden section search is done. The initial point in this grid is the smoothing parameter value corresponding to the smallest number of points, n , in the local neighborhoods that yields a fit that does not interpolate all the data points. Subsequent fits with number of local points $n + 1$, $n + 2$, $n + 4$, $n + 8$, ... are evaluated until either the number of local points exceeds the number of fitting points or the SELECT=criterion starts increasing. This suboption is ignored if you additionally specify the GLOBAL suboption of the SELECT= option or if you specify the SMOOTH= option in the MODEL statement. If you additionally specify the RANGE= suboption, then the golden section search is done on the intersection of the range found by this grid search and the range that you specify in the RANGE= suboption. This option is useful for data exhibiting features at multiple scales, because in such cases the SELECT= criterion often has multiple local minima. Using the PRESEARCH option increases the likelihood that the golden section search will find the global minimum of the SELECT= criterion. See [Example 53.4](#) for such an example.

RANGE(lower,upper)

specifies that only smoothing parameter values greater than or equal to *lower* and less than or equal to *upper* be examined.

STEPS

specifies that all models evaluated in the selection process be displayed.

For models with one dependent variable, if you specify neither the SELECT= nor the SMOOTH= options in the MODEL statement, then PROC LOESS uses SELECT=AICC.

The following table summarizes how the smoothing parameter values are chosen for various combinations of the SMOOTH= option, the SELECT= option, and the SELECT= option modifiers.

Table 53.3 Smoothing Parameter Value(s) Used for Combinations of SMOOTH= and SELECT= OPTIONS for Models with One Dependent Variable

Syntax	Search Method	Search Domain
<i>default</i>	golden section using AICC	(0, 1]
SMOOTH= <i>list</i>	no selection	values in <i>list</i>
SMOOTH= <i>list</i> SELECT= <i>criterion</i>	global	values in <i>list</i>
SMOOTH= <i>list</i> SELECT= <i>criterion</i> (RANGE(<i>l</i> , <i>u</i>))	global	values in <i>list</i> within [<i>l</i> , <i>u</i>]
SELECT= <i>criterion</i>	golden section	(0, 1]
SELECT= <i>criterion</i> (RANGE(<i>l</i> , <i>u</i>))	golden section	[<i>l</i> , <i>u</i>]
SELECT= <i>criterion</i> (GLOBAL)	global	(0, 1]
SELECT= <i>criterion</i> (GLOBAL RANGE(<i>l</i> , <i>u</i>))	global	[<i>l</i> , <i>u</i>]

Some examples of using the SELECT= option follow:

SELECT=GCV	specifies selection that uses the GCV <i>criterion</i> .
SELECT=DF1(6.3)	specifies selection that uses the DF1 <i>DFCriterion</i> with target value 6.3.
SELECT=AICC(STEPS)	specifies selection that uses the AICC <i>criterion</i> , showing all step details.
SELECT=DF2(7 GLOBAL)	specifies selection that uses a global search algorithm to find the smoothing parameter that yields the DF2 <i>DFCriterion</i> closest to the target value 7.

NOTE: The SELECT= option cannot be used for models with more than one dependent variable.

SMOOTH=value-list

specifies a list of positive smoothing parameter values. If you do not specify the SELECT= option in the MODEL statement, then a separate fit is obtained for each SMOOTH= value specified. If you do specify the SELECT= option, then models with all values specified in the SMOOTH= list are examined, and PROC LOESS selects the value that minimizes the criterion specified in the SELECT= option.

For models with two or more dependent variables, if the SMOOTH= option is not specified in the MODEL statement, then SMOOTH=0.5 is used as a default.

STD

specifies that standard errors of the mean predicted values be included in the “Output Statistics” table. The use of this option implicitly selects the model option DFMETHOD=EXACT if the DFMETHOD= option has not been explicitly used.

T

specifies that *t* statistics are to be included in the “Output Statistics” table. The use of this option implicitly selects the model option DFMETHOD=EXACT if the DFMETHOD= option has not been explicitly used.

TRACEL

specifies that the trace of the prediction matrix as well as the GCV and AICC statistics be included in the “Fit Summary” table. The use of any of the MODEL statement options ALL, CLM, DFMETHOD=EXACT, DIRECT, SELECT=, STD, and T implicitly selects the TRACEL option.

OUTPUT Statement

OUTPUT <OUT= SAS-data-set> <keyword <= name>> <... keyword <=name>> </ options> ;

The OUTPUT statement creates a new SAS data set that saves the predicted values and other requested statistics that are calculated after models for all smoothing parameter values that are specified in the SMOOTH= option in the MODEL statement have been fit. If you do not specify a *keyword*, then only the predicted response is included.

All the variables in the original data set are included in the new data set, along with variables created by the OUTPUT statement. These new variables contain the predicted values and a variety of other statistics that are calculated for each observation in the data set.

If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

You can specify the following *options* in the OUTPUT statement:

OUT=SAS data set

specifies the name of the new data set. By default, the procedure uses the *DATA_n* convention to name the new data set.

keyword <=name>

specifies the statistics to include in the output data set as new variables and optionally names the new variables. Specify a keyword for each desired statistic (see the following list of keywords), followed optionally by an equal sign and a variable to contain the statistic.

The new variables are named as follows: If you specify *keyword=name*, the new variable has the specified *name*. If you omit the optional *=name* after a *keyword*, then the new variable name is formed by using a default character string that identifies the statistic. In either case, if you also specify the ROWWISE option after a slash and you specify more than one dependent variable or smoothing value in the MODEL statement, the variable name is appended with an order number. For details, see the ROWWISE option.

The keywords allowed and the statistics they represent are as follows:

PREDICTED P	creates a new variable that contains predicted values. The default <i>name</i> is Predicted.
RESIDUAL R	creates a new variable that contains residual values, which are calculated as ACTUAL – PREDICTED. The default <i>name</i> is Residual.
STD	creates a new variable that contains standard errors of the mean predicted values. The use of this option implicitly selects the model option DFMETHOD=EXACT even if the DFMETHOD= option has not been explicitly used. The default <i>name</i> is StdErr.
T	creates a new variable that contains <i>t</i> statistics. The use of this option implicitly selects the model option DFMETHOD=EXACT even if the DFMETHOD= option has not been explicitly used. The default <i>name</i> is tValue.
LCLM	creates a new variable that contains the lower part of $100(1 - \alpha)\%$ confidence limits on the mean predicted value. By default, the 95% limits are computed; the ALPHA= option in the MODEL statement can be used to change the significance level. The use of this option implicitly selects the model option DFMETHOD=EXACT even if the DFMETHOD= option has not been explicitly used. The default <i>name</i> is LowerCL.
UCLM	creates a new variable that contains the upper part of $100(1 - \alpha)\%$ confidence limits on the mean predicted value. By default, the 95% limits are computed; the ALPHA= option in the MODEL statement can be used to change the significance level. The use of this option implicitly selects the model option DFMETHOD=EXACT even if the DFMETHOD= option has not been explicitly used. The default <i>name</i> is UpperCL.

You can specify the following *options* in the OUTPUT statement after a slash (/).

ALL

requests all these keywords: PREDICTED, RESIDUAL, STD, T, LCLM, and UCLM.

ROWWISE | ROW

arranges the created OUTPUT data set in rowwise format. For each dependent variable and each smoothing value specified in the SMOOTH= option in the MODEL statement, one variable is generated for each specified keyword and the variable name is appended with an order number if there are multiple occurrences of the requested statistic. Those variables appear in an order that corresponds to the specified order of the dependent variables and the smoothing values in the MODEL statement. For each variable generated, a label is also created automatically; the label contains the default name of the represented statistic, the name of the dependent variable selected to be modeled, and the smoothing value used for calculating the represented statistic.

By default, the OUTPUT data set is created in columnwise format, where the input data is repeated for each dependent variable and for each smoothing value. Three extra columns, named SmoothingParameter for smoothing parameter values, DepVar for dependent variable names, and Obs for observation numbers, are also added to the OUTPUT data set to distinguish each model.

SCORE Statement

SCORE DATA=SAS-data-set < ID=(variable-list) > < / options > ;

The fitted loess model is used to score the data in the specified SAS data set. This data set must contain all the regressor variables specified in the **MODEL** statement. Furthermore, when a **BY** statement is used, the score data set must also contain all the BY variables sorted in the order of the BY variables. A SCORE statement is optional, and more than one SCORE statement can be used. SCORE statements cannot be used if the **DIRECT** option is specified in the **MODEL** statement. The optional ID= (variable-list) specifies ID variables to be included in the “Score Results” table.

You find the results of the SCORE statement in the “Score Results” table. This table contains all the data in the data set named in the SCORE statement, including observations with missing values. However, only those observations with nonmissing regressor variables are scored. If no data set is named in the SCORE statement, the data set named in the **PROC LOESS** statement is scored. You use the **PRINT** option in the SCORE statement to request that the “Score Results” table be displayed. You can place the “Score Results” table in an output data set by using an ODS OUTPUT statement even if this table is not displayed.

You can specify the following *options* in the SCORE statement after a slash (/).

CLM

requests that $100(1 - \alpha)\%$ confidence limits on the mean predicted value be added to the “Score Results” table. By default the 95% limits are computed; the ALPHA= option in the **MODEL** statement can be used to change the significance level. The use of this option implicitly selects the model option **DFMETHOD=EXACT** if the **DFMETHOD=** option has not been explicitly used.

PRINT <(VAR=variables) >

specifies that the “Score Results” table be displayed. By default only the variables named in the **MODEL** statement, the variables listed in the ID list in the SCORE statement, and the scored dependent variables are displayed. You can use the VAR= option to specify additional variables in the score data set that are to be included in the displayed output. Note, however, that all columns in the SCORE

data set are placed in the SCORE results table, even if you do not request that they be included in the displayed output.

RESIDUAL | R

requests that residuals be added to the “Score Results” table. If the data set you specify in DATA= option in the SCORE statement does not contain one or more of the model dependent variables, then the corresponding residual values in the “Score Results” table are set to missing.

SCALEDINDEP

specifies that scaled regressor coordinates be included in the “Score Results” table. This option is ignored if the SCALE= option is not specified in the [MODEL](#) statement.

STEPS

requests that all models evaluated during smoothing parameter value selection be scored, provided that the SELECT= option together with the STEPS modifier is specified in the [MODEL](#) statement. By default only the selected model is scored.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement specifies a variable in the input data set that contains values to be used as a priori weights for a loess fit.

The values of the weight variable must be nonnegative. If an observation’s weight is zero, negative, or missing, the observation is deleted from the analysis.

Details: LOESS Procedure

Missing Values

PROC LOESS deletes any observation with missing values for any variable specified in the [MODEL](#) statement. This enables the procedure to reuse the k -d tree for all the dependent variables that appear in the [MODEL](#) statement. If you have multiple dependent variables with different missing value structures for the same set of independent variables, you might want to use separate PROC LOESS steps for each dependent variable.

Output Data Sets

PROC LOESS assigns a name to each table it creates. You can use the ODS OUTPUT statement to place one or more of these tables in output data sets. See the section “[ODS Table Names](#)” on page 4131 for a list of the table names created by PROC LOESS. For detailed information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

For example, the following statements create an output data set named `MyOutStats` containing the “Output Statistics” table and an output data set named `MySummary` containing the “Fit Summary” table.

```
proc loess data=Melanoma;
  model Incidences=Year;
  ods output OutputStatistics = MyOutStats
             FitSummary      = MySummary;
run;
```

Often, a single `MODEL` statement describes more than one model. For example, the following statements fit eight different models (four smoothing parameter values for each dependent variable).

```
proc loess;
  model y1 y2 = x1 x2 x3/smooth =0.1 to 0.7 by 0.2;
  ods output OutputStatistics = MyOutStats;
run;
```

The eight “Output Statistics” tables for these models are stacked in a single data set called `MyOutStats`. The data set contains a column named `DepVarName` and a column named `SmoothingParameter` that distinguish each model (see [Figure 53.8](#) for an example). If you want the “Output Statistics” table for each model to be in its own data set, you can use the `MATCH_ALL` option in the `ODS OUTPUT` statement. The following statements create eight data sets named `MyOutStats`, `MyOutStats1`, ..., `MyOutStats7`.

```
proc loess;
  model y1 y2 = x1 x2 x3/smooth =0.1 to 0.7 by 0.2;
  ods output OutputStatistics(match_all) = MyOutStats;
run;
```

For further options available in the `ODS OUTPUT` statement, see Chapter 20, “[Using the Output Delivery System](#).”

Only the “Scale Details” and “Fit Summary” tables are displayed by default. The other tables are optionally displayed by using the `DETAILS` option in the `MODEL` statement and the `PRINT` option in the `SCORE` statement. Note that it is not necessary to display a table in order for that table to be used in an `ODS OUTPUT` statement. For example, the following statements display the “Output Statistics” and “*k*-d Tree” tables but place the “Output Statistics” and “Prediction at Vertices” tables in output data sets.

```
proc loess data=Melanoma;
  model Incidences=Year/details(OutputStatistics kdTree);
  ods output OutputStatistics = MyOutStats
             PredAtVertices   = MyVerticesOut;
run;
```

Using the `DETAILS` option alone causes all tables to be displayed.

The `MODEL` statement options `CLM`, `RESIDUAL`, `STD`, `SCALEDINDEP`, and `T` control which optional columns are added to the `OutputStatistics` table. For example, to obtain an `OutputStatistics` output data set containing residuals and confidence limits in addition to the model variables and predicted value, you need to specify the `RESIDUAL` and `CLM` options in the `MODEL` statement as in the following example:

```
proc loess data=Melanoma;
  model Incidences=Year/residual clm;
  ods output OutputStatistics = MyOutStats;
run;
```

Finally, note that using the ALL option in the **MODEL** statement causes all optional columns to be included in the output. Also, ID columns can be added to the OutputStatistics table by using the **ID** statement.

Data Scaling

The loess algorithm to obtain a predicted value at a given point in the predictor space proceeds by doing a least squares fit that uses all data points close to the given point. Thus the algorithm depends critically on the metric used to define closeness. This has the consequence that if you have more than one predictor variable and these predictor variables have significantly different scales, then closeness depends almost entirely on the variable with the largest scaling. It also means that merely changing the units of one of your predictors can significantly change the loess model fit.

To circumvent this problem, it is necessary to standardize the scale of the independent variables in the loess model. The **SCALE=** option in the **MODEL** statement is provided for this purpose. PROC LOESS uses a symmetrically trimmed standard deviation as the scale estimate for each independent variable of the loess model. This is a robust scale estimator in that extreme values of a variable are discarded before estimating the data scaling. For example, to compute a 10% trimmed standard deviation of a sample, you discard the smallest and largest 5% of the data and compute the standard deviation of the remaining 90% of the data points. In this case, the trimming fraction is 0.1.

For example, the following statement specifies that the variables **Temperature** and **Catalyst** are scaled before performing the loess fitting. In this case, because the trimming fraction is 0.1, the scale estimate used for each of these variables is a 10% trimmed standard deviation.

```
model Yield=Temperature Catalyst / scale = SD(0.1);
```

The default trimming fraction used by PROC LOESS is 0.1 and need not be specified by the **SCALE=** option. Thus the following **MODEL** statement is equivalent to the previous **MODEL** statement.

```
model Yield=Temperature Catalyst / scale = SD;
```

If the **SCALE=** option is not specified, no scaling of the independent variables is done. This is appropriate when there is only a single independent variable or when all the independent variables are a priori scaled similarly.

When the **SCALE=** option is specified, the scaling details for each independent variable are added to the **ScaleDetails** table (see [Output 53.3.2](#) for an example). By default, this table contains only the minimum and maximum values of each independent variable in the model. Finally, note that when the **SCALE=** option is used, specifying the **SCALEDINDEP** option in the **MODEL** statement adds the scaled values of the independent variables to the **OutputStatistics** and **PredAtVertices** tables. If the **SCALEDINDEP** option is specified in the **SCORE** statement, then scaled values of the independent variables are included in the **ScoreResults** table. By default, only the unscaled values are placed in these tables.

Direct versus Interpolated Fitting

Local regression to obtain a predicted value at a given point in the predictor space is done by doing a least squares fit that uses all data points in a local neighborhood of the given point. This method is computationally expensive because a local neighborhood must be determined and a least squares problem must be solved for each point at which a fitted value is required. A faster method is to obtain such fits at a representative sample of points in the predictor space and to obtain fitted values at all other points by interpolation.

PROC LOESS can fit models by using either of these two methods. By default, PROC LOESS uses fitting at a sample of points and interpolation. The method fitting a local model at every data point is selected by specifying the **DIRECT** option in the **MODEL** statement.

k-d Trees and Blending

PROC LOESS uses a *k*-d tree to divide the box (also called the *initial cell* or *bucket*) enclosing all the predictor data points into rectangular cells. The vertices of these cells are the points at which local least squares fitting is done.

Starting from the initial cell, the direction of the longest cell edge is selected as the split direction. The median of this coordinate of the data in the cell is the split value. The data in the starting cell are partitioned into two child cells. The left child consists of all data from the parent cell whose coordinate in the split direction is less than the split value. This procedure is repeated for each child cell that has more than a prespecified number of points, called the *bucket size* of the *k*-d tree.

You can specify the bucket size with the **BUCKET=** option in the **MODEL** statement. If you do not specify the **BUCKET=** option, the default value used is the largest integer less than or equal to $ns/5$, where n is the number of observations and s is the value of the smoothing parameter. Note that if fitting is being done for a range of smoothing parameter values, the bucket size can change for each value.

The set of vertices of all the cells of the *k*-d tree are the points at which PROC LOESS performs its local fitting. The fitted value at an original data point (or at any other point within the original data cell) is obtained by blending the fitted values at the vertices of the *k*-d tree cell that contains that data point.

The univariate blending methods available in PROC LOESS are linear and cubic polynomial interpolation, with linear interpolation being the default. You can request cubic interpolation by specifying the **INTERP=CUBIC** option in the **MODEL** statement. In this case, PROC LOESS uses the unique cubic polynomial whose values and first derivatives match those of the fitted local polynomials evaluated at the two endpoints of the *k*-d tree cell edge.

In the multivariate case, such univariate interpolating polynomials are computed on each edge of the *k*-d tree cells and are combined using blending functions (Gordon 1971). In the case of two regressors, if you specify **INTERP=CUBIC** in the **MODEL** statement, PROC LOESS uses Hermite cubic polynomials as blending functions. If you do not specify **INTERP=CUBIC**, or if you specify a model with more than two regressors, then PROC LOESS uses linear polynomials as blending functions. In these cases, the blending method reduces to tensor product interpolation from the 2^p vertices of each *k*-d tree cell, where p is the number of regressors.

While the details of the *k*-d tree and the fitted values at the vertices of the *k*-d tree are implementation details that seldom need to be examined, PROC LOESS does provide options for their display. Each *k*-d tree subdivision of the data used by PROC LOESS is placed in the “kdTree” table. The predicted values at

the vertices of each k -d tree are placed in the “PredAtVertices” table. You can request these tables by using the DETAILS option in the MODEL statement.

Local Weighting

The size of the local neighborhoods that PROC LOESS uses in performing local fitting is determined by the smoothing parameter value s . When $s < 1$, the local neighborhood used at a point x_i contains the s fraction of the data points closest to the point x_i . When $s \geq 1$, all data points are used.

Suppose q denotes the number of points in the local neighborhoods and d_1, d_2, \dots, d_q denote the distances in increasing order of the q points closest to x_i . The point at distance d_i from x_i is given a weight w_i in the local regression that decreases as the distance from x_i increases. PROC LOESS uses a tricube weight function to define

$$w_i = \frac{32}{5} \left(1 - \left(\frac{d_i}{d_q} \right)^3 \right)^3$$

If $s > 1$, then d_q is replaced by $d_q s^{1/p}$ in the previous formula, where p is the number of predictors in the model.

Finally, note that if a weight variable has been specified using a **WEIGHT** statement, then w_i is multiplied by the corresponding value of the specified weight variable.

Iterative Reweighting

PROC LOESS can do iterative reweighting to improve the robustness of the fit in the presence of outliers in the data. Iterative reweighting is also appropriate when statistical inference is requested and the error distribution is symmetric but not Gaussian.

The number of iterations is specified by the ITERATIONS= option in the **MODEL** statement. The default is ITERATIONS=1, which corresponds to no reweighting.

At iterations beyond the first iteration, the local weights w_i of the previous section are replaced by $r_i w_i$, where r_i is a weight that decreases as the residual of the fitted value at the previous iteration at the point corresponding to d_i increases. See Cleveland and Grosse (1991) and Cleveland, Grosse, and Shyu (1992) for details.

Specifying the Local Polynomials

PROC LOESS uses linear or quadratic polynomials in doing the local least squares fitting. The option DEGREE = in the **MODEL** statement is used to specify the degree of the local polynomials used by PROC LOESS, with DEGREE = 1 being the default. In addition, when DEGREE = 2 is specified, the MODEL statement DROPSQUARE= option can be used to exclude specific monomials during the least squares fitting.

For example, the following statements use the monomials 1, x_1 , x_2 , $x_1 \cdot x_2$, and $x_2 \cdot x_2$ for the local least squares fitting.

```
proc loess;
  model y= x1 x2/ degree=2 dropsquare=(x1);
run;
```

Smoothing Matrix

When no iterative reweighting is done, the “Smoothing Matrix” denoted by \mathbf{L} defines the linear relationship between the fitted and observed dependent variable values of a loess model. You can obtain the predicted values of a loess fit from the observed values via

$$\hat{\mathbf{y}} = \mathbf{L}\mathbf{y}$$

where \mathbf{y} is the vector of observed values and $\hat{\mathbf{y}}$ is the corresponding vector of predicted values of the dependent variable. Note that \mathbf{L} is an n by n matrix, where n is the number of observations in the analysis. PROC LOESS does not explicitly form \mathbf{L} if the DFMETHOD=EXACT option is not explicitly or implicitly selected.

Model Degrees of Freedom

The approximate model degrees of freedom in a nonparametric fit is a number that is analogous to the number of free parameters in a parametric model. There are three commonly used measures of model degrees of freedom in nonparametric models. These criteria are as follows:

$$\begin{aligned} \text{DF1} &\equiv \text{Trace}(\mathbf{L}) \\ \text{DF2} &\equiv \text{Trace}(\mathbf{L}'\mathbf{L}) \\ \text{DF3} &\equiv 2\text{Trace}\mathbf{L} - \text{Trace}(\mathbf{L}'\mathbf{L}) \end{aligned}$$

A discussion of their properties can be found in Hastie and Tibshirani (1990). DF2 is also referred to as the “Equivalent Number of Parameters,” and this is the name that PROC LOESS uses for DF2 when it appears in the “Fit Summary” table.

Statistical Inference and Lookup Degrees of Freedom

If you denote the i th measurement of the response by y_i and the corresponding measurement of predictors by x_i , then

$$y_i = g(x_i) + \epsilon_i$$

where g is the regression function and ϵ_i are independent random errors with mean zero. If the errors are normally distributed with constant variance, then you can obtain confidence intervals for the predictions

from PROC LOESS. You can also obtain confidence limits in the case where ϵ_i is heteroscedastic but $a_i\epsilon_i$ has constant variance and a_i are a priori weights that are specified using the **WEIGHT** statement of PROC LOESS. You can do inference in the case in which the error distribution is symmetric by using iterative reweighting. Formulas for doing statistical inference under the preceding conditions can be found in Cleveland and Grosse (1991) and Cleveland, Grosse, and Shyu (1992). Cleveland and Grosse (1991) show that standardized residuals for a loess model follow a t distribution with ρ degrees of freedom where

$$\begin{aligned}\delta_1 &\equiv \text{Trace}(\mathbf{I} - \mathbf{L})'(\mathbf{I} - \mathbf{L}) \\ \delta_2 &\equiv \text{Trace}((\mathbf{I} - \mathbf{L})'(\mathbf{I} - \mathbf{L}))^2 \\ \rho &\equiv \text{Lookup Degrees of Freedom} \\ &\equiv \delta_1^2/\delta_2\end{aligned}$$

The residual standard error that you find in the “Fit Summary” table is defined by

$$\text{Residual Standard Error} \equiv \sqrt{\text{Residual SS}/\delta_1}$$

The determination of ρ is computationally expensive and is not done by default. It is computed if you specify the **DFMETHOD=EXACT** or **DFMETHOD=APPROX** option in the **MODEL** statement. It is also computed if you specify any of the options **CLM**, **STD**, and **T** in the **MODEL** statement. Note that the values of δ_1 , δ_2 , and ρ are reported in the “Fit Summary” table.

If you specify the **CLM** option in the **MODEL** statement, confidence limits are added to the **OutputStatistics** table. By default, 95% limits are computed, but you can change this by using the **ALPHA=** option in the **MODEL** statement.

Automatic Smoothing Parameter Selection

There are several methodologies for automatic smoothing parameter selection. One class of methods chooses the smoothing parameter value to minimize a criterion that incorporates both the tightness of the fit and model complexity. Such a criterion can usually be written as a function of the error mean square, $\hat{\sigma}^2$, and a penalty function designed to decrease with increasing smoothness of the fit. This penalty function is usually defined in terms of the smoothing matrix \mathbf{L} (see the section “**Smoothing Matrix**” on page 4126).

Examples of specific criteria are generalized cross validation (Craven and Wahba 1979) and the Akaike information criterion (Akaike 1973). These classical selectors have two undesirable properties when used with local polynomial and kernel estimators: they tend to undersmooth small data sets and tend to be nonrobust in the sense that small variations of the input data can change the choice of smoothing parameter value significantly. Hurvich, Simonoff, and Tsai (1998) obtained several corrected AIC criteria that address the small-sample bias and perform comparably with the *plug-in selectors* (Ruppert, Sheather, and Wand 1995). PROC LOESS provides automatic smoothing parameter selection that uses two of these corrected AIC criteria, named AIC_{C_1} and AIC_C in Hurvich, Simonoff, and Tsai (1998), and generalized cross validation, denoted by GCV.

The relevant formulas are

$$\begin{aligned}
AIC_{C_1} &= n \log(\hat{\sigma}^2) + n \frac{\delta_1/\delta_2(n + \nu_1)}{\delta_1^2/\delta_2 - 2} \\
AIC_C &= \log(\hat{\sigma}^2) + 1 + \frac{2(\text{Trace}(\mathbf{L}) + 1)}{n - \text{Trace}(\mathbf{L}) - 2} \\
GCV &= \frac{n\hat{\sigma}^2}{(n - \text{Trace}(\mathbf{L}))^2}
\end{aligned}$$

where n is the number of observations and

$$\begin{aligned}
\delta_1 &\equiv \text{Trace}(\mathbf{I} - \mathbf{L})'(\mathbf{I} - \mathbf{L}) \\
\delta_2 &\equiv \text{Trace}((\mathbf{I} - \mathbf{L})'(\mathbf{I} - \mathbf{L}))^2 \\
\nu_1 &\equiv \text{Equivalent Number of Parameters} \\
&\equiv \text{Trace}(\mathbf{L}'\mathbf{L})
\end{aligned}$$

You invoke these methods for automatic smoothing parameter selection by specifying the `SELECT=criterion` option in the `MODEL` statement, where *criterion* is AICC1, AICC, or GCV. The LOESS procedure evaluates the specified criterion for a sequence of smoothing parameter values and selects the value in this sequence that minimizes the specified criterion. If multiple values yield the optimum, then the largest of these values is selected.

A second class of methods seeks to set an approximate measure of model degrees of freedom to a specified target value. These methods are useful for making meaningful comparisons between loess fits and other nonparametric and parametric fits. Three approximate model degrees of freedom for a loess model are defined in the section “[Model Degrees of Freedom](#)” on page 4126. You invoke these methods by specifying the `SELECT=DFcriterion(target)` option in the `MODEL` statement, where *DFcriterion* is DF1, DF2, or DF3. The criterion that is minimized is given in the following table.

Table 53.4 Minimization Criteria

Syntax	Minimization Criterion
SELECT=DF1(<i>target</i>)	$\text{Trace}(\mathbf{L}) - \text{target}$
SELECT=DF2(<i>target</i>)	$\text{Trace}(\mathbf{L}'\mathbf{L}) - \text{target}$
SELECT=DF3(<i>target</i>)	$2\text{Trace}(\mathbf{L}) - \text{Trace}(\mathbf{L}'\mathbf{L}) - \text{target}$

The results are summarized in the “Smoothing Criterion” table. This table is displayed whenever automatic smoothing parameter selection is performed. You can obtain details of the sequence of models examined by specifying the `DETAILS(MODELSUMMARY)` option in the `MODEL` statement to display the “Model Summary” table.

There are several ways in which you can control the sequence of models examined by PROC LOESS. If you specify the `SMOOTH=value-list` option in the `MODEL` statement, then only the values in this list are examined in performing the selection. For example, the following statements select the model that

minimizes the AICC1 criterion among the three models with smoothing parameter values 0.1, 0.3, and 0.4:

```
proc loess;
  model y= x1/ smooth=0.1 0.3 0.4 select=AICC1;
run;
```

If you do not specify the SMOOTH= option in the **MODEL** statement, then by default PROC LOESS uses a golden section search method to find a local minimum of the specified criterion in the range (0, 1]. You can use the RANGE(*lower,upper*) modifier in the SELECT= option to change the interval in which the golden section search is performed. For example, the following statements request a golden section search to find a local minimizer of the GCV criterion for smoothing parameter values in the interval [0.1,0.5]:

```
proc loess;
  model y= x1/select=GCV( range(0.1,0.5) );
run;
```

If you want to be sure of obtaining a global minimum in the range of smoothing parameter values examined, you can specify the GLOBAL modifier in the SELECT= option. For example, the following statements request that a global minimizer of the AICC criterion be obtained for smoothing parameter values in the interval [0.2, 0.8]:

```
proc loess;
  model y= x1/select=AICC( global range(0.2,0.8) );
run;
```

Note that even though the smoothing parameter is a continuous variable, a given range of smoothing parameter values corresponds to a finite set of local models. For example, for a data set with 100 observations, the range [0.2, 0.4] corresponds to models with 20, 21, 22, . . . , 40 points in the local neighborhoods. If the GLOBAL modifier is specified, all possible models in the range are evaluated sequentially.

Note that by default PROC LOESS displays a “Fit Summary” and other optionally requested tables only for the selected model. You can request that these tables be displayed for all models in the selection process by adding the STEPS modifier in the SELECT= option. Also note that by default scoring requested with SCORE statements is done only for the selected model. However, if you specify the STEPS in both the **MODEL** and **SCORE** statements, then all models evaluated in the selection process are scored.

In terms of computation, AIC_C , GCV, and DF1 depend on the smoothing matrix **L** only through its trace. In the direct method, this trace can be computed efficiently. In the interpolated method that uses *k*-d trees, there is some additional computational cost but the overall work is not significant compared to the rest of the computation. In contrast, the quantities δ_1 , δ_2 , and ν_1 that appear in the AIC_{C_1} criterion, and the DF2 and DF3 criteria, depend on the entire **L** matrix and for this reason, the time needed to compute these quantities dominates the time required for the model fitting. Hence SELECT=AICC1, SELECT=DF2, and SELECT=DF3 are much more computationally expensive than SELECT=AICC, SELECT=GCV, and SELECT=DF1, especially when combined with the GLOBAL modifier. Hurvich, Simonoff, and Tsai (1998) note that AIC_C can be regarded as an approximation of AIC_{C_1} and that “the AIC_C selector generally performs well in all circumstances.”

For models with one dependent variable, PROC LOESS uses SELECT=AICC as its default, if you specify neither the SMOOTH= nor the SELECT= option in the **MODEL** statement. With two or more dependent variables, automatic smoothing parameter selection needs to be done separately for each dependent variable. For this reason automatic smoothing parameter selection is not available for models with multiple dependent

variables. In such cases you should use a separate PROC LOESS step for each dependent variable, if you want to use automatic smoothing parameter selection.

Sparse and Approximate Degrees of Freedom Computation

As noted in the section “Statistical Inference and Lookup Degrees of Freedom” on page 4126, obtaining confidence limits in loess models requires the computation of the lookup degrees of freedom. This in turn requires the computation of

$$\delta_2 \equiv \text{Trace}((\mathbf{I} - \mathbf{L})'(\mathbf{I} - \mathbf{L}))^2$$

where \mathbf{L} is the loess smoothing matrix (see the section “Smoothing Matrix” on page 4126).

The work in a direct implementation of this formula grows as n^3 , where n is the number of observations in analysis. For large n , this work dominates the time needed to fit the loess model itself. To alleviate this computational bottleneck, Cleveland and Grosse (1991) and Cleveland, Grosse, and Shyu (1992) developed approximate methods for estimating this quantity in terms of more readily computable statistics. A different approach to obtaining a computationally cheap estimate of δ_2 has been implemented in PROC LOESS.

For large data sets with significant local structure, the loess model is often used with small values of the smoothing parameter. Recalling that the smoothing parameter defines the fraction of the data used in each local regression, this means that the loess fit at any point in regressor space depends on only a small fraction of the data. This is reflected in the smoothing matrix \mathbf{L} whose (i, j) entry is nonzero only if the i th and j th observations lie in at least one common local neighborhood. Hence the smoothing matrix is a sparse matrix (has mostly zero entries) in such cases. By exploiting this sparsity, PROC LOESS now computes δ_2 orders of magnitude faster than in previous implementations.

When each local neighborhood contains a large subset of the data—i.e., when the smoothing parameter is large—then it is no longer true that the smoothing matrix is sparse. However, since a point in a local neighborhood is given a local weight that decreases with its distance from the center of the neighborhood, many of the coefficients in the smoothing matrix turn out to be nonzero but with orders of magnitude smaller than that of the larger coefficients in the matrix. The approximate method for computing δ_2 that has been implemented in PROC LOESS exploits these disparities in magnitudes of the elements in the smoothing matrix by setting the small elements to zero. This creates a sparse approximation of the smoothing matrix to which the fast sparse methods can be applied.

In order to decide the threshold at which elements in the smoothing matrix are set to zero, PROC LOESS samples the elements in the smoothing matrix to obtain the value of the element in a specified lower quantile in this sample. The magnitude of the element at this quantile is used as a cutoff value, and all elements in the smoothing matrix whose magnitude is less than this cutoff are set to zero for the approximate computation. By default all elements in the lower ninetieth percentile are set to zero. You can use the `DFMETHOD=APPROX(QUANTILE=)` option in the **MODEL** statement to change this value. As you increase the value for the quantile to be zeroed, you speed up the degrees of freedom computation at the expense of increasing approximation errors. You can also use the `DFMETHOD=APPROX(CUTOFF=)` option in the **MODEL** statement to specify the cutoff value directly.

For small data sets, the approximate computation is not needed and would be rougher than for larger data sets. Hence PROC LOESS performs the exact computation for analyses with fewer than 500 points, even if `DFMETHOD=APPROX` is specified in the model statement. Also, for small values of the smoothing

parameter, elements in the lower specified quantile might already all be zero. In such cases the approximate method is the same as the exact method. PROC LOESS labels as approximate any statistics that depend on the approximate computation of δ_2 only in the cases where the approximate computation was used and is different from the exact computation.

Scoring Data Sets

One or more **SCORE** statements can be used with PROC LOESS. A data set that includes all the variables specified in the **MODEL** and **BY** statements must be specified in each **SCORE** statement. Score results are placed in the ScoreResults table. This table is not displayed by default, but specifying the **PRINT** option in the **SCORE** statement produces the table. If you specify the **CLM** option in the **SCORE** statement, confidence intervals are included in the ScoreResults table.

Note that scoring is not supported when the **DIRECT** option is specified in the **MODEL** statement. Scoring at a point specified in a score data set is done by first finding the cell in the k -d tree containing this point and then interpolating the scored value from the predicted values at the vertices of this cell. This methodology precludes scoring any points that are not contained in the box that surrounds the data used in fitting the loess model.

ODS Table Names

PROC LOESS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

Table 53.5 ODS Tables Produced by PROC LOESS

ODS Table Name	Description	Statement	Option
FitSummary	Specified fit parameters and fit summary		default
kdTree	Structure of k -d tree used	MODEL	DETAILS(kdTree)
ModelSummary	Summary of all models evaluated	MODEL	DETAILS(ModelSummary)
OutputStatistics	Coordinates and fit results at input data points	MODEL	DETAILS(OutputStatistics)
PredAtVertices	Coordinates and fitted values at k -d tree vertices	MODEL	DETAILS(PredAtVertices)
ScaleDetails	Extent and scaling of the independent variables		default
ScoreResults	Coordinates and fit results at scoring points	SCORE	PRINT
SmoothingCriterion	Criterion value and selected smoothing parameter	MODEL	SELECT

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS.](#)”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC LOESS generates are listed in [Table 53.6](#), along with the relevant PLOTS= options.

Table 53.6 Graphs Produced by PROC LOESS

ODS Graph Name	Plot Description	PLOTS Option
ContourFitPanel	Panel of loess contour surfaces overlaid on scatter plots of data	CONTOURFITPANEL
ContourFit	Loess contour surface overlaid on scatter plot of data	CONTOURFITPANEL
DiagnosticsPanel	Panel of fit diagnostics	DIAGNOSTICS
FitPanel	Panel of loess curves overlaid on scatter plots of data	FITPANEL
FitPlot	Loess curve overlaid on scatter plot of data	FIT
ObservedByPredicted	Dependent variable versus loess fit	OBSERVEDBYPREDICTED
QQPlot	Normal quantile plot of residuals	QQPLOT
ResidualsBySmooth	Panel of residuals versus regressor by smoothing parameter values	RESIDUALSBYSMOOTH
ResidualByPredicted	Residuals versus loess fit	RESIDUALBYPREDICTED
ResidualHistogram	Histogram of fit residuals	RESIDUALHISTOGRAM
ResidualPanel	Panel of residuals versus regressors for fixed smoothing parameter value	RESIDUALS
ResidualPlot	Plot of residuals versus regressor	RESIDUALS
RFPlot	Side-by-side plots of quantiles of centered fit and residuals	RFPLOT
ScorePlot	Loess fit evaluated at scoring points	SCOREPLOT
CriterionPlot	Selection criterion versus smoothing parameter	CRITERION

Examples: LOESS Procedure

Example 53.1: Engine Exhaust Emissions

Investigators studied the exhaust emissions of a one-cylinder engine (Brinkman 1981). The SAS data set Gas contains the results data. The dependent variable, NO_x, measures the concentration, in micrograms per joule, of nitric oxide and nitrogen dioxide normalized by the amount of work of the engine. The independent variable, E, is a measure of the richness of the air and fuel mixture.

```
data Gas;
  input NOx E @@;
  format NOx f3.1;
  format E f3.1;
  datalines;
4.818 0.831 2.849 1.045
3.275 1.021 4.691 0.97
4.255 0.825 5.064 0.891
2.118 0.71 4.602 0.801
2.286 1.074 0.97 1.148
3.965 1 5.344 0.928
3.834 0.767 1.99 0.701
5.199 0.807 5.283 0.902
3.752 0.997 0.537 1.224
1.64 1.089 5.055 0.973
4.937 0.98 1.561 0.665
;
```

The following PROC SGPLOT statements produce the simple scatter plot of these data displayed in [Output 53.1.1](#).

```
proc sgplot data=Gas;
  scatter x=E y=NOx;
run;
```

Output 53.1.1 Scatter Plot of the Gas Data

The following statements fit two loess models for these data. Because this is a small data set, it is reasonable to do direct fitting at every data point. As there is substantial curvature in the data, quadratic local polynomials are used. An ODS OUTPUT statement creates two output data sets containing the “Output Statistics” and “Fit Summary” tables.

```
ods graphics on;

proc loess data=Gas;
  ods output OutputStatistics = GasFit
             FitSummary=Summary;
  model NOx = E / degree=2 select=AICC(steps) smooth = 0.6 1.0
                direct alpha=.01 all details;
run;

ods graphics off;
```

Output 53.1.2 Fit Summary Table

The LOESS Procedure	
Selected Smoothing Parameter: 0.6	
Dependent Variable: NOx	
Fit Summary	
Fit Method	Direct

GCV	0.00708
AICC	-0.45637
AICC1	-9.39715
Delta1	15.12582
Delta2	14.73089
Equivalent Number of Parameters	5.96950
Lookup Degrees of Freedom	15.53133
Residual Standard Error	0.33707

The “Fit Summary” table for smoothing parameter value 0.6, shown in [Output 53.1.2](#), records the fitting parameters specified and some overall fit statistics. See the section “[Smoothing Matrix](#)” on page 4126 for a definition of the smoothing matrix **L**, and the sections “[Model Degrees of Freedom](#)” on page 4126 and “[Statistical Inference and Lookup Degrees of Freedom](#)” on page 4126 for definitions of the statistics that appear in this table.

The “Output Statistics” table for smoothing parameter value 0.6 is shown in [Output 53.1.3](#). Note that, because the ALL option is specified in the **MODEL** statement, this table includes all the relevant optional columns. Furthermore, because the ALPHA=0.01 option is specified in the **MODEL** statement, the confidence limits in this table are 99% limits.

Output 53.1.4 Output Statistics Table

Optimal Smoothing Criterion	
AICC	Smoothing Parameter
-0.45637	0.60000

The combination of the options `SELECT=AICC` and `SMOOTH=0.6 1` in the `MODEL` statement specifies that PROC LOESS fit models with smoothing parameters of 0.6 and 1 and select the model that yields the smaller value of the AICC statistic. The “Smoothing Criterion” shown in [Output 53.1.4](#) shows that PROC LOESS selects the model with smoothing parameter value 0.6 as it yields the smaller value of the AICC statistic.

With ODS Graphics enabled, PROC LOESS produces a panel of fit plots whenever you specify the `SMOOTH=` option in the `MODEL` statement. These fit plots include confidence limits if you additionally specify the `CLM` option in the `MODEL` statement.

Output 53.1.5 Loess Fits with 99% Confidence Limits for the Gas Data

[Output 53.1.5](#) shows the “Fit Panel” that displays the fitted models with 99% confidence limits overlaid on scatter plots of the data.

Based on the AICC criterion, the model with smoothing parameter 0.6 is preferred. You can address the question of whether the differences between these models are significant using analysis of variance. You do this by using the model with smoothing parameter value 1 as the null model.

The statistic

$$F = \frac{(\text{rss}^{(n)} - \text{rss}) / (\delta_1^{(n)} - \delta_1)}{\text{rss} / \delta_1}$$

has a distribution that is well approximated by an F distribution with

$$\nu = \frac{(\delta_1^{(n)} - \delta_1)^2}{\delta_2^{(n)} - \delta_2}$$

numerator degrees of freedom and ρ denominator degrees of freedom (Cleveland and Grosse 1991). Here quantities with superscript n refer to the null model, rss is the residual sum of squares, and δ_1 , δ_2 , and ρ are defined in the section “[Statistical Inference and Lookup Degrees of Freedom](#)” on page 4126.

The “Fit Summary” tables contain the information needed to carry out such an analysis. These tables have been captured in the output data set named `Summary` by using an `ODS OUTPUT` statement. The following statements extract the relevant information from this data set and carry out the analysis of variance:

```
data h0 h1;
  set Summary(keep=SmoothingParameter Label1 nValue1
               where=(Label1 in ('Residual Sum of Squares', 'Delta1',
                                'Delta2', 'Lookup Degrees of Freedom')));
  if SmoothingParameter = 1 then output h0;
  else output h1;
run;

proc transpose data=h0(drop=SmoothingParameter Label1) out=h0;
run;

data h0(drop=_NAME_);
  set h0;
  rename Col1 = RSSNull
         Col2 = delta1Null
         Col3 = delta2Null;
run;

proc transpose data=h1(drop=SmoothingParameter Label1) out=h1;
run;

data h1(drop=_NAME_);
  set h1;
  rename Col1 = RSS      Col2 = delta1
         Col3 = delta2   Col4 = rho;
run;

data ftest;
  merge h0 h1;
  nu = (delta1Null - delta1)**2 / (delta2Null - delta2);
  Numerator = (RSSNull - RSS)/(delta1Null - delta1);
  Denominator = RSS/delta1;
  FValue = Numerator / Denominator;
  PValue = 1 - ProbF(FValue, nu, rho);
  label nu      = 'Num DF'    rho      = 'Den DF'
        FValue = 'F Value'   PValue = 'Pr > F';
```

```
run;

proc print data=fctest label;
  var nu rho Numerator Denominator FValue PValue;
  format nu rho FValue 7.2 PValue 6.4;
run;
```

The results are shown in [Output 53.1.6](#).

Output 53.1.6 Test ANOVA for Loess Models of Gas Data

Obs	Num DF	Den DF	Numerator	Denominator	F Value	Pr > F
1	2.67	15.53	1.05946	0.11362	9.32	0.0012

The small p -value confirms that the fit with smoothing parameter value 0.6 is significantly different from the loess model with smoothing parameter value 1.

Alternatively, you can use the OUTPUT statement to generate the statistics you want to include in the output data set. The following statements produce essentially the same results as the ODS OUTPUT statement does, except all the statistics for each of the two smoothing parameter values are included because the SELECT= option is not specified in the MODEL statement. In addition, with the ROW option specified, the output data set is arranged in rowwise format which enables you to compare statistics side-by-side for a sequence of smoothing values. The ALL option after the slash produces all the statistics (predicted values, residual values, standard errors of the mean predicted values, t statistics, and the lower and upper parts of $100(1 - \alpha)\%$ confidence limits on the mean predicted value). All these requested statistics are given their respective default names in the output data set except the predicted value. The P=PREDVAL option causes the name for the predicted value to start with predval.

```
proc loess data=Gas;
  model NOx = E / degree=2 smooth = 0.6 1.0
    direct alpha=.01;
  output out=GasFit p=predval /all row;
run;
```

Example 53.2: Sulfate Deposits in the U.S. for 1990

The following data set contains measurements in grams per square meter of sulfate (SO_4) deposits during 1990 at 179 sites throughout the 48 contiguous states.

```
data SO4;
  input Latitude Longitude SO4 @@;
  format Latitude f4.0;
  format Longitude f4.0;
  format SO4 f4.1;
  datalines;
32.45833 87.24222 1.403 34.28778 85.96889 2.103
33.07139 109.86472 0.299 36.07167 112.15500 0.304
31.95056 112.80000 0.263 33.60500 92.09722 1.950
```

```

34.17944  93.09861  2.168 36.08389  92.58694  1.578

... more lines ...

43.87333 104.19222  0.306 44.91722 110.42028  0.210
45.07611  72.67556  2.646
;

```

As longitudes decrease from west to east in the western hemisphere, the roles of east and west get interchanged if you use these longitudes on the horizontal axis of a plot. You can address this by using negative values to represent longitudes in the western hemisphere. The following statements change the sign of longitude in the SO4 data set and define a format to display these negative values with a suffix of “W”.

```

proc format;
  picture latitude -90 - 0 = '000S'
                  0 - 90 = '000N';
  picture longitude -180 - 0 = '000W'
                  0 - 180 = '000E';
run;
data SO4;
  set SO4;
  format longitude longitude. latitude latitude.;
  longitude = -longitude;
run;

```

The following statements use ODS Graphics to plot the locations of the sulfate measurements. The circles indicating the locations are colored using a gradient that denotes the value of SO4.

```

proc template;
  define statgraph gradientScatter;
    beginGraph;
      layout overlay;
        scatterPlot x=longitude y=latitude /
          markercolorgradient = SO4
          markerattrs         = (symbol=circleFilled)
          colormodel           = ThreeColorRamp
          name                  = "Scatter";
        scatterPlot x=longitude y=latitude /
          markerattrs         = (symbol=circle);
        continuousLegend "Scatter"/title= "SO4";
      endlayout;
    endgraph;
  end;
run;

proc sgrender data=SO4 template=gradientScatter;
run;

```

Output 53.2.1 Sulfate Measurements

Figure 53.2.1 shows that the largest concentrations of sulfate deposits occur in the northeastern United States.

The following statements fit a loess model.

```
ods graphics on;

proc loess data=SO4;
  model SO4=Longitude Latitude / degree=2 interp=cubic;
run;

ods graphics off;
```

Output 53.2.2 Fit Plot for the SO₄ Data

Figure 53.2.2 shows a contour plot of the fitted loess surface overlaid with a scatter plot of the data. The data are colored by the observed sulfate concentrations, using the same color gradient as the gradient-filled contour plot of the fitted surface. Note that for observations where the residual is small, the observations blend in with the contour plot. The greater the size of the residual, the greater the contrast between the observation color and the surface color.

The sulfate measurements are irregularly spaced. To facilitate producing a plot of the fitted loess surface, you can create a data set containing a regular grid of longitudes and latitudes and then use the [SCORE](#) statement to evaluate the loess surface at these points. The following statements show how you do this:

```
data PredPoints;
  format longitude longitude.
         latitude latitude.;
  do Latitude = 26 to 46 by 1;
    do Longitude = -79 to -123 by -1;
      output;
    end;
  end;
run;

proc loess data=S04;
  model S04=Longitude Latitude;
  score data=PredPoints / print;
  ods Output ScoreResults=ScoreOut;
run;
```

The PRINT option in the [SCORE](#) statement requests that the “Score Results” table be displayed as part of the PROC LOESS output. The ODS OUTPUT statement outputs this table to a data set named ScoreOut. If you do not want to display the score results but you do want the score results in an output data set, then you can omit the PRINT option from the [SCORE](#) statement. To plot the surface shown in [Figure 53.2.3](#) by using ODS Graphics, use the following statements:

```
proc template;
  define statgraph surface;
    begingraph;
      layout overlay3d / rotate=340 tilt=30 cube=false;
      surfaceplotparm x=Longitude y=Latitude z=p_S04;
    endlayout;
  endgraph;
end;
run;

proc sgrender data=ScoreOut template=surface;
run;
```

Output 53.2.3 Loess Fit of SO4 Surface

Example 53.3: Catalyst Experiment

The following data set records the results of an experiment to determine how the yield of a chemical reaction varies with temperature and amount of a catalyst used.

```
data Experiment;
  input Temperature Catalyst MeasuredYield;
  if ranuni(1) < 0.1
    then CorruptedYield = MeasuredYield + 10 * ranuni(1);
    else CorruptedYield = MeasuredYield;
  datalines;
80    0.000    6.85601
80    0.002    7.26355
80    0.004    7.41448
80    0.006    7.82640

... more lines ...

140   0.078    5.20562
140   0.080    5.49371
;
```

The aim of this example is to show how you can use PROC LOESS for robust fitting in the presence of outliers. To simulate an intermittent equipment malfunction, the variable `CorruptedYield` is the same as the variable `MeasuredYield` except for about 10% of the observations where an offset has been added. This example shows how you can use PROC LOESS obtain a fit for `CorruptedYield` that is close to the fit you obtain for `MeasuredYield`.

The following statements produce a scatter plot of Temperature by Catalyst where the observations are colored by `CorruptedYield`:

```
proc template;
  define statgraph gradientScatter;
    beginGraph;
      layout overlay;
        scatterPlot x=Catalyst y=Temperature /
          markercolorgradient = CorruptedYield
          markerattrs         = (symbol=circleFilled)
          colormodel           = ThreeColorRamp
          name                 = "Yield";

        scatterPlot x=Catalyst y=Temperature /
          markerattrs         = (symbol=circle);

        continuousLegend "Yield" / title= "CorruptedYield";
      endlayout;
    endgraph;
  end;
run;

proc sgrender data=Experiment template=gradientScatter;
run;
```

Output 53.3.1 Scatter Plot of Experiment Data Colored by CorruptedYield

Output 53.3.1 shows a scatter plot of the data where the observations are shaded by the value of CorruptedYield. The darkly shaded points that are surrounded by lightly shaded points are points where the simulated incorrect measurements occur.

The following code fits a loess model to the measured data:

```
ods graphics on;

proc loess data=Experiment;
  model MeasuredYield = Temperature Catalyst / scale=sd(0.1);
run;
```

Output 53.3.2 Scale Details for the Experiment Data

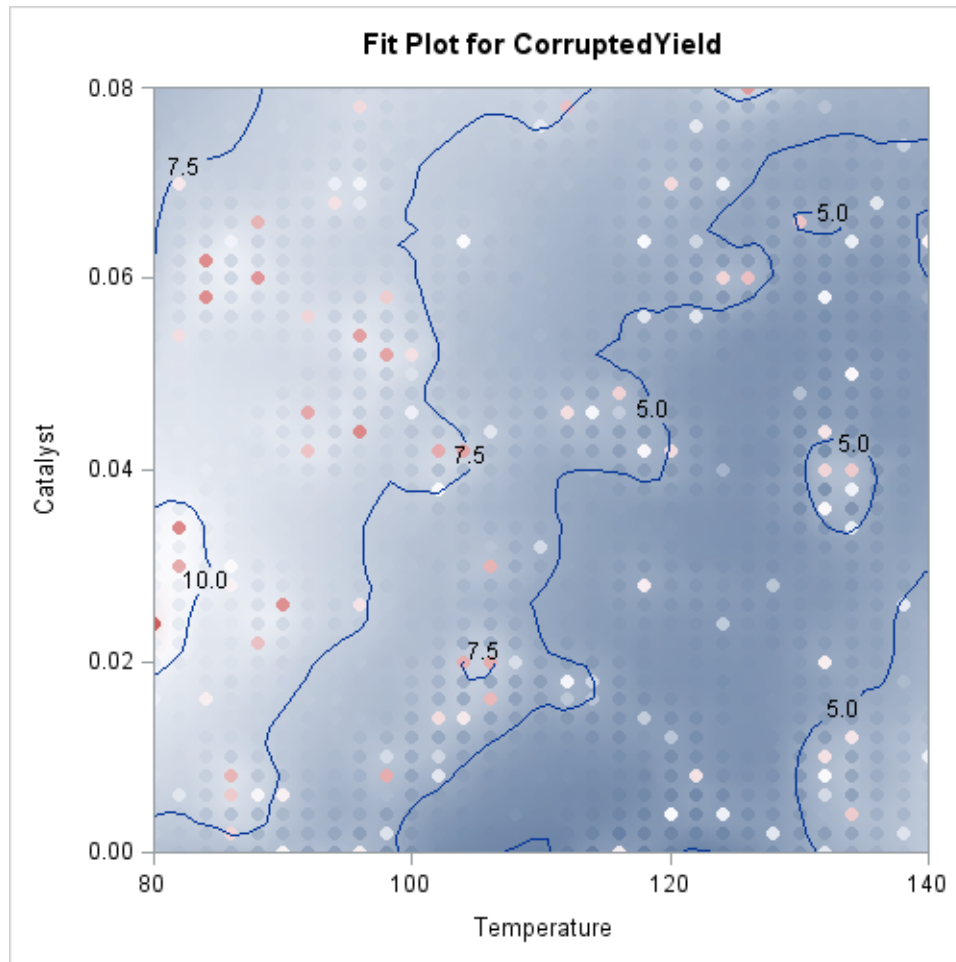

The LOESS Procedure		
Independent Variable Scaling		
Scaling applied: 10% trimmed standard deviation		
Statistic	Temperature	Catalyst
Minimum Value	80.00000	0
Maximum Value	140.00000	0.08000
Trimmed Mean	110.00000	0.04000
Trimmed Standard Deviation	14.32149	0.01894

The `SCALE=SD(0.1)` option in the `MODEL` statement specifies that the independent variables in the model are to be divided by their respective 10% trimmed standard deviations before the fitted model is computed. This is appropriate because the independent variables `Temperature` and `Catalyst` are not similarly scaled. The “Scale Details” table in [Output 53.3.2](#) displays the details of ranges of the regressors and the scale factors applied to each regressor.

[Output 53.3.3](#) displays the loess fit. Because the fitted surface is a good fit of the observed data, the observations on this plot are not clearly distinguishable from the fitted surface. The results are dramatically different when the outliers are included. The following statements fit a loess model to the corrupted response, using the same smoothing parameter that was selected for the measured response.

Output 53.3.3 Fit for MeasuredYield

```
proc loess data=Experiment;  
  model CorruptedYield = Temperature Catalyst /  
    scale=sd(0.1) smooth=0.018;  
run;
```

Output 53.3.4 Fit for CorruptedYield

Output 53.3.4 displays the loess fit. The fit is pulled upward in the neighborhoods of these outliers. If you use a larger smoothing parameter value, then these local perturbations in the fit get smoothed out, but at the expense of smoothing away the information in the underlying measured response. In such cases a robust fitting method is indicated. The following statements show how you do this:

```
proc loess data=Experiment;
  model CorruptedYield = Temperature Catalyst /
    scale = sd(0.1)
    smooth = 0.018
    iterations=4;
run;
```

The ITERATIONS=4 option in the **MODEL** statement requests the initial loess fit followed by three iteratively reweighted iterations.

Output 53.3.5 Robust Fit for CorruptedYield

You can see the impact of the robust fitting by comparing the robust fit shown in [Output 53.3.5](#) with the nonrobust fit in [Output 53.3.4](#). In the robust fit you see that the local perturbations caused by the outliers have been eliminated as these the outlying observations get down-weighted during the robustness iterations. By comparing the labeled contours on the fit plot for the uncorrupted response shown in [Output 53.3.3](#) with the labeled contours for the corrupted response shown in [Output 53.3.4](#), you can see that the robust fit has produced a reasonable fit for the underlying measured data. The color gradient in [Output 53.3.5](#) is chosen to accommodate the outliers that are present in the observed data, and so you cannot easily compare the color gradient in this plot with that in [Output 53.3.3](#). The following statements repeat the robust analysis with an option added to suppress the display of the observations on the fit plot:

```
proc loess data=Experiment plots=contourFit(obs=None);
  model CorruptedYield = Temperature Catalyst /
    scale = sd(0.1)
    smooth = 0.018
    iterations=4;
run;

ods graphics off;
```

Output 53.3.6 Robust Fit for CorruptedYield with Observations Suppressed

Output 53.3.6 shows the robust fit with the observations suppressed. The range of the fitted surface values in this plot is similar to the range in Output 53.3.3. By comparing this contour plot with the contour plot in Output 53.3.3, you clearly see that the robust loess fit has successfully modeled the underlying surface despite the presence of the outliers.

Example 53.4: El Niño Southern Oscillation

The data set `sashelp.ENS0`, which is available in the `Sashelp` library, contains measurements of monthly averaged atmospheric pressure differences between Easter Island and Darwin, Australia, for a period of 168 months (National Institute of Standards and Technology 1998).

The following PROC SGPLOT statements produce the simple scatter plot of the ENSO data, displayed in Output 53.4.1.

```
proc sgplot data=sashelp.ENS0;  
    scatter y=Pressure x=Month;  
run;
```

Output 53.4.1 Scatter Plot of ENSO Data

You can compute a loess fit and obtain graphical results for these data by using the following statements:

```
ods graphics on;

proc loess data=sashelp.ENS0 plots=residuals(smooth);
  model Pressure=Month;
run;
```

The “Smoothing Criterion” and “Fit Summary” tables are shown in [Output 53.4.2](#), and the fit plot is shown in [Output 53.4.3](#).

Output 53.4.2 Output from PROC LOESS

The LOESS Procedure	
Dependent Variable: Pressure	
Optimal Smoothing	
Criterion	
AICC	Smoothing Parameter
3.41105	0.22321
The LOESS Procedure	
Selected Smoothing Parameter: 0.223	
Dependent Variable: Pressure	
Fit Summary	
Fit Method	kd Tree
Blending	Linear
Number of Observations	168
Number of Fitting Points	33
kd Tree Bucket Size	7
Degree of Local Polynomials	1
Smoothing Parameter	0.22321
Points in Local Neighborhood	37
Residual Sum of Squares	1654.27725
Trace[L]	8.74180
GCV	0.06522
AICC	3.41105

Output 53.4.3 Oversmoothed Loess Fit for the ENSO Data

This weather-related data should exhibit an annual cycle. However, the loess fit in [Output 53.4.3](#) indicates a longer cycle but no annual cycle. This suggests that the loess fit is oversmoothed. One way to detect oversmoothing is to look for patterns in the fit residuals. With ODS Graphics enabled, PROC LOESS produces a scatter plot of the residuals versus each regressor in the model. To aid in visually detecting patterns in these scatter plots, it is useful to superimpose a nonparametric fit on these scatter plots. You can request this by specifying the SMOOTH suboption of the PLOTS=RESIDUALS option in the [PROC LOESS](#) statement. The nonparametric fit that is produced is again a loess fit that is produced independently of the loess fit used to obtain these residuals.

With the superimposed loess fit shown in [Output 53.4.4](#), you can clearly identify an annual cycle in the residuals, which confirms that the loess fit for the ENSO is oversmoothed. What accounts for this poor fit?

Output 53.4.4 Residuals for the Loess Fit for the ENSO Data

The smoothing parameter value used for the loess fit shown in [Output 53.4.3](#) was chosen using the default method of PROC LOESS, namely a golden section minimization of the AICC criterion over the interval (0, 1]. One possibility is that the golden section search has found a local rather than a global minimum of the AICC criterion. You can test this by redoing the fit requesting a global minimum. You do this with the following statements:

```
proc loess data=sashelp.ENS0;
  model Pressure=Month/select=AICC(global);
run;
```

Output 53.4.5 AICC versus Smoothing Parameter Showing Local Minima

The explanation for the oversmoothed fit in [Output 53.4.3](#) is now apparent. [Output 53.4.5](#) shows that the golden section search algorithm found the local minimum that occurs near the value 0.22 of the smoothing parameter rather than the global minimum that occurs near 0.06. Note that if you restrict the range of smoothing parameter values examined to lie below 0.2, then the golden section search finds the global minimum, as the following statements demonstrate:

```
proc loess data=sashelp.ENS0;
  model Pressure=Month/select=AICC(range(0.03,0.2));
run;
```

Output 53.4.6 Selected Smoothing Parameter Value

The LOESS Procedure	
Dependent Variable: Pressure	
Optimal Smoothing Criterion	
AICC	Smoothing Parameter
2.86660	0.05655

Output 53.4.6 shows that with the restricted range of smoothing parameter values examined, PROC LOESS finds the global minimum of the AICC criterion. Often you might not know an appropriate range of smoothing parameter values to examine. In such cases, you can use the PRESEARCH suboption of the SELECT= option in the **MODEL** statement. When you specify this option, PROC LOESS does a preliminary search to try to locate a smoothing parameter value range that contains just the first local minimum of the criterion being used for the selection. The following statements provide an example.

```
proc loess data=sashelp.ENS0 plots=residuals(smooth);
  model Pressure=Month/select=AICC(presearch);
run;

ods graphics off;
```

Output 53.4.7 Selected Smoothing Parameter Value When Presearch Is Specified

The LOESS Procedure	
Dependent Variable: Pressure	
Optimal Smoothing Criterion	
AICC	Smoothing Parameter
2.86660	0.05655

Output 53.4.7 shows that with the PRESEARCH suboption specified, PROC LOESS selects the smoothing parameter value that yields the global minimum of the AICC criterion. The fit obtained is shown in Output 53.4.8, and a plot of the residuals with a superimposed loess fit is shown in Output 53.4.9.

Output 53.4.8 Loess Fit Showing an Annual Cycle

Output 53.4.9 Residuals of the Selected Model

In contrast to the residual plot shown in [Output 53.4.4](#), the residuals plotted in [Output 53.4.9](#) do not exhibit any pattern, indicating that the corresponding loess fit has captured all the systematic variation in the data.

An interesting question is whether there is some phenomenon captured in the data that would explain the presence of the local minimum near 0.22 in the AICC curve. Note that there is some evidence of a cycle of about 42 months in the oversmoothed fit in [Output 53.4.3](#). You can see this cycle because the strong annual cycle in [Output 53.4.8](#) has been smoothed out. The physical phenomenon that accounts for the existence of this cycle has been identified as the periodic warming of the Pacific Ocean known as “El Niño.”

Overview: LOGISTIC Procedure

Binary responses (for example, success and failure), ordinal responses (for example, normal, mild, and severe), and nominal responses (for example, major TV networks viewed at a certain hour) arise in many fields of study. Logistic regression analysis is often used to investigate the relationship between these discrete responses and a set of explanatory variables. Texts that discuss logistic regression include Agresti (2002); Allison (1999); Collett (2003); Cox and Snell (1989); Hosmer and Lemeshow (2000); Stokes, Davis, and Koch (2012).

For binary response models, the response, Y , of an individual or an experimental unit can take on one of two possible values, denoted for convenience by 1 and 2 (for example, $Y = 1$ if a disease is present, otherwise $Y = 2$). Suppose \mathbf{x} is a vector of explanatory variables and $\pi = \Pr(Y = 1 \mid \mathbf{x})$ is the response probability to be modeled. The linear logistic model has the form

$$\text{logit}(\pi) \equiv \log\left(\frac{\pi}{1 - \pi}\right) = \alpha + \boldsymbol{\beta}'\mathbf{x}$$

where α is the intercept parameter and $\boldsymbol{\beta} = (\beta_1, \dots, \beta_s)'$ is the vector of s slope parameters. Notice that the LOGISTIC procedure, by default, models the probability of the *lower* response levels.

The logistic model shares a common feature with a more general class of linear models: a function $g = g(\mu)$ of the mean of the response variable is assumed to be linearly related to the explanatory variables. Since the mean μ implicitly depends on the stochastic behavior of the response, and the explanatory variables are assumed to be fixed, the function g provides the link between the random (stochastic) component and the systematic (deterministic) component of the response variable Y . For this reason, Nelder and Wedderburn (1972) refer to $g(\mu)$ as a link function. One advantage of the logit function over other link functions is that differences on the logistic scale are interpretable regardless of whether the data are sampled prospectively or retrospectively (McCullagh and Nelder 1989, Chapter 4). Other link functions that are widely used in practice are the probit function and the complementary log-log function. The LOGISTIC procedure enables you to choose one of these link functions, resulting in fitting a broader class of binary response models of the form

$$g(\pi) = \alpha + \boldsymbol{\beta}'\mathbf{x}$$

For ordinal response models, the response, Y , of an individual or an experimental unit might be restricted to one of a (usually small) number of ordinal values, denoted for convenience by $1, \dots, k, k + 1$. For example, the severity of coronary disease can be classified into three response categories as 1=no disease, 2=angina pectoris, and 3=myocardial infarction. The LOGISTIC procedure fits a common slopes cumulative model, which is a parallel lines regression model based on the cumulative probabilities of the response categories rather than on their individual probabilities. The cumulative model has the form

$$g(\Pr(Y \leq i \mid \mathbf{x})) = \alpha_i + \boldsymbol{\beta}'\mathbf{x}, \quad i = 1, \dots, k$$

where $\alpha_1, \dots, \alpha_k$ are k intercept parameters, and $\boldsymbol{\beta}$ is the vector of slope parameters. This model has been considered by many researchers. Aitchison and Silvey (1957) and Ashford (1959) employ a probit scale and provide a maximum likelihood analysis; Walker and Duncan (1967) and Cox and Snell (1989) discuss the use of the log odds scale. For the log odds scale, the cumulative logit model is often referred to as the *proportional odds* model.

For nominal response logistic models, where the $k + 1$ possible responses have no natural ordering, the logit model can also be extended to a *multinomial* model known as a *generalized* or *baseline-category* logit model, which has the form

$$\log \left(\frac{\Pr(Y = i \mid \mathbf{x})}{\Pr(Y = k + 1 \mid \mathbf{x})} \right) = \alpha_i + \boldsymbol{\beta}_i' \mathbf{x}, \quad i = 1, \dots, k$$

where the $\alpha_1, \dots, \alpha_k$ are k intercept parameters, and the $\boldsymbol{\beta}_1, \dots, \boldsymbol{\beta}_k$ are k vectors of slope parameters. These models are a special case of the *discrete choice* or *conditional logit* models introduced by McFadden (1974).

The LOGISTIC procedure fits linear logistic regression models for discrete response data by the method of maximum likelihood. It can also perform conditional logistic regression for binary response data and exact logistic regression for binary and nominal response data. The maximum likelihood estimation is carried out with either the Fisher scoring algorithm or the Newton-Raphson algorithm, and you can perform the bias-reducing penalized likelihood optimization as discussed by Firth (1993) and Heinze and Schemper (2002). You can specify starting values for the parameter estimates. The logit link function in the logistic regression models can be replaced by the probit function, the complementary log-log function, or the generalized logit function.

Any term specified in the model is referred to as an *effect*. The LOGISTIC procedure enables you to specify categorical variables (also known as *classification* or *CLASS variables*) and continuous variables as explanatory effects. You can also specify more complex model terms such as interactions and nested terms in the same way as in the GLM procedure. You can create complex *constructed effects* with the **EFFECT** statement. An effect in the model that is not an interaction or a nested term or a constructed effect is referred to as a *main effect*.

The LOGISTIC procedure allows either a full-rank parameterization or a less-than-full-rank parameterization of the CLASS variables. The full-rank parameterization offers eight coding methods: effect, reference, ordinal, polynomial, and orthogonalizations of these. The effect coding is the same method that is used in the CATMOD procedure. The less-than-full-rank parameterization, often called *dummy coding*, is the same coding as that used in the GLM procedure.

The LOGISTIC procedure provides four effect selection methods: forward selection, backward elimination, stepwise selection, and best subset selection. The best subset selection is based on the likelihood score statistic. This method identifies a specified number of best models containing one, two, three effects, and so on, up to a single model containing effects for all the explanatory variables.

The LOGISTIC procedure has some additional options to control how to move effects in and out of a model with the forward selection, backward elimination, or stepwise selection model-building strategies. When there are no interaction terms, a main effect can enter or leave a model in a single step based on the p -value of the score or Wald statistic. When there are interaction terms, the selection process also depends on whether you want to preserve model hierarchy. These additional options enable you to specify whether model hierarchy is to be preserved, how model hierarchy is applied, and whether a single effect or multiple effects can be moved in a single step.

Odds ratio estimates are displayed along with parameter estimates. You can also specify the change in the continuous explanatory main effects for which odds ratio estimates are desired. Confidence intervals for the regression parameters and odds ratios can be computed based either on the profile-likelihood function or on the asymptotic normality of the parameter estimators. You can also produce odds ratios for effects that are involved in interactions or nestings, and for any type of parameterization of the CLASS variables.

Various methods to correct for overdispersion are provided, including Williams' method for grouped binary response data. The adequacy of the fitted model can be evaluated by various goodness-of-fit tests, including the Hosmer-Lemeshow test for binary response data.

Like many procedures in SAS/STAT software that enable the specification of CLASS variables, the LOGISTIC procedure provides a **CONTRAST** statement for specifying customized hypothesis tests concerning the model parameters. The **CONTRAST** statement also provides estimation of individual rows of contrasts, which is particularly useful for obtaining odds ratio estimates for various levels of the CLASS variables. The LOGISTIC procedure also provides testing capability through the **ESTIMATE** and **TEST** statements. Analyses of LS-means are enabled with the **LSMEANS**, **LSMESTIMATE**, and **SLICE** statements.

You can perform a conditional logistic regression on binary response data by specifying the **STRATA** statement. This enables you to perform matched-set and case-control analyses. The number of events and nonevents can vary across the strata. Many of the features available with the unconditional analysis are also available with a conditional analysis.

The LOGISTIC procedure enables you to perform exact logistic regression, also known as exact conditional logistic regression, by specifying one or more **EXACT** statements. You can test individual parameters or conduct a joint test for several parameters. The procedure computes two exact tests: the exact conditional score test and the exact conditional probability test. You can request exact estimation of specific parameters and corresponding odds ratios where appropriate. Point estimates, standard errors, and confidence intervals are provided. You can perform stratified exact logistic regression by specifying the **STRATA** statement.

Further features of the LOGISTIC procedure enable you to do the following:

- control the ordering of the response categories
- compute a generalized R Square measure for the fitted model
- reclassify binary response observations according to their predicted response probabilities
- test linear hypotheses about the regression parameters
- create a data set for producing a receiver operating characteristic curve for each fitted model
- specify contrasts to compare several receiver operating characteristic curves
- create a data set containing the estimated response probabilities, residuals, and influence diagnostics
- score a data set by using a previously fitted model

The LOGISTIC procedure uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For more information about the plots implemented in PROC LOGISTIC, see the section “[ODS Graphics](#)” on page 4294.

The remaining sections of this chapter describe how to use PROC LOGISTIC and discuss the underlying statistical methodology. The section “[Getting Started: LOGISTIC Procedure](#)” on page 4166 introduces PROC LOGISTIC with an example for binary response data. The section “[Syntax: LOGISTIC Procedure](#)” on page 4174 describes the syntax of the procedure. The section “[Details: LOGISTIC Procedure](#)” on page 4237 summarizes the statistical technique employed by PROC LOGISTIC. The section “[Examples: LOGISTIC Procedure](#)” on page 4295 illustrates the use of the LOGISTIC procedure.

For more examples and discussion on the use of PROC LOGISTIC, see Stokes, Davis, and Koch (2012); Allison (1999); SAS Institute Inc. (1995).

Getting Started: LOGISTIC Procedure

The LOGISTIC procedure is similar in use to the other regression procedures in the SAS System. To demonstrate the similarity, suppose the response variable y is binary or ordinal, and x_1 and x_2 are two explanatory variables of interest. To fit a logistic regression model, you can specify a MODEL statement similar to that used in the REG procedure. For example:

```
proc logistic;
  model y=x1 x2;
run;
```

The response variable y can be either character or numeric. PROC LOGISTIC enumerates the total number of response categories and orders the response levels according to the response variable option **ORDER=** in the **MODEL** statement.

You can also input binary response data that are grouped. In the following statements, n represents the number of trials and r represents the number of events:

```
proc logistic;
  model r/n=x1 x2;
run;
```

The following example illustrates the use of PROC LOGISTIC. The data, taken from Cox and Snell (1989, pp. 10–11), consist of the number, r , of ingots not ready for rolling, out of n tested, for a number of combinations of heating time and soaking time.

```
data ingots;
  input Heat Soak r n @@;
  datalines;
7 1.0 0 10 14 1.0 0 31 27 1.0 1 56 51 1.0 3 13
7 1.7 0 17 14 1.7 0 43 27 1.7 4 44 51 1.7 0 1
7 2.2 0 7 14 2.2 2 33 27 2.2 0 21 51 2.2 0 1
7 2.8 0 12 14 2.8 0 31 27 2.8 1 22 51 4.0 0 1
7 4.0 0 9 14 4.0 0 19 27 4.0 1 16
;
```

The following invocation of PROC LOGISTIC fits the binary logit model to the grouped data. The continuous covariates Heat and Soak are specified as predictors, and the bar notation (“|”) includes their interaction, Heat*Soak. The **ODDSRATIO** statement produces odds ratios in the presence of interactions, and a graphical display of the requested odds ratios is produced when ODS Graphics is enabled.

```
ods graphics on;
proc logistic data=ingots;
  model r/n = Heat | Soak;
  oddsratio Heat / at (Soak=1 2 3 4);
run;
ods graphics off;
```

The results of this analysis are shown in the following figures. PROC LOGISTIC first lists background information in [Figure 54.1](#) about the fitting of the model. Included are the name of the input data set, the response variable(s) used, the number of observations used, and the link function used.

Figure 54.1 Binary Logit Model

The LOGISTIC Procedure	
Model Information	
Data Set	WORK.INGOTS
Response Variable (Events)	r
Response Variable (Trials)	n
Model	binary logit
Optimization Technique	Fisher's scoring
Number of Observations Read	19
Number of Observations Used	19
Sum of Frequencies Read	387
Sum of Frequencies Used	387

The “Response Profile” table (Figure 54.2) lists the response categories (which are Event and Nonevent when grouped data are input), their ordered values, and their total frequencies for the given data.

Figure 54.2 Response Profile with Events/Trials Syntax

Response Profile		
Ordered Value	Binary Outcome	Total Frequency
1	Event	12
2	Nonevent	375
Model Convergence Status		
Convergence criterion (GCONV=1E-8) satisfied.		

The “Model Fit Statistics” table (Figure 54.3) contains Akaike’s information criterion (AIC), the Schwarz criterion (SC), and the negative of twice the log likelihood ($-2 \text{ Log } L$) for the intercept-only model and the fitted model. AIC and SC can be used to compare different models, and the ones with smaller values are preferred. Results of the likelihood ratio test and the efficient score test for testing the joint significance of the explanatory variables (Soak, Heat, and their interaction) are included in the “Testing Global Null Hypothesis: BETA=0” table (Figure 54.3); the small p -values reject the hypothesis that all slope parameters are equal to zero.

Figure 54.3 Fit Statistics and Hypothesis Tests

Model Fit Statistics			
Criterion	Intercept	Intercept and Covariates	
	Only	Log Likelihood	Full Log Likelihood
AIC	108.988	103.222	35.957
SC	112.947	119.056	51.791
-2 Log L	106.988	95.222	27.957

Testing Global Null Hypothesis: BETA=0			
Test	Chi-Square	DF	Pr > ChiSq
Likelihood Ratio	11.7663	3	0.0082
Score	16.5417	3	0.0009
Wald	13.4588	3	0.0037

The “Analysis of Maximum Likelihood Estimates” table in [Figure 54.4](#) lists the parameter estimates, their standard errors, and the results of the Wald test for individual parameters. Note that the Heat*Soak parameter is not significantly different from zero ($p=0.727$), nor is the Soak variable ($p=0.6916$).

Figure 54.4 Parameter Estimates

Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	1	-5.9901	1.6666	12.9182	0.0003
Heat	1	0.0963	0.0471	4.1895	0.0407
Soak	1	0.2996	0.7551	0.1574	0.6916
Heat*Soak	1	-0.00884	0.0253	0.1219	0.7270

The “Association of Predicted Probabilities and Observed Responses” table ([Figure 54.5](#)) contains four measures of association for assessing the predictive ability of a model. They are based on the number of pairs of observations with different response values, the number of concordant pairs, and the number of discordant pairs, which are also displayed. Formulas for these statistics are given in the section “[Rank Correlation of Observed Responses and Predicted Probabilities](#)” on page 4253.

Figure 54.5 Association Table

Association of Predicted Probabilities and Observed Responses			
Percent Concordant	70.9	Somers' D	0.537
Percent Discordant	17.3	Gamma	0.608
Percent Tied	11.8	Tau-a	0.032
Pairs	4500	c	0.768

The **ODDSRATIO** statement produces the “Odds Ratio Estimates and Wald Confidence Intervals” table (Figure 54.6), and a graphical display of these estimates is shown in Figure 54.7. The differences between the odds ratios are small compared to the variability shown by their confidence intervals, which confirms the previous conclusion that the Heat*Soak parameter is not significantly different from zero.

Figure 54.6 Odds Ratios of Heat at Several Values of Soak

Odds Ratio Estimates and Wald Confidence Intervals			
Label	Estimate	95% Confidence Limits	
Heat at Soak=1	1.091	1.032	1.154
Heat at Soak=2	1.082	1.028	1.139
Heat at Soak=3	1.072	0.986	1.166
Heat at Soak=4	1.063	0.935	1.208

Figure 54.7 Plot of Odds Ratios of Heat at Several Values of Soak

Since the Heat*Soak interaction is nonsignificant, the following statements fit a main-effects model:

```
proc logistic data=ingots;
  model r/n = Heat Soak;
run;
```

The results of this analysis are shown in the following figures. The model information and response profiles are the same as those in Figure 54.1 and Figure 54.2 for the saturated model. The “Model Fit Statistics” table in Figure 54.8 shows that the AIC and SC for the main-effects model are smaller than for the saturated model, indicating that the main-effects model might be the preferred model. As in the preceding model, the “Testing Global Null Hypothesis: BETA=0” table indicates that the parameters are significantly different from zero.

Figure 54.8 Fit Statistics and Hypothesis Tests

The LOGISTIC Procedure			
Model Fit Statistics			
Criterion	Intercept Only	Intercept and Covariates Log Likelihood	Full Log Likelihood
AIC	108.988	101.346	34.080
SC	112.947	113.221	45.956
-2 Log L	106.988	95.346	28.080
Testing Global Null Hypothesis: BETA=0			
Test	Chi-Square	DF	Pr > ChiSq
Likelihood Ratio	11.6428	2	0.0030
Score	15.1091	2	0.0005
Wald	13.0315	2	0.0015

The “Analysis of Maximum Likelihood Estimates” table in [Figure 54.9](#) again shows that the Soak parameter is not significantly different from zero ($p=0.8639$). The odds ratio for each effect parameter, estimated by exponentiating the corresponding parameter estimate, is shown in the “Odds Ratios Estimates” table ([Figure 54.9](#)), along with 95% Wald confidence intervals. The confidence interval for the Soak parameter contains the value 1, which also indicates that this effect is not significant.

Figure 54.9 Parameter Estimates and Odds Ratios

Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	1	-5.5592	1.1197	24.6503	<.0001
Heat	1	0.0820	0.0237	11.9454	0.0005
Soak	1	0.0568	0.3312	0.0294	0.8639
Odds Ratio Estimates					
Effect	Point Estimate	95% Wald Confidence Limits			
Heat	1.085	1.036	1.137		
Soak	1.058	0.553	2.026		

Figure 54.9 continued

Association of Predicted Probabilities and Observed Responses			
Percent Concordant	64.4	Somers' D	0.460
Percent Discordant	18.4	Gamma	0.555
Percent Tied	17.2	Tau-a	0.028
Pairs	4500	c	0.730

Using these parameter estimates, you can calculate the estimated logit of π as

$$-5.5592 + 0.082 \times \text{Heat} + 0.0568 \times \text{Soak}$$

For example, if Heat=7 and Soak=1, then $\text{logit}(\hat{\pi}) = -4.9284$. Using this logit estimate, you can calculate $\hat{\pi}$ as follows:

$$\hat{\pi} = 1/(1 + e^{4.9284}) = 0.0072$$

This gives the predicted probability of the event (ingot not ready for rolling) for Heat=7 and Soak=1. Note that PROC LOGISTIC can calculate these statistics for you; use the **OUTPUT** statement with the **PREDICTED=** option, or use the **SCORE** statement.

To illustrate the use of an alternative form of input data, the following program creates the **ingots** data set with the new variables **NotReady** and **Freq** instead of **n** and **r**. The variable **NotReady** represents the response of individual units; it has a value of 1 for units not ready for rolling (event) and a value of 0 for units ready for rolling (nonevent). The variable **Freq** represents the frequency of occurrence of each combination of Heat, Soak, and NotReady. Note that, compared to the previous data set, NotReady=1 implies Freq=r, and NotReady=0 implies Freq=n-r.

```
data ingots;
  input Heat Soak NotReady Freq @@;
  datalines;
7 1.0 0 10 14 1.0 0 31 14 4.0 0 19 27 2.2 0 21 51 1.0 1 3
7 1.7 0 17 14 1.7 0 43 27 1.0 1 1 27 2.8 1 1 51 1.0 0 10
7 2.2 0 7 14 2.2 1 2 27 1.0 0 55 27 2.8 0 21 51 1.7 0 1
7 2.8 0 12 14 2.2 0 31 27 1.7 1 4 27 4.0 1 1 51 2.2 0 1
7 4.0 0 9 14 2.8 0 31 27 1.7 0 40 27 4.0 0 15 51 4.0 0 1
;
```

The following statements invoke PROC LOGISTIC to fit the main-effects model by using the alternative form of the input data set:

```
proc logistic data=ingots;
  model NotReady(event='1') = Heat Soak;
  freq Freq;
run;
```

Results of this analysis are the same as the preceding single-trial main-effects analysis. The displayed output for the two runs are identical except for the background information of the model fit and the “Response Profile” table shown in [Figure 54.10](#).

Figure 54.10 Response Profile with Single-Trial Syntax

The LOGISTIC Procedure		
Response Profile		
Ordered Value	NotReady	Total Frequency
1	0	375
2	1	12
Probability modeled is NotReady=1.		

By default, Ordered Values are assigned to the sorted response values in ascending order, and PROC LOGISTIC models the probability of the response level that corresponds to the Ordered Value 1. There are several methods to change these defaults; the preceding statements specify the response variable option `EVENT=` to model the probability of NotReady=1 as displayed in [Figure 54.10](#). See the section “[Response Level Ordering](#)” on page 4237 for more details.

Syntax: LOGISTIC Procedure

The following statements are available in the LOGISTIC procedure:

```

PROC LOGISTIC < options > ;
  BY variables ;
  CLASS variable < (options) > < variable < (options) > ... > < / options > ;
  CODE < options > ;
  CONTRAST 'label' effect values<, effect values, ... > < / options > ;
  EFFECT name=effect-type(variables < / options >) ;
  EFFECTPLOT < plot-type < (plot-definition-options) > > < / options > ;
  ESTIMATE < 'label' > estimate-specification < / options > ;
  EXACT < 'label' > < INTERCEPT > < effects > < / options > ;
  EXACTOPTIONS options ;
  FREQ variable ;
  ID variables ;
  LSMEANS < model-effects > < / options > ;
  LSMESTIMATE model-effect lsestimate-specification < / options > ;
  < label: > MODEL variable < (variable_options) > = < effects > < / options > ;
  < label: > MODEL events/trials = < effects > < / options > ;
  NLOPTIONS options ;
  ODDSRATIO < 'label' > variable < / options > ;
  OUTPUT < OUT=SAS-data-set > < keyword=name < keyword=name ... > > < / option > ;
  ROC < 'label' > < specification > < / options > ;
  ROCCONTRAST < 'label' > < contrast > < / options > ;
  SCORE < options > ;
  SLICE model-effect < / options > ;
  STORE < OUT= > item-store-name < / LABEL= 'label' > ;
  STRATA effects < / options > ;
  < label: > TEST equation1 <, equation2, ... > < / option > ;
  UNITS < independent1=list1 < independent2=list2 ... > > < / option > ;
  WEIGHT variable < / option > ;

```

The PROC LOGISTIC and MODEL statements are required. The CLASS and EFFECT statements (if specified) must precede the MODEL statement, and the CONTRAST, EXACT, and ROC statements (if specified) must follow the MODEL statement.

The PROC LOGISTIC, MODEL, and ROCCONTRAST statements can be specified at most once. If a FREQ or WEIGHT statement is specified more than once, the variable specified in the first instance is used. If a BY, OUTPUT, or UNITS statement is specified more than once, the last instance is used.

The rest of this section provides detailed syntax information for each of the preceding statements, beginning with the PROC LOGISTIC statement. The remaining statements are covered in alphabetical order. The CODE, EFFECT, EFFECTPLOT, ESTIMATE, LSMEANS, LSMESTIMATE, SLICE, and STORE statements are also available in many other procedures. Summary descriptions of functionality and syntax for these statements are provided, but you can find full documentation on them in the corresponding sections of Chapter 19, “Shared Concepts and Topics.”

PROC LOGISTIC Statement

PROC LOGISTIC < options > ;

The PROC LOGISTIC statement invokes the LOGISTIC procedure. Optionally, it identifies input and output data sets, suppresses the display of results, and controls the ordering of the response levels. Table 54.1 summarizes the options available in the PROC LOGISTIC statement.

Table 54.1 PROC LOGISTIC Statement Options

Option	Description
Input/Output Data Set Options	
COVOUT	Displays the estimated covariance matrix in the OUTEST= data set
DATA=	Names the input SAS data set
INEST=	Specifies the initial estimates SAS data set
INMODEL=	Specifies the model information SAS data set
NOCOVAR	Does not save covariance matrix in the OUTMODEL= data set
OUTDESIGN=	Specifies the design matrix output SAS data set
OUTDESIGNONLY	Outputs the design matrix only
OUTEST=	Specifies the parameter estimates output SAS data set
OUTMODEL=	Specifies the model output data set for scoring
Response and CLASS Variable Options	
DESCENDING	Reverses the sort order of the response variable
NAMELEN=	Specifies the maximum length of effect names
ORDER=	Specifies the sort order of the response variable
TRUNCATE	Truncates class level names
Displayed Output Options	
ALPHA=	Specifies the significance level for confidence intervals
NOPRINT	Suppresses all displayed output
PLOTS	Specifies options for plots
SIMPLE	Displays descriptive statistics
Large Data Set Option	
MULTIPASS	Does not copy the input SAS data set for internal computations
Control of Other Statement Options	
EXACTONLY	Performs exact analysis only
EXACTOPTIONS	Specifies global options for EXACT statements
ROCOPTIONS	Specifies global options for ROC statements

ALPHA=number

specifies the level of significance α for $100(1 - \alpha)\%$ confidence intervals. The value *number* must be between 0 and 1; the default value is 0.05, which results in 95% intervals. This value is used as the default confidence level for limits computed by the following options:

Statement	Options
CONTRAST	ESTIMATE=
EXACT	ESTIMATE=
MODEL	CLODDS= CLPARM=
ODDSRATIO	CL=
OUTPUT	LOWER= UPPER=
PROC LOGISTIC	PLOTS=EFFECT(CLBAR CLBAND)
ROCONTRAST	ESTIMATE=
SCORE	CLM

You can override the default in most of these cases by specifying the ALPHA= option in the separate statements.

COVOUT

adds the estimated covariance matrix to the OUTEST= data set. For the COVOUT option to have an effect, the OUTEST= option must be specified. See the section “OUTEST= Output Data Set” on page 4279 for more information.

DATA=SAS-data-set

names the SAS data set containing the data to be analyzed. If you omit the DATA= option, the procedure uses the most recently created SAS data set. The INMODEL= option cannot be specified with this option.

DESCENDING

DESC

reverses the sort order for the levels of the response variable. If both the DESCENDING and ORDER= options are specified, PROC LOGISTIC orders the levels according to the ORDER= option and then reverses that order. This option has the same effect as the response variable option DESCENDING in the MODEL statement. See the section “Response Level Ordering” on page 4237 for more detail.

EXACTONLY

requests only the exact analyses. The asymptotic analysis that PROC LOGISTIC usually performs is suppressed.

EXACTOPTIONS (options)

specifies options that apply to every EXACT statement in the program. The available options are summarized here, and full descriptions are available in the EXACTOPTIONS statement.

Option	Description
ADDTOBS	Adds the observed sufficient statistic to the sampled exact distribution
BUILDSUBSETS	Builds every distribution for sampling
EPSILON=	Specifies the comparison fuzz for partial sums of sufficient statistics
MAXTIME=	Specifies the maximum time allowed in seconds
METHOD=	Specifies the DIRECT, NETWORK, or NETWORKMC algorithm
N=	Specifies the number of Monte Carlo samples
ONDISK	Uses disk space
SEED=	Specifies the initial seed for sampling
STATUSN=	Specifies the sampling interval for printing a status line
STATUSTIME=	Specifies the time interval for printing a status line

INEST=SAS-data-set

names the SAS data set that contains initial estimates for all the parameters in the model. If BY-group processing is used, it must be accommodated in setting up the INEST= data set. See the section “[INEST= Input Data Set](#)” on page 4280 for more information.

INMODEL=SAS-data-set

specifies the name of the SAS data set that contains the model information needed for scoring new data. This INMODEL= data set is the [OUTMODEL=](#) data set saved in a previous PROC LOGISTIC call. The OUTMODEL= data set should not be modified before its use as an INMODEL= data set.

The [DATA=](#) option cannot be specified with this option; instead, specify the data sets to be scored in the [SCORE](#) statements. [FORMAT](#) statements are not allowed when the INMODEL= data set is specified; variables in the [DATA=](#) and [PRIOR=](#) data sets in the [SCORE](#) statement should be formatted within the data sets.

You can specify the [BY](#) statement provided that the INMODEL= data set is created under the same BY-group processing.

The [CLASS](#), [EFFECT](#), [EFFECTPLOT](#), [ESTIMATE](#), [EXACT](#), [LSMEANS](#), [LSMESTIMATE](#), [MODEL](#), [OUTPUT](#), [ROC](#), [ROCONTRAST](#), [SLICE](#), [STORE](#), [TEST](#), and [UNIT](#) statements are not available with the INMODEL= option.

MULTIPASS

forces the procedure to reread the [DATA=](#) data set as needed rather than require its storage in memory or in a temporary file on disk. By default, the data set is cleaned up and stored in memory or in a temporary file. This option can be useful for large data sets. All exact analyses are ignored in the presence of the MULTIPASS option. If a [STRATA](#) statement is specified, then the data set must first be grouped or sorted by the strata variables.

NAMELEN=*n*

specifies the maximum length of effect names in tables and output data sets to be *n* characters, where *n* is a value between 20 and 200. The default length is 20 characters.

NOCOV

specifies that the covariance matrix not be saved in the [OUTMODEL=](#) data set. The covariance matrix is needed for computing the confidence intervals for the posterior probabilities in the [OUT=](#) data set in the [SCORE](#) statement. Specifying this option will reduce the size of the [OUTMODEL=](#) data set.

NOPRINT

suppresses all displayed output. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, “[Using the Output Delivery System](#),” for more information.

ORDER=DATA | FORMATTED | FREQ | INTERNAL**RORDER=DATA | FORMATTED | INTERNAL**

specifies the sort order for the levels of the response variable. See the response variable option [ORDER=](#) in the [MODEL](#) statement for more information. For ordering of [CLASS](#) variable levels, see the [ORDER=](#) option in the [CLASS](#) statement.

OUTDESIGN=SAS-data-set

specifies the name of the data set that contains the design matrix for the model. The data set contains the same number of observations as the corresponding [DATA=](#) data set and includes the response

variable (with the same format as in the DATA= data set), the **FREQ** variable, the **WEIGHT** variable, the **OFFSET=** variable, and the design variables for the covariates, including the Intercept variable of constant value 1 unless the **NOINT** option in the **MODEL** statement is specified.

OUTDESIGNONLY

suppresses the model fitting and creates only the **OUTDESIGN=** data set. This option is ignored if the **OUTDESIGN=** option is not specified.

OUTEST=SAS-data-set

creates an output SAS data set that contains the final parameter estimates and, optionally, their estimated covariances (see the preceding **COVOUT** option). The output data set also includes a variable named **_LNLIKE_**, which contains the log likelihood. See the section “**OUTEST= Output Data Set**” on page 4279 for more information.

OUTMODEL=SAS-data-set

specifies the name of the SAS data set that contains the information about the fitted model. This data set contains sufficient information to score new data without having to refit the model. It is solely used as the input to the **INMODEL=** option in a subsequent PROC LOGISTIC call. The **OUTMODEL=** option is not available with the **STRATA** statement. Information in this data set is stored in a very compact form, so you should not modify it manually.

NOTE: The **STORE** statement can also be used to save your model. See the section “**STORE Statement**” on page 4233 for more information.

PLOTS < (*global-plot-options*) > < =*plot-request*< (*options*)> >

PLOTS < (*global-plot-options*) > =(*plot-request*< (*options*)>< ... *plot-request*< (*options*)>>)

controls the plots produced through ODS Graphics. When you specify only one *plot-request*, you can omit the parentheses from around the *plot-request*. For example:

```
PLOTS = ALL
PLOTS = (ROC EFFECT INFLUENCE (UNPACK) )
PLOTS (ONLY) = EFFECT (CLBAR SHOWOBS)
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc logistic plots=all;
    model y=x;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “**Enabling and Disabling ODS Graphics**” on page 600 in Chapter 21, “**Statistical Graphics Using ODS**.”

If the **PLOTS** option is not specified or is specified with no *plot-requests*, then graphics are produced by default in the following situations:

- If the **INFLUENCE** or **IPLOTS** option is specified in the **MODEL** statement, then the line-printer plots are suppressed, and the **INFLUENCE** plots are produced unless the **MAXPOINTS=** cutoff is exceeded.

- If you specify the **OUTROC=** option in the **MODEL** statement, then ROC curves are produced. If you also specify a **SELECTION=** method, then an overlaid plot of all the ROC curves for each step of the selection process is displayed.
- If the **OUTROC=** option is specified in a **SCORE** statement, then the ROC curve for the scored data set is displayed.
- If you specify **ROC** statements, then an overlaid plot of the ROC curves for the model (or the selected model if a **SELECTION=** method is specified) and for all the ROC statement models is displayed.
- If an odds ratio table is produced, then a plot of the odds ratios and their confidence limits is displayed. These plots correspond to the default odds ratio table and the tables produced by the **CLODDS=** option in the **MODEL** statement and the tables produced by the **ODDSRATIO** statement.

For general information about ODS Graphics, see Chapter 21, “Statistical Graphics Using ODS.”

The following *global-plot-options* are available:

LABEL

displays a label on diagnostic plots to aid in identifying the outlying observations. This option enhances the plots produced by the **DFBETAS**, **DPC**, **INFLUENCE**, **LEVERAGE**, and **PHAT** options. If an **ID** statement is specified, then the plots are labeled with the ID variables. Otherwise, the observation number is displayed.

MAXPOINTS=NONE | *number*

suppresses the plots produced by the **DFBETAS**, **DPC**, **INFLUENCE**, **LEVERAGE**, and **PHAT** options if there are more than *number* observations. Also, observations are not displayed on the **EFFECT** plots when the cutoff is exceeded. The default is **MAXPOINTS=5000**. The cutoff is ignored if you specify **MAXPOINTS=NONE**.

ONLY

specifically requested *plot-requests* are displayed.

UNPACKPANELS | **UNPACK**

suppresses paneling. By default, multiple plots can appear in some output *panels*. Specify **UNPACKPANEL** to display each plot separately.

The following *plot-requests* are available:

ALL

produces all appropriate plots. You can specify other options with **ALL**. For example, to display all plots and unpack the **DFBETAS** plots you can specify **plots=(all dfbetas(unpack))**.

DFBETAS <(UNPACK)>

displays plots of **DFBETAS** versus the case (observation) number. This displays the statistics generated by the **DFBETAS=_ALL_** option in the **OUTPUT** statement. The **UNPACK** option displays the plots separately. See [Output 54.6.5](#) for an example of this plot.

DPC<(UNPACK)>

displays plots of **DIFCHISQ** and **DIFDEV** versus the predicted event probability, and colors the markers according to the value of the confidence interval displacement **C**. The **UNPACK** option displays the plots separately. See [Output 54.6.8](#) for an example of this plot.

EFFECT<(effect-options)>

displays and enhances the effect plots for the model. For more information about effect plots and the available *effect-options*, see the section “**PLOTS=EFFECT Plots**” on page 4182.

NOTE: The **EFFECTPLOT** statement provides you with much of the same functionality and more options for creating effect plots. See [Outputs 54.2.11, 54.3.5, 54.4.8, 54.7.4, and 54.15.4](#) for examples of effect plots.

INFLUENCE<(UNPACK | STDRES)>

displays index plots of **RESCHI**, **RESDEV**, leverage, confidence interval displacements **C** and **CBar**, **DIFCHISQ**, and **DIFDEV**. These plots are produced by default when any *plot-request* is specified and the **MAXPOINTS=** cutoff is not exceeded. The **UNPACK** option displays the plots separately. The **STDRES** option also displays index plots of **STDRESCHI**, **STDRESDEV**, and **RESLIK**. See [Outputs 54.6.3 and 54.6.4](#) for examples of these plots.

LEVERAGE<(UNPACK)>

displays plots of **DIFCHISQ**, **DIFDEV**, confidence interval displacement **C**, and the predicted probability versus the leverage. The **UNPACK** option displays the plots separately. See [Output 54.6.7](#) for an example of this plot.

NONE

suppresses all plots.

ODDSRATIO <(oddsratio-options)>

displays and enhances the odds ratio plots for the model. For more information about odds ratio plots and the available *oddsratio-options*, see the section “**Odds Ratio Plots**” on page 4185. See [Outputs 54.7, 54.2.9, 54.3.3, and 54.4.5](#) for examples of this plot.

PHAT<(UNPACK)>

displays plots of **DIFCHISQ**, **DIFDEV**, confidence interval displacement **C**, and leverage versus the predicted event probability. The **UNPACK** option displays the plots separately. See [Output 54.6.6](#) for an example of this plot.

ROC<(ID=<keyword>)>

displays the ROC curve. If you also specify a **SELECTION=** method, then an overlaid plot of all the ROC curves for each step of the selection process is displayed. If you specify **ROC** statements, then an overlaid plot of the model (or the selected model if a **SELECTION=** method is specified) and the ROC statement models is displayed. If the **OUTROC=** option is specified in a **SCORE** statement, then the ROC curve for the scored data set is displayed.

The **ID=** option labels certain points on the ROC curve. Typically, the labeled points are closest to the upper-left corner of the plot, and points directly below or to the right of a labeled point are suppressed. This option is identical to, and has the same *keywords* as, the **ID=** suboption of the **ROCOPTIONS** option.

See [Output 54.7.3](#) and [Example 54.8](#) for examples of these ROC plots.

ROCOPTIONS (*options*)

specifies options that apply to every model specified in a **ROC** statement. Some of these options also apply to the **SCORE** statement. The following *options* are available:

ALPHA=*number*

sets the significance level for creating confidence limits of the areas and the pairwise differences. The **ALPHA=** value specified in the PROC LOGISTIC statement is the default. If neither **ALPHA=** value is specified, then **ALPHA=0.05** by default.

EPS=*value*

is an alias for the **ROCEPS=** option in the MODEL statement. This value is used to determine which predicted probabilities are equal. The default value is the square root of the machine epsilon, which is about 1E–8.

ID<=*keyword*>

displays labels on certain points on the individual ROC curves and also on the **SCORE** statement's ROC curve. This option overrides the **ID=** suboption of the **PLOTS=ROC** option. If several observations lie at the same place on the ROC curve, the value for the last observation is displayed. If you specify the **ID** option with no *keyword*, any variables that are listed in the **ID** statement are used. If no **ID** statement is specified, the observation number is displayed. The following *keywords* are available:

PROB	displays the model predicted probability.
OBS	displays the (last) observation number.
SENSIT	displays the true positive fraction (sensitivity).
1MSPEC	displays the false positive fraction (1–specificity).
FALPOS	displays the fraction of nonevents that are predicted as events.
FALNEG	displays the fraction of events that are predicted as nonevents.
POSPRED	displays the positive predictive value (1–FALPOS).
NEGPRED	displays the negative predictive value (1–FALNEG).
MISCLASS	displays the misclassification rate.
ID	displays the ID variables.

The **SENSIT**, **1MSPEC**, **FALPOS**, and **FALNEG** statistics are defined in the section “**Receiver Operating Characteristic Curves**” on page 4260. The misclassification rate is the number of events that are predicted as nonevents and the number of nonevents that are predicted as events as calculated by using the given cutpoint (predicted probability) divided by the number of observations. If the **PEVENT=** option is also specified, then **FALPOS** and **FALNEG** are computed using the first **PEVENT=** value and Bayes’ theorem, as discussed in the section “**Predicted Probability of an Event for Classification**” on page 4255.

NODETAILS

suppresses the display of the model fitting information for the models specified in the **ROC** statements.

OUT=SAS-data-set-name

is an alias for the **OUTROC=** option in the **MODEL** statement.

WEIGHTED

uses frequency×weight in the ROC computations (Izrael et al. 2002) instead of just frequency. Typically, weights are considered in the fit of the model only, and hence are accounted for in the parameter estimates. The “Association of Predicted Probabilities and Observed Responses” table uses frequency (unless the **BINWIDTH=0** option is also specified on the **MODEL** statement), and is suppressed when ROC comparisons are performed. This option also affects **SCORE** statement ROC and AUC computations.

SIMPLE

displays simple descriptive statistics (mean, standard deviation, minimum and maximum) for each continuous explanatory variable. For each **CLASS** variable involved in the modeling, the frequency counts of the classification levels are displayed. The **SIMPLE** option generates a breakdown of the simple descriptive statistics or frequency counts for the entire data set and also for individual response categories.

TRUNCATE

determines class levels by using no more than the first 16 characters of the formatted values of **CLASS**, response, and strata variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases previous to SAS 9.0. This option invokes the same option in the **CLASS** statement.

PLOTS=EFFECT Plots

Only one **PLOTS=EFFECT** plot is produced by default; you must specify other *effect-options* to produce multiple plots. For binary response models, the following plots are produced when an **EFFECT** option is specified with no *effect-options*:

- If you only have continuous covariates in the model, then a plot of the predicted probability versus the first continuous covariate fixing all other continuous covariates at their means is displayed. See [Output 54.7.4](#) for an example with one continuous covariate.
- If you only have classification covariates in the model, then a plot of the predicted probability versus the first **CLASS** covariate at each level of the second **CLASS** covariate, if any, holding all other **CLASS** covariates at their reference levels is displayed.
- If you have **CLASS** and continuous covariates, then a plot of the predicted probability versus the first continuous covariate at up to 10 cross-classifications of the **CLASS** covariate levels, while fixing all other continuous covariates at their means and all other **CLASS** covariates at their reference levels, is displayed. For example, if your model has four binary covariates, there are 16 cross-classifications of the **CLASS** covariate levels. The plot displays the 8 cross-classifications of the levels of the first three covariates while the fourth covariate is fixed at its reference level.

For polytomous response models, similar plots are produced by default, except that the response levels are used in place of the **CLASS** covariate levels. Plots for polytomous response models involving **OFFSET=** variables with multiple values are not available.

The following *effect-options* specify the type of graphic to produce:

AT(variable=value-list | ALL<...variable=value-list | ALL>)

specifies fixed values for a covariate. For continuous covariates, you can specify one or more numbers in the *value-list*. For classification covariates, you can specify one or more formatted levels of the covariate enclosed in single quotes (for example, **A='cat' 'dog'**), or you can specify the keyword **ALL** to select all levels of the classification variable. You can specify a variable at most once in the **AT** option. By default, continuous covariates are set to their means when they are not used on an axis, while classification covariates are set to their reference level when they are not used as an **X=**, **SLICEBY=**, or **PLOTBY=** effect. For example, for a model that includes a classification variable **A={cat,dog}** and a continuous covariate **X**, specifying **AT (A='cat' X=7 9)** will set **A** to 'cat' when **A** does not appear in the plot. When **X** does not define an axis it first produces plots setting **X = 7** and then produces plots setting **X = 9**. Note in this example that specifying **AT (A=ALL)** is the same as specifying the **PLOTBY=A** option.

FITOBSONLY

computes the predicted values only at the observed data. If the **FITOBSONLY** option is omitted and the **X-axis** variable is continuous, the predicted values are computed at a grid of points extending slightly beyond the range of the data (see the **EXTEND=** option for more information). If the **FITOBSONLY** option is omitted and the **X-axis** effect is categorical, the predicted values are computed at all possible categories.

INDIVIDUAL

displays the individual probabilities instead of the cumulative probabilities. This option is available only with cumulative models, and it is not available with the **LINK** option.

LINK

displays the linear predictors instead of the probabilities on the **Y** axis. For example, for a binary logistic regression, the **Y** axis will be displayed on the logit scale. The **INDIVIDUAL** and **POLYBAR** options are not available with the **LINK** option.

PLOTBY=effect

displays an effect plot at each unique level of the **PLOTBY=** effect. You can specify *effect* as one **CLASS** variable or as an interaction of classification covariates. For polytomous-response models, you can also specify the response variable as the lone **PLOTBY=** effect. For nonsingular parameterizations, the complete cross-classification of the **CLASS** variables specified in the effect define the different **PLOTBY=** levels. When the **GLM** parameterization is used, the **PLOTBY=** levels can depend on the model and the data.

SLICEBY=effect

displays predicted probabilities at each unique level of the **SLICEBY=** effect. You can specify *effect* as one **CLASS** variable or as an interaction of classification covariates. For polytomous-response models, you can also specify the response variable as the lone **SLICEBY=** effect. For nonsingular parameterizations, the complete cross-classification of the **CLASS** variables specified in the effect define the different **SLICEBY=** levels. When the **GLM** parameterization is used, the **SLICEBY=** levels can depend on the model and the data.

X=effect**X=(effect...effect)**

specifies effects to be used on the **X** axis of the effect plots. You can specify several different **X** axes: continuous variables must be specified as main effects, while **CLASS** variables can be crossed. For nonsingular parameterizations, the complete cross-classification of the **CLASS** variables specified in

the effect define the axes. When the **GLM** parameterization is used, the X= levels can depend on the model and the data. The response variable is not allowed as an *effect*.

NOTE: Any variable not specified in a **SLICEBY=** or **PLOTBY=** option is available to be displayed on the X axis. A variable can be specified in at most one of the **SLICEBY=**, **PLOTBY=**, and **X=** options.

The following *effect-options* enhance the graphical output:

ALPHA=*number*

specifies the size of the confidence limits. The **ALPHA=** value specified in the PROC LOGISTIC statement is the default. If neither **ALPHA=** value is specified, then **ALPHA=0.05** by default.

CLBAND<=**YES** | **NO**>

displays confidence limits on the plots. This option is not available with the **INDIVIDUAL** option. If you have **CLASS** covariates on the X axis, then error bars are displayed (see the **CLBAR** option) unless you also specify the **CONNECT** option.

CLBAR

displays the error bars on the plots when you have **CLASS** covariates on the X axis; if the X axis is continuous, then this invokes the **CLBAND** option. For polytomous-response models with **CLASS** covariates only and with the **POLYBAR** option specified, the stacked bar charts are replaced by side-by-side bar charts with error bars.

CLUSTER<=*percent*>

displays the levels of the **SLICEBY=** effect in a side-by-side fashion instead of stacking them. This option is available when you have **CLASS** covariates on the X axis. You can specify *percent* as a percentage of half the distance between X levels. The *percent* value must be between 0.1 and 1; the default *percent* depends on the number of X levels and the number of **SLICEBY=** levels. Default clustering can be removed by specifying the **NOCLUSTER** option.

CONNECT<=**YES** | **NO**>

JOIN<=**YES** | **NO**>

connects the predicted values with a line. This option is available when you have **CLASS** covariates on the X axis. Default connecting lines can be suppressed by specifying the **NOCONNECT** option.

EXTEND=*value*

extends continuous X axes by a factor of *value*/2 in each direction. By default, **EXTEND=0.2**.

MAXATLEN=*length*

specifies the maximum number of characters used to display the levels of all the fixed variables. If the text is too long, it is truncated and ellipses (“...”) are appended. By default, *length* is equal to its maximum allowed value, 256.

NOCLUSTER

prevents clustering of the levels of the **SLICEBY=** effect. This option is available when you have **CLASS** covariates on the X axis.

NOCONNECT

removes the line that connects the predicted values. This option is available when you have **CLASS** covariates on the X axis.

POLYBAR

replaces scatter plots of polytomous response models with bar charts. This option has no effect on binary-response models, and it is overridden by the **CONNECT** option. By default, the X axis is chosen to be a crossing of available classification variables so that there are no more than 16 levels; if no such crossing is possible then the first available classification variable is used. You can override this default by specifying the **X=** option.

SHOWOBS<=YES | NO>

displays observations on the plot when the **MAXPOINTS=** cutoff is not exceeded. For events/trials notation, the observed proportions are displayed; for single-trial binary-response models, the observed events are displayed at $\hat{p} = 1$ and the observed nonevents are displayed at $\hat{p} = 0$. For polytomous response models the predicted probabilities at the observed values of the covariate are computed and displayed.

YRANGE=(*< min>* , *< max>*)

displays the Y axis as [*min*, *max*]. Note that the axis might extend beyond your specified values. By default, the entire Y axis, [0,1], is displayed for the predicted probabilities. This option is useful if your predicted probabilities are all contained in some subset of this range.

Odds Ratio Plots

The odds ratios and confidence limits from the default Odds Ratio Estimates table and from the tables produced by the **CLODDS=** option or the **ODDSRATIO** statement can be displayed in a graphic. If you have many odds ratios, you can produce multiple graphics, or *panels*, by displaying subsets of the odds ratios. Odds ratios with duplicate labels are not displayed. See Outputs 54.2.9 and 54.3.3 for examples of odds ratio plots.

The following *oddsratio-options* modify the default odds ratio plot:

CLDISPLAY=SERIF | LINE | BAR< width>

controls the look of the confidence limit error bars. The default **CLDISPLAY=SERIF** displays the confidence limits as lines with serifs, **CLDISPLAY=LINE** removes the serifs from the error bars, and **CLDISPLAY=BAR < width>** displays the limits with a bar of width equal to the size of the marker. You can control the width of the bars and the size of the marker by specifying the *width* value as a percentage of the distance between the bars, $0 < \textit{width} \leq 1$.

NOTE: Your bar might disappear with small values of *width*.

DOTPLOT

displays dotted gridlines on the plot.

GROUP

displays the odds ratios in panels defined by the **ODDSRATIO** statements. The **NPANELPOS=** option is ignored when this option is specified.

LOGBASE=2 | E | 10

displays the odds ratio axis on the specified log scale.

NPANELPOS=*n*

breaks the plot into multiple graphics having at most $|n|$ odds ratios per graphic. If n is positive, then the number of odds ratios per graphic is balanced; but if n is negative, then no balancing of the number of odds ratios takes place. By default, $n = 0$ and all odds ratios are displayed in a single plot. For example, suppose you want to display 21 odds ratios. Then specifying **NPANELPOS=20** displays two plots, the first with 11 odds ratios and the second with 10; but specifying **NPANELPOS=-20** displays 20 odds ratios in the first plot and only 1 odds ratio in the second.

ORDER=ASCENDING | DESCENDING

displays the odds ratios in sorted order. By default the odds ratios are displayed in the order in which they appear in the corresponding table.

RANGE=(*< min >* ,*< max >*) | CLIP

specifies the range of the displayed odds ratio axis. The RANGE=CLIP option has the same effect as specifying the minimum odds ratio as *min* and the maximum odds ratio as *max*. By default, all odds ratio confidence intervals are displayed.

TYPE=HORIZONTAL | HORIZONTALSTAT | VERTICAL | VERTICALBLOCK

controls the look of the graphic. The default TYPE=HORIZONTAL option places the odds ratio values on the X axis, while the TYPE=HORIZONTALSTAT option also displays the values of the odds ratios and their confidence limits on the right side of the graphic. The TYPE=VERTICAL option places the odds ratio values on the Y axis, while the TYPE=VERTICALBLOCK option (available only with the **CLODDS=** option) places the odds ratio values on the Y axis and puts boxes around the labels.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC LOGISTIC to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the LOGISTIC procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

If a **SCORE** statement is specified, then define the *training data set* to be the **DATA=** data set or the **IN-MODEL=** data set in the PROC LOGISTIC statement, and define the *scoring data set* to be the **DATA=** data set and **PRIOR=** data set in the SCORE statement. The training data set contains all of the BY variables, and

the scoring data set must contain either all of them or none of them. If the scoring data set contains all the BY variables, matching is carried out between the training and scoring data sets. If the scoring data set does not contain any of the BY variables, the entire scoring data set is used for every BY group in the training data set and the BY variables are added to the output data sets that are specified in the [SCORE](#) statement.

CAUTION: The order of the levels in the response and classification variables is determined from all the data regardless of BY groups. However, different sets of levels might appear in different BY groups. This might affect the value of the reference level for these variables, and hence your interpretation of the model and the parameters.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* <(*options*)> ... <*variable* <(*options*)>> </*global-options*> ;

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. Response variables do not need to be specified in the CLASS statement.

The CLASS statement must precede the [MODEL](#) statement. Most options can be specified either as individual variable *options* or as *global-options*. You can specify *options* for each variable by enclosing the options in parentheses after the variable name. You can also specify *global-options* for the CLASS statement by placing them after a slash (/). *Global-options* are applied to all the variables specified in the CLASS statement. If you specify more than one CLASS statement, the *global-options* specified in any one CLASS statement apply to all CLASS statements. However, individual CLASS variable *options* override the *global-options*. You can specify the following values for either an *option* or a *global-option*:

CPREFIX=*n*

specifies that, at most, the first *n* characters of a CLASS variable name be used in creating names for the corresponding design variables. The default is $32 - \min(32, \max(2, f))$, where *f* is the formatted length of the CLASS variable.

DESCENDING

DESC

reverses the sort order of the classification variable. If both the DESCENDING and [ORDER=](#) options are specified, PROC LOGISTIC orders the categories according to the ORDER= option and then reverses that order.

LPREFIX=*n*

specifies that, at most, the first *n* characters of a CLASS variable label be used in creating labels for the corresponding design variables. The default is $256 - \min(256, \max(2, f))$, where *f* is the formatted length of the CLASS variable.

MISSING

treats missing values ('.', '_', 'A', ..., 'Z' for numeric variables and blanks for character variables) as valid values for the CLASS variable.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of classification variables. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option can be useful when you use the CONTRAST statement. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent. When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values.

The following table shows how PROC LOGISTIC interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted values, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) values
FREQ	Descending frequency count; levels with more observations come earlier in the order
INTERNAL	Unformatted value

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PARAM=keyword

specifies the parameterization method for the classification variable or variables. You can specify any of the *keywords* shown in the following table; the default is PARAM=EFFECT. Design matrix columns are created from CLASS variables according to the corresponding coding schemes:

Value of PARAM=	Coding
EFFECT	Effect coding
GLM	Less-than-full-rank reference cell coding (this <i>keyword</i> can be used only in a global option)
ORDINAL THERMOMETER	Cumulative parameterization for an ordinal CLASS variable
POLYNOMIAL POLY	Polynomial coding
REFERENCE REF	Reference cell coding
ORTHEFFECT	Orthogonalizes PARAM=EFFECT coding
ORTHORDINAL ORTHOTHERM	Orthogonalizes PARAM=ORDINAL coding
ORTHPOLY	Orthogonalizes PARAM=POLYNOMIAL coding
ORTHREF	Orthogonalizes PARAM=REFERENCE coding

All parameterizations are full rank, except for the GLM parameterization. The [REF=](#) option in the

CLASS statement determines the reference level for EFFECT and REFERENCE coding and for their orthogonal parameterizations. It also indirectly determines the reference level for a singular GLM parameterization through the order of levels.

If PARAM=ORTHOPOLY or PARAM=POLY and the classification variable is numeric, then the ORDER= option in the CLASS statement is ignored, and the internal unformatted values are used. See the section “Other Parameterizations” on page 387 of Chapter 19, “Shared Concepts and Topics,” for further details.

REF= *'level' | keyword*

specifies the reference level for PARAM=EFFECT, PARAM=REFERENCE, and their orthogonalizations. For PARAM=GLM, the REF= option specifies a level of the classification variable to be put at the end of the list of levels. This level thus corresponds to the reference level in the usual interpretation of the linear estimates with a singular parameterization.

For an individual variable REF= option (but not for a global REF= option), you can specify the *level* of the variable to use as the reference level. Specify the formatted value of the variable if a format is assigned. For a global or individual variable REF= option, you can use one of the following *keywords*. The default is REF=LAST.

FIRST designates the first ordered level as reference.

LAST designates the last ordered level as reference.

TRUNCATE <=*n*>

specifies the length *n* of CLASS variable values to use in determining CLASS variable levels. The default is to use the full formatted length of the CLASS variable. If you specify TRUNCATE without the length *n*, the first 16 characters of the formatted values are used. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases before SAS 9. The TRUNCATE option is available only as a global option.

Class Variable Naming Convention

Parameter names for a CLASS predictor variable are constructed by concatenating the CLASS variable name with the CLASS levels. However, for the POLYNOMIAL and orthogonal parameterizations, parameter names are formed by concatenating the CLASS variable name and keywords that reflect the parameterization. See the section “Other Parameterizations” on page 387 in Chapter 19, “Shared Concepts and Topics,” for examples and further details.

Class Variable Parameterization with Unbalanced Designs

PROC LOGISTIC initially parameterizes the CLASS variables by looking at the levels of the variables across the complete data set. If you have an *unbalanced* replication of levels across variables or BY groups, then the design matrix and the parameter interpretation might be different from what you expect. For instance, suppose you have a model with one CLASS variable A with three levels (1, 2, and 3), and another CLASS variable B with two levels (1 and 2). If the third level of A occurs only with the first level of B, if you use the EFFECT parameterization, and if your model contains the effect A(B) and an intercept, then the design for A within the second level of B is not a differential effect. In particular, the design looks like the following:

B	A	Design Matrix			
		A(B=1)		A(B=2)	
		A1	A2	A1	A2
1	1	1	0	0	0
1	2	0	1	0	0
1	3	-1	-1	0	0
2	1	0	0	1	0
2	2	0	0	0	1

PROC LOGISTIC detects linear dependency among the last two design variables and sets the parameter for A2(B=2) to zero, resulting in an interpretation of these parameters as if they were reference- or dummy-coded. The REFERENCE or GLM parameterization might be more appropriate for such problems.

CODE Statement

CODE < options > ;

The CODE statement enables you to write SAS DATA step code for computing predicted values of the fitted model either to a file or to a catalog entry. This code can then be included in a DATA step to score new data.

Table 54.2 summarizes the *options* available in the CODE statement.

Table 54.2 CODE Statement Options

Option	Description
CATALOG=	Names the catalog entry where the generated code is saved
DUMMIES	Retains the dummy variables in the data set
ERROR	Computes the error function
FILE=	Names the file where the generated code is saved
FORMAT=	Specifies the numeric format for the regression coefficients
GROUP=	Specifies the group identifier for array names and statement labels
IMPUTE	Imputes predicted values for observations with missing or invalid covariates
LINESIZE=	Specifies the line size of the generated code
LOOKUP=	Specifies the algorithm for looking up CLASS levels
RESIDUAL	Computes residuals

For details about the syntax of the CODE statement, see the section “CODE Statement” on page 390 in Chapter 19, “Shared Concepts and Topics.”

CONTRAST Statement

CONTRAST 'label' row-description< , ... , row-description > < / options > ;

where a *row-description* is defined as follows:

effect values<, ..., *effect values*>

The CONTRAST statement provides a mechanism for obtaining customized hypothesis tests. It is similar to the CONTRAST and ESTIMATE statements in other modeling procedures.

The CONTRAST statement enables you to specify a matrix, \mathbf{L} , for testing the hypothesis $\mathbf{L}\boldsymbol{\beta} = \mathbf{0}$, where $\boldsymbol{\beta}$ is the vector of intercept and slope parameters. You must be familiar with the details of the model parameterization that PROC LOGISTIC uses (for more information, see the [PARAM=](#) option in the section “[CLASS Statement](#)” on page 4187). Optionally, the CONTRAST statement enables you to estimate each row, $\mathbf{l}_i'\boldsymbol{\beta}$, of $\mathbf{L}\boldsymbol{\beta}$ and test the hypothesis $\mathbf{l}_i'\boldsymbol{\beta} = 0$. Computed statistics are based on the asymptotic chi-square distribution of the Wald statistic.

There is no limit to the number of CONTRAST statements that you can specify, but they must appear after the [MODEL](#) statement.

The following parameters are specified in the CONTRAST statement:

<i>label</i>	identifies the contrast in the displayed output. A label is required for every contrast specified, and it must be enclosed in quotes.
<i>effect</i>	identifies an effect that appears in the MODEL statement. The name INTERCEPT can be used as an effect when one or more intercepts are included in the model. You do not need to include all effects that are included in the MODEL statement.
<i>values</i>	are constants that are elements of the \mathbf{L} matrix associated with the effect. To correctly specify your contrast, it is crucial to know the ordering of parameters within each effect and the variable levels associated with any parameter. The “Class Level Information” table shows the ordering of levels within variables. The E option, described later in this section, enables you to verify the proper correspondence of <i>values</i> to parameters. If too many values are specified for an effect, the extra ones are ignored. If too few values are specified, the remaining ones are set to 0.

Multiple degree-of-freedom hypotheses can be tested by specifying multiple *row-descriptions*; the rows of \mathbf{L} are specified in order and are separated by commas. The degrees of freedom is the number of linearly independent constraints implied by the CONTRAST statement—that is, the rank of \mathbf{L} .

More details for specifying contrasts involving effects with full-rank parameterizations are given in the section “[Full-Rank Parameterized Effects](#)” on page 4192, while details for less-than-full-rank parameterized effects are given in the section “[Less-Than-Full-Rank Parameterized Effects](#)” on page 4193.

You can specify the following options after a slash (/):

ALPHA=number

specifies the level of significance α for the $100(1-\alpha)\%$ confidence interval for each contrast when the ESTIMATE option is specified. The value of *number* must be between 0 and 1. By default, *number* is equal to the value of the [ALPHA=](#) option in the PROC LOGISTIC statement, or 0.05 if that option is not specified.

E

displays the \mathbf{L} matrix.

ESTIMATE=keyword

estimates and tests each individual contrast (that is, each row, $l'_i\beta$, of $\mathbf{L}\beta$), exponentiated contrast ($e^{l'_i\beta}$), or predicted probability for the contrast ($g^{-1}(l'_i\beta)$). PROC LOGISTIC displays the point estimate, its standard error, a Wald confidence interval, and a Wald chi-square test. The significance level of the confidence interval is controlled by the **ALPHA=** option. You can estimate the individual contrast, the exponentiated contrast, or the predicted probability for the contrast by specifying one of the following *keywords*:

PARM

estimates the individual contrast.

EXP

estimates the exponentiated contrast.

BOTH

estimates both the individual contrast and the exponentiated contrast.

PROB

estimates the predicted probability of the contrast.

ALL

estimates the individual contrast, the exponentiated contrast, and the predicted probability of the contrast.

For details about the computations of the standard errors and confidence limits, see the section “[Linear Predictor, Predicted Probability, and Confidence Limits](#)” on page 4253.

SINGULAR=number

tunes the estimability check. This option is ignored when a full-rank parameterization is specified. If \mathbf{v} is a vector, define $\text{ABS}(\mathbf{v})$ to be the largest absolute value of the elements of \mathbf{v} . For a row vector l' of the contrast matrix \mathbf{L} , define $c = \text{ABS}(l')$ if $\text{ABS}(l')$ is greater than 0; otherwise, $c = 1$. If $\text{ABS}(l' - l'\mathbf{T})$ is greater than $c*\text{number}$, then l is declared nonestimable. The \mathbf{T} matrix is the Hermite form matrix $\mathbf{I}_0^{-1}\mathbf{I}_0$, where \mathbf{I}_0^{-1} represents a generalized inverse of the (observed or expected) information matrix \mathbf{I}_0 of the null model. The value for *number* must be between 0 and 1; the default value is 1E-4.

Full-Rank Parameterized Effects

If an effect involving a CLASS variable with a full-rank parameterization does not appear in the CONTRAST statement, then all of its coefficients in the \mathbf{L} matrix are set to 0.

If you use effect coding by default or by specifying **PARAM=EFFECT** in the **CLASS** statement, then all parameters are directly estimable and involve no other parameters. For example, suppose an effect-coded CLASS variable A has four levels. Then there are three parameters ($\beta_1, \beta_2, \beta_3$) representing the first three levels, and the fourth parameter is represented by

$$-\beta_1 - \beta_2 - \beta_3$$

To test the first versus the fourth level of A, you would test

$$\beta_1 = -\beta_1 - \beta_2 - \beta_3$$

or, equivalently,

$$2\beta_1 + \beta_2 + \beta_3 = 0$$

which, in the form $\mathbf{L}\boldsymbol{\beta} = 0$, is

$$\begin{bmatrix} 2 & 1 & 1 \end{bmatrix} \begin{bmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \end{bmatrix} = 0$$

Therefore, you would use the following CONTRAST statement:

```
contrast '1 vs. 4' A 2 1 1;
```

To contrast the third level with the average of the first two levels, you would test

$$\frac{\beta_1 + \beta_2}{2} = \beta_3$$

or, equivalently,

$$\beta_1 + \beta_2 - 2\beta_3 = 0$$

Therefore, you would use the following CONTRAST statement:

```
contrast '1&2 vs. 3' A 1 1 -2;
```

Other CONTRAST statements are constructed similarly. For example:

```
contrast '1 vs. 2' A 1 -1 0;
contrast '1&2 vs. 4' A 3 3 2;
contrast '1&2 vs. 3&4' A 2 2 0;
contrast 'Main Effect' A 1 0 0,
                        A 0 1 0,
                        A 0 0 1;
```

Less-Than-Full-Rank Parameterized Effects

When you use the less-than-full-rank parameterization (by specifying `PARAM=GLM` in the `CLASS` statement), each row is checked for estimability; see the section “[Estimable Functions](#)” on page 59 in Chapter 3, “[Introduction to Statistical Modeling with SAS/STAT Software](#),” for more information. If PROC LOGISTIC finds a contrast to be nonestimable, it displays missing values in corresponding rows in the results. PROC LOGISTIC handles missing level combinations of classification variables in the same manner as PROC GLM: parameters corresponding to missing level combinations are not included in the model. This convention can affect the way in which you specify the \mathbf{L} matrix in your CONTRAST statement. If the elements of \mathbf{L} are not specified for an effect that contains a specified effect, then the elements of the specified effect are distributed over the levels of the higher-order effect just as the GLM procedure does for its CONTRAST and ESTIMATE statements. For example, suppose that the model contains effects A and B and their interaction A*B. If you specify a CONTRAST statement involving A alone, the \mathbf{L} matrix contains nonzero terms for both A and A*B, since A*B contains A. See rule 4 in the section “[Construction of Least Squares Means](#)” on page 3363 in Chapter 42, “[The GLM Procedure](#),” for more details.

EFFECT Statement

EFFECT *name=effect-type (variables < / options>)* ;

The EFFECT statement enables you to construct special collections of columns for design matrices. These collections are referred to as *constructed effects* to distinguish them from the usual model effects that are formed from continuous or classification variables, as discussed in the section “GLM Parameterization of Classification Variables and Effects” on page 383 in Chapter 19, “Shared Concepts and Topics.”

You can specify the following *effect-types*:

COLLECTION	is a collection effect that defines one or more variables as a single effect with multiple degrees of freedom. The variables in a collection are considered as a unit for estimation and inference.
LAG	is a classification effect in which the level that is used for a given period corresponds to the level in the preceding period.
MULTIMEMBER MM	is a multimember classification effect whose levels are determined by one or more variables that appear in a CLASS statement.
POLYNOMIAL POLY	is a multivariate polynomial effect in the specified numeric variables.
SPLINE	is a regression spline effect whose columns are univariate spline expansions of one or more variables. A spline expansion replaces the original variable with an expanded or larger set of new variables.

Table 54.3 summarizes the *options* available in the EFFECT statement.

Table 54.3 EFFECT Statement Options

Option	Description
Collection Effects Options	
DETAILS	Displays the constituents of the collection effect
Lag Effects Options	
DESIGNROLE=	Names a variable that controls to which lag design an observation is assigned
DETAILS	Displays the lag design of the lag effect
NLAG=	Specifies the number of periods in the lag
PERIOD=	Names the variable that defines the period
WITHIN=	Names the variable or variables that define the group within which each period is defined
Multimember Effects Options	
NOEFFECT	Specifies that observations with all missing levels for the multimember variables should have zero values in the corresponding design matrix columns
WEIGHT=	Specifies the weight variable for the contributions of each of the classification effects

Table 54.3 *continued*

Option	Description
Polynomial Effects Options	
DEGREE=	Specifies the degree of the polynomial
MDEGREE=	Specifies the maximum degree of any variable in a term of the polynomial
STANDARDIZE=	Specifies centering and scaling suboptions for the variables that define the polynomial
Spline Effects Options	
BASIS=	Specifies the type of basis (B-spline basis or truncated power function basis) for the spline expansion
DEGREE=	Specifies the degree of the spline transformation
KNOTMETHOD=	Specifies how to construct the knots for spline effects

For more information about the syntax of these *effect-types* and how columns of constructed effects are computed, see the section “EFFECT Statement” on page 393 in Chapter 19, “Shared Concepts and Topics.”

EFFECTPLOT Statement

EFFECTPLOT < *plot-type* < (*plot-definition-options*) > > < / *options* > ;

The EFFECTPLOT statement produces a display of the fitted model and provides options for changing and enhancing the displays. Table 54.4 describes the available *plot-types* and their *plot-definition-options*.

Table 54.4 *Plot-Types and Plot-Definition-Options*

Plot-Type and Description	Plot-Definition-Options
BOX Displays a box plot of continuous response data at each level of a CLASS effect, with predicted values superimposed and connected by a line. This is an alternative to the INTERACTION <i>plot-type</i> .	PLOTBY= variable or CLASS effect X= CLASS variable or effect
CONTOUR Displays a contour plot of predicted values against two continuous covariates.	PLOTBY= variable or CLASS effect X= continuous variable Y= continuous variable
FIT Displays a curve of predicted values versus a continuous variable.	PLOTBY= variable or CLASS effect X= continuous variable

Table 54.4 continued

Plot-Type and Description	Plot-Definition-Options
INTERACTION Displays a plot of predicted values (possibly with error bars) versus the levels of a CLASS effect. The predicted values are connected with lines and can be grouped by the levels of another CLASS effect.	PLOTBY= variable or CLASS effect SLICEBY= variable or CLASS effect X= CLASS variable or effect
SLICEFIT Displays a curve of predicted values versus a continuous variable grouped by the levels of a CLASS effect.	PLOTBY= variable or CLASS effect SLICEBY= variable or CLASS effect X= continuous variable

For full details about the syntax and options of the EFFECTPLOT statement, see the section “[EFFECTPLOT Statement](#)” on page 411 in Chapter 19, “[Shared Concepts and Topics](#).”

See Outputs [54.2.11](#), [54.2.12](#), [54.3.5](#), [54.4.8](#), [54.7.4](#), and [54.15.4](#) for examples of plots produced by this statement.

ESTIMATE Statement

```
ESTIMATE <'label'> estimate-specification <(divisor=n)>
      <,...<'label'> estimate-specification <(divisor=n)>>
      </options>;
```

The ESTIMATE statement provides a mechanism for obtaining custom hypothesis tests. Estimates are formed as linear estimable functions of the form $\mathbf{L}\boldsymbol{\beta}$. You can perform hypothesis tests for the estimable functions, construct confidence limits, and obtain specific nonlinear transformations.

Table 54.5 summarizes the options available in the ESTIMATE statement.

Table 54.5 ESTIMATE Statement Options

Option	Description
Construction and Computation of Estimable Functions	
DIVISOR=	Specifies a list of values to divide the coefficients
NOFILL	Suppresses the automatic fill-in of coefficients for higher-order effects
SINGULAR=	Tunes the estimability checking difference

Table 54.5 *continued*

Option	Description
Degrees of Freedom and p-values	
ADJUST=	Determines the method for multiple comparison adjustment of estimates
ALPHA= α	Determines the confidence level $(1 - \alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiplicity-corrected p -values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits
CORR	Displays the correlation matrix of estimates
COV	Displays the covariance matrix of estimates
E	Prints the L matrix
JOINT	Produces a joint F or chi-square test for the estimable functions
SEED=	Specifies the seed for computations that depend on random numbers
Generalized Linear Modeling	
CATEGORY=	Specifies how to construct estimable functions with multinomial data
EXP	Exponentiates and displays estimates
ILINK	Computes and displays estimates and standard errors on the inverse linked scale

For details about the syntax of the ESTIMATE statement, see the section “[ESTIMATE Statement](#)” on page 437 in Chapter 19, “[Shared Concepts and Topics](#).”

EXACT Statement

EXACT < *label* > < **INTERCEPT** > < *effects* > < / *options* > ;

The EXACT statement performs exact tests of the parameters for the specified *effects* and optionally estimates the parameters and outputs the exact conditional distributions. You can specify the keyword **INTERCEPT** and any effects in the [MODEL](#) statement. Inference on the parameters of the specified effects is performed by conditioning on the sufficient statistics of all the other model parameters (possibly including the intercept).

You can specify several EXACT statements, but they must follow the [MODEL](#) statement. Each statement can optionally include an identifying *label*. If several EXACT statements are specified, any statement without a label is assigned a label of the form “Exact n ,” where n indicates the n th EXACT statement. The label is included in the headers of the displayed exact analysis tables.

If a **STRATA** statement is also specified, then a stratified exact logistic regression is performed. The model contains a different intercept for each stratum, and these intercepts are conditioned out of the model along with any other nuisance parameters (parameters for effects specified in the **MODEL** statement that are not in the **EXACT** statement).

If the **LINK=GLOGIT** option is specified in the **MODEL** statement, then the **METHOD=DIRECT** option is invoked in the **EXACTOPTIONS** statement by default and a generalized logit model is fit. Since each effect specified in the **MODEL** statement adds k parameters to the model (where $k + 1$ is the number of response levels), exact analysis of the generalized logit model by using this method is limited to rather small problems.

The **CONTRAST**, **ESTIMATE**, **LSMEANS**, **LSMESTIMATE**, **ODDSRATIO**, **OUTPUT**, **ROC**, **ROCCONTRAST**, **SCORE**, **SLICE**, **STORE**, **TEST**, and **UNITS** statements are not available with an exact analysis; results from these statements are based on the asymptotic results. Exact analyses are not performed when you specify a **WEIGHT** statement, a link other than **LINK=LOGIT** or **LINK=GLOGIT**, an offset variable, the **NOFIT** option, or a model selection method. Exact estimation is not available for ordinal response models.

For classification variables, use of the reference parameterization is recommended.

The following options can be specified in each **EXACT** statement after a slash (/):

ALPHA=number

specifies the level of significance α for $100(1 - \alpha)\%$ confidence limits for the parameters or odds ratios. The value of *number* must be between 0 and 1. By default, *number* is equal to the value of the **ALPHA=** option in the **PROC LOGISTIC** statement, or 0.05 if that option is not specified.

CLTYPE=EXACT | MIDP

requests either the exact or mid- p confidence intervals for the parameter estimates. By default, the exact intervals are produced. The confidence coefficient can be specified with the **ALPHA=** option. The mid- p interval can be modified with the **MIDPFACTOR=** option. See the section “Exact Conditional Logistic Regression” on page 4274 for details.

ESTIMATE <=keyword>

estimates the individual parameters (conditioned on all other parameters) for the effects specified in the **EXACT** statement. For each parameter, a point estimate, a standard error, a confidence interval, and a p -value for a two-sided test that the parameter is zero are displayed. Note that the two-sided p -value is twice the one-sided p -value. You can optionally specify one of the following keywords:

PARM specifies that the parameters be estimated. This is the default.

ODDS specifies that the odds ratios be estimated. If you have classification variables, then you must also specify the **PARAM=REF** option in the **CLASS** statement.

BOTH specifies that both the parameters and odds ratios be estimated.

JOINT

performs the joint test that all of the parameters are simultaneously equal to zero, performs individual hypothesis tests for the parameter of each continuous variable, and performs joint tests for the parameters of each classification variable. The joint test is indicated in the “Conditional Exact Tests” table by the label “Joint.”

JOINTONLY

performs only the joint test of the parameters. The test is indicated in the “Conditional Exact Tests” table by the label “Joint.” When this option is specified, individual tests for the parameters of each continuous variable and joint tests for the parameters of the classification variables are not performed.

MIDPFACTOR= δ_1 | (δ_1, δ_2)

sets the tie factors used to produce the mid- p hypothesis statistics and the mid- p confidence intervals. δ_1 modifies both the hypothesis tests and confidence intervals, while δ_2 affects only the hypothesis tests. By default, $\delta_1 = 0.5$ and $\delta_2 = 1.0$. See the section “[Exact Conditional Logistic Regression](#)” on page 4274 for details.

ONESIDED

requests one-sided confidence intervals and p -values for the individual parameter estimates and odds ratios. The one-sided p -value is the smaller of the left- and right-tail probabilities for the observed sufficient statistic of the parameter under the null hypothesis that the parameter is zero. The two-sided p -values (default) are twice the one-sided p -values. See the section “[Exact Conditional Logistic Regression](#)” on page 4274 for more details.

OUTDIST=*SAS-data-set*

names the SAS data set that contains the exact conditional distributions. This data set contains all of the exact conditional distributions that are required to process the corresponding EXACT statement. This data set contains the possible sufficient statistics for the parameters of the effects specified in the EXACT statement, the counts, and, when hypothesis tests are performed on the parameters, the probability of occurrence and the score value for each sufficient statistic. When you request an OUTDIST= data set, the observed sufficient statistics are displayed in the “Sufficient Statistics” table. See the section “[OUTDIST= Output Data Set](#)” on page 4281 for more information.

EXACT Statement Examples

In the following example, two exact tests are computed: one for x_1 and the other for x_2 . The test for x_1 is based on the exact conditional distribution of the sufficient statistic for the x_1 parameter given the observed values of the sufficient statistics for the intercept, x_2 , and x_3 parameters; likewise, the test for x_2 is conditional on the observed sufficient statistics for the intercept, x_1 , and x_3 .

```
proc logistic;
  model y= x1 x2 x3;
  exact x1 x2;
run;
```

PROC LOGISTIC determines, from all the specified EXACT statements, the distinct conditional distributions that need to be evaluated. For example, there is only one exact conditional distribution for the following two EXACT statements:

```
exact 'One' x1 / estimate=parm;
exact 'Two' x1 / estimate=parm onesided;
```

For each EXACT statement, individual tests for the parameters of the specified effects are computed unless the **JOINTONLY** option is specified. Consider the following EXACT statements:

```

exact 'E12' x1 x2 / estimate;
exact 'E1'  x1      / estimate;
exact 'E2'  x2      / estimate;
exact 'J12' x1 x2 / joint;

```

In the E12 statement, the parameters for x1 and x2 are estimated and tested separately. Specifying the E12 statement is equivalent to specifying both the E1 and E2 statements. In the J12 statement, the joint test for the parameters of x1 and x2 is computed in addition to the individual tests for x1 and x2.

EXACTOPTIONS Statement

EXACTOPTIONS *options* ;

The EXACTOPTIONS statement specifies options that apply to every **EXACT** statement in the program. The following *options* are available:

ABSFCNV=*value*

specifies the absolute function convergence criterion. Convergence requires a small change in the log-likelihood function in subsequent iterations,

$$|l_i - l_{i-1}| < \text{value}$$

where l_i is the value of the log-likelihood function at iteration i .

By default, ABSFCNV=1E-12. You can also specify the **FCONV=** and **XCONV=** criteria; optimizations are terminated as soon as one criterion is satisfied.

ADDTOBS

adds the observed sufficient statistic to the sampled exact distribution if the statistic was not sampled. This option has no effect unless the **METHOD=NETWORKMC** option is specified and the **ESTIMATE** option is specified in the **EXACT** statement. If the observed statistic has not been sampled, then the parameter estimate does not exist; by specifying this option, you can produce (biased) estimates.

BUILDSUBSETS

builds every distribution for sampling. By default, some exact distributions are created by taking a subset of a previously generated exact distribution. When the **METHOD=NETWORKMC** option is invoked, this subsetting behavior has the effect of using fewer than the desired n samples; see the **N=** option for more details. Use the **BUILDSUBSETS** option to suppress this subsetting.

EPSILON=*value*

controls how the partial sums $\sum_{i=1}^j y_i x_i$ are compared. *value* must be between 0 and 1; by default, *value*=1E-8.

FCONV=*value*

specifies the relative function convergence criterion. Convergence requires a small relative change in the log-likelihood function in subsequent iterations,

$$\frac{|l_i - l_{i-1}|}{|l_{i-1}| + 1\text{E-}6} < \text{value}$$

where l_i is the value of the log likelihood at iteration i .

By default, FCONV=1E-8. You can also specify the **ABSFCNV=** and **XCONV=** criteria; if more than one criterion is specified, then optimizations are terminated as soon as one criterion is satisfied.

MAXTIME=seconds

specifies the maximum clock time (in seconds) that PROC LOGISTIC can use to calculate the exact distributions. If the limit is exceeded, the procedure halts all computations and prints a note to the LOG. The default maximum clock time is seven days.

METHOD=keyword

specifies which exact conditional algorithm to use for every **EXACT** statement specified. You can specify one of the following *keywords*:

DIRECT invokes the multivariate shift algorithm of Hirji, Mehta, and Patel (1987). This method directly builds the exact distribution, but it can require an excessive amount of memory in its intermediate stages. **METHOD=DIRECT** is invoked by default when you are conditioning out at most the intercept, or when the **LINK=GLOGIT** option is specified in the **MODEL** statement.

NETWORK invokes an algorithm described in Mehta, Patel, and Senchaudhuri (1992). This method builds a network for each parameter that you are conditioning out, combines the networks, then uses the multivariate shift algorithm to create the exact distribution. The **NETWORK** method can be faster and require less memory than the **DIRECT** method. The **NETWORK** method is invoked by default for most analyses.

NETWORKMC invokes the hybrid network and Monte Carlo algorithm of Mehta, Patel, and Senchaudhuri (1992). This method creates a network, then samples from that network; this method does not reject any of the samples at the cost of using a large amount of memory to create the network. **METHOD=NETWORKMC** is most useful for producing parameter estimates for problems that are too large for the **DIRECT** and **NETWORK** methods to handle and for which asymptotic methods are invalid—for example, for sparse data on a large grid.

N=n

specifies the number of Monte Carlo samples to take when the **METHOD=NETWORKMC** option is specified. By default, $n = 10,000$. If the procedure cannot obtain n samples due to a lack of memory, then a note is printed in the SAS log (the number of valid samples is also reported in the listing) and the analysis continues.

The number of samples used to produce any particular statistic might be smaller than n . For example, let $X1$ and $X2$ be continuous variables, denote their joint distribution by $f(X1, X2)$, and let $f(X1 | X2 = x2)$ denote the marginal distribution of $X1$ conditioned on the observed value of $X2$. If you request the **JOINT** test of $X1$ and $X2$, then n samples are used to generate the estimate $\hat{f}(X1, X2)$ of $f(X1, X2)$, from which the test is computed. However, the parameter estimate for $X1$ is computed from the subset of $\hat{f}(X1, X2)$ that has $X2 = x2$, and this subset need not contain n samples. Similarly, the distribution for each level of a classification variable is created by extracting the appropriate subset from the joint distribution for the **CLASS** variable.

In some cases, the marginal sample size can be too small to admit accurate estimation of a particular statistic; a note is printed in the SAS log when a marginal sample size is less than 100. Increasing n

increases the number of samples used in a marginal distribution; however, if you want to control the sample size exactly, you can either specify the **BUILDSUBSETS** option or do both of the following:

- Remove the **JOINT** option from the **EXACT** statement.
- Create dummy variables in a DATA step to represent the levels of a **CLASS** variable, and specify them as independent variables in the **MODEL** statement.

NOLOGSCALE

specifies that computations for the exact conditional models be computed by using normal scaling. Log scaling can handle numerically larger problems than normal scaling; however, computations in the log scale are slower than computations in normal scale.

ONDISK

uses disk space instead of random access memory to build the exact conditional distribution. Use this option to handle larger problems at the cost of slower processing.

SEED=seed

specifies the initial seed for the random number generator used to take the Monte Carlo samples when the **METHOD=NETWORKMC** option is specified. The value of the **SEED=** option must be an integer. If you do not specify a seed, or if you specify a value less than or equal to zero, then PROC LOGISTIC uses the time of day from the computer's clock to generate an initial seed.

STATUSN=number

prints a status line in the SAS log after every *number* of Monte Carlo samples when the **METHOD=NETWORKMC** option is specified. The number of samples taken and the current exact *p*-value for testing the significance of the model are displayed. You can use this status line to track the progress of the computation of the exact conditional distributions.

STATUSTIME=seconds

specifies the time interval (in seconds) for printing a status line in the LOG. You can use this status line to track the progress of the computation of the exact conditional distributions. The time interval you specify is approximate; the actual time interval varies. By default, no status reports are produced.

XCONV=value

specifies the relative parameter convergence criterion. Convergence requires a small relative parameter change in subsequent iterations,

$$\max_j |\delta_j^{(i)}| < \text{value}$$

where

$$\delta_j^{(i)} = \begin{cases} \beta_j^{(i)} - \beta_j^{(i-1)} & |\beta_j^{(i-1)}| < 0.01 \\ \frac{\beta_j^{(i)} - \beta_j^{(i-1)}}{\beta_j^{(i-1)}} & \text{otherwise} \end{cases}$$

and $\beta_j^{(i)}$ is the estimate of the *j*th parameter at iteration *i*.

By default, **XCONV=1E-4**. You can also specify the **ABSFCNV=** and **FCNV=** criteria; if more than one criterion is specified, then optimizations are terminated as soon as one criterion is satisfied.

FREQ Statement

FREQ *variable* ;

The FREQ statement identifies a *variable* that contains the frequency of occurrence of each observation. PROC LOGISTIC treats each observation as if it appears n times, where n is the value of the FREQ variable for the observation. If it is not an integer, the frequency value is truncated to an integer. If the frequency value is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1. If you specify more than one FREQ statement, then the first statement is used.

If a **SCORE** statement is specified, then the FREQ variable is used for computing fit statistics and the ROC curve, but they are not required for scoring. If the **DATA=** data set in the **SCORE** statement does not contain the FREQ variable, the frequency values are assumed to be 1 and a warning message is issued in the LOG. If you fit a model and perform the scoring in the same run, the same FREQ variable is used for fitting and scoring. If you fit a model in a previous run and input it with the **INMODEL=** option in the current run, then the FREQ variable can be different from the one used in the previous run. However, if a FREQ variable was not specified in the previous run, you can still specify a FREQ variable in the current run.

ID Statement

ID *variable* < *variable*,... > ;

The ID statement specifies variables in the **DATA=** data set that are used for labeling ROC curves and influence diagnostic plots. If more than one ID variable is specified, then the plots are labeled by concatenating the ID variable values together. See the **PLOTS(LABEL)** and **ROCOPTIONS(ID)** options in the PROC LOGISTIC statement for more details.

LSMEANS Statement

LSMEANS < *model-effects* > < / *options* > ;

The LSMEANS statement computes and compares least squares means (LS-means) of fixed effects. LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs.

Table 54.6 summarizes the options available in the LSMEANS statement.

Table 54.6 LSMEANS Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies the covariate value in computing LS-means
BYLEVEL	Computes separate margins
DIFF	Requests differences of LS-means
OM=	Specifies the weighting scheme for LS-means computation as determined by the input data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and p-values	
ADJUST=	Determines the method for multiple-comparison adjustment of LS-means differences
ALPHA= α	Determines the confidence level ($1 - \alpha$)
STEPPDOWN	Adjusts multiple-comparison p -values further in a step-down fashion
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the L matrix
LINES	Produces a “Lines” display for pairwise LS-means differences
MEANS	Prints the LS-means
PLOTS=	Requests graphs of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers
Generalized Linear Modeling	
EXP	Exponentiates and displays estimates of LS-means or LS-means differences
ILINK	Computes and displays estimates and standard errors of LS-means (but not differences) on the inverse linked scale
ODDSRATIO	Reports (simple) differences of least squares means in terms of odds ratios if permitted by the link function

For details about the syntax of the LSMEANS statement, see the section “[LSMEANS Statement](#)” on page 453 in Chapter 19, “[Shared Concepts and Topics](#).”

NOTE: If you have classification variables in your model, then the LSMEANS statement is allowed only if you also specify the [PARAM=GLM](#) option.

LSMESTIMATE Statement

```
LSMESTIMATE model-effect < 'label' > values < divisor=n >
           < , ... < 'label' > values < divisor=n > >
           < / options > ;
```

The LSMESTIMATE statement provides a mechanism for obtaining custom hypothesis tests among least squares means.

Table 54.7 summarizes the options available in the LSMESTIMATE statement.

Table 54.7 LSMESTIMATE Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies covariate values in computing LS-means
BYLEVEL	Computes separate margins
DIVISOR=	Specifies a list of values to divide the coefficients
OM=	Specifies the weighting scheme for LS-means computation as determined by a data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and <i>p</i>-values	
ADJUST=	Determines the method for multiple-comparison adjustment of LS-means differences
ALPHA= α	Determines the confidence level $(1 - \alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiple-comparison <i>p</i> -values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the L matrix
ELSM	Prints the K matrix
JOINT	Produces a joint <i>F</i> or chi-square test for the LS-means and LS-means differences
SEED=	Specifies the seed for computations that depend on random numbers

Table 54.7 *continued*

Option	Description
Generalized Linear Modeling	
CATEGORY=	Specifies how to construct estimable functions with multinomial data
EXP	Exponentiates and displays LS-means estimates
ILINK	Computes and displays estimates and standard errors of LS-means (but not differences) on the inverse linked scale

For details about the syntax of the LSMESTIMATE statement, see the section “[LSMESTIMATE Statement](#)” on page 470 in Chapter 19, “[Shared Concepts and Topics](#).”

NOTE: If you have classification variables in your model, then the LSMESTIMATE statement is allowed only if you also specify the [PARAM=GLM](#) option.

MODEL Statement

```
< label:> MODEL variable<(variable_options)> = < effects> </ options> ;
```

```
< label:> MODEL events/trials = < effects> </ options> ;
```

The MODEL statement names the response variable and the explanatory effects, including covariates, main effects, interactions, and nested effects; see the section “[Specification of Effects](#)” on page 3324 of Chapter 42, “[The GLM Procedure](#),” for more information. If you omit the explanatory effects, the procedure fits an intercept-only model. You must specify exactly one MODEL statement.

Two forms of the MODEL statement can be specified. The first form, referred to as *single-trial* syntax, is applicable to binary, ordinal, and nominal response data. The second form, referred to as *events/trials* syntax, is restricted to the case of binary response data. The single-trial syntax is used when each observation in the DATA= data set contains information about only a single trial, such as a single subject in an experiment. When each observation contains information about multiple binary-response trials, such as the counts of the number of subjects observed and the number responding, then events/trials syntax can be used.

In the events/trials syntax, you specify two variables that contain count data for a binomial experiment. These two variables are separated by a slash. The value of the first variable, *events*, is the number of positive responses (or events). The value of the second variable, *trials*, is the number of trials. The values of both *events* and (*trials*–*events*) must be nonnegative and the value of *trials* must be positive for the response to be valid.

In the single-trial syntax, you specify one variable (on the left side of the equal sign) as the response variable. This variable can be character or numeric. [Variable_options](#) specific to the response variable can be specified immediately after the response variable with parentheses around them.

For both forms of the MODEL statement, explanatory *effects* follow the equal sign. Variables can be either continuous or classification variables. Classification variables can be character or numeric, and they must be declared in the [CLASS](#) statement. When an effect is a classification variable, the procedure inserts a set of coded columns into the design matrix instead of directly entering a single column containing the values of the variable.

Response Variable Options

DESCENDING | DESC

reverses the order of the response categories. If both the DESCENDING and **ORDER=** options are specified, PROC LOGISTIC orders the response categories according to the **ORDER=** option and then reverses that order. See the section “[Response Level Ordering](#)” on page 4237 for more detail.

EVENT='category' | keyword

specifies the event category for the binary response model. PROC LOGISTIC models the probability of the event category. The **EVENT=** option has no effect when there are more than two response categories. You can specify the value (formatted if a format is applied) of the event category in quotes, or you can specify one of the following keywords. The default is **EVENT=FIRST**.

FIRST

designates the first ordered category as the event.

LAST

designates the last ordered category as the event.

One of the most common sets of response levels is {0,1}, with 1 representing the event for which the probability is to be modeled. Consider the example where *Y* takes the values 1 and 0 for event and nonevent, respectively, and *Exposure* is the explanatory variable. To specify the value 1 as the event category, use the following MODEL statement:

```
model Y(event='1') = Exposure;
```

ORDER= DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of the response variable. The following table displays the available **ORDER=** options:

ORDER=	Levels Sorted By
DATA	order of appearance in the input data set
FORMATTED	external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	descending frequency count; levels with the most observations come first in the order
INTERNAL	unformatted value

By default, **ORDER=FORMATTED**. For **ORDER=FORMATTED** and **ORDER=INTERNAL**, the sort order is machine dependent. When **ORDER=FORMATTED** is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values.

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

REFERENCE='category' | keyword

REF='category' | keyword

specifies the reference category for the generalized logit model and the binary response model. For the generalized logit model, each logit contrasts a nonreference category with the reference category. For the binary response model, specifying one response category as the reference is the same as specifying the other response category as the event category. You can specify the value (formatted if a format is applied) of the reference category in quotes, or you can specify one of the following keywords:

FIRST designates the first ordered category as the reference.

LAST designates the last ordered category as the reference. This is the default.

Model Options

Table 54.8 summarizes the options available in the MODEL statement. These options can be specified after a slash (/).

Table 54.8 Model Statement Options

Option	Description
Model Specification Options	
LINK=	Specifies the link function
NOFIT	Suppresses model fitting
NOINT	Suppresses the intercept
OFFSET=	Specifies the offset variable
SELECTION=	Specifies the effect selection method
UNEQUALSLOPES	Specifies cumulative partial proportional odds models
Effect Selection Options	
BEST=	Controls the number of models displayed for SCORE selection
DETAILS	Requests detailed results at each step
FAST	Uses the fast elimination method
HIERARCHY=	Specifies whether and how hierarchy is maintained and whether a single effect or multiple effects are allowed to enter or leave the model per step
INCLUDE=	Specifies the number of effects included in every model
MAXSTEP=	Specifies the maximum number of steps for STEPWISE selection
SEQUENTIAL	Adds or deletes effects in sequential order
SLENTY=	Specifies the significance level for entering effects
SLSTAY=	Specifies the significance level for removing effects
START=	Specifies the number of variables in the first model
STOP=	Specifies the number of variables in the final model
STOPRES	Adds or deletes variables by the residual chi-square criterion
Model-Fitting Specification Options	
ABSFCONV=	Specifies the absolute function convergence criterion
FCONV=	Specifies the relative function convergence criterion

Table 54.8 continued

Option	Description
FIRTH	Specifies Firth's penalized likelihood method
GCONV=	Specifies the relative gradient convergence criterion
MAXFUNCTION=	Specifies the maximum number of function calls for the conditional analysis
MAXITER=	Specifies the maximum number of iterations
NOCHECK	Suppresses checking for infinite parameters
RIDGING=	Specifies the technique used to improve the log-likelihood function when its value is worse than that of the previous step
SINGULAR=	Specifies the tolerance for testing singularity
TECHNIQUE=	Specifies the iterative algorithm for maximization
XCONV=	Specifies the relative parameter convergence criterion
Confidence Interval Options	
ALPHA=	Specifies α for the $100(1 - \alpha)\%$ confidence intervals
CLODDS=	Computes confidence intervals for odds ratios
CLPARM=	Computes confidence intervals for parameters
PLCONV=	Specifies the profile-likelihood convergence criterion
Classification Options	
CTABLE	Displays the classification table
PEVENT=	Specifies prior event probabilities
PPROB=	Specifies probability cutpoints for classification
Overdispersion and Goodness-of-Fit Test Options	
AGGREGATE=	Determines subpopulations for Pearson chi-square and deviance
LACKFIT	Requests the Hosmer and Lemeshow goodness-of-fit test
SCALE=	Specifies the method to correct overdispersion
ROC Curve Options	
OUTROC=	Names the output ROC data set
ROCEPS=	Specifies the probability grouping criterion
Regression Diagnostics Options	
INFLUENCE	Displays influence statistics
IPLOTS	Requests index plots
Display Options	
CORRB	Displays the correlation matrix
COVB	Displays the covariance matrix
EXPB	Displays exponentiated values of the estimates
ITPRINT	Displays the iteration history
NODUMMYPRINT	Suppresses the "Class Level Information" table
PARMLABEL	Displays parameter labels
PCORR	Displays the partial correlation statistic
RSQUARE	Displays the generalized R Square
STB	Displays standardized estimates

Table 54.8 continued

Option	Description
Computational Options	
BINWIDTH=	Specifies the bin size for estimating association statistics
NOLOGSCALE	Performs calculations by using normal scaling

The following list describes these options.

ABSFCNV=*value*

specifies the absolute function convergence criterion. Convergence requires a small change in the log-likelihood function in subsequent iterations,

$$|l_i - l_{i-1}| < \text{value}$$

where l_i is the value of the log-likelihood function at iteration i . See the section “[Convergence Criteria](#)” on page 4242 for more information.

AGGREGATE<=(*variable-list*)>

specifies the subpopulations on which the Pearson chi-square test statistic and the likelihood ratio chi-square test statistic (deviance) are calculated. Observations with common values in the given list of variables are regarded as coming from the same subpopulation. Variables in the list can be any variables in the input data set. Specifying the AGGREGATE option is equivalent to specifying the AGGREGATE= option with a variable list that includes all explanatory variables in the MODEL statement. The deviance and Pearson goodness-of-fit statistics are calculated only when the [SCALE=](#) option is specified. Thus, the AGGREGATE (or AGGREGATE=) option has no effect if the [SCALE=](#) option is not specified.

See the section “[Rescaling the Covariance Matrix](#)” on page 4257 for more information.

ALPHA=*number*

sets the level of significance α for $100(1 - \alpha)\%$ confidence intervals for regression parameters or odds ratios. The value of *number* must be between 0 and 1. By default, *number* is equal to the value of the [ALPHA=](#) option in the PROC LOGISTIC statement, or 0.05 if the option is not specified. This option has no effect unless confidence limits for the parameters ([CLPARM=](#) option) or odds ratios ([CLODDS=](#) option or [ODDSRATIO](#) statement) are requested.

BEST=*n*

specifies that n models with the highest score chi-square statistics are to be displayed for each model size. It is used exclusively with the [SCORE](#) model selection method. If the BEST= option is omitted and there are no more than 10 explanatory variables, then all possible models are listed for each model size. If the option is omitted and there are more than 10 explanatory variables, then the number of models selected for each model size is, at most, equal to the number of explanatory variables listed in the MODEL statement.

BINWIDTH=*width*

specifies the size of the bins used for estimating the association statistics. See the section “[Rank Correlation of Observed Responses and Predicted Probabilities](#)” on page 4253 for details. Valid values are $0 \leq \text{width} < 1$ (for polytomous response models, $0 < \text{width} < 1$). The default *width* is 0.002. If the *width* does not evenly divide the unit interval, it is reduced to a valid value and a message

is displayed in the SAS log. The width is also constrained by the amount of memory available on your machine; if you specify a *width* that is too small, it is adjusted to a value for which memory can be allocated and a note is displayed in the SAS log.

If you have a binary response and specify **BINWIDTH=0**, then no binning is performed and the exact values of the statistics are computed; this method is a bit slower and might require more memory than the binning approach.

The **BINWIDTH=** option is ignored and no binning is performed when a **ROC** statement is specified, when ROC graphics are produced, or when the **SCORE** statement computes an ROC area.

CLODDS=PL | WALD | BOTH

produces confidence intervals for odds ratios of main effects not involved in interactions or nestings. Computation of these confidence intervals is based on the profile likelihood (**CLODDS=PL**) or based on individual Wald tests (**CLODDS=WALD**). By specifying **CLODDS=BOTH**, the procedure computes two sets of confidence intervals for the odds ratios, one based on the profile likelihood and the other based on the Wald tests. The confidence coefficient can be specified with the **ALPHA=** option. The **CLODDS=PL** option is not available with the **STRATA** statement. Classification main effects that use parameterizations other than REF, EFFECT, or GLM are ignored. If you need to compute odds ratios for an effect involved in interactions or nestings, or using some other parameterization, then you should specify an **ODDSRATIO** statement for that effect.

CLPARM=PL | WALD | BOTH

requests confidence intervals for the parameters. Computation of these confidence intervals is based on the profile likelihood (**CLPARM=PL**) or individual Wald tests (**CLPARM=WALD**). If you specify **CLPARM=BOTH**, the procedure computes two sets of confidence intervals for the parameters, one based on the profile likelihood and the other based on individual Wald tests. The confidence coefficient can be specified with the **ALPHA=** option. The **CLPARM=PL** option is not available with the **STRATA** statement.

See the section “[Confidence Intervals for Parameters](#)” on page 4248 for more information.

CORRB

displays the correlation matrix of the parameter estimates.

COVB

displays the covariance matrix of the parameter estimates.

CTABLE

classifies the input binary response observations according to whether the predicted event probabilities are above or below some cutpoint value z in the range (0, 1). An observation is predicted as an event if the predicted event probability exceeds or equals z . You can supply a list of cutpoints other than the default list by specifying the **PPROB=** option (page 4217). Also, false positive and negative rates can be computed as posterior probabilities by using Bayes’ theorem. You can use the **PEVENT=** option to specify prior probabilities for computing these rates. The **CTABLE** option is ignored if the data have more than two response levels. The **CTABLE** option is not available with the **STRATA** statement.

For more information, see the section “[Classification Table](#)” on page 4255.

DETAILS

produces a summary of computational details for each step of the effect selection process. It produces the “Analysis of Effects Eligible for Entry” table before displaying the effect selected for entry for forward or stepwise selection. For each model fitted, it produces the “Type 3 Analysis of Effects” table if the fitted model involves CLASS variables, the “Analysis of Maximum Likelihood Estimates” table, and measures of association between predicted probabilities and observed responses. For the statistics included in these tables, see the section “[Displayed Output](#)” on page 4286. The DETAILS option has no effect when `SELECTION=NONE`.

EXPB**EXPEST**

displays the exponentiated values ($e^{\hat{\beta}_i}$) of the parameter estimates $\hat{\beta}_i$ in the “Analysis of Maximum Likelihood Estimates” table for the logit model. These exponentiated values are the estimated odds ratios for parameters corresponding to the continuous explanatory variables, and for CLASS effects that use reference or GLM parameterizations.

FAST

uses a computational algorithm of Lawless and Singhal (1978) to compute a first-order approximation to the remaining slope estimates for each subsequent elimination of a variable from the model. Variables are removed from the model based on these approximate estimates. The FAST option is extremely efficient because the model is not refitted for every variable removed. The FAST option is used when `SELECTION=BACKWARD` and in the backward elimination steps when `SELECTION=STEPWISE`. The FAST option is ignored when `SELECTION=FORWARD` or `SELECTION=NONE`.

FCONV=value

specifies the relative function convergence criterion. Convergence requires a small relative change in the log-likelihood function in subsequent iterations,

$$\frac{|l_i - l_{i-1}|}{|l_{i-1}| + 1\text{E-}6} < \text{value}$$

where l_i is the value of the log likelihood at iteration i . See the section “[Convergence Criteria](#)” on page 4242 for more information.

FIRTH

performs Firth’s penalized maximum likelihood estimation to reduce bias in the parameter estimates (Heinze and Schemper 2002; Firth 1993). This method is useful in cases of separability, as often occurs when the event is rare, and is an alternative to performing an exact logistic regression. See the section “[Firth’s Bias-Reducing Penalized Likelihood](#)” on page 4242 for more information.

NOTE: The intercept-only log likelihood is modified by using the full-model Hessian, computed with the slope parameters equal to zero. Therefore, in order to use the likelihood ratio test to compare models, you should use the log likelihoods from the “Model Fit Statistics” tables instead of the Likelihood Ratio statistic that is reported in the “Testing Global Null Hypothesis: BETA=0” table. When fitting a model and scoring a data set in the same PROC LOGISTIC step, the model is fit using Firth’s penalty for parameter estimation purposes, but the penalty is not applied to the scored log likelihood.

GCONV=value

specifies the relative gradient convergence criterion. Convergence requires that the normalized prediction function reduction is small,

$$\frac{\mathbf{g}_i' \mathbf{I}_i^{-1} \mathbf{g}_i}{|l_i| + 1\text{E-}6} < \text{value}$$

where l_i is the value of the log-likelihood function, \mathbf{g}_i is the gradient vector, and \mathbf{I}_i is the negative (expected) Hessian matrix, all at iteration i . This is the default convergence criterion, and the default value is 1E-8. See the section “[Convergence Criteria](#)” on page 4242 for more information.

HIERARCHY=keyword**HIER=keyword**

specifies whether and how the model hierarchy requirement is applied and whether a single effect or multiple effects are allowed to enter or leave the model in one step. You can specify that only CLASS effects, or both CLASS and interval effects, be subject to the hierarchy requirement. The HIERARCHY= option is ignored unless you also specify one of the following options: [SELECTION=FORWARD](#), [SELECTION=BACKWARD](#), or [SELECTION=STEPWISE](#).

Model hierarchy refers to the requirement that, for any term to be in the model, all effects contained in the term must be present in the model. For example, in order for the interaction A*B to enter the model, the main effects A and B must be in the model. Likewise, neither effect A nor B can leave the model while the interaction A*B is in the model.

The keywords you can specify in the HIERARCHY= option are as follows:

- NONE** indicates that the model hierarchy is not maintained. Any single effect can enter or leave the model at any given step of the selection process.
- SINGLE** indicates that only one effect can enter or leave the model at one time, subject to the model hierarchy requirement. For example, suppose that you specify the main effects A and B and the interaction A*B in the model. In the first step of the selection process, either A or B can enter the model. In the second step, the other main effect can enter the model. The interaction effect can enter the model only when both main effects have already been entered. Also, before A or B can be removed from the model, the A*B interaction must first be removed. All effects (CLASS and interval) are subject to the hierarchy requirement.
- SINGLECLASS** is the same as HIERARCHY=SINGLE except that only CLASS effects are subject to the hierarchy requirement.
- MULTIPLE** indicates that more than one effect can enter or leave the model at one time, subject to the model hierarchy requirement. In a forward selection step, a single main effect can enter the model, or an interaction can enter the model together with all the effects that are contained in the interaction. In a backward elimination step, an interaction itself, or the interaction together with all the effects that the interaction contains, can be removed. All effects (CLASS and continuous) are subject to the hierarchy requirement.
- MULTIPLECLASS** is the same as HIERARCHY=MULTIPLE except that only CLASS effects are subject to the hierarchy requirement.

The default value is HIERARCHY=SINGLE, which means that model hierarchy is to be maintained for all effects (that is, both CLASS and continuous effects) and that only a single effect can enter or leave the model at each step.

INCLUDE=*n*

includes the first *n* effects in the MODEL statement in every model. By default, INCLUDE=0. The INCLUDE= option has no effect when SELECTION=NONE.

Note that the INCLUDE= and START= options perform different tasks: the INCLUDE= option includes the first *n* effects variables in every model, whereas the START= option requires only that the first *n* effects appear in the first model.

INFLUENCE<(STDRES)>

displays diagnostic measures for identifying influential observations in the case of a binary response model. For each observation, the INFLUENCE option displays the case number (which is the sequence number of the observation), the values of the explanatory variables included in the final model, and the regression diagnostic measures developed by Pregibon (1981). The STDRES option includes standardized and likelihood residuals in the display.

For a discussion of these diagnostic measures, see the section “Regression Diagnostics” on page 4263. When a STRATA statement is specified, the diagnostics are computed following Storer and Crowley (1985); see the section “Regression Diagnostic Details” on page 4272 for details.

IPLOTS

produces an index plot for the regression diagnostic statistics developed by Pregibon (1981). An index plot is a scatter plot with the regression diagnostic statistic represented on the Y axis and the case number on the X axis. See Example 54.6 for an illustration.

ITPRINT

displays the iteration history of the maximum-likelihood model fitting. The ITPRINT option also displays the last evaluation of the gradient vector and the final change in the -2 Log Likelihood.

LACKFIT<(n)>

performs the Hosmer and Lemeshow goodness-of-fit test (Hosmer and Lemeshow 2000) for the case of a binary response model. The subjects are divided into approximately 10 groups of roughly the same size based on the percentiles of the estimated probabilities. The discrepancies between the observed and expected number of observations in these groups are summarized by the Pearson chi-square statistic, which is then compared to a chi-square distribution with *t* degrees of freedom, where *t* is the number of groups minus *n*. By default, *n* = 2. A small *p*-value suggests that the fitted model is not an adequate model. The LACKFIT option is not available with the STRATA statement. See the section “The Hosmer-Lemeshow Goodness-of-Fit Test” on page 4259 for more information.

LINK=keyword**L=keyword**

specifies the link function linking the response probabilities to the linear predictors. You can specify one of the following keywords. The default is LINK=LOGIT.

CLOGLOG is the complementary log-log function. PROC LOGISTIC fits the binary complementary log-log model when there are two response categories and fits the cumulative complementary log-log model when there are more than two response categories. The aliases are CCLOGLOG, CCLL, and CUMCLOGLOG.

- GLOGIT** is the generalized logit function. PROC LOGISTIC fits the generalized logit model where each nonreference category is contrasted with the reference category. You can use the response variable option **REF=** to specify the reference category.
- LOGIT** is the log odds function. PROC LOGISTIC fits the binary logit model when there are two response categories and fits the cumulative logit model when there are more than two response categories. The aliases are CLOGIT and CUMLOGIT.
- PROBIT** is the inverse standard normal distribution function. PROC LOGISTIC fits the binary probit model when there are two response categories and fits the cumulative probit model when there are more than two response categories. The aliases are NORMIT, CPROBIT, and CUMPROBIT.

The **LINK=** option is not available with the **STRATA** statement.

See the section “[Link Functions and the Corresponding Distributions](#)” on page 4238 for more details.

MAXFUNCTION=*number*

specifies the maximum number of function calls to perform when maximizing the conditional likelihood. This option is valid only when a **STRATA** statement or the **UNEQUALSLOPES** option is specified. The default values are as follows:

- 125 when the number of parameters $p < 40$
- 500 when $40 \leq p < 400$
- 1000 when $p \geq 400$

Since the optimization is terminated only after completing a full iteration, the number of function calls that are actually performed can exceed *number*. If convergence is not attained, the displayed output and all output data sets created by the procedure contain results based on the last maximum likelihood iteration.

MAXITER=*number*

specifies the maximum number of iterations to perform. By default, **MAXITER=25**. If convergence is not attained in *number* iterations, the displayed output and all output data sets created by the procedure contain results that are based on the last maximum likelihood iteration.

MAXSTEP=*n*

specifies the maximum number of times any explanatory variable is added to or removed from the model when **SELECTION=STEPWISE**. The default number is twice the number of explanatory variables in the MODEL statement. When the **MAXSTEP=** limit is reached, the stepwise selection process is terminated. All statistics displayed by the procedure (and included in output data sets) are based on the last model fitted. The **MAXSTEP=** option has no effect when **SELECTION=NONE**, **FORWARD**, or **BACKWARD**.

NOCHECK

disables the checking process to determine whether maximum likelihood estimates of the regression parameters exist. If you are sure that the estimates are finite, this option can reduce the execution time if the estimation takes more than eight iterations. For more information, see the section “[Existence of Maximum Likelihood Estimates](#)” on page 4242.

NODUMMYPRINT**NODESIGNPRINT****NODP**

suppresses the “Class Level Information” table, which shows how the design matrix columns for the CLASS variables are coded.

NOINT

suppresses the intercept for the binary response model, the first intercept for the ordinal response model (which forces all intercepts to be nonnegative), or all intercepts for the generalized logit model. This can be particularly useful in conditional logistic analysis; see [Example 54.11](#).

NOFIT

performs the global score test without fitting the model. The global score test evaluates the joint significance of the effects in the MODEL statement. No further analyses are performed. If the NOFIT option is specified along with other MODEL statement options, NOFIT takes effect and all other options except FIRTH, LINK=, NOINT, OFFSET=, ROC, and TECHNIQUE= are ignored. The NOFIT option is not available with the STRATA statement.

NOLOGSCALE

specifies that computations for the conditional and exact logistic regression models should be computed by using normal scaling. Log scaling can handle numerically larger problems than normal scaling; however, computations in the log scale are slower than computations in normal scale.

OFFSET=name

names the offset variable. The regression coefficient for this variable will be fixed at 1. For an example that uses this option, see [Example 54.13](#). You can also use the OFFSET= option to restrict parameters to a fixed value. For example, if you want to restrict the parameter for variable X1 to 1 and the parameter for X2 to 2, compute Restrict= $X1 + 2 * X2$ in a DATA step, specify the option **offset=Restrict**, and leave X1 and X2 out of the model.

OUTROC=SAS-data-set**OUTR=SAS-data-set**

creates, for binary response models, an output SAS data set that contains the data necessary to produce the receiver operating characteristic (ROC) curve. The OUTROC= option is not available with the STRATA statement. See the section “[OUTROC= Output Data Set](#)” on page 4283 for the list of variables in this data set.

PARMLABEL

displays the labels of the parameters in the “Analysis of Maximum Likelihood Estimates” table.

PCORR

computes the partial correlation statistic $\text{sign}(\beta_i) \sqrt{\frac{\chi_i^2 - 2}{-2 \log L_0}}$ for each parameter i , where χ_i^2 is the Wald chi-square statistic for the parameter and $\log L_0$ is the log-likelihood of the intercept-only model (Hilbe 2009, p. 101). If $\chi_i^2 < 2$ then the partial correlation is set to 0. The partial correlation for the intercept terms is set to missing.

PEVENT=*value*

PEVENT=(*list*)

specifies one prior probability or a list of prior probabilities for the event of interest. The false positive and false negative rates are then computed as posterior probabilities by Bayes' theorem. The prior probability is also used in computing the rate of correct prediction. For each prior probability in the given list, a classification table of all observations is computed. By default, the prior probability is the total sample proportion of events. The PEVENT= option is useful for stratified samples. It has no effect if the CTABLE option is not specified. For more information, see the section “[False Positive, False Negative, and Correct Classification Rates Using Bayes' Theorem](#)” on page 4256. Also see the PPROB= option for information about how the *list* is specified.

PLCL

is the same as specifying **CLPARM=PL**.

PLCONV=*value*

controls the convergence criterion for confidence intervals based on the profile-likelihood function. The quantity *value* must be a positive number, with a default value of 1E-4. The PLCONV= option has no effect if profile-likelihood confidence intervals (**CLPARM=PL**) are not requested.

PLRL

is the same as specifying **CLODDS=PL**.

PPROB=*value*

PPROB=(*list*)

specifies one critical probability value (or cutpoint) or a list of critical probability values for classifying observations with the **CTABLE** option. Each *value* must be between 0 and 1. A response that has a cross validated predicted probability greater than or equal to the current PPROB= value is classified as an event response. The PPROB= option is ignored if the **CTABLE** option is not specified.

A classification table for each of several cutpoints can be requested by specifying a list. For example, the following statement requests a classification of the observations for each of the cutpoints 0.3, 0.5, 0.6, 0.7, and 0.8:

```
pprob= (0.3, 0.5 to 0.8 by 0.1)
```

If the PPROB= option is not specified, the default is to display the classification for a range of probabilities from the smallest estimated probability (rounded down to the nearest 0.02) to the highest estimated probability (rounded up to the nearest 0.02) with 0.02 increments.

RIDGING=ABSOLUTE | RELATIVE | NONE

specifies the technique used to improve the log-likelihood function when its value in the current iteration is less than that in the previous iteration. If you specify the RIDGING=ABSOLUTE option, the diagonal elements of the negative (expected) Hessian are inflated by adding the ridge value. If you specify the RIDGING=RELATIVE option, the diagonal elements are inflated by a factor of 1 plus the ridge value. If you specify the RIDGING=NONE option, the crude line search method of taking half a step is used instead of ridging. By default, RIDGING=RELATIVE.

RISKLIMITS**RL****WALDRL**

is the same as specifying **CLODDS=WALD**.

ROCEPS=number

specifies a criterion for the ROC curve used for grouping estimated event probabilities that are close to each other. In each group, the difference between the largest and the smallest estimated event probabilities does not exceed the given value. The value for *number* must be between 0 and 1; the default value is the square root of the machine epsilon, which is about 1E–8 (in releases prior to 9.2, the default was 1E–4). The smallest estimated probability in each group serves as a cutpoint for predicting an event response. The **ROCEPS=** option has no effect unless the **OUTROC=** option, the **BINWIDTH=0** option, or a **ROC statement** is specified.

RSQUARE**RSQ**

requests a generalized R Square measure for the fitted model. For more information, see the section “**Generalized Coefficient of Determination**” on page 4246.

SCALE=scale

enables you to supply the value of the dispersion parameter or to specify the method for estimating the dispersion parameter. It also enables you to display the “Deviance and Pearson Goodness-of-Fit Statistics” table. To correct for overdispersion or underdispersion, the covariance matrix is multiplied by the estimate of the dispersion parameter. Valid values for *scale* are as follows:

D | DEVIANCE specifies that the dispersion parameter be estimated by the deviance divided by its degrees of freedom.

P | PEARSON specifies that the dispersion parameter be estimated by the Pearson chi-square statistic divided by its degrees of freedom.

WILLIAMS *<(constant)>* specifies that Williams’ method be used to model overdispersion. This option can be used only with the events/trials syntax. An optional *constant* can be specified as the scale parameter; otherwise, a scale parameter is estimated under the full model. A set of weights is created based on this scale parameter estimate. These weights can then be used in fitting subsequent models of fewer terms than the full model. When fitting these submodels, specify the computed scale parameter as *constant*. See [Example 54.10](#) for an illustration.

N | NONE specifies that no correction is needed for the dispersion parameter; that is, the dispersion parameter remains as 1. This specification is used for requesting the deviance and the Pearson chi-square statistic without adjusting for overdispersion.

constant sets the estimate of the dispersion parameter to be the square of the given *constant*. For example, **SCALE=2** sets the dispersion parameter to 4. The value *constant* must be a positive number.

You can use the **AGGREGATE** (or **AGGREGATE=**) option to define the subpopulations for calculating the Pearson chi-square statistic and the deviance. In the absence of the **AGGREGATE** (or **AGGREGATE=**) option, each observation is regarded as coming from a different subpopulation. For the events/trials syntax, each observation consists of *n* Bernoulli trials, where *n* is the value of the

trials variable. For single-trial syntax, each observation consists of a single response, and for this setting it is not appropriate to carry out the Pearson or deviance goodness-of-fit analysis. Thus, PROC LOGISTIC ignores specifications SCALE=P, SCALE=D, and SCALE=N when single-trial syntax is specified without the **AGGREGATE** (or AGGREGATE=) option.

The “Deviance and Pearson Goodness-of-Fit Statistics” table includes the Pearson chi-square statistic, the deviance, the degrees of freedom, the ratio of each statistic divided by its degrees of freedom, and the corresponding *p*-value. The SCALE= option is not available with the **STRATA** statement. For more information, see the section “**Overdispersion**” on page 4257.

SELECTION=BACKWARD | B
| FORWARD | F
| NONE | N
| STEPWISE | S
| SCORE

specifies the method used to select the variables in the model. BACKWARD requests backward elimination, FORWARD requests forward selection, NONE fits the complete model specified in the MODEL statement, and STEPWISE requests stepwise selection. SCORE requests best subset selection. By default, SELECTION=NONE.

For more information, see the section “**Effect-Selection Methods**” on page 4244.

SEQUENTIAL

SEQ

forces effects to be added to the model in the order specified in the MODEL statement or eliminated from the model in the reverse order of that specified in the MODEL statement. The model-building process continues until the next effect to be added has an insignificant adjusted chi-square statistic or until the next effect to be deleted has a significant Wald chi-square statistic. The SEQUENTIAL option has no effect when **SELECTION=NONE**.

SINGULAR=value

specifies the tolerance for testing the singularity of the Hessian matrix (Newton-Raphson algorithm) or the expected value of the Hessian matrix (Fisher scoring algorithm). The Hessian matrix is the matrix of second partial derivatives of the log-likelihood function. The test requires that a pivot for sweeping this matrix be at least this number times a norm of the matrix. Values of the SINGULAR= option must be numeric. By default, *value* is the machine epsilon times 1E7, which is approximately 1E-9.

SLENTRY=value

SLE=value

specifies the significance level of the score chi-square for entering an effect into the model in the FORWARD or STEPWISE method. Values of the SLENTRY= option should be between 0 and 1, inclusive. By default, SLENTRY=0.05. The SLENTRY= option has no effect when **SELECTION=NONE**, **SELECTION=BACKWARD**, or **SELECTION=SCORE**.

SLSTAY=value**SLS=value**

specifies the significance level of the Wald chi-square for an effect to stay in the model in a backward elimination step. Values of the SLSTAY= option should be between 0 and 1, inclusive. By default, SLSTAY=0.05. The SLSTAY= option has no effect when **SELECTION=NONE**, **SELECTION=FORWARD**, or **SELECTION=SCORE**.

START=n

begins the FORWARD, BACKWARD, or STEPWISE effect selection process with the first n effects listed in the MODEL statement. The value of n ranges from 0 to s , where s is the total number of effects in the MODEL statement. The default value of n is s for the BACKWARD method and 0 for the FORWARD and STEPWISE methods. Note that START= n specifies only that the first n effects appear in the first model, while **INCLUDE= n** requires that the first n effects be included in every model. For the SCORE method, START= n specifies that the smallest models contain n effects, where n ranges from 1 to s ; the default value is 1. The START= option has no effect when **SELECTION=NONE**.

STB

displays the standardized estimates for the parameters in the “Analysis of Maximum Likelihood Estimates” table. The standardized estimate of β_i is given by $\hat{\beta}_i/(s/s_i)$, where s_i is the total sample standard deviation for the i th explanatory variable and

$$s = \begin{cases} \pi/\sqrt{3} & \text{Logistic} \\ 1 & \text{Normal} \\ \pi/\sqrt{6} & \text{Extreme-value} \end{cases}$$

The sample standard deviations for parameters associated with **CLASS** and **EFFECT** variables are computed using their codings. For the intercept parameters, the standardized estimates are set to missing.

STOP=n

specifies the maximum (**SELECTION=FORWARD**) or minimum (**SELECTION=BACKWARD**) number of effects to be included in the final model. The effect selection process is stopped when n effects are found. The value of n ranges from 0 to s , where s is the total number of effects in the MODEL statement. The default value of n is s for the FORWARD method and 0 for the BACKWARD method. For the SCORE method, STOP= n specifies that the largest models contain n effects, where n ranges from 1 to s ; the default value of n is s . The STOP= option has no effect when **SELECTION=NONE** or **STEPWISE**.

STOPRES**SR**

specifies that the removal or entry of effects be based on the value of the residual chi-square. If **SELECTION=FORWARD**, then the STOPRES option adds the effects into the model one at a time until the residual chi-square becomes insignificant (until the p -value of the residual chi-square exceeds the **SLENTY= value**). If **SELECTION=BACKWARD**, then the STOPRES option removes effects from the model one at a time until the residual chi-square becomes significant (until the p -value of the residual chi-square becomes less than the **SLSTAY= value**). The STOPRES option has no effect when **SELECTION=NONE** or **SELECTION=STEPWISE**.

TECHNIQUE=FISHER | NEWTON**TECH=FISHER | NEWTON**

specifies the optimization technique for estimating the regression parameters. NEWTON (or NR) is the Newton-Raphson algorithm and FISHER (or FS) is the Fisher scoring algorithm. Both techniques yield the same estimates, but the estimated covariance matrices are slightly different except for the case when the LOGIT link is specified for binary response data. The default is TECHNIQUE=FISHER. If the [LINK=GLOGIT](#) option is specified, then Newton-Raphson is the default and only available method. The TECHNIQUE= option is not applied to conditional and exact conditional analyses. This option is not available when the [UNEQUALSLOPES](#) option is specified. See the section “[Iterative Algorithms for Model Fitting](#)” on page 4240 for more details.

UNEQUALSLOPES<=effect | (effect-list)>

specifies one or more effects in a cumulative response model that have a different set of parameters for each response function. If you specify more than one effect, enclose the effects in parentheses. The effects must be explanatory effects that are specified in the MODEL statement.

If you do not specify this option, the cumulative response models make the parallel lines assumption, $F(\Pr(Y < i)) = \alpha_i + \mathbf{x}'\boldsymbol{\beta}$, where each response function has the same slope parameters $\boldsymbol{\beta}$. If you specify this option without an *effect* or *effect-list*, all slope parameters vary across the response functions, resulting in the model $F(\Pr(Y < i)) = \alpha_i + \mathbf{x}'\boldsymbol{\beta}_i$. Specifying an *effect* or *effect-list* enables you to choose which effects have different parameters across the response functions. If you select the first \mathbf{x}_1 parameters to have equal slopes and the remaining \mathbf{x}_2 parameters to have unequal slopes, the model can be written as $F(\Pr(Y < i)) = \alpha_i + \mathbf{x}'_1\boldsymbol{\beta}_1 + \mathbf{x}'_2\boldsymbol{\beta}_{2i}$. A model that uses the [CLOGIT](#) link is called a *partial proportional odds model* (Peterson and Harrell 1990).

For more information, see [Example 54.17](#). The following statements are not available with this option: EFFECTPLOT, ESTIMATE, EXACT, LSMEANS, LSMESTIMATE, ROC, ROCCONTRAST, SLICE, STORE, and STRATA. The following options are not available with this option: FIRTH, RIDGING=, TECHNIQUE=, CTABLE, PEVENT=, PPROB=, OUTROC=, and ROCEPS=.

WALDCL**CL**

is the same as specifying [CLPARM=WALD](#).

XCONV=value

specifies the relative parameter convergence criterion. Convergence requires a small relative parameter change in subsequent iterations,

$$\max_j |\delta_j^{(i)}| < \text{value}$$

where

$$\delta_j^{(i)} = \begin{cases} \beta_j^{(i)} - \beta_j^{(i-1)} & |\beta_j^{(i-1)}| < 0.01 \\ \frac{\beta_j^{(i)} - \beta_j^{(i-1)}}{\beta_j^{(i-1)}} & \text{otherwise} \end{cases}$$

and $\beta_j^{(i)}$ is the estimate of the j th parameter at iteration i . See the section “[Convergence Criteria](#)” on page 4242 for more information.

NLOPTIONS Statement

NLOPTIONS < options > ;

The NLOPTIONS statement controls the optimization process for conditional analyses (which result from specifying a **STRATA** statement) and for partial parallel slope models (which result from specifying the **UNEQUALSLOPES** option in the MODEL statement). An *option* specified in the NLOPTIONS statement takes precedence over the same option specified in the MODEL statement.

The default optimization techniques are chosen according to the number of parameters, p , as follows:

- Newton-Raphson with ridging when $p < 40$
- quasi-Newton when $40 \leq p < 400$
- conjugate gradient when $p \geq 400$

The available *options* are described in the section “NLOPTIONS Statement” on page 482 of Chapter 19, “Shared Concepts and Topics.”

ODDSRATIO Statement

ODDSRATIO < 'label' > variable < / options > ;

The ODDSRATIO statement produces odds ratios for *variable* even when the variable is involved in interactions with other covariates, and for classification variables that use any parameterization. You can also specify variables on which **constructed effects** are based, in addition to the names of **COLLECTION** or **MULTIMEMBER** effects. You can specify several ODDSRATIO statements.

If *variable* is continuous, then the odds ratios honor any values specified in the **UNITS** statement. If *variable* is a classification variable, then odds ratios comparing each pairwise difference between the levels of *variable* are produced. If *variable* interacts with a continuous variable, then the odds ratios are produced at the mean of the interacting covariate by default. If *variable* interacts with a classification variable, then the odds ratios are produced at each level of the interacting covariate by default. The computed odds ratios are independent of the parameterization of any classification variable.

The odds ratios are uniquely labeled by concatenating the following terms to *variable*:

1. If this is a polytomous response model, then prefix the response variable and the level describing the logit followed by a colon; for example, “Y 0:”.
2. If *variable* is continuous and the **UNITS** statement provides a value that is not equal to 1, then append “Units=value”; otherwise, if *variable* is a classification variable, then append the levels being contrasted; for example, “cat vs dog”.
3. Append all interacting covariates preceded by “At”; for example, “At X=1.2 A=cat”.

If you are also creating odds ratio plots, then this label is displayed on the plots (see the **PLOTS** option for more information). If you specify a ‘label’ in the ODDSRATIO statement, then the odds ratios produced by this statement are also labeled: ‘label’, ‘label 2’, ‘label 3’, ..., and these are the labels used in the plots. If

there are any duplicated labels across all ODDSRATIO statements, then the corresponding odds ratios are not displayed on the plots.

The following *options* are available:

AT(*covariate=value-list* | **REF** | **ALL**< ...*covariate=value-list* | **REF** | **ALL**>)

specifies fixed levels of the interacting covariates. If a specified *covariate* does not interact with the *variable*, then its AT list is ignored.

For continuous interacting covariates, you can specify one or more numbers in the *value-list*. For classification covariates, you can specify one or more formatted levels of the covariate enclosed in single quotes (for example, **A='cat' 'dog'**), you can specify the keyword **REF** to select the reference-level, or you can specify the keyword **ALL** to select all levels of the classification variable. By default, continuous covariates are set to their means, while **CLASS** covariates are set to **ALL**. For a model that includes a classification variable **A={cat,dog}** and a continuous covariate **X**, specifying **AT (A='cat' X=7 9)** will set **A** to 'cat', and **X** to 7 and then 9.

CL=WALD | **PL** | **BOTH**

specifies whether to create Wald or profile-likelihood confidence limits, or both. By default, Wald confidence limits are produced.

DIFF=REF | **ALL**

specifies whether the odds ratios for a classification variable are computed against the reference level, or all pairs of variable are compared. By default, **DIFF=ALL**. The **DIFF=** option is ignored when variable is continuous.

PLCONV=value

controls the convergence criterion for confidence intervals based on the profile-likelihood function. The quantity *value* must be a positive number, with a default value of 1E-4. The **PLCONV=** option has no effect if profile-likelihood confidence intervals (**CL=PL**) are not requested.

PLMAXITER=n

specifies the maximum number of iterations to perform. By default, **PLMAXITER=25**. If convergence is not attained in *n* iterations, the odds ratio or the confidence limits are set to missing. The **PLMAXITER=** option has no effect if profile-likelihood confidence intervals (**CL=PL**) are not requested.

PLSINGULAR=value

specifies the tolerance for testing the singularity of the Hessian matrix (Newton-Raphson algorithm) or the expected value of the Hessian matrix (Fisher scoring algorithm). The test requires that a pivot for sweeping this matrix be at least this number times a norm of the matrix. Values of the **PLSINGULAR=** option must be numeric. By default, *value* is the machine epsilon times 1E7, which is approximately 1E-9. The **PLSINGULAR=** option has no effect if profile-likelihood confidence intervals (**CL=PL**) are not requested.

OUTPUT Statement

OUTPUT < **OUT=SAS-data-set** > < *options* > ;

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimated linear predictors and their standard error estimates, the estimates of the cumulative or individual response probabilities, and the confidence limits for the cumulative probabilities. Regression diagnostic statistics and estimates of cross validated response probabilities are also available for binary response models. If you specify more than one OUTPUT statement, only the last one is used. Formulas for the statistics are given in the sections “[Linear Predictor, Predicted Probability, and Confidence Limits](#)” on page 4253 and “[Regression Diagnostics](#)” on page 4263, and, for conditional logistic regression, in the section “[Conditional Logistic Regression](#)” on page 4271.

If you use the single-trial syntax, the data set also contains a variable named `_LEVEL_`, which indicates the level of the response that the given row of output is referring to. For instance, the value of the cumulative probability variable is the probability that the response variable is as large as the corresponding value of `_LEVEL_`. For details, see the section “[OUT= Output Data Set in the OUTPUT Statement](#)” on page 4280.

The estimated linear predictor, its standard error estimate, all predicted probabilities, and the confidence limits for the cumulative probabilities are computed for all observations in which the explanatory variables have no missing values, even if the response is missing. By adding observations with missing response values to the input data set, you can compute these statistics for new observations or for settings of the explanatory variables not present in the data without affecting the model fit. Alternatively, the [SCORE](#) statement can be used to compute predicted probabilities and confidence intervals for new observations.

Table 54.9 summarizes the options available in the OUTPUT statement. These options can be specified after a slash (/). The statistic and diagnostic options specify the statistics to be included in the output data set and name the new variables that contain the statistics. If a [STRATA](#) statement is specified, only the [PREDICTED=](#), [DFBETAS=](#), and [H=](#) options are available; see the section “[Regression Diagnostic Details](#)” on page 4272 for details.

Table 54.9 OUTPUT Statement Options

Option	Description
ALPHA=	Specifies α for the $100(1 - \alpha)\%$ confidence intervals
OUT=	Names the output data set
Statistic Options	
LOWER=	Names the lower confidence limit
PREDICTED=	Names the predicted probabilities
PREDPROBS=	Requests the individual, cumulative, or cross validated predicted probabilities
STDXBETA=	Names the standard error estimate of the linear predictor
UPPER=	Names the upper confidence limit
XBETA=	Names the linear predictor
Diagnostic Options for Binary Response	
C=	Names the confidence interval displacement
CBAR=	Names the confidence interval displacement
DFBETAS=	Names the standardized deletion parameter differences
DIFCHISQ=	Names the deletion chi-square goodness-of-fit change
DIFDEV=	Names the deletion deviance change
H=	Names the leverage
RESCHI=	Names the Pearson chi-square residual
RESDEV=	Names the deviance residual

Table 54.9 *continued*

Option	Description
RESLIK=	Names the likelihood residual
STDRESCHI=	Names the standardized Pearson chi-square residual
STDRESDEV=	Names the standardized deviance residual

The following list describes these options.

ALPHA=*number*

sets the level of significance α for $100(1 - \alpha)\%$ confidence limits for the appropriate response probabilities. The value of *number* must be between 0 and 1. By default, *number* is equal to the value of the **ALPHA=** option in the PROC LOGISTIC statement, or 0.05 if that option is not specified.

C=*name*

specifies the confidence interval displacement diagnostic that measures the influence of individual observations on the regression estimates.

CBAR=*name*

specifies the confidence interval displacement diagnostic that measures the overall change in the global regression estimates due to deleting an individual observation.

DFBETAS=**_ALL_**

DFBETAS=*var-list*

specifies the standardized differences in the regression estimates for assessing the effects of individual observations on the estimated regression parameters in the fitted model. You can specify a list of up to $s + 1$ variable names, where s is the number of explanatory variables in the **MODEL** statement, or you can specify just the keyword **_ALL_**. In the former specification, the first variable contains the standardized differences in the intercept estimate, the second variable contains the standardized differences in the parameter estimate for the first explanatory variable in the **MODEL** statement, and so on. In the latter specification, the DFBETAS statistics are named DFBETA_XXX, where XXX is the name of the regression parameter. For example, if the model contains two variables X1 and X2, the specification **DFBETAS=_ALL_** produces three DFBETAS statistics: DFBETA_Intercept, DFBETA_X1, and DFBETA_X2. If an explanatory variable is not included in the final model, the corresponding output variable named in **DFBETAS=***var-list* contains missing values.

DIFCHISQ=*name*

specifies the change in the chi-square goodness-of-fit statistic attributable to deleting the individual observation.

DIFDEV=*name*

specifies the change in the deviance attributable to deleting the individual observation.

H=*name*

specifies the diagonal element of the hat matrix for detecting extreme points in the design space.

LOWER=*name*

L=*name*

names the variable containing the lower confidence limits for π , where π is the probability of the event response if events/trials syntax or single-trial syntax with binary response is specified; for a cumulative model, π is cumulative probability (that is, the probability that the response is less than

or equal to the value of `_LEVEL_`); for the generalized logit model, it is the individual probability (that is, the probability that the response category is represented by the value of `_LEVEL_`). See the [ALPHA=](#) option to set the confidence level.

OUT=SAS-data-set

names the output data set. If you omit the `OUT=` option, the output data set is created and given a default name by using the `DATA` convention.

PREDICTED=name

PRED=name

PROB=name

P=name

names the variable containing the predicted probabilities. For the events/trials syntax or single-trial syntax with binary response, it is the predicted event probability. For a cumulative model, it is the predicted cumulative probability (that is, the probability that the response variable is less than or equal to the value of `_LEVEL_`); and for the generalized logit model, it is the predicted individual probability (that is, the probability of the response category represented by the value of `_LEVEL_`).

PREDPROBS=(keywords)

requests individual, cumulative, or cross validated predicted probabilities. Descriptions of the *keywords* are as follows.

INDIVIDUAL | I requests the predicted probability of each response level. For a response variable `Y` with three levels, 1, 2, and 3, the individual probabilities are $\Pr(Y=1)$, $\Pr(Y=2)$, and $\Pr(Y=3)$.

CUMULATIVE | C requests the cumulative predicted probability of each response level. For a response variable `Y` with three levels, 1, 2, and 3, the cumulative probabilities are $\Pr(Y \leq 1)$, $\Pr(Y \leq 2)$, and $\Pr(Y \leq 3)$. The cumulative probability for the last response level always has the constant value of 1. For generalized logit models, the cumulative predicted probabilities are not computed and are set to missing.

CROSSVALIDATE | XVALIDATE | X requests the cross validated individual predicted probability of each response level. These probabilities are derived from the leave-one-out principle—that is, dropping the data of one subject and reestimating the parameter estimates. PROC LOGISTIC uses a less expensive one-step approximation to compute the parameter estimates. This option is valid only for binary response models; for nominal and ordinal models, the cross validated probabilities are not computed and are set to missing.

See the section “[Details of the PREDPROBS= Option](#)” on page 4227 at the end of this section for further details.

RESCHI=name

specifies the Pearson (chi-square) residual for identifying observations that are poorly accounted for by the model.

RESDEV=name

specifies the deviance residual for identifying poorly fitted observations.

RESLIK=*name*

specifies the likelihood residual for identifying poorly fitted observations.

STDRESCHI=*name*

specifies the standardized Pearson (chi-square) residual for identifying observations that are poorly accounted for by the model.

STDRESDEV=*name*

specifies the standardized deviance residual for identifying poorly fitted observations.

STDXBETA=*name*

names the variable containing the standard error estimates of **XBETA**. See the section “[Linear Predictor, Predicted Probability, and Confidence Limits](#)” on page 4253 for details.

UPPER=*name***U=***name*

names the variable containing the upper confidence limits for π , where π is the probability of the event response if events/trials syntax or single-trial syntax with binary response is specified; for a cumulative model, π is cumulative probability (that is, the probability that the response is less than or equal to the value of `_LEVEL_`); for the generalized logit model, it is the individual probability (that is, the probability that the response category is represented by the value of `_LEVEL_`). See the [ALPHA=](#) option to set the confidence level.

XBETA=*name*

names the variable containing the estimates of the linear predictor $\alpha_i + \beta'x$, where i is the corresponding ordered value of `_LEVEL_`.

Details of the PREDPROBS= Option

You can request any of the three types of predicted probabilities. For example, you can request both the individual predicted probabilities and the cross validated probabilities by specifying `PREDPROBS=(I X)`.

When you specify the `PREDPROBS=` option, two automatic variables, `_FROM_` and `_INTO_`, are included for the single-trial syntax and only one variable, `_INTO_`, is included for the events/trials syntax. The variable `_FROM_` contains the formatted value of the observed response. The variable `_INTO_` contains the formatted value of the response level with the largest individual predicted probability.

If you specify `PREDPROBS=INDIVIDUAL`, the `OUT=` data set contains k additional variables representing the individual probabilities, one for each response level, where k is the maximum number of response levels across all BY groups. The names of these variables have the form `IP_xxx`, where `xxx` represents the particular level. The representation depends on the following situations:

- If you specify events/trials syntax, `xxx` is either ‘Event’ or ‘Nonevent’. Thus, the variable containing the event probabilities is named `IP_Event` and the variable containing the nonevent probabilities is named `IP_Nonevent`.
- If you specify the single-trial syntax with more than one BY group, `xxx` is 1 for the first ordered level of the response, 2 for the second ordered level of the response, and so forth, as given in the “Response Profile” table. The variable containing the predicted probabilities $\Pr(Y=1)$ is named `IP_1`, where Y is the response variable. Similarly, `IP_2` is the name of the variable containing the predicted probabilities $\Pr(Y=2)$, and so on.

- If you specify the single-trial syntax with no BY-group processing, *xxx* is the left-justified formatted value of the response level (the value might be truncated so that `IP_`*xxx* does not exceed 32 characters). For example, if *Y* is the response variable with response levels ‘None’, ‘Mild’, and ‘Severe’, the variables representing individual probabilities $\Pr(Y=\text{‘None’})$, $\Pr(Y=\text{‘Mild’})$, and $\Pr(Y=\text{‘Severe’})$ are named `IP_None`, `IP_Mild`, and `IP_Severe`, respectively.

If you specify `PREDPROBS=CUMULATIVE`, the `OUT=` data set contains *k* additional variables representing the cumulative probabilities, one for each response level, where *k* is the maximum number of response levels across all BY groups. The names of these variables have the form `CP_`*xxx*, where *xxx* represents the particular response level. The naming convention is similar to that given by `PREDPROBS=INDIVIDUAL`. The `PREDPROBS=CUMULATIVE` values are the same as those output by the `PREDICT=` option, but are arranged in variables on each output observation rather than in multiple output observations.

If you specify `PREDPROBS=CROSSVALIDATE`, the `OUT=` data set contains *k* additional variables representing the cross validated predicted probabilities of the *k* response levels, where *k* is the maximum number of response levels across all BY groups. The names of these variables have the form `XP_`*xxx*, where *xxx* represents the particular level. The representation is the same as that given by `PREDPROBS=INDIVIDUAL` except that for the events/trials syntax there are four variables for the cross validated predicted probabilities instead of two:

`XP_EVENT_R1E` is the cross validated predicted probability of an event when a single event is removed from the current observation.

`XP_NONEVENT_R1E` is the cross validated predicted probability of a nonevent when a single event is removed from the current observation.

`XP_EVENT_R1N` is the cross validated predicted probability of an event when a single nonevent is removed from the current observation.

`XP_NONEVENT_R1N` is the cross validated predicted probability of a nonevent when a single nonevent is removed from the current observation.

The cross validated predicted probabilities are precisely those used in the `CTABLE` option. See the section “[Predicted Probability of an Event for Classification](#)” on page 4255 for details of the computation.

ROC Statement

ROC < *label* > < *specification* > < / *options* > ;

The ROC statements specify models to be used in the ROC comparisons. You can specify more than one ROC statement. ROC statements are identified by their *label*—if you do not specify a *label*, the *i*th ROC statement is labeled “ROC*i*”. Additionally, the specified or selected model is labeled with the `MODEL` statement label or “Model” if the `MODEL` label is not present. The *specification* can be either a list of effects that have previously been specified in the `MODEL` statement, or `PRED=variable`, where the *variable* does not have to be specified in the `MODEL` statement. The `PRED=` option enables you to input a criterion produced outside PROC LOGISTIC; for example, you can fit a random-intercept model by using PROC GLIMMIX or use survey weights in PROC SURVEYLOGISTIC, then use the predicted values from those models to produce an ROC curve for the comparisons. If you do not make a *specification*, then an intercept-only model is fit to the data, resulting in a noninformative ROC curve that can be used for comparing the area under another ROC curve to 0.5.

You can specify a **ROCCONTRAST** statement and a **ROCOPTIONS** option in the PROC LOGISTIC statement to control how the models are compared, while the **PLOTS=ROC** option controls the ODS Graphics displays. See [Example 54.8](#) for an example that uses the ROC statement.

If you specify any *options*, then a “ROC Model Information” table summarizing the new ROC model is displayed. The *options* are ignored for the PRED= specification. The following *options* are available:

NOOFFSET

does not include an offset variable if the OFFSET= option is specified in the **MODEL** statement. A constant offset has no effect on the ROC curve, although the cutpoints might be different, but a nonconstant offset can affect the parameter estimates and hence the ROC curve.

LINK=keyword

specifies the link function to be used in the model. The available keywords are LOGIT, NORMIT, and CLOGLOG. The logit link is the default. Note that the **LINK=** option in the MODEL statement is ignored.

ROCCONTRAST Statement

ROCCONTRAST < 'label' > < contrast > < / options > ;

The ROCCONTRAST statement compares the different ROC models. You can specify only one ROCCONTRAST statement. The **ROCOPTIONS** options in the PROC LOGISTIC statement control how the models are compared. You can specify one of the following *contrast* specifications:

REFERENCE<(MODEL | 'roc-label')>

produces a contrast matrix of differences between each ROC curve and a reference curve. The MODEL keyword specifies that the reference curve is that produced from the MODEL statement; the *roc-label* specifies the *label* of the ROC curve that is to be used as the reference curve. If neither the MODEL keyword nor the *roc-label* label is specified, then the reference ROC curve is either the curve produced from the MODEL statement, the selected model if a selection method is specified, or the model from the first ROC statement if the **NOFIT** option is specified.

ADJACENTPAIRS

produces a contrast matrix of each ROC curve minus the succeeding curve.

matrix

specifies the contrast in the form **row1, row2, . . .**, where each *row* contains the coefficients used to compare the ROC curves. Each *row* must contain the same number of entries as there are ROC curves being compared. The elements of each *row* refer to the ROC statements in the order in which they are specified. However, the first element of each *row* refers either to the fitted model, the selected model if a **SELECTION=** method is specified, or the first specified ROC statement if the **NOFIT** option is specified.

If no *contrast* is specified, then the REFERENCE contrast with the default reference curve is used. See the section “[Comparing ROC Curves](#)” on page 4261 for more information about comparing ROC curves, and see [Example 54.8](#) for an example.

The following *options* are available:

E

displays the contrast.

ESTIMATE <= ROWS | ALLPAIRS >

produces estimates of each row of the contrast when ESTIMATE or ESTIMATE=ROWS is specified. If the ESTIMATE=ALLPAIRS option is specified, then estimates of every pairwise difference of ROC curves are produced.

The row contrasts are labeled “ModelLabel1 – ModelLabel2”, where the model labels are as described in the [ROC](#) statement; in particular, for the REFERENCE contrast, ModelLabel2 is the reference model label. If you specify your own contrast matrix, then the *i*th contrast row estimate is labeled “Row*i*”.

COV

displays covariance matrices used in the computations.

SCORE Statement

SCORE < options > ;

The SCORE statement creates a data set that contains all the data in the [DATA=](#) data set together with posterior probabilities and, optionally, prediction confidence intervals. Fit statistics are displayed on request. If you have binary response data, the SCORE statement can be used to create a data set containing data for the ROC curve. You can specify several SCORE statements. [FREQ](#), [WEIGHT](#), and [BY](#) statements can be used with the SCORE statements. The SCORE statement is not available with the [STRATA](#) statement.

If a [SCORE](#) statement is specified in the same run as fitting the model, [FORMAT](#) statements should be specified after the [SCORE](#) statement in order for the formats to apply to all the [DATA=](#) and [PRIOR=](#) data sets in the [SCORE](#) statement.

See the section “[Scoring Data Sets](#)” on page 4266 for more information, and see [Example 54.15](#) for an illustration of how to use this statement.

[Table 54.10](#) summarizes the options available in the SCORE statement.

Table 54.10 SCORE Statement Options

Option	Description
ALPHA=	Specifies the significance level
CLM	Outputs the Wald-test-based confidence limits
CUMULATIVE	Outputs the cumulative predicted probabilities
DATA=	Names the SAS data that you want to score
FITSTAT	Displays fit statistics
OUT=	Names the SAS data set that contains the predicted information
OUTROC=	Names the SAS data set that contains the ROC curve
PRIOR=	Names the SAS data set that contains the priors of the response categories
PRIOREVENT=	Specifies the prior event probability
ROCEPS=	Specifies the criterion for grouping estimated event probabilities

You can specify the following options:

ALPHA=number

specifies the significance level α for $100(1 - \alpha)\%$ confidence intervals. By default, the value of *number* is equal to the **ALPHA=** option in the PROC LOGISTIC statement, or 0.05 if that option is not specified. This option has no effect unless the **CLM** option in the SCORE statement is requested.

CLM

outputs the Wald-test-based confidence limits for the predicted probabilities. This option is not available when the **INMODEL=** data set is created with the **NOCOV** option.

CUMULATIVE

outputs the cumulative predicted probabilities $\Pr(Y \leq i), i = 1, \dots, k + 1$, to the **OUT=** data set. This option is valid only when you have more than two response levels; otherwise, the option is ignored and a note is printed in the SAS log. These probabilities are named *CP_level_i*, where *level_i* is the *i*th response level.

If the **CLM** option is also specified in the SCORE statement, then the Wald-based confidence limits for the cumulative predicted probabilities are also output. The confidence limits are named *CLCL_level_i* and *CUCL_level_i*. In particular, for the lowest response level, the cumulative values (CP, CLCL, CUCL) should be identical to the individual values (P, LCL, UCL), and for the highest response level $CP=CLCL=CUCL=1$.

DATA=SAS-data-set

names the SAS data set that you want to score. If you omit the **DATA=** option in the SCORE statement, then scoring is performed on the **DATA=** input data set in the PROC LOGISTIC statement, if specified; otherwise, the **DATA=_LAST_** data set is used.

It is not necessary for the **DATA=** data set in the SCORE statement to contain the response variable unless you are specifying the **FITSTAT** or **OUTROC=** option.

Only those variables involved in the fitted model effects are required in the **DATA=** data set in the SCORE statement. For example, the following statements use forward selection to select effects:

```
proc logistic data=Neuralgia outmodel=sasuser.Model;
  class Treatment Sex;
  model Pain(event='Yes') = Treatment|Sex Age
    / selection=forward sle=.01;
run;
```

Suppose Treatment and Age are the effects selected for the final model. You can score a data set that does not contain the variable Sex since the effect Sex is not in the model that the scoring is based on. For example, the following statements score the Neuralgia data set after dropping the Sex variable:

```
proc logistic inmodel=sasuser.Model;
  score data=Neuralgia(drop=Sex);
run;
```

FITSTAT

displays fit statistics for the data set you are scoring. The data set must contain the response variable. See the section “[Fit Statistics for Scored Data Sets](#)” on page 4266 for details.

OUT=SAS-data-set

names the SAS data set that contains the predicted information. If you omit the OUT= option, the output data set is created and given a default name by using the DATA n convention.

OUTROC=SAS-data-set

names the SAS data set that contains the ROC curve for the DATA= data set. The ROC curve is computed only for binary response data. See the section “[OUTROC= Output Data Set](#)” on page 4283 for the list of variables in this data set.

PRIOR=SAS-data-set

names the SAS data set that contains the priors of the response categories. The priors can be values proportional to the prior probabilities; thus, they do not necessarily sum to one. This data set should include a variable named `_PRIOR_` that contains the prior probabilities. For events/trials MODEL statement syntax, this data set should also include an `_OUTCOME_` variable that contains the values EVENT and NONEVENT; for single-trial syntax, this data set should include the response variable that contains the unformatted response categories. See [Example 54.15](#) for an example.

PRIOREVENT=value

specifies the prior event probability for a binary response model. If both **PRIOR=** and **PRIOREVENT=** options are specified, the **PRIOR=** option takes precedence.

ROCEPS=value

specifies the criterion for grouping estimated event probabilities that are close to each other for the ROC curve. In each group, the difference between the largest and the smallest estimated event probability does not exceed the given value. The *value* must be between 0 and 1; the default value is the square root of the machine epsilon, which is about 1E–8 (in releases prior to 9.2, the default was 1E–4). The smallest estimated probability in each group serves as a cutpoint for predicting an event response. The ROCEPS= option has no effect if the **OUTROC=** option is not specified in the SCORE statement.

SLICE Statement

SLICE *model-effect* </ options> ;

The SLICE statement provides a general mechanism for performing a partitioned analysis of the LS-means for an interaction. This analysis is also known as an analysis of simple effects.

The SLICE statement uses the same options as the **LSMEANS** statement, which are summarized in [Table 19.21](#). For details about the syntax of the SLICE statement, see the section “[SLICE Statement](#)” on page 498 in Chapter 19, “[Shared Concepts and Topics](#).”

NOTE: If you have classification variables in your model, then the SLICE statement is allowed only if you also specify the **PARAM=GLM** option.

STORE Statement

STORE <OUT= >*item-store-name* </ LABEL='label'> ;

The STORE statement requests that the procedure save the context and results of the statistical analysis. The resulting item store has a binary file format that cannot be modified. The contents of the item store can be processed with the PLM procedure.

For details about the syntax of the STORE statement, see the section “STORE Statement” on page 501 in Chapter 19, “Shared Concepts and Topics.”

STRATA Statement

STRATA *variable* <(option)> ... <*variable* <(option)>> </ options> ;

The STRATA statement names the *variables* that define *strata* or *matched sets* to use in *stratified logistic regression* of binary response data.

Observations that have the same *variable* values are in the same matched set. For a stratified logistic model, you can analyze 1: 1, 1: n , m : n , and general m_i : n_i matched sets where the number of cases and controls varies across strata. At least one variable must be specified to invoke the stratified analysis, and the usual unconditional asymptotic analysis is not performed. The stratified logistic model has the form

$$\text{logit}(\pi_{hi}) = \alpha_h + \mathbf{x}_{hi}'\boldsymbol{\beta}$$

where π_{hi} is the event probability for the i th observation in stratum h with covariates \mathbf{x}_{hi} and where the stratum-specific intercepts α_h are the nuisance parameters that are to be conditioned out.

STRATA variables can also be specified in the MODEL statement as classification or continuous covariates; however, the effects are nondegenerate only when crossed with a nonstratification variable. Specifying several STRATA statements is the same as specifying one STRATA statement that contains all the strata variables. The STRATA variables can be either character or numeric, and the formatted values of the STRATA variables determine the levels. Thus, you can also use formats to group values into levels; see the discussion of the FORMAT procedure in the *Base SAS Procedures Guide*.

The “Strata Summary” table is displayed by default. For an exact logistic regression, it displays the number of strata that have a specific number of events and non-events. For example, if you are analyzing a 1: 5 matched study, this table enables you to verify that every stratum in the analysis has exactly one event and five non-events. Strata that contain only events or only non-events are reported in this table, but such strata are uninformative and are not used in the analysis.

If an EXACT statement is also specified, then a stratified *exact* logistic regression is performed.

The EFFECTPLOT, SCORE, and WEIGHT statements are not available with a STRATA statement. The following MODEL options are also not supported with a STRATA statement: CLPARM=PL, CLODDS=PL, CTABLE, FIRTH, LACKFIT, LINK=, NOFIT, OUTMODEL=, OUTROC=, ROC, and SCALE=.

The following *option* can be specified for a stratification variable by enclosing the option in parentheses after the variable name, or it can be specified globally for all STRATA variables after a slash (/).

MISSING

treats missing values ('.', '_', 'A', ..., 'Z' for numeric variables and blanks for character variables) as valid STRATA variable values.

The following strata *options* are also available after the slash:

CHECKDEPENDENCY | CHECK=keyword

specifies which variables are to be tested for dependency before the analysis is performed. The available *keywords* are as follows:

NONE performs no dependence checking. Typically, a message about a singular information matrix is displayed if you have dependent variables. Dependent variables can be identified after the analysis by noting any missing parameter estimates.

COVARIATES checks dependence between covariates and an added intercept. Dependent covariates are removed from the analysis. However, covariates that are linear functions of the strata variable might not be removed, which results in a singular information matrix message being displayed in the SAS log. This is the default.

ALL checks dependence between all the strata and covariates. This option can adversely affect performance if you have a large number of strata.

NOSUMMARY

suppresses the display of the “Strata Summary” table.

INFO

displays the “Strata Information” table, which includes the stratum number, levels of the STRATA variables that define the stratum, the number of events, the number of non-events, and the total frequency for each stratum. Since the number of strata can be very large, this table is displayed only by request.

TEST Statement

```
<label> TEST equation1 <, equation2, ... > </option>;
```

The TEST statement tests linear hypotheses about the regression coefficients. The Wald test is used to perform a joint test of the null hypotheses $H_0: \mathbf{L}\boldsymbol{\beta} = \mathbf{c}$ specified in a single TEST statement, where $\boldsymbol{\beta}$ is the vector of intercept and slope parameters. When $\mathbf{c} = \mathbf{0}$ you should specify a CONTRAST statement instead.

Each *equation* specifies a linear hypothesis (a row of the **L** matrix and the corresponding element of the **c** vector). Multiple *equations* are separated by commas. The *label*, which must be a valid SAS name, is used to identify the resulting output and should always be included. You can submit multiple TEST statements.

The form of an *equation* is as follows:

```
term<± term ...> <= ±term <±term...>>
```

where *term* is a parameter of the model, or a constant, or a constant times a parameter. Intercept and CLASS variable parameter names should be specified as described in the section “Parameter Names in the OUTEST= Data Set” on page 4279. Note for generalized logit models that this enables you to construct tests of parameters from specific logits. When no equal sign appears, the expression is set to 0. The following statements illustrate possible uses of the TEST statement:

```
proc logistic;
  model y= a1 a2 a3 a4;
  test1: test intercept + .5 * a2 = 0;
  test2: test intercept + .5 * a2;
  test3: test a1=a2=a3;
  test4: test a1=a2, a2=a3;
run;
```

Note that the first and second TEST statements are equivalent, as are the third and fourth TEST statements.

You can specify the following option in the TEST statement after a slash(/):

PRINT

displays intermediate calculations in the testing of the null hypothesis $H_0: \mathbf{L}\boldsymbol{\beta} = \mathbf{c}$. This includes $\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}'$ bordered by $(\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{c})$ and $[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}']^{-1}$ bordered by $[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}']^{-1}(\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{c})$, where $\hat{\boldsymbol{\beta}}$ is the maximum likelihood estimator of $\boldsymbol{\beta}$ and $\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})$ is the estimated covariance matrix of $\hat{\boldsymbol{\beta}}$.

For more information, see the section “[Testing Linear Hypotheses about the Regression Coefficients](#)” on page 4262.

UNITS Statement

UNITS < *independent1=list1* < *independent2=list2* . . . > < / *option* > ;

The UNITS statement enables you to specify units of change for the continuous explanatory variables so that customized odds ratios can be estimated. If you specify more than one UNITS statement, only the last one is used. An estimate of the corresponding odds ratio is produced for each unit of change specified for an explanatory variable. The UNITS statement is ignored for CLASS variables. Odds ratios are computed only for main effects that are not involved in interactions or nestings, unless an **ODDSRATIO** statement is also specified. If the **CLODDS=** option is specified in the MODEL statement, the corresponding confidence limits for the odds ratios are also displayed, as are odds ratios and confidence limits for any CLASS main effects that are not involved in interactions or nestings. The CLASS effects must use the GLM, reference, or effect coding.

The UNITS statement also enables you to customize the odds ratios for effects specified in **ODDSRATIO** statements, in which case interactions and nestings are allowed, and CLASS variables can be specified with any parameterization.

The term *independent* is the name of an explanatory variable and *list* represents a list of units of change, separated by spaces, that are of interest for that variable. Each unit of change in a list has one of the following forms:

- *number*
- SD or –SD
- *number* * SD

where *number* is any nonzero number, and SD is the sample standard deviation of the corresponding independent variable. For example, $X = -2$ requests an odds ratio that represents the change in the odds when

the variable X is decreased by two units. $X = 2*SD$ requests an estimate of the change in the odds when X is increased by two sample standard deviations.

You can specify the following option in the UNITS statement after a slash(/):

DEFAULT=*list*

gives a list of units of change for all explanatory variables that are not specified in the UNITS statement. Each unit of change can be in any of the forms described previously. If the DEFAULT= option is not specified, PROC LOGISTIC does not produce customized odds ratio estimates for any continuous explanatory variable that is not listed in the UNITS statement.

For more information, see the section “[Odds Ratio Estimation](#)” on page 4250.

WEIGHT Statement

WEIGHT *variable* < / *option* > ;

When a WEIGHT statement appears, each observation in the input data set is weighted by the value of the WEIGHT variable. Unlike a [FREQ](#) variable, the values of the WEIGHT variable can be nonintegral and are not truncated. Observations with negative, zero, or missing values for the WEIGHT variable are not used in the model fitting. When the WEIGHT statement is not specified, each observation is assigned a weight of 1. The WEIGHT statement is not available with the [STRATA](#) statement. If you specify more than one WEIGHT statement, then the first WEIGHT variable is used.

If a [SCORE](#) statement is specified, then the WEIGHT variable is used for computing fit statistics and the ROC curve, but it is not required for scoring. If the [DATA=](#) data set in the [SCORE](#) statement does not contain the WEIGHT variable, the weights are assumed to be 1 and a warning message is issued in the SAS log. If you fit a model and perform the scoring in the same run, the same WEIGHT variable is used for fitting and scoring. If you fit a model in a previous run and input it with the [INMODEL=](#) option in the current run, then the WEIGHT variable can be different from the one used in the previous run; however, if a WEIGHT variable was not specified in the previous run, you can still specify a WEIGHT variable in the current run.

CAUTION: PROC LOGISTIC does not compute the proper variance estimators if you are analyzing survey data and specifying the sampling weights through the WEIGHT statement. The [SURVEYLOGISTIC](#) procedure is designed to perform the necessary, and correct, computations.

The following option can be added to the WEIGHT statement after a slash (/):

NORMALIZE

NORM

causes the weights specified by the WEIGHT variable to be normalized so that they add up to the actual sample size. Weights w_i are normalized by multiplying them by $\frac{n}{\sum_{i=1}^n w_i}$, where n is the sample size. With this option, the estimated covariance matrix of the parameter estimators is invariant to the scale of the WEIGHT variable.

Details: LOGISTIC Procedure

Missing Values

Any observation with missing values for the response, offset, strata, or explanatory variables is excluded from the analysis; however, missing values are valid for variables specified with the **MISSING** option in the **CLASS** or **STRATA** statement. Observations with a nonpositive or missing weight or with a frequency less than 1 are also excluded. The estimated linear predictor and its standard error estimate, the fitted probabilities and confidence limits, and the regression diagnostic statistics are not computed for any observation with missing offset or explanatory variable values. However, if only the response value is missing, the linear predictor, its standard error, the fitted individual and cumulative probabilities, and confidence limits for the cumulative probabilities can be computed and output to a data set by using the **OUTPUT** statement.

Response Level Ordering

Response level ordering is important because, by default, PROC LOGISTIC models the probability of response levels with *lower Ordered Value*. Ordered Values are assigned to response levels in ascending sorted order (that is, the lowest response level is assigned Ordered Value 1, the next lowest is assigned Ordered Value 2, and so on) and are displayed in the “Response Profiles” table. If your response variable Y takes values in $\{1, \dots, k + 1\}$, then, by default, the functions modeled with the binary or cumulative model are

$$\text{logit}(\Pr(Y \leq i | \mathbf{x})), \quad i = 1, \dots, k$$

and for the generalized logit model the functions modeled are

$$\log \left(\frac{\Pr(Y = i | \mathbf{x})}{\Pr(Y = k + 1 | \mathbf{x})} \right), \quad i = 1, \dots, k$$

where the highest Ordered Value $Y = k + 1$ is the reference level. You can change which probabilities are modeled by specifying the **EVENT=**, **REF=**, **DESCENDING**, or **ORDER=** response variable options in the **MODEL** statement.

For binary response data with event and nonevent categories, if your event category has a higher Ordered Value, then by default the nonevent is modeled. Since the default response function modeled is

$$\text{logit}(\pi) = \log \left(\frac{\pi}{1 - \pi} \right)$$

where π is the probability of the response level assigned Ordered Value 1, and since

$$\text{logit}(\pi) = -\text{logit}(1 - \pi)$$

the effect of modeling the nonevent is to change the signs of α and β in the model for the event, $\text{logit}(\pi) = \alpha + \beta' \mathbf{x}$.

For example, suppose the binary response variable Y takes the values 1 and 0 for event and nonevent, respectively, and *Exposure* is the explanatory variable. By default, PROC LOGISTIC assigns Ordered

Value 1 to response level Y=0, and Ordered Value 2 to response level Y=1. As a result, PROC LOGISTIC models the probability of the nonevent (Ordered Value=1) category, and your parameter estimates have the opposite sign from those in the model for the event. To model the event without using a DATA step to change the values of the variable Y, you can control the ordering of the response levels or select the event or reference level, as shown in the following list:

- Explicitly state which response level is to be modeled by using the response variable option **EVENT=** in the **MODEL** statement:

```
model Y(event='1') = Exposure;
```

- Specify the nonevent category for the response variable in the response variable option **REF=** in the **MODEL** statement. This option is most useful for generalized logit models where the **EVENT=** option cannot be used.

```
model Y(ref='0') = Exposure;
```

- Specify the response variable option **DESCENDING** in the **MODEL** statement to assign the lowest Ordered Value to Y=1:

```
model Y(descending)=Exposure;
```

- Assign a format to Y such that the first formatted value (when the formatted values are put in sorted order) corresponds to the event. In the following example, Y=1 is assigned the formatted value 'event' and Y=0 is assigned the formatted value 'nonevent'. Since **ORDER=FORMATTED** by default, Ordered Value 1 is assigned to response level Y=1, so the procedure models the event.

```
proc format;
  value Disease 1='event' 0='nonevent';
run;
proc logistic;
  format Y Disease.;
  model Y=Exposure;
run;
```

Link Functions and the Corresponding Distributions

Four link functions are available in the LOGISTIC procedure. The logit function is the default. To specify a different link function, use the **LINK=** option in the **MODEL** statement. The link functions and the corresponding distributions are as follows:

- The logit function

$$g(p) = \log(p/(1 - p))$$

is the inverse of the cumulative logistic distribution function, which is

$$F(x) = 1/(1 + \exp(-x)) = \exp(x)/(1 + \exp(x))$$

- The probit (or normit) function

$$g(p) = \Phi^{-1}(p)$$

is the inverse of the cumulative standard normal distribution function, which is

$$F(x) = \Phi(x) = (2\pi)^{-1/2} \int_{-\infty}^x \exp(-z^2/2) dz$$

Traditionally, the probit function contains the additive constant 5, but throughout PROC LOGISTIC, the terms probit and normit are used interchangeably.

- The complementary log-log function

$$g(p) = \log(-\log(1 - p))$$

is the inverse of the cumulative extreme-value function (also called the Gompertz distribution), which is

$$F(x) = 1 - \exp(-\exp(x))$$

- The generalized logit function extends the binary logit link to a vector of levels (p_1, \dots, p_{k+1}) by contrasting each level with a fixed level

$$g(p_i) = \log(p_i/p_{k+1}) \quad i = 1, \dots, k$$

The variances of the normal, logistic, and extreme-value distributions are not the same. Their respective means and variances are shown in the following table:

Distribution	Mean	Variance
Normal	0	1
Logistic	0	$\pi^2/3$
Extreme-value	$-\gamma$	$\pi^2/6$

Here γ is the Euler constant. In comparing parameter estimates from different link functions, you need to take into account the different scalings of the corresponding distributions and, for the complementary log-log function, a possible shift in location. For example, if the fitted probabilities are in the neighborhood of 0.1 to 0.9, then the parameter estimates from the logit link function should be about $\pi/\sqrt{3}$ larger than the estimates from the probit link function.

Determining Observations for Likelihood Contributions

If you use events/trials MODEL statement syntax, split each observation into two observations. One has response value 1 with a frequency equal to the frequency of the original observation (which is 1 if the FREQ statement is not used) times the value of the *events* variable. The other observation has response value 2 and a frequency equal to the frequency of the original observation times the value of (*trials*–*events*). These two observations will have the same explanatory variable values and the same FREQ and WEIGHT values as the original observation.

For either single-trial or events/trials syntax, let j index all observations. In other words, for single-trial syntax, j indexes the actual observations. And, for events/trials syntax, j indexes the observations after splitting (as described in the preceding paragraph). If your data set has 30 observations and you use single-trial syntax, j has values from 1 to 30; if you use events/trials syntax, j has values from 1 to 60.

Suppose the response variable in a cumulative response model can take on the ordered values $1, \dots, k, k+1$, where k is an integer ≥ 1 . The likelihood for the j th observation with ordered response value y_j and explanatory variables vector \mathbf{x}_j is given by

$$L_j = \begin{cases} F(\alpha_1 + \boldsymbol{\beta}'\mathbf{x}_j) & y_j = 1 \\ F(\alpha_i + \boldsymbol{\beta}'\mathbf{x}_j) - F(\alpha_{i-1} + \boldsymbol{\beta}'\mathbf{x}_j) & 1 < y_j = i \leq k \\ 1 - F(\alpha_k + \boldsymbol{\beta}'\mathbf{x}_j) & y_j = k + 1 \end{cases}$$

where $F(\cdot)$ is the logistic, normal, or extreme-value distribution function, $\alpha_1, \dots, \alpha_k$ are ordered intercept parameters, and $\boldsymbol{\beta}$ is the common slope parameter vector.

For the generalized logit model, letting the $k+1$ st level be the reference level, the intercepts $\alpha_1, \dots, \alpha_k$ are unordered and the slope vector $\boldsymbol{\beta}_i$ varies with each logit. The likelihood for the j th observation with response value y_j and explanatory variables vector \mathbf{x}_j is given by

$$L_j = \Pr(Y = y_j | \mathbf{x}_j) = \begin{cases} \frac{e^{\alpha_i + \mathbf{x}_j' \boldsymbol{\beta}_i}}{1 + \sum_{m=1}^k e^{\alpha_m + \mathbf{x}_j' \boldsymbol{\beta}_m}} & 1 \leq y_j = i \leq k \\ \frac{1}{1 + \sum_{m=1}^k e^{\alpha_m + \mathbf{x}_j' \boldsymbol{\beta}_m}} & y_j = k + 1 \end{cases}$$

Iterative Algorithms for Model Fitting

Two iterative maximum likelihood algorithms are available in PROC LOGISTIC for fitting an unconditional logistic regression, and these two methods are discussed in this section. For conditional logistic regression and models with the [UNEQUALSLOPES](#) specification, see the section “[NLOPTIONS Statement](#)” on page 4222 for details about available optimization techniques. Exact logistic regression uses a special algorithm described in the section “[Exact Conditional Logistic Regression](#)” on page 4274.

The default maximum likelihood algorithm is the Fisher scoring method, which is equivalent to fitting by iteratively reweighted least squares. The alternative algorithm is the Newton-Raphson method. Both algorithms give the same parameter estimates; however, the estimated covariance matrix of the parameter estimators can differ slightly. This is due to the fact that Fisher scoring is based on the expected information matrix while the Newton-Raphson method is based on the observed information matrix. In the case of a binary logit model, the observed and expected information matrices are identical, resulting in identical estimated covariance matrices for both algorithms. You can specify the [TECHNIQUE=](#) option to select a fitting algorithm, and specify the [FIRTH](#) option to perform a bias-reducing penalized maximum likelihood fit. Note for generalized logit models that only the Newton-Raphson technique is available.

Iteratively Reweighted Least Squares Algorithm (Fisher Scoring)

Consider the multinomial variable $\mathbf{Z}_j = (Z_{1j}, \dots, Z_{k+1,j})'$ such that

$$Z_{ij} = \begin{cases} 1 & \text{if } Y_j = i \\ 0 & \text{otherwise} \end{cases}$$

With π_{ij} denoting the probability that the j th observation has response value i , the expected value of \mathbf{Z}_j is $\boldsymbol{\pi}_j = (\pi_{1j}, \dots, \pi_{k+1,j})'$ where $\pi_{k+1,j} = 1 - \sum_{i=1}^k \pi_{ij}$. The covariance matrix of \mathbf{Z}_j is \mathbf{V}_j , which is the covariance matrix of a multinomial random variable for one trial with parameter vector $\boldsymbol{\pi}_j$. Let $\boldsymbol{\beta}$ be the vector of regression parameters; in other words, $\boldsymbol{\beta} = (\alpha_1, \dots, \alpha_k, \beta_1, \dots, \beta_s)'$. Let \mathbf{D}_j be the matrix of partial derivatives of $\boldsymbol{\pi}_j$ with respect to $\boldsymbol{\beta}$. The estimating equation for the regression parameters is

$$\sum_j \mathbf{D}_j' \mathbf{W}_j (\mathbf{Z}_j - \boldsymbol{\pi}_j) = \mathbf{0}$$

where $\mathbf{W}_j = w_j f_j \mathbf{V}_j^{-}$, w_j and f_j are the weight and frequency of the j th observation, and \mathbf{V}_j^{-} is a generalized inverse of \mathbf{V}_j . PROC LOGISTIC chooses \mathbf{V}_j^{-} as the inverse of the diagonal matrix with $\boldsymbol{\pi}_j$ as the diagonal.

With a starting value of $\boldsymbol{\beta}^{(0)}$, the maximum likelihood estimate of $\boldsymbol{\beta}$ is obtained iteratively as

$$\boldsymbol{\beta}^{(m+1)} = \boldsymbol{\beta}^{(m)} + \left(\sum_j \mathbf{D}_j' \mathbf{W}_j \mathbf{D}_j \right)^{-1} \sum_j \mathbf{D}_j' \mathbf{W}_j (\mathbf{Z}_j - \boldsymbol{\pi}_j)$$

where \mathbf{D}_j , \mathbf{W}_j , and $\boldsymbol{\pi}_j$ are evaluated at $\boldsymbol{\beta}^{(m)}$. The expression after the plus sign is the step size. If the likelihood evaluated at $\boldsymbol{\beta}^{(m+1)}$ is less than that evaluated at $\boldsymbol{\beta}^{(m)}$, then $\boldsymbol{\beta}^{(m+1)}$ is recomputed by step-halving or ridging as determined by the value of the **RIDGING=** option. The iterative scheme continues until convergence is obtained—that is, until $\boldsymbol{\beta}^{(m+1)}$ is sufficiently close to $\boldsymbol{\beta}^{(m)}$. Then the maximum likelihood estimate of $\boldsymbol{\beta}$ is $\hat{\boldsymbol{\beta}} = \boldsymbol{\beta}^{(m+1)}$.

The covariance matrix of $\hat{\boldsymbol{\beta}}$ is estimated by

$$\widehat{\text{Cov}}(\hat{\boldsymbol{\beta}}) = \left(\sum_j \hat{\mathbf{D}}_j' \hat{\mathbf{W}}_j \hat{\mathbf{D}}_j \right)^{-1} = \hat{\mathbf{I}}^{-1}$$

where $\hat{\mathbf{D}}_j$ and $\hat{\mathbf{W}}_j$ are, respectively, \mathbf{D}_j and \mathbf{W}_j evaluated at $\hat{\boldsymbol{\beta}}$. $\hat{\mathbf{I}}$ is the information matrix, or the negative expected Hessian matrix, evaluated at $\hat{\boldsymbol{\beta}}$.

By default, starting values are zero for the slope parameters, and for the intercept parameters, starting values are the observed cumulative logits (that is, logits of the observed cumulative proportions of response). Alternatively, the starting values can be specified with the **INEST=** option.

Newton-Raphson Algorithm

For cumulative models, let the parameter vector be $\boldsymbol{\beta} = (\alpha_1, \dots, \alpha_k, \beta_1, \dots, \beta_s)'$, and for the generalized logit model let $\boldsymbol{\beta} = (\alpha_1, \dots, \alpha_k, \beta_1', \dots, \beta_k')'$. The gradient vector and the Hessian matrix are given, respectively, by

$$\begin{aligned} \mathbf{g} &= \sum_j w_j f_j \frac{\partial l_j}{\partial \boldsymbol{\beta}} \\ \mathbf{H} &= \sum_j w_j f_j \frac{\partial^2 l_j}{\partial \boldsymbol{\beta}^2} \end{aligned}$$

where $l_j = \log L_j$ is the log likelihood for the j th observation. With a starting value of $\boldsymbol{\beta}^{(0)}$, the maximum likelihood estimate $\hat{\boldsymbol{\beta}}$ of $\boldsymbol{\beta}$ is obtained iteratively until convergence is obtained:

$$\boldsymbol{\beta}^{(m+1)} = \boldsymbol{\beta}^{(m)} - \mathbf{H}^{-1} \mathbf{g}$$

where \mathbf{H} and \mathbf{g} are evaluated at $\boldsymbol{\beta}^{(m)}$. If the likelihood evaluated at $\boldsymbol{\beta}^{(m+1)}$ is less than that evaluated at $\boldsymbol{\beta}^{(m)}$, then $\boldsymbol{\beta}^{(m+1)}$ is recomputed by step-halving or ridging.

The covariance matrix of $\hat{\boldsymbol{\beta}}$ is estimated by

$$\widehat{\text{Cov}}(\hat{\boldsymbol{\beta}}) = \hat{\mathbf{I}}^{-1}$$

where the observed information matrix $\hat{\mathbf{I}} = -\hat{\mathbf{H}}$ is computed by evaluating \mathbf{H} at $\hat{\boldsymbol{\beta}}$.

Firth's Bias-Reducing Penalized Likelihood

Firth's method is currently available only for binary logistic models. It replaces the usual score (gradient) equation

$$g(\beta_j) = \sum_{i=1}^n (y_i - \pi_i) x_{ij} = 0 \quad (j = 1, \dots, p)$$

where p is the number of parameters in the model, with the modified score equation

$$g(\beta_j)^* = \sum_{i=1}^n \{y_i - \pi_i + h_i(0.5 - \pi_i)\} x_{ij} = 0 \quad (j = 1, \dots, p)$$

where the h_i s are the i th diagonal elements of the hat matrix $\mathbf{W}^{1/2} \mathbf{X}(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1} \mathbf{X}'\mathbf{W}^{1/2}$ and $\mathbf{W} = \text{diag}\{\pi_i(1 - \pi_i)\}$. The Hessian matrix is not modified by this penalty, and the optimization method is performed in the usual manner.

Convergence Criteria

Four convergence criteria are available: **ABSFCNV=**, **FCONV=**, **GCONV=**, and **XCONV=**. If you specify more than one convergence criterion, the optimization is terminated as soon as one of the criteria is satisfied. If none of the criteria is specified, the default is **GCONV=1E-8**.

If you specify a **STRATA** statement or the **UNEQUALSLOPES** option in the **MODEL** statement, all unspecified (or nondefault) criteria are also compared to zero. For example, specifying only the criterion **XCONV=1E-8** but attaining **FCONV=0** terminates the optimization even if the **XCONV=** criterion is not satisfied, because the log likelihood has reached its maximum. More convergence criteria are also available; see the section “**NLOPTIONS Statement**” on page 4222 for details.

Existence of Maximum Likelihood Estimates

The likelihood equation for a logistic regression model does not always have a finite solution. Sometimes there is a nonunique maximum on the boundary of the parameter space, at infinity. The existence, finiteness, and uniqueness of maximum likelihood estimates for the logistic regression model depend on the patterns of data points in the observation space (Albert and Anderson 1984; Santner and Duffy 1986). Existence checks are not performed for conditional logistic regression.

Consider a binary response model. Let Y_j be the response of the j th subject, and let \mathbf{x}_j be the vector of explanatory variables (including the constant 1 associated with the intercept). There are three mutually exclusive and exhaustive types of data configurations: complete separation, quasi-complete separation, and overlap.

Complete Separation There is a complete separation of data points if there exists a vector \mathbf{b} that correctly allocates all observations to their response groups; that is,

$$\begin{cases} \mathbf{b}'\mathbf{x}_j > 0 & Y_j = 1 \\ \mathbf{b}'\mathbf{x}_j < 0 & Y_j = 2 \end{cases}$$

This configuration gives nonunique infinite estimates. If the iterative process of maximizing the likelihood function is allowed to continue, the log likelihood diminishes to zero, and the dispersion matrix becomes unbounded.

Quasi-complete Separation The data are not completely separable, but there is a vector \mathbf{b} such that

$$\begin{cases} \mathbf{b}'\mathbf{x}_j \geq 0 & Y_j = 1 \\ \mathbf{b}'\mathbf{x}_j \leq 0 & Y_j = 2 \end{cases}$$

and equality holds for at least one subject in each response group. This configuration also yields nonunique infinite estimates. If the iterative process of maximizing the likelihood function is allowed to continue, the dispersion matrix becomes unbounded and the log likelihood diminishes to a nonzero constant.

Overlap If neither complete nor quasi-complete separation exists in the sample points, there is an overlap of sample points. In this configuration, the maximum likelihood estimates exist and are unique.

Complete separation and quasi-complete separation are problems typically encountered with small data sets. Although complete separation can occur with any type of data, quasi-complete separation is not likely with truly continuous explanatory variables.

The LOGISTIC procedure uses a simple empirical approach to recognize the data configurations that lead to infinite parameter estimates. The basis of this approach is that any convergence method of maximizing the log likelihood must yield a solution giving complete separation, if such a solution exists. In maximizing the log likelihood, there is no checking for complete or quasi-complete separation if convergence is attained in eight or fewer iterations. Subsequent to the eighth iteration, the probability of the observed response is computed for each observation. If the predicted response equals the observed response for every observation, there is a complete separation of data points and the iteration process is stopped. If the complete separation of data has not been determined and an observation is identified to have an extremely large probability (≥ 0.95) of predicting the observed response, there are two possible situations. First, there is overlap in the data set, and the observation is an atypical observation of its own group. The iterative process, if allowed to continue, will stop when a maximum is reached. Second, there is quasi-complete separation in the data set, and the asymptotic dispersion matrix is unbounded. If any of the diagonal elements of the dispersion matrix for the standardized observations vectors (all explanatory variables standardized to zero mean and unit variance) exceeds 5000, quasi-complete separation is declared and the iterative process is stopped. If either complete separation or quasi-complete separation is detected, a warning message is displayed in the procedure output.

Checking for quasi-complete separation is less foolproof than checking for complete separation. The **NOCHECK** option in the **MODEL** statement turns off the process of checking for infinite parameter estimates. In cases of complete or quasi-complete separation, turning off the checking process typically results

in the procedure failing to converge. The presence of a **WEIGHT** statement also turns off the checking process.

To address the separation issue, you can change your model, specify the **FIRTH** option to use Firth's penalized likelihood method, or for small data sets specify an **EXACT** statement to perform an exact logistic regression.

Effect-Selection Methods

Five effect-selection methods are available by specifying the **SELECTION=** option in the **MODEL** statement. The simplest method (and the default) is **SELECTION=NONE**, for which PROC LOGISTIC fits the complete model as specified in the **MODEL** statement. The other four methods are **FORWARD** for forward selection, **BACKWARD** for backward elimination, **STEPWISE** for stepwise selection, and **SCORE** for best subsets selection. Intercept parameters are forced to stay in the model unless the **NOINT** option is specified.

When **SELECTION=FORWARD**, PROC LOGISTIC first estimates parameters for effects forced into the model. These effects are the intercepts and the first n explanatory effects in the **MODEL** statement, where n is the number specified by the **START=** or **INCLUDE=** option in the **MODEL** statement (n is zero by default). Next, the procedure computes the score chi-square statistic for each effect not in the model and examines the largest of these statistics. If it is significant at the **SLENTRY=** level, the corresponding effect is added to the model. Once an effect is entered in the model, it is never removed from the model. The process is repeated until none of the remaining effects meet the specified level for entry or until the **STOP=** value is reached.

When **SELECTION=BACKWARD**, parameters for the complete model as specified in the **MODEL** statement are estimated unless the **START=** option is specified. In that case, only the parameters for the intercepts and the first n explanatory effects in the **MODEL** statement are estimated, where n is the number specified by the **START=** option. Results of the Wald test for individual parameters are examined. The least significant effect that does not meet the **SLSTAY=** level for staying in the model is removed. Once an effect is removed from the model, it remains excluded. The process is repeated until no other effect in the model meets the specified level for removal or until the **STOP=** value is reached. Backward selection is often less successful than forward or stepwise selection because the full model fit in the first step is the model most likely to result in a complete or quasi-complete separation of response values as described in the section “Existence of Maximum Likelihood Estimates” on page 4242.

The **SELECTION=STEPWISE** option is similar to the **SELECTION=FORWARD** option except that effects already in the model do not necessarily remain. Effects are entered into and removed from the model in such a way that each forward selection step can be followed by one or more backward elimination steps. The stepwise selection process terminates if no further effect can be added to the model or if the current model is identical to a previously visited model.

For **SELECTION=SCORE**, PROC LOGISTIC uses the branch-and-bound algorithm of Furnival and Wilson (1974) to find a specified number of models with the highest likelihood score (chi-square) statistic for all possible model sizes, from 1, 2, 3 effect models, and so on, up to the single model containing all of the explanatory effects. The number of models displayed for each model size is controlled by the **BEST=** option. You can use the **START=** option to impose a minimum model size, and you can use the **STOP=** option to impose a maximum model size. For instance, with **BEST=3**, **START=2**, and **STOP=5**, the **SCORE** selection method displays the best three models (that is, the three models with the highest score chi-squares)

containing 2, 3, 4, and 5 effects. The **SELECTION=SCORE** option is not available for models with CLASS variables.

The options **FAST**, **SEQUENTIAL**, and **STOPRES** can alter the default criteria for entering or removing effects from the model when they are used with the **FORWARD**, **BACKWARD**, or **STEPWISE** selection method.

Model Fitting Information

For the j th observation, let $\hat{\pi}_j$ be the estimated probability of the observed response. The three criteria displayed by the LOGISTIC procedure are calculated as follows:

- $-2 \log$ likelihood:

$$-2 \text{ Log L} = -2 \sum_j \frac{w_j}{\sigma^2} f_j \log(\hat{\pi}_j)$$

where w_j and f_j are the weight and frequency values of the j th observation, and σ^2 is the dispersion parameter, which equals 1 unless the **SCALE=** option is specified. For binary response models that use events/trials MODEL statement syntax, this is

$$-2 \text{ Log L} = -2 \sum_j \frac{w_j}{\sigma^2} f_j \left[\log \binom{n_j}{r_j} + r_j \log(\hat{\pi}_j) + (n_j - r_j) \log(1 - \hat{\pi}_j) \right]$$

where r_j is the number of events, n_j is the number of trials, $\hat{\pi}_j$ is the estimated event probability, and the statistic is reported both with and without the constant term.

- Akaike's information criterion:

$$\text{AIC} = -2 \text{ Log L} + 2p$$

where p is the number of parameters in the model. For cumulative response models, $p = k + s$, where k is the total number of response levels minus one and s is the number of explanatory effects. For the generalized logit model, $p = k(s + 1)$.

- Schwarz (Bayesian information) criterion:

$$\text{SC} = -2 \text{ Log L} + p \log \left(\sum_j f_j n_j \right)$$

where p is the number of parameters in the model, n_j is the number of trials when events/trials syntax is specified, and $n_j = 1$ with single-trial syntax.

The AIC and SC statistics give two different ways of adjusting the -2 Log L statistic for the number of terms in the model and the number of observations used. These statistics can be used when comparing different models for the same data (for example, when you use the **SELECTION=STEPWISE** option in the **MODEL** statement). The models being compared do not have to be nested; lower values of the statistics indicate a more desirable model.

The difference in the $-2 \log L$ statistics between the intercepts-only model and the specified model has a $p - k$ degree-of-freedom chi-square distribution under the null hypothesis that all the explanatory effects in the model are zero, where p is the number of parameters in the specified model and k is the number of intercepts. The likelihood ratio test in the “Testing Global Null Hypothesis: BETA=0” table displays this difference and the associated p -value for this statistic. The score and Wald tests in that table test the same hypothesis and are asymptotically equivalent; see the sections “Residual Chi-Square” on page 4247 and “Testing Linear Hypotheses about the Regression Coefficients” on page 4262 for details.

Generalized Coefficient of Determination

Cox and Snell (1989, pp. 208–209) propose the following generalization of the coefficient of determination to a more general linear model:

$$R^2 = 1 - \left\{ \frac{L(\mathbf{0})}{L(\hat{\boldsymbol{\beta}})} \right\}^{\frac{2}{n}}$$

where $L(\mathbf{0})$ is the likelihood of the intercept-only model, $L(\hat{\boldsymbol{\beta}})$ is the likelihood of the specified model, $n = \sum_j f_j n_j$ is the sample size, f_j is the frequency of the j th observation, and n_j is the number of trials when events/trials syntax is specified or $n_j = 1$ with single-trial syntax.

The quantity R^2 achieves a maximum of less than one for discrete models, where the maximum is given by

$$R_{\max}^2 = 1 - \{L(\mathbf{0})\}^{\frac{2}{n}}$$

Nagelkerke (1991) proposes the following adjusted coefficient, which can achieve a maximum value of one:

$$\tilde{R}^2 = \frac{R^2}{R_{\max}^2}$$

Specifying the **NORMALIZE** option in the **WEIGHT** statement makes these coefficients invariant to the scale of the weights.

Like the AIC and SC statistics described in the section “Model Fitting Information” on page 4245, R^2 and \tilde{R}^2 are most useful for comparing competing models that are not necessarily nested—larger values indicate better models. More properties and interpretation of R^2 and \tilde{R}^2 are provided in Nagelkerke (1991). In the “Testing Global Null Hypothesis: BETA=0” table, R^2 is labeled as “RSquare” and \tilde{R}^2 is labeled as “Max-rescaled RSquare.” Use the **RSQUARE** option to request R^2 and \tilde{R}^2 .

Score Statistics and Tests

To understand the general form of the score statistics, let $\mathbf{g}(\boldsymbol{\beta})$ be the vector of first partial derivatives of the log likelihood with respect to the parameter vector $\boldsymbol{\beta}$, and let $\mathbf{H}(\boldsymbol{\beta})$ be the matrix of second partial derivatives of the log likelihood with respect to $\boldsymbol{\beta}$. That is, $\mathbf{g}(\boldsymbol{\beta})$ is the gradient vector, and $\mathbf{H}(\boldsymbol{\beta})$ is the Hessian matrix. Let $\mathbf{I}(\boldsymbol{\beta})$ be either $-\mathbf{H}(\boldsymbol{\beta})$ or the expected value of $-\mathbf{H}(\boldsymbol{\beta})$. Consider a null hypothesis H_0 . Let $\hat{\boldsymbol{\beta}}_{H_0}$ be the MLE of $\boldsymbol{\beta}$ under H_0 . The chi-square score statistic for testing H_0 is defined by

$$\mathbf{g}'(\hat{\boldsymbol{\beta}}_{H_0}) \mathbf{I}^{-1}(\hat{\boldsymbol{\beta}}_{H_0}) \mathbf{g}(\hat{\boldsymbol{\beta}}_{H_0})$$

and it has an asymptotic χ^2 distribution with r degrees of freedom under H_0 , where r is the number of restrictions imposed on $\boldsymbol{\beta}$ by H_0 .

Residual Chi-Square

When you use **SELECTION=FORWARD**, **BACKWARD**, or **STEPWISE**, the procedure calculates a residual chi-square score statistic and reports the statistic, its degrees of freedom, and the p -value. This section describes how the statistic is calculated.

Suppose there are s explanatory effects of interest. The full cumulative response model has a parameter vector

$$\boldsymbol{\beta} = (\alpha_1, \dots, \alpha_k, \beta_1, \dots, \beta_s)'$$

where $\alpha_1, \dots, \alpha_k$ are intercept parameters, and β_1, \dots, β_s are the common slope parameters for the s explanatory effects. The full generalized logit model has a parameter vector

$$\begin{aligned}\boldsymbol{\beta} &= (\alpha_1, \dots, \alpha_k, \boldsymbol{\beta}'_1, \dots, \boldsymbol{\beta}'_k)' \quad \text{with} \\ \boldsymbol{\beta}'_i &= (\beta_{i1}, \dots, \beta_{is}), \quad i = 1, \dots, k\end{aligned}$$

where β_{ij} is the slope parameter for the j th effect in the i th logit.

Consider the null hypothesis $H_0: \beta_{t+1} = \dots = \beta_s = 0$, where $t < s$ for the cumulative response model, and $H_0: \beta_{i,t+1} = \dots = \beta_{is} = 0, t < s, i = 1, \dots, k$, for the generalized logit model. For the reduced model with t explanatory effects, let $\hat{\alpha}_1, \dots, \hat{\alpha}_k$ be the MLEs of the unknown intercept parameters, let $\hat{\beta}_1, \dots, \hat{\beta}_t$ be the MLEs of the unknown slope parameters, and let $\hat{\boldsymbol{\beta}}'_{i(t)} = (\hat{\beta}_{i1}, \dots, \hat{\beta}_{it}), i = 1, \dots, k$, be those for the generalized logit model. The residual chi-square is the chi-square score statistic testing the null hypothesis H_0 ; that is, the residual chi-square is

$$\mathbf{g}'(\hat{\boldsymbol{\beta}}_{H_0}) \mathbf{I}^{-1}(\hat{\boldsymbol{\beta}}_{H_0}) \mathbf{g}(\hat{\boldsymbol{\beta}}_{H_0})$$

where for the cumulative response model $\hat{\boldsymbol{\beta}}_{H_0} = (\hat{\alpha}_1, \dots, \hat{\alpha}_k, \hat{\beta}_1, \dots, \hat{\beta}_t, 0, \dots, 0)'$, and for the generalized logit model $\hat{\boldsymbol{\beta}}_{H_0} = (\hat{\alpha}_1, \dots, \hat{\alpha}_k, \hat{\boldsymbol{\beta}}'_{1(t)}, \mathbf{0}'_{(s-t)}, \dots, \hat{\boldsymbol{\beta}}'_{k(t)}, \mathbf{0}'_{(s-t)})'$, where $\mathbf{0}_{(s-t)}$ denotes a vector of $s - t$ zeros.

The residual chi-square has an asymptotic chi-square distribution with $s - t$ degrees of freedom ($k(s - t)$ for the generalized logit model). A special case is the global score chi-square, where the reduced model consists of the k intercepts and no explanatory effects. The global score statistic is displayed in the “Testing Global Null Hypothesis: BETA=0” table. The table is not produced when the **NOFIT** option is used, but the global score statistic is displayed.

Testing Individual Effects Not in the Model

These tests are performed when you specify **SELECTION=FORWARD** or **STEPWISE**, and are displayed when the **DETAILS** option is specified. In the displayed output, the tests are labeled “Score Chi-Square” in the “Analysis of Effects Not in the Model” table and in the “Summary of Stepwise (Forward) Selection” table. This section describes how the tests are calculated.

Suppose that k intercepts and t explanatory variables (say v_1, \dots, v_t) have been fit to a model and that v_{t+1} is another explanatory variable of interest. Consider a full model with the k intercepts and $t + 1$ explanatory variables (v_1, \dots, v_t, v_{t+1}) and a reduced model with v_{t+1} excluded. The significance of v_{t+1} adjusted for v_1, \dots, v_t can be determined by comparing the corresponding residual chi-square with a chi-square distribution with one degree of freedom (k degrees of freedom for the generalized logit model).

Testing the Parallel Lines Assumption

For an ordinal response, PROC LOGISTIC performs a test of the parallel lines assumption. In the displayed output, this test is labeled “Score Test for the Equal Slopes Assumption” when the `LINK=` option is `NORMIT` or `CLOGLOG`. When `LINK=LOGIT`, the test is labeled as “Score Test for the Proportional Odds Assumption” in the output. For small sample sizes, this test might be too liberal (Stokes, Davis, and Koch 2000, p. 249). This section describes the methods used to calculate the test.

For this test the number of response levels, $k + 1$, is assumed to be strictly greater than 2. Let Y be the response variable taking values $1, \dots, k, k + 1$. Suppose there are s explanatory variables. Consider the general cumulative model without making the parallel lines assumption

$$g(\Pr(Y \leq i \mid \mathbf{x})) = (1, \mathbf{x}')\boldsymbol{\beta}_i, \quad 1 \leq i \leq k$$

where $g(\cdot)$ is the link function, and $\boldsymbol{\beta}_i = (\alpha_i, \beta_{i1}, \dots, \beta_{is})'$ is a vector of unknown parameters consisting of an intercept α_i and s slope parameters $\beta_{i1}, \dots, \beta_{is}$. The parameter vector for this general cumulative model is

$$\boldsymbol{\beta} = (\boldsymbol{\beta}'_1, \dots, \boldsymbol{\beta}'_k)'$$

Under the null hypothesis of parallelism $H_0: \beta_{1m} = \beta_{2m} = \dots = \beta_{km}, 1 \leq m \leq s$, there is a single common slope parameter for each of the s explanatory variables. Let β_1, \dots, β_s be the common slope parameters. Let $\hat{\alpha}_1, \dots, \hat{\alpha}_k$ and $\hat{\beta}_1, \dots, \hat{\beta}_s$ be the MLEs of the intercept parameters and the common slope parameters. Then, under H_0 , the MLE of $\boldsymbol{\beta}$ is

$$\hat{\boldsymbol{\beta}}_{H_0} = (\hat{\boldsymbol{\beta}}'_1, \dots, \hat{\boldsymbol{\beta}}'_k)' \quad \text{with} \quad \hat{\boldsymbol{\beta}}_i = (\hat{\alpha}_i, \hat{\beta}_1, \dots, \hat{\beta}_s)' \quad 1 \leq i \leq k$$

and the chi-square score statistic $\mathbf{g}'(\hat{\boldsymbol{\beta}}_{H_0})\mathbf{I}^{-1}(\hat{\boldsymbol{\beta}}_{H_0})\mathbf{g}(\hat{\boldsymbol{\beta}}_{H_0})$ has an asymptotic chi-square distribution with $s(k - 1)$ degrees of freedom. This tests the parallel lines assumption by testing the equality of separate slope parameters simultaneously for all explanatory variables.

Confidence Intervals for Parameters

There are two methods of computing confidence intervals for the regression parameters. One is based on the profile-likelihood function, and the other is based on the asymptotic normality of the parameter estimators. The latter is not as time-consuming as the former, since it does not involve an iterative scheme; however, it is not thought to be as accurate as the former, especially with small sample size. You use the `CLPARM=` option to request confidence intervals for the parameters.

Likelihood Ratio-Based Confidence Intervals

The likelihood ratio-based confidence interval is also known as the profile-likelihood confidence interval. The construction of this interval is derived from the asymptotic χ^2 distribution of the generalized likelihood ratio test (Venzon and Moolgavkar 1988). Suppose that the parameter vector is $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots, \beta_s)'$ and you want to compute a confidence interval for β_j . The profile-likelihood function for $\beta_j = \gamma$ is defined as

$$l_j^*(\gamma) = \max_{\boldsymbol{\beta} \in \mathcal{B}_j(\gamma)} l(\boldsymbol{\beta})$$

where $\mathcal{B}_j(\gamma)$ is the set of all $\boldsymbol{\beta}$ with the j th element fixed at γ , and $l(\boldsymbol{\beta})$ is the log-likelihood function for $\boldsymbol{\beta}$. If $l_{\max} = l(\hat{\boldsymbol{\beta}})$ is the log likelihood evaluated at the maximum likelihood estimate $\hat{\boldsymbol{\beta}}$, then $2(l_{\max} - l_j^*(\beta_j))$ has a limiting chi-square distribution with one degree of freedom if β_j is the true parameter value. Let $l_0 = l_{\max} - 0.5\chi_1^2(1 - \alpha)$, where $\chi_1^2(1 - \alpha)$ is the $100(1 - \alpha)$ percentile of the chi-square distribution with one degree of freedom. A $100(1 - \alpha)\%$ confidence interval for β_j is

$$\{\gamma : l_j^*(\gamma) \geq l_0\}$$

The endpoints of the confidence interval are found by solving numerically for values of β_j that satisfy equality in the preceding relation. To obtain an iterative algorithm for computing the confidence limits, the log-likelihood function in a neighborhood of $\boldsymbol{\beta}$ is approximated by the quadratic function

$$\tilde{l}(\boldsymbol{\beta} + \boldsymbol{\delta}) = l(\boldsymbol{\beta}) + \boldsymbol{\delta}'\mathbf{g} + \frac{1}{2}\boldsymbol{\delta}'\mathbf{V}\boldsymbol{\delta}$$

where $\mathbf{g} = \mathbf{g}(\boldsymbol{\beta})$ is the gradient vector and $\mathbf{V} = \mathbf{V}(\boldsymbol{\beta})$ is the Hessian matrix. The increment $\boldsymbol{\delta}$ for the next iteration is obtained by solving the likelihood equations

$$\frac{d}{d\boldsymbol{\delta}} \{\tilde{l}(\boldsymbol{\beta} + \boldsymbol{\delta}) + \lambda(\mathbf{e}_j'\boldsymbol{\delta} - \gamma)\} = \mathbf{0}$$

where λ is the Lagrange multiplier, \mathbf{e}_j is the j th unit vector, and γ is an unknown constant. The solution is

$$\boldsymbol{\delta} = -\mathbf{V}^{-1}(\mathbf{g} + \lambda\mathbf{e}_j)$$

By substituting this $\boldsymbol{\delta}$ into the equation $\tilde{l}(\boldsymbol{\beta} + \boldsymbol{\delta}) = l_0$, you can estimate λ as

$$\lambda = \pm \left(\frac{2(l_0 - l(\boldsymbol{\beta}) + \frac{1}{2}\mathbf{g}'\mathbf{V}^{-1}\mathbf{g})}{\mathbf{e}_j'\mathbf{V}^{-1}\mathbf{e}_j} \right)^{\frac{1}{2}}$$

The upper confidence limit for β_j is computed by starting at the maximum likelihood estimate of $\boldsymbol{\beta}$ and iterating with positive values of λ until convergence is attained. The process is repeated for the lower confidence limit by using negative values of λ .

Convergence is controlled by the value ϵ specified with the **PLCONV=** option in the **MODEL** statement (the default value of ϵ is 1E-4). Convergence is declared on the current iteration if the following two conditions are satisfied:

$$|l(\boldsymbol{\beta}) - l_0| \leq \epsilon$$

and

$$(\mathbf{g} + \lambda\mathbf{e}_j)'\mathbf{V}^{-1}(\mathbf{g} + \lambda\mathbf{e}_j) \leq \epsilon$$

Wald Confidence Intervals

Wald confidence intervals are sometimes called the normal confidence intervals. They are based on the asymptotic normality of the parameter estimators. The $100(1 - \alpha)\%$ Wald confidence interval for β_j is given by

$$\hat{\beta}_j \pm z_{1-\alpha/2} \hat{\sigma}_j$$

where z_p is the 100 p percentile of the standard normal distribution, $\hat{\beta}_j$ is the maximum likelihood estimate of β_j , and $\hat{\sigma}_j$ is the standard error estimate of $\hat{\beta}_j$.

Odds Ratio Estimation

Consider a dichotomous response variable with outcomes *event* and *nonevent*. Consider a dichotomous risk factor variable X that takes the value 1 if the risk factor is present and 0 if the risk factor is absent. According to the logistic model, the log odds function, $\text{logit}(X)$, is given by

$$\text{logit}(X) \equiv \log\left(\frac{\Pr(\text{event} \mid X)}{\Pr(\text{nonevent} \mid X)}\right) = \alpha + X\beta$$

The odds ratio ψ is defined as the ratio of the odds for those with the risk factor ($X = 1$) to the odds for those without the risk factor ($X = 0$). The log of the odds ratio is given by

$$\log(\psi) \equiv \log(\psi(X = 1, X = 0)) = \text{logit}(X = 1) - \text{logit}(X = 0) = (\alpha + 1 \times \beta) - (\alpha + 0 \times \beta) = \beta$$

In general, the odds ratio can be computed by exponentiating the difference of the logits between any two population profiles. This is the approach taken by the **ODDSRATIO** statement, so the computations are available regardless of parameterization, interactions, and nestings. However, as shown in the preceding equation for $\log(\psi)$, odds ratios of main effects can be computed as functions of the parameter estimates, and the remainder of this section is concerned with this methodology.

The parameter, β , associated with X represents the change in the log odds from $X = 0$ to $X = 1$. So the odds ratio is obtained by simply exponentiating the value of the parameter associated with the risk factor. The odds ratio indicates how the odds of the event change as you change X from 0 to 1. For instance, $\psi = 2$ means that the odds of an event when $X = 1$ are twice the odds of an event when $X = 0$. You can also express this as follows: the percent change in the odds of an event from $X = 0$ to $X = 1$ is $(\psi - 1)100\% = 100\%$.

Suppose the values of the dichotomous risk factor are coded as constants a and b instead of 0 and 1. The odds when $X = a$ become $\exp(\alpha + a\beta)$, and the odds when $X = b$ become $\exp(\alpha + b\beta)$. The odds ratio corresponding to an increase in X from a to b is

$$\psi = \exp[(b - a)\beta] = [\exp(\beta)]^{b-a} \equiv [\exp(\beta)]^c$$

Note that for any a and b such that $c = b - a = 1$, $\psi = \exp(\beta)$. So the odds ratio can be interpreted as the change in the odds for any increase of one unit in the corresponding risk factor. However, the change in odds for some amount other than one unit is often of greater interest. For example, a change of one pound in body weight might be too small to be considered important, while a change of 10 pounds might be more meaningful. The odds ratio for a change in X from a to b is estimated by raising the odds ratio estimate for a unit change in X to the power of $c = b - a$ as shown previously.

For a polytomous risk factor, the computation of odds ratios depends on how the risk factor is parameterized. For illustration, suppose that **Race** is a risk factor with four categories: White, Black, Hispanic, and Other.

For the effect parameterization scheme (**PARAM=EFFECT**) with White as the reference group (**REF='White'**), the design variables for **Race** are as follows:

Race	Design Variables		
	X_1	X_2	X_3
Black	1	0	0
Hispanic	0	1	0
Other	0	0	1
White	-1	-1	-1

The log odds for Black is

$$\begin{aligned}\text{logit(Black)} &= \alpha + (X_1 = 1)\beta_1 + (X_2 = 0)\beta_2 + (X_3 = 0)\beta_3 \\ &= \alpha + \beta_1\end{aligned}$$

The log odds for White is

$$\begin{aligned}\text{logit(White)} &= \alpha + (X_1 = -1)\beta_1 + (X_2 = -1)\beta_2 + (X_3 = -1)\beta_3 \\ &= \alpha - \beta_1 - \beta_2 - \beta_3\end{aligned}$$

Therefore, the log odds ratio of Black versus White becomes

$$\begin{aligned}\log(\psi(\text{Black, White})) &= \text{logit(Black)} - \text{logit(White)} \\ &= 2\beta_1 + \beta_2 + \beta_3\end{aligned}$$

For the reference cell parameterization scheme (**PARAM=REF**) with White as the reference cell, the design variables for race are as follows:

Race	Design Variables		
	X_1	X_2	X_3
Black	1	0	0
Hispanic	0	1	0
Other	0	0	1
White	0	0	0

The log odds ratio of Black versus White is given by

$$\begin{aligned}\log(\psi(\text{Black, White})) &= \text{logit(Black)} - \text{logit(White)} \\ &= (\alpha + (X_1 = 1)\beta_1 + (X_2 = 0)\beta_2 + (X_3 = 0)\beta_3) - \\ &\quad (\alpha + (X_1 = 0)\beta_1 + (X_2 = 0)\beta_2 + (X_3 = 0)\beta_3) \\ &= \beta_1\end{aligned}$$

For the GLM parameterization scheme (**PARAM=GLM**), the design variables are as follows:

Race	Design Variables			
	X_1	X_2	X_3	X_4
Black	1	0	0	0
Hispanic	0	1	0	0
Other	0	0	1	0
White	0	0	0	1

The log odds ratio of Black versus White is

$$\begin{aligned}
 \log(\psi(\text{Black, White})) &= \text{logit}(\text{Black}) - \text{logit}(\text{White}) \\
 &= (\alpha + (X_1 = 1)\beta_1 + (X_2 = 0)\beta_2 + (X_3 = 0)\beta_3 + (X_4 = 0)\beta_4) - \\
 &\quad (\alpha + (X_1 = 0)\beta_1 + (X_2 = 0)\beta_2 + (X_3 = 0)\beta_3 + (X_4 = 1)\beta_4) \\
 &= \beta_1 - \beta_4
 \end{aligned}$$

Consider the hypothetical example of heart disease among race in Hosmer and Lemeshow (2000, p. 56). The entries in the following contingency table represent counts:

Disease Status	Race			
	White	Black	Hispanic	Other
Present	5	20	15	10
Absent	20	10	10	10

The computation of odds ratio of Black versus White for various parameterization schemes is tabulated in Table 54.11.

Table 54.11 Odds Ratio of Heart Disease Comparing Black to White

PARAM=	Parameter Estimates				Odds Ratio Estimates
	$\hat{\beta}_1$	$\hat{\beta}_2$	$\hat{\beta}_3$	$\hat{\beta}_4$	
EFFECT	0.7651	0.4774	0.0719		$\exp(2 \times 0.7651 + 0.4774 + 0.0719) = 8$
REF	2.0794	1.7917	1.3863		$\exp(2.0794) = 8$
GLM	2.0794	1.7917	1.3863	0.0000	$\exp(2.0794) = 8$

Since the log odds ratio ($\log(\psi)$) is a linear function of the parameters, the Wald confidence interval for $\log(\psi)$ can be derived from the parameter estimates and the estimated covariance matrix. Confidence intervals for the odds ratios are obtained by exponentiating the corresponding confidence limits for the log odds ratios. In the displayed output of PROC LOGISTIC, the “Odds Ratio Estimates” table contains the odds ratio estimates and the corresponding 95% Wald confidence intervals. For continuous explanatory variables, these odds ratios correspond to a unit increase in the risk factors.

To customize odds ratios for specific units of change for a continuous risk factor, you can use the **UNITS** statement to specify a list of relevant units for each explanatory variable in the model. Estimates of these customized odds ratios are given in a separate table. Let (L_j, U_j) be a confidence interval for $\log(\psi)$. The corresponding lower and upper confidence limits for the customized odds ratio $\exp(c\beta_j)$ are $\exp(cL_j)$ and $\exp(cU_j)$, respectively (for $c > 0$), or $\exp(cU_j)$ and $\exp(cL_j)$, respectively (for $c < 0$). You use the **CLODDS=** option or **ODDSRATIO** statement to request the confidence intervals for the odds ratios.

For a generalized logit model, odds ratios are computed similarly, except k odds ratios are computed for each effect, corresponding to the k logits in the model.

Rank Correlation of Observed Responses and Predicted Probabilities

The predicted mean score of an observation is the sum of the Ordered Values (shown in the “Response Profile” table) minus one, weighted by the corresponding predicted probabilities for that observation; that is, the predicted means score = $\sum_{i=1}^{k+1} (i-1)\hat{\pi}_i$, where $k+1$ is the number of response levels and $\hat{\pi}_i$ is the predicted probability of the i th (ordered) response.

A pair of observations with different observed responses is said to be *concordant* if the observation with the lower ordered response value has a lower predicted mean score than the observation with the higher ordered response value. If the observation with the lower ordered response value has a higher predicted mean score than the observation with the higher ordered response value, then the pair is *discordant*. If the pair is neither concordant nor discordant, it is a *tie*. Enumeration of the total numbers of concordant and discordant pairs is carried out by categorizing the predicted mean score into intervals of length $k/500$ and accumulating the corresponding frequencies of observations. Note that the length of these intervals can be modified by specification of the `BINWIDTH=` option in the `MODEL` statement.

Let N be the sum of observation frequencies in the data. Suppose there are a total of t pairs with different responses: n_c of them are concordant, n_d of them are discordant, and $t - n_c - n_d$ of them are tied. PROC LOGISTIC computes the following four indices of rank correlation for assessing the predictive ability of a model:

$$\begin{aligned} c &= (n_c + 0.5(t - n_c - n_d))/t \\ \text{Somers' } D \text{ (Gini coefficient)} &= (n_c - n_d)/t \\ \text{Goodman-Kruskal Gamma} &= (n_c - n_d)/(n_c + n_d) \\ \text{Kendall's Tau-}a &= (n_c - n_d)/(0.5N(N - 1)) \end{aligned}$$

If there are no ties, then Somers' D (Gini's coefficient) = $2c - 1$. Note that the concordance index, c , also gives an estimate of the area under the receiver operating characteristic (ROC) curve when the response is binary (Hanley and McNeil 1982). See the section “[ROC Computations](#)” on page 4261 for more information about this area.

For binary responses, the predicted mean score is equal to the predicted probability for Ordered Value 2. As such, the preceding definition of concordance is consistent with the definition used in previous releases for the binary response model.

These statistics are not available when the `STRATA` statement is specified.

Linear Predictor, Predicted Probability, and Confidence Limits

This section describes how predicted probabilities and confidence limits are calculated by using the maximum likelihood estimates (MLEs) obtained from PROC LOGISTIC. For a specific example, see the section “[Getting Started: LOGISTIC Procedure](#)” on page 4166. Predicted probabilities and confidence limits can be output to a data set with the `OUTPUT` statement.

Binary and Cumulative Response Models

For a vector of explanatory variables \mathbf{x} , the linear predictor

$$\eta_i = g(\Pr(Y \leq i | \mathbf{x})) = \alpha_i + \mathbf{x}'\boldsymbol{\beta} \quad 1 \leq i \leq k$$

is estimated by

$$\hat{\eta}_i = \hat{\alpha}_i + \mathbf{x}'\hat{\boldsymbol{\beta}}$$

where $\hat{\alpha}_i$ and $\hat{\boldsymbol{\beta}}$ are the MLEs of α_i and $\boldsymbol{\beta}$. The estimated standard error of η_i is $\hat{\sigma}(\hat{\eta}_i)$, which can be computed as the square root of the quadratic form $(1, \mathbf{x}')\hat{\mathbf{V}}_{\mathbf{b}}(1, \mathbf{x})'$, where $\hat{\mathbf{V}}_{\mathbf{b}}$ is the estimated covariance matrix of the parameter estimates. The asymptotic $100(1 - \alpha)\%$ confidence interval for η_i is given by

$$\hat{\eta}_i \pm z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i)$$

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile point of a standard normal distribution.

The predicted probability and the $100(1 - \alpha)\%$ confidence limits for $\pi_i = \Pr(Y \leq i | \mathbf{x})$ are obtained by back-transforming the corresponding measures for the linear predictor, as shown in the following table:

Link	Predicted Probability	100(1- α)% Confidence Limits
LOGIT	$1/(1 + \exp(-\hat{\eta}_i))$	$1/(1 + \exp(-\hat{\eta}_i \pm z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i)))$
PROBIT	$\Phi(\hat{\eta}_i)$	$\Phi(\hat{\eta}_i \pm z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i))$
CLOGLOG	$1 - \exp(-\exp(\hat{\eta}_i))$	$1 - \exp(-\exp(\hat{\eta}_i \pm z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i)))$

The **CONTRAST** statement also enables you to estimate the exponentiated contrast, $e^{\hat{\eta}_i}$. The corresponding standard error is $e^{\hat{\eta}_i}\hat{\sigma}(\hat{\eta}_i)$, and the confidence limits are computed by exponentiating those for the linear predictor: $\exp\{\hat{\eta}_i \pm z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i)\}$.

Generalized Logit Model

For a vector of explanatory variables \mathbf{x} , define the linear predictors $\eta_i = \alpha_i + \mathbf{x}'\boldsymbol{\beta}_i$, and let π_i denote the probability of obtaining the response value i :

$$\pi_i = \begin{cases} \frac{\pi_{k+1}e^{\eta_i}}{1 + \sum_{j=1}^k e^{\eta_j}} & 1 \leq i \leq k \\ 1 & i = k + 1 \end{cases}$$

By the *delta method*,

$$\sigma^2(\pi_i) = \left(\frac{\partial \pi_i}{\partial \boldsymbol{\beta}} \right)' \mathbf{V}(\boldsymbol{\beta}) \frac{\partial \pi_i}{\partial \boldsymbol{\beta}}$$

A $100(1 - \alpha)\%$ confidence level for π_i is given by

$$\hat{\pi}_i \pm z_{\alpha/2}\hat{\sigma}(\hat{\pi}_i)$$

where $\hat{\pi}_i$ is the estimated expected probability of response i , and $\hat{\sigma}(\hat{\pi}_i)$ is obtained by evaluating $\sigma(\pi_i)$ at $\boldsymbol{\beta} = \hat{\boldsymbol{\beta}}$.

Note that the contrast $\hat{\eta}_i$ and exponentiated contrast $e^{\hat{\eta}_i}$, their standard errors, and their confidence intervals are computed in the same fashion as for the cumulative response models, replacing $\boldsymbol{\beta}$ with $\boldsymbol{\beta}_i$.

Classification Table

For binary response data, the response is either an *event* or a *nonevent*. In PROC LOGISTIC, the response with Ordered Value 1 is regarded as the event, and the response with Ordered Value 2 is the nonevent. PROC LOGISTIC models the probability of the event. From the fitted model, a predicted event probability can be computed for each observation. A method to compute a reduced-bias estimate of the predicted probability is given in the section “[Predicted Probability of an Event for Classification](#)” on page 4255. If the predicted event probability exceeds or equals some cutpoint value $z \in [0, 1]$, the observation is predicted to be an event observation; otherwise, it is predicted as a nonevent. A 2×2 frequency table can be obtained by cross-classifying the observed and predicted responses. The [CTABLE](#) option produces this table, and the [PPROB=](#) option selects one or more cutpoints. Each cutpoint generates a classification table. If the [PEVENT=](#) option is also specified, a classification table is produced for each combination of [PEVENT=](#) and [PPROB=](#) values.

The accuracy of the classification is measured by its *sensitivity* (the ability to predict an event correctly) and *specificity* (the ability to predict a nonevent correctly). *Sensitivity* is the proportion of event responses that were predicted to be events. *Specificity* is the proportion of nonevent responses that were predicted to be nonevents. PROC LOGISTIC also computes three other conditional probabilities: *false positive rate*, *false negative rate*, and *rate of correct classification*. The *false positive rate* is the proportion of predicted event responses that were observed as nonevents. The *false negative rate* is the proportion of predicted nonevent responses that were observed as events. Given prior probabilities specified with the [PEVENT=](#) option, these conditional probabilities can be computed as posterior probabilities by using Bayes’ theorem.

Predicted Probability of an Event for Classification

When you classify a set of binary data, if the same observations used to fit the model are also used to estimate the classification error, the resulting error-count estimate is biased. One way of reducing the bias is to remove the binary observation to be classified from the data, reestimate the parameters of the model, and then classify the observation based on the new parameter estimates. However, it would be costly to fit the model by leaving out each observation one at a time. The LOGISTIC procedure provides a less expensive one-step approximation to the preceding parameter estimates. Let $\hat{\beta}$ be the MLE of the parameter vector $(\alpha, \beta_1, \dots, \beta_s)'$ based on all observations. Let $\hat{\beta}_{(j)}$ denote the MLE computed without the j th observation. The one-step estimate of $\hat{\beta}_{(j)}$ is given by

$$\hat{\beta}_{(j)}^1 = \hat{\beta} - \frac{w_j(y_j - \hat{\pi}_j)}{1 - h_j} \hat{\mathbf{V}}(\hat{\beta}) \begin{pmatrix} 1 \\ \mathbf{x}_j \end{pmatrix}$$

where

- y_j is 1 for an observed event response and 0 otherwise
- w_j is the weight of the observation
- $\hat{\pi}_j$ is the predicted event probability based on $\hat{\beta}$
- h_j is the [hat diagonal element](#) (defined on page 4263) with $n_j = 1$ and $r_j = y_j$
- $\hat{\mathbf{V}}(\hat{\beta})$ is the estimated covariance matrix of $\hat{\beta}$

False Positive, False Negative, and Correct Classification Rates Using Bayes' Theorem

Suppose n_1 of n individuals experience an event, such as a disease. Let this group be denoted by \mathcal{C}_1 , and let the group of the remaining $n_2 = n - n_1$ individuals who do not have the disease be denoted by \mathcal{C}_2 . The j th individual is classified as giving a positive response if the predicted probability of disease ($\hat{\pi}_{(j)}^*$) is large. The probability $\hat{\pi}_{(j)}^*$ is the reduced-bias estimate based on the one-step approximation given in the preceding section. For a given cutpoint z , the j th individual is predicted to give a positive response if $\hat{\pi}_{(j)}^* \geq z$.

Let B denote the event that a subject has the disease, and let \bar{B} denote the event of not having the disease. Let A denote the event that the subject responds positively, and let \bar{A} denote the event of responding negatively. Results of the classification are represented by two conditional probabilities, $\Pr(A|B)$ and $\Pr(A|\bar{B})$, where $\Pr(A|B)$ is the sensitivity and $\Pr(A|\bar{B})$ is one minus the specificity.

These probabilities are given by

$$\Pr(A|B) = \frac{\sum_{j \in \mathcal{C}_1} I(\hat{\pi}_{(j)}^* \geq z)}{n_1}$$

$$\Pr(A|\bar{B}) = \frac{\sum_{j \in \mathcal{C}_2} I(\hat{\pi}_{(j)}^* \geq z)}{n_2}$$

where $I(\cdot)$ is the indicator function.

Bayes' theorem is used to compute several rates of the classification. For a given prior probability $\Pr(B)$ of the disease, the false positive rate P_{F+} , the false negative rate P_{F-} , and the correct classification rate P_C are given by Fleiss (1981, pp. 4–5) as follows:

$$P_{F+} = \Pr(\bar{B}|A) = \frac{\Pr(A|\bar{B})[1 - \Pr(B)]}{\Pr(A|\bar{B}) + \Pr(B)[\Pr(A|B) - \Pr(A|\bar{B})]}$$

$$P_{F-} = \Pr(B|\bar{A}) = \frac{[1 - \Pr(A|B)]\Pr(B)}{1 - \Pr(A|\bar{B}) - \Pr(B)[\Pr(A|B) - \Pr(A|\bar{B})]}$$

$$P_C = \Pr(B|A) + \Pr(\bar{B}|\bar{A}) = \Pr(A|B)\Pr(B) + \Pr(\bar{A}|\bar{B})[1 - \Pr(B)]$$

The prior probability $\Pr(B)$ can be specified by the **PEVENT=** option. If the **PEVENT=** option is not specified, the sample proportion of diseased individuals is used; that is, $\Pr(B) = n_1/n$. In such a case, the false positive rate and the false negative rate reduce to

$$P_{F+} = \frac{\sum_{j \in \mathcal{C}_2} I(\hat{\pi}_{(j)}^* \geq z)}{\sum_{j \in \mathcal{C}_1} I(\hat{\pi}_{(j)}^* \geq z) + \sum_{j \in \mathcal{C}_2} I(\hat{\pi}_{(j)}^* \geq z)}$$

$$P_{F-} = \frac{\sum_{j \in \mathcal{C}_1} I(\hat{\pi}_{(j)}^* < z)}{\sum_{j \in \mathcal{C}_1} I(\hat{\pi}_{(j)}^* < z) + \sum_{j \in \mathcal{C}_2} I(\hat{\pi}_{(j)}^* < z)}$$

$$P_C = \frac{\sum_{j \in \mathcal{C}_1} I(\hat{\pi}_{(j)}^* \geq z) + \sum_{j \in \mathcal{C}_2} I(\hat{\pi}_{(j)}^* < z)}{n}$$

Note that for a stratified sampling situation in which n_1 and n_2 are chosen a priori, n_1/n is not a desirable estimate of $\Pr(B)$. For such situations, the **PEVENT=** option should be specified.

Overdispersion

For a correctly specified model, the Pearson chi-square statistic and the deviance, divided by their degrees of freedom, should be approximately equal to one. When their values are much larger than one, the assumption of binomial variability might not be valid and the data are said to exhibit overdispersion. Underdispersion, which results in the ratios being less than one, occurs less often in practice.

When fitting a model, there are several problems that can cause the goodness-of-fit statistics to exceed their degrees of freedom. Among these are such problems as outliers in the data, using the wrong link function, omitting important terms from the model, and needing to transform some predictors. These problems should be eliminated before proceeding to use the following methods to correct for overdispersion.

Rescaling the Covariance Matrix

One way of correcting overdispersion is to multiply the covariance matrix by a dispersion parameter. This method assumes that the sample sizes in each subpopulation are approximately equal. You can supply the value of the dispersion parameter directly, or you can estimate the dispersion parameter based on either the Pearson chi-square statistic or the deviance for the fitted model.

The Pearson chi-square statistic χ_P^2 and the deviance χ_D^2 are given by

$$\chi_P^2 = \sum_{i=1}^m \sum_{j=1}^{k+1} \frac{(r_{ij} - n_i \hat{\pi}_{ij})^2}{n_i \hat{\pi}_{ij}}$$

$$\chi_D^2 = 2 \sum_{i=1}^m \sum_{j=1}^{k+1} r_{ij} \log \left(\frac{r_{ij}}{n_i \hat{\pi}_{ij}} \right)$$

where m is the number of subpopulation profiles, $k + 1$ is the number of response levels, r_{ij} is the total weight (sum of the product of the frequencies and the weights) associated with j th level responses in the i th profile, $n_i = \sum_{j=1}^{k+1} r_{ij}$, and $\hat{\pi}_{ij}$ is the fitted probability for the j th level at the i th profile. Each of these chi-square statistics has $mk - p$ degrees of freedom, where p is the number of parameters estimated. The dispersion parameter is estimated by

$$\hat{\sigma}^2 = \begin{cases} \chi_P^2 / (mk - p) & \text{SCALE=PEARSON} \\ \chi_D^2 / (mk - p) & \text{SCALE=DEVIANC} \\ (\text{constant})^2 & \text{SCALE=constant} \end{cases}$$

In order for the Pearson statistic and the deviance to be distributed as chi-square, there must be sufficient replication within the subpopulations. When this is not true, the data are sparse, and the p -values for these statistics are not valid and should be ignored. Similarly, these statistics, divided by their degrees of freedom, cannot serve as indicators of overdispersion. A large difference between the Pearson statistic and the deviance provides some evidence that the data are too sparse to use either statistic.

You can use the **AGGREGATE** (or **AGGREGATE=**) option to define the subpopulation profiles. If you do not specify this option, each observation is regarded as coming from a separate subpopulation. For events/trials syntax, each observation represents n Bernoulli trials, where n is the value of the *trials* variable; for single-trial syntax, each observation represents a single trial. Without the **AGGREGATE**

(or AGGREGATE=) option, the Pearson chi-square statistic and the deviance are calculated only for events/trials syntax.

Note that the parameter estimates are not changed by this method. However, their standard errors are adjusted for overdispersion, affecting their significance tests.

Williams' Method

Suppose that the data consist of n binomial observations. For the i th observation, let r_i/n_i be the observed proportion and let \mathbf{x}_i be the associated vector of explanatory variables. Suppose that the response probability for the i th observation is a random variable P_i with mean and variance

$$E(P_i) = \pi_i \quad \text{and} \quad V(P_i) = \phi \pi_i (1 - \pi_i)$$

where π_i is the probability of the event, and ϕ is a nonnegative but otherwise unknown scale parameter. Then the mean and variance of r_i are

$$E(r_i) = n_i \pi_i \quad \text{and} \quad V(r_i) = n_i \pi_i (1 - \pi_i) [1 + (n_i - 1)\phi]$$

Williams (1982) estimates the unknown parameter ϕ by equating the value of Pearson's chi-square statistic for the full model to its approximate expected value. Suppose w_i^* is the weight associated with the i th observation. The Pearson chi-square statistic is given by

$$\chi^2 = \sum_{i=1}^n \frac{w_i^* (r_i - n_i \hat{\pi}_i)^2}{n_i \hat{\pi}_i (1 - \hat{\pi}_i)}$$

Let $g'(\cdot)$ be the first derivative of the link function $g(\cdot)$. The approximate expected value of χ^2 is

$$E_{\chi^2} = \sum_{i=1}^n w_i^* (1 - w_i^* v_i d_i) [1 + \phi(n_i - 1)]$$

where $v_i = n_i / (\pi_i (1 - \pi_i) [g'(\pi_i)]^2)$ and d_i is the variance of the linear predictor $\hat{\alpha}_i + \mathbf{x}_i' \hat{\boldsymbol{\beta}}$. The scale parameter ϕ is estimated by the following iterative procedure.

At the start, let $w_i^* = 1$ and let π_i be approximated by r_i/n_i , $i = 1, 2, \dots, n$. If you apply these weights and approximated probabilities to χ^2 and E_{χ^2} and then equate them, an initial estimate of ϕ is

$$\hat{\phi}_0 = \frac{\chi^2 - (n - p)}{\sum_i (n_i - 1)(1 - v_i d_i)}$$

where p is the total number of parameters. The initial estimates of the weights become $\hat{w}_{i0}^* = [1 + (n_i - 1)\hat{\phi}_0]^{-1}$. After a weighted fit of the model, the $\hat{\alpha}_i$ and $\hat{\boldsymbol{\beta}}$ are recalculated, and so is χ^2 . Then a revised estimate of ϕ is given by

$$\hat{\phi}_1 = \frac{\chi^2 - \sum_i w_i^* (1 - w_i^* v_i d_i)}{w_i^* (n_i - 1)(1 - w_i^* v_i d_i)}$$

The iterative procedure is repeated until χ^2 is very close to its degrees of freedom.

Once ϕ has been estimated by $\hat{\phi}$ under the full model, weights of $(1 + (n_i - 1)\hat{\phi})^{-1}$ can be used to fit models that have fewer terms than the full model. See [Example 54.10](#) for an illustration.

NOTE: If the **WEIGHT** statement is specified with the **NORMALIZE** option, then the initial w_i^* values are set to the normalized weights, and the weights resulting from Williams' method will not add up to the actual sample size. However, the estimated covariance matrix of the parameter estimates remains invariant to the scale of the **WEIGHT** variable.

The Hosmer-Lemeshow Goodness-of-Fit Test

Sufficient replication within subpopulations is required to make the Pearson and deviance goodness-of-fit tests valid. When there are one or more continuous predictors in the model, the data are often too sparse to use these statistics. Hosmer and Lemeshow (2000) proposed a statistic that they show, through simulation, is distributed as chi-square when there is no replication in any of the subpopulations. This test is available only for binary response models.

First, the observations are sorted in increasing order of their estimated event probability. The event is the response level specified in the response variable option **EVENT=**, or the response level that is not specified in the **REF=** option, or, if neither of these options was specified, then the event is the response level identified in the “Response Profiles” table as “Ordered Value 1”. The observations are then divided into approximately 10 groups according to the following scheme. Let N be the total number of subjects. Let M be the target number of subjects for each group given by

$$M = [0.1 \times N + 0.5]$$

where $[x]$ represents the integral value of x . If the single-trial syntax is used, blocks of subjects are formed of observations with identical values of the explanatory variables. Blocks of subjects are not divided when being placed into groups.

Suppose there are n_1 subjects in the first block and n_2 subjects in the second block. The first block of subjects is placed in the first group. Subjects in the second block are added to the first group if

$$n_1 < M \quad \text{and} \quad n_1 + [0.5 \times n_2] \leq M$$

Otherwise, they are placed in the second group. In general, suppose subjects of the $(j - 1)$ block have been placed in the k th group. Let c be the total number of subjects currently in the k th group. Subjects for the j th block (containing n_j subjects) are also placed in the k th group if

$$c < M \quad \text{and} \quad c + [0.5 \times n_j] \leq M$$

Otherwise, the n_j subjects are put into the next group. In addition, if the number of subjects in the last group does not exceed $[0.05 \times N]$ (half the target group size), the last two groups are collapsed to form only one group.

Note that the number of groups, g , can be smaller than 10 if there are fewer than 10 patterns of explanatory variables. There must be at least three groups in order for the Hosmer-Lemeshow statistic to be computed.

The Hosmer-Lemeshow goodness-of-fit statistic is obtained by calculating the Pearson chi-square statistic from the $2 \times g$ table of observed and expected frequencies, where g is the number of groups. The statistic is written

$$\chi_{HL}^2 = \sum_{i=1}^g \frac{(O_i - N_i \bar{\pi}_i)^2}{N_i \bar{\pi}_i (1 - \bar{\pi}_i)}$$

where N_i is the total frequency of subjects in the i th group, O_i is the total frequency of event outcomes in the i th group, and $\bar{\pi}_i$ is the average estimated predicted probability of an event outcome for the i th group. (Note that the predicted probabilities are computed as shown in the section “**Linear Predictor, Predicted Probability, and Confidence Limits**” on page 4253 and are not the cross validated estimates discussed in the section “**Classification Table**” on page 4255.) The Hosmer-Lemeshow statistic is then compared to a chi-square distribution with $(g - n)$ degrees of freedom, where the value of n can be specified in the **LACKFIT** option in the **MODEL** statement. The default is $n = 2$. Large values of χ_{HL}^2 (and small p -values) indicate a lack of fit of the model.

Receiver Operating Characteristic Curves

ROC curves are used to evaluate and compare the performance of diagnostic tests; they can also be used to evaluate model fit. An ROC curve is just a plot of the proportion of true positives (events predicted to be events) versus the proportion of false positives (nonevents predicted to be events).

In a sample of n individuals, suppose n_1 individuals are observed to have a certain condition or event. Let this group be denoted by \mathcal{C}_1 , and let the group of the remaining $n_2 = n - n_1$ individuals who do not have the condition be denoted by \mathcal{C}_2 . Risk factors are identified for the sample, and a logistic regression model is fitted to the data. For the j th individual, an estimated probability $\hat{\pi}_j$ of the event of interest is calculated. Note that the $\hat{\pi}_j$ are computed as shown in the section “[Linear Predictor, Predicted Probability, and Confidence Limits](#)” on page 4253 and are not the cross validated estimates discussed in the section “[Classification Table](#)” on page 4255.

Suppose the n individuals undergo a test for predicting the event and the test is based on the estimated probability of the event. Higher values of this estimated probability are assumed to be associated with the event. A receiver operating characteristic (ROC) curve can be constructed by varying the cutpoint that determines which estimated event probabilities are considered to predict the event. For each cutpoint z , the following measures can be output to a data set by specifying the `OUTROC=` option in the `MODEL` statement or the `OUTROC=` option in the `SCORE` statement:

$$\begin{aligned} _POS_ (z) &= \sum_{i \in \mathcal{C}_1} I(\hat{\pi}_i \geq z) \\ _NEG_ (z) &= \sum_{i \in \mathcal{C}_2} I(\hat{\pi}_i < z) \\ _FALPOS_ (z) &= \sum_{i \in \mathcal{C}_2} I(\hat{\pi}_i \geq z) \\ _FALNEG_ (z) &= \sum_{i \in \mathcal{C}_1} I(\hat{\pi}_i < z) \\ _SENSIT_ (z) &= \frac{_POS_ (z)}{n_1} \\ _1MSPEC_ (z) &= \frac{_FALPOS_ (z)}{n_2} \end{aligned}$$

where $I(\cdot)$ is the indicator function.

Note that $_POS_ (z)$ is the number of correctly predicted event responses, $_NEG_ (z)$ is the number of correctly predicted nonevent responses, $_FALPOS_ (z)$ is the number of falsely predicted event responses, $_FALNEG_ (z)$ is the number of falsely predicted nonevent responses, $_SENSIT_ (z)$ is the sensitivity of the test, and $_1MSPEC_ (z)$ is one minus the specificity of the test.

The ROC curve is a plot of sensitivity ($_SENSIT_$) against 1–specificity ($_1MSPEC_$). The plot can be produced by using the `PLOTS` option or by using the `GPLOT` or `SGPLOT` procedure with the `OUTROC=` data set. See [Example 54.7](#) for an illustration. The area under the ROC curve, as determined by the trapezoidal rule, is estimated by the concordance index, c , in the “Association of Predicted Probabilities and Observed Responses” table.

Comparing ROC Curves

ROC curves can be created from each model fit in a selection routine, from the specified model in the **MODEL** statement, from specified models in ROC statements, or from input variables which act as $\hat{\pi}$ in the preceding discussion. Association statistics are computed for these models, and the models are compared when the **ROCCONTRAST** statement is specified. The ROC comparisons are performed by using a contrast matrix to take differences of the areas under the empirical ROC curves (DeLong, DeLong, and Clarke-Pearson 1988). For example, if you have three curves and the second curve is the reference, the contrast used for the overall test is

$$\mathbf{L}_1 = \begin{pmatrix} l'_1 \\ l'_2 \end{pmatrix} = \begin{bmatrix} 1 & -1 & 0 \\ 0 & -1 & 1 \end{bmatrix}$$

and you can optionally estimate and test each row of this contrast, in order to test the difference between the reference curve and each of the other curves. If you do not want to use a reference curve, the global test optionally uses the following contrast:

$$\mathbf{L}_2 = \begin{pmatrix} l'_1 \\ l'_2 \end{pmatrix} = \begin{bmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \end{bmatrix}$$

You can also specify your own contrast matrix. Instead of estimating the rows of these contrasts, you can request that the difference between every pair of ROC curves be estimated and tested.

By default for the reference contrast, the specified or selected model is used as the reference unless the **NOFIT** option is specified in the **MODEL** statement, in which case the first ROC model is the reference.

In order to label the contrasts, a name is attached to every model. The name for the specified or selected model is the **MODEL** statement label, or “Model” if the **MODEL** label is not present. The ROC statement models are named with their labels, or as “ROC*i*” for the *i*th ROC statement if a label is not specified. The contrast \mathbf{L}_1 is labeled as “Reference = ModelName”, where ModelName is the reference model name, while \mathbf{L}_2 is labeled “Adjacent Pairwise Differences”. The estimated rows of the contrast matrix are labeled “ModelName1 – ModelName2”. In particular, for the rows of \mathbf{L}_1 , ModelName2 is the reference model name. If you specify your own contrast matrix, then the contrast is labeled “Specified” and the *i*th contrast row estimates are labeled “Row*i*”.

If ODS Graphics is enabled, then all ROC curves are displayed individually and are also overlaid in a final display. If a selection method is specified, then the curves produced in each step of the model selection process are overlaid onto a single plot and are labeled “Step*i*”, and the selected model is displayed on a separate plot and on a plot with curves from specified ROC statements. See [Example 54.8](#) for an example.

ROC Computations

The trapezoidal area under an empirical ROC curve is equal to the Mann-Whitney two-sample rank measure of association statistic (a generalized *U*-statistic) applied to two samples, $\{X_i\}, i = 1, \dots, n_1$, in \mathcal{C}_1 and $\{Y_i\}, i = 1, \dots, n_2$, in \mathcal{C}_2 . PROC LOGISTIC uses the predicted probabilities in place of **X** and **Y**; however, in general any criterion could be used. Denote the frequency of observation *i* in \mathcal{C}_k as f_{ki} , and denote the total frequency in \mathcal{C}_k as F_k . The **WEIGHTED** option replaces f_{ki} with $f_{ki}w_{ki}$, where w_{ki} is the weight of

observation i in group C_k . The trapezoidal area under the curve is computed as

$$\hat{c} = \frac{1}{F_1 F_2} \sum_{i=1}^{n_1} \sum_{j=1}^{n_2} \psi(X_i, Y_j) f_{1i} f_{2j}$$

$$\psi(X, Y) = \begin{cases} 1 & Y < X \\ \frac{1}{2} & Y = X \\ 0 & Y > X \end{cases}$$

so that $E(\hat{c}) = \Pr(Y < X) + \frac{1}{2} \Pr(Y = X)$. Note that the concordance index, c , in the “Association of Predicted Probabilities and Observed Responses” table does not use weights unless both the **WEIGHTED** and **BINWIDTH=0** options are specified. Also, in this table, c is computed by creating 500 bins and binning the X_i and Y_j ; this results in more ties than the preceding method (unless the **BINWIDTH=0** or **ROCEPS=0** option is specified), so c is not necessarily equal to $E(\hat{c})$.

To compare K empirical ROC curves, first compute the trapezoidal areas. Asymptotic normality of the estimated area follows from U -statistic theory, and a covariance matrix \mathbf{S} can be computed; see DeLong, DeLong, and Clarke-Pearson (1988) for details. A Wald confidence interval for the r th area, $1 \leq r \leq K$, can be constructed as

$$\hat{c}_r \pm z_{1-\frac{\alpha}{2}} s_{r,r}$$

where $s_{r,r}$ is the r th diagonal of \mathbf{S} .

For a contrast of ROC curve areas, \mathbf{Lc} , the statistic

$$(\hat{\mathbf{c}} - \mathbf{c})' \mathbf{L}' [\mathbf{LSL}']^{-1} \mathbf{L}(\hat{\mathbf{c}} - \mathbf{c})$$

has a chi-square distribution with $\text{df} = \text{rank}(\mathbf{LSL}')$. For a row of the contrast, $\mathbf{l}'\mathbf{c}$,

$$\frac{\mathbf{l}'\hat{\mathbf{c}} - \mathbf{l}'\mathbf{c}}{[\mathbf{l}'\mathbf{S}\mathbf{l}]^{1/2}}$$

has a standard normal distribution. The corresponding confidence interval is

$$\mathbf{l}'\hat{\mathbf{c}} \pm z_{1-\frac{\alpha}{2}} [\mathbf{l}'\mathbf{S}\mathbf{l}]^{1/2}$$

Testing Linear Hypotheses about the Regression Coefficients

Linear hypotheses for $\boldsymbol{\beta}$ are expressed in matrix form as

$$H_0: \mathbf{L}\boldsymbol{\beta} = \mathbf{c}$$

where \mathbf{L} is a matrix of coefficients for the linear hypotheses, and \mathbf{c} is a vector of constants. The vector of regression coefficients $\boldsymbol{\beta}$ includes slope parameters as well as intercept parameters. The Wald chi-square statistic for testing H_0 is computed as

$$\chi_W^2 = (\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{c})' [\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}']^{-1} (\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{c})$$

where $\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})$ is the estimated covariance matrix. Under H_0 , χ_W^2 has an asymptotic chi-square distribution with r degrees of freedom, where r is the rank of \mathbf{L} .

Regression Diagnostics

For binary response data, regression diagnostics developed by Pregibon (1981) can be requested by specifying the **INFLUENCE** option. For diagnostics available with conditional logistic regression, see the section “Regression Diagnostic Details” on page 4272. These diagnostics can also be obtained from the **OUTPUT** statement.

This section uses the following notation:

- r_j, n_j r_j is the number of event responses out of n_j trials for the j th observation. If events/trials syntax is used, r_j is the value of *events* and n_j is the value of *trials*. For single-trial syntax, $n_j = 1$, and $r_j = 1$ if the ordered response is 1, and $r_j = 0$ if the ordered response is 2.
- w_j is the weight of the j th observation.
- π_j is the probability of an event response for the j th observation given by $\pi_j = F(\alpha + \beta'x_j)$, where $F(\cdot)$ is the **inverse link function** defined on page 4238.
- $\hat{\beta}$ is the maximum likelihood estimate (MLE) of $(\alpha, \beta_1, \dots, \beta_s)'$.
- $\hat{V}(\hat{\beta})$ is the estimated covariance matrix of $\hat{\beta}$.
- \hat{p}_j, \hat{q}_j \hat{p}_j is the estimate of π_j evaluated at $\hat{\beta}$, and $\hat{q}_j = 1 - \hat{p}_j$.

Pregibon (1981) suggests using the index plots of several diagnostic statistics to identify influential observations and to quantify the effects on various aspects of the maximum likelihood fit. In an index plot, the diagnostic statistic is plotted against the observation number. In general, the distributions of these diagnostic statistics are not known, so cutoff values cannot be given for determining when the values are large. However, the **IPLOTS** and **INFLUENCE** options in the **MODEL** statement and the **PLOTS** option in the **PROC LOGISTIC** statement provide displays of the diagnostic values, allowing visual inspection and comparison of the values across observations. In these plots, if the model is correctly specified and fits all observations well, then no extreme points should appear.

The next five sections give formulas for these diagnostic statistics.

Hat Matrix Diagonal (Leverage)

The diagonal elements of the hat matrix are useful in detecting extreme points in the design space where they tend to have larger values. The j th diagonal element is

$$h_j = \begin{cases} \tilde{w}_j(1, \mathbf{x}'_j)\hat{V}(\hat{\beta})(1, \mathbf{x}'_j)' & \text{Fisher scoring} \\ \hat{w}_j(1, \mathbf{x}'_j)\hat{V}(\hat{\beta})(1, \mathbf{x}'_j)' & \text{Newton-Raphson} \end{cases}$$

where

$$\begin{aligned} \tilde{w}_j &= \frac{w_j n_j}{\hat{p}_j \hat{q}_j [g'(\hat{p}_j)]^2} \\ \hat{w}_j &= \tilde{w}_j + \frac{w_j(r_j - n_j \hat{p}_j)[\hat{p}_j \hat{q}_j g''(\hat{p}_j) + (\hat{q}_j - \hat{p}_j)g'(\hat{p}_j)]}{(\hat{p}_j \hat{q}_j)^2 [g'(\hat{p}_j)]^3} \end{aligned}$$

and $g'(\cdot)$ and $g''(\cdot)$ are the first and second derivatives of the link function $g(\cdot)$, respectively.

For a binary response logit model, the hat matrix diagonal elements are

$$h_j = w_j n_j \hat{p}_j \hat{q}_j (1, \mathbf{x}'_j) \hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}) \begin{pmatrix} 1 \\ \mathbf{x}_j \end{pmatrix}$$

If the estimated probability is extreme (less than 0.1 and greater than 0.9, approximately), then the hat diagonal might be greatly reduced in value. Consequently, when an observation has a very large or very small estimated probability, its hat diagonal value is not a good indicator of the observation's distance from the design space (Hosmer and Lemeshow 2000, p. 171).

Residuals

Residuals are useful in identifying observations that are not explained well by the model. Pearson residuals are components of the Pearson chi-square statistic and deviance residuals are components of the deviance. The Pearson residual for the j th observation is

$$\chi_j = \frac{\sqrt{w_j}(r_j - n_j \hat{p}_j)}{\sqrt{n_j \hat{p}_j \hat{q}_j}}$$

The Pearson chi-square statistic is the sum of squares of the Pearson residuals.

The deviance residual for the j th observation is

$$d_j = \begin{cases} -\sqrt{-2w_j n_j \log(\hat{q}_j)} & \text{if } r_j = 0 \\ \pm \sqrt{2w_j [r_j \log(\frac{r_j}{n_j \hat{p}_j}) + (n_j - r_j) \log(\frac{n_j - r_j}{n_j \hat{q}_j})]} & \text{if } 0 < r_j < n_j \\ \sqrt{-2w_j n_j \log(\hat{p}_j)} & \text{if } r_j = n_j \end{cases}$$

where the plus (minus) in \pm is used if r_j/n_j is greater (less) than \hat{p}_j . The deviance is the sum of squares of the deviance residuals.

The STDRES option in the **INFLUENCE** and **PLOTS=INFLUENCE** options computes three more residuals (Collett 2003). The Pearson and deviance residuals are standardized to have approximately unit variance:

$$e_{pj} = \frac{\chi_j}{\sqrt{1 - h_j}}$$

$$e_{dj} = \frac{d_j}{\sqrt{1 - h_j}}$$

The likelihood residuals, which estimate components of a likelihood ratio test of deleting an individual observation, are a weighted combination of the standardized Pearson and deviance residuals

$$e_{lj} = \text{sign}(r_j - n_j \hat{p}_j) \sqrt{h_j e_{pj}^2 + (1 - h_j) e_{dj}^2}$$

DFBETAS

For each parameter estimate, the procedure calculates a DFBETAS diagnostic for each observation. The DFBETAS diagnostic for an observation is the standardized difference in the parameter estimate due to deleting the observation, and it can be used to assess the effect of an individual observation on each estimated parameter of the fitted model. Instead of reestimating the parameter every time an observation is deleted, PROC LOGISTIC uses the one-step estimate. See the section “[Predicted Probability of an Event for Classification](#)” on page 4255. For the j th observation, the DFBETAS are given by

$$\text{DFBETAS}_{ij} = \Delta_i \hat{\beta}_j^1 / \hat{\sigma}_i$$

where $i = 0, 1, \dots, s$, $\hat{\sigma}_i$ is the standard error of the i th component of $\hat{\beta}$, and $\Delta_i \hat{\beta}_j^1$ is the i th component of the one-step difference

$$\Delta \hat{\beta}_j^1 = \frac{w_j(r_j - n_j \hat{p}_j)}{1 - h_j} \hat{\mathbf{V}}(\hat{\beta}) \begin{pmatrix} 1 \\ \mathbf{x}_j \end{pmatrix}$$

$\Delta \hat{\beta}_j^1$ is the approximate change ($\hat{\beta} - \hat{\beta}_j^1$) in the vector of parameter estimates due to the omission of the j th observation. The DFBETAS are useful in detecting observations that are causing instability in the selected coefficients.

C and CBAR

C and CBAR are confidence interval displacement diagnostics that provide scalar measures of the influence of individual observations on $\hat{\beta}$. These diagnostics are based on the same idea as the Cook distance in linear regression theory (Cook and Weisberg 1982), but use the one-step estimate. C and CBAR for the j th observation are computed as

$$C_j = \chi_j^2 h_j / (1 - h_j)^2$$

and

$$\bar{C}_j = \chi_j^2 h_j / (1 - h_j)$$

respectively.

Typically, to use these statistics, you plot them against an index and look for outliers.

DIFDEV and DIFCHISQ

DIFDEV and DIFCHISQ are diagnostics for detecting ill-fitted observations; in other words, observations that contribute heavily to the disagreement between the data and the predicted values of the fitted model. DIFDEV is the change in the deviance due to deleting an individual observation while DIFCHISQ is the change in the Pearson chi-square statistic for the same deletion. By using the one-step estimate, DIFDEV and DIFCHISQ for the j th observation are computed as

$$\text{DIFDEV} = d_j^2 + \bar{C}_j$$

and

$$\text{DIFCHISQ} = \bar{C}_j / h_j$$

Scoring Data Sets

Scoring a data set, which is especially important for predictive modeling, means applying a previously fitted model to a new data set in order to compute the conditional, or *posterior*, probabilities of each response category given the values of the explanatory variables in each observation.

The **SCORE** statement enables you to score new data sets and output the scored values and, optionally, the corresponding confidence limits into a SAS data set. If the response variable is included in the new data set, then you can request **fit statistics** for the data, which is especially useful for test or validation data. If the response is binary, you can also create a SAS data set containing the *receiver operating characteristic* (ROC) curve. You can specify multiple **SCORE** statements in the same invocation of PROC LOGISTIC.

By default, the posterior probabilities are based on implicit prior probabilities that are proportional to the frequencies of the response categories in the *training data* (the data used to fit the model). Explicit prior probabilities should be specified with the **PRIOR=** or **PRIOREVENT=** option when the sample proportions of the response categories in the training data differ substantially from the operational data to be scored. For example, to detect a rare category, it is common practice to use a training set in which the rare categories are overrepresented; without prior probabilities that reflect the true incidence rate, the predicted posterior probabilities for the rare category will be too high. By specifying the correct priors, the posterior probabilities are adjusted appropriately.

The model fit to the **DATA=** data set in the PROC LOGISTIC statement is the default model used for the scoring. Alternatively, you can save a model fit in one run of PROC LOGISTIC and use it to score new data in a subsequent run. The **OUTMODEL=** option in the PROC LOGISTIC statement saves the model information in a SAS data set. Specifying this data set in the **INMODEL=** option of a new PROC LOGISTIC run will score the **DATA=** data set in the **SCORE** statement without refitting the model.

The **STORE** statement can also be used to save your model. The PLM procedure can use this model to score new data sets; see Chapter 69, “[The PLM Procedure](#),” for more information. You cannot specify priors in PROC PLM.

Fit Statistics for Scored Data Sets

Specifying the **FITSTAT** option displays the following fit statistics when the data set being scored includes the response variable:

Statistic	Description
Total frequency	$F = \sum_i f_i n_i$
Total weight	$W = \sum_i f_i w_i n_i$
Log likelihood	$\log L = \sum_i f_i w_i \log(\hat{\pi}_i)$
Full log likelihood	$\log L_f = \text{constant} + \log L$
Misclassification (error) rate	$\frac{\sum_i 1\{F_Y_i \neq I_Y_i\} f_i n_i}{F}$
AIC	$-2 \log L_f + 2p$
AICC	$-2 \log L_f + \frac{2pn}{n - p - 1}$
BIC	$-2 \log L_f + p \log(n)$
SC	$-2 \log L_f + p \log(F)$
R-square	$R^2 = 1 - \left(\frac{L_0}{L}\right)^{2/F}$
Maximum-rescaled R-square	$\frac{R^2}{1 - L_0^{2/F}}$
AUC	Area under the ROC curve
Brier score (polytomous response)	$\frac{1}{W} \sum_i f_i w_i \sum_j (y_{ij} - \hat{\pi}_{ij})^2$
Brier score (binary response)	$\frac{1}{W} \sum_i f_i w_i (r_i (1 - \hat{\pi}_i)^2 + (n_i - r_i) \hat{\pi}_i^2)$
Brier reliability (events/trials syntax)	$\frac{1}{W} \sum_i f_i w_i (r_i / n_i - \hat{\pi}_i)^2$

In the preceding table, f_i is the frequency of the i th observation in the data set being scored, w_i is the weight of the observation, and $n = \sum_i f_i$. The number of trials when events/trials syntax is specified is n_i , and with single-trial syntax $n_i = 1$. The values F_Y_i and I_Y_i are described in the section “[OUT= Output Data Set in a SCORE Statement](#)” on page 4281. The indicator function $1\{A\}$ is 1 if A is true and 0 otherwise. The likelihood of the model is L , and L_0 denotes the likelihood of the intercept-only model. For polytomous response models, y_i is the observed polytomous response level, $\hat{\pi}_{ij}$ is the predicted probability of the j th response level for observation i , and $y_{ij} = 1\{y_i = j\}$. For binary response models, $\hat{\pi}_i$ is the predicted probability of the observation, r_i is the number of events when you specify events/trials syntax, and $r_i = y_i$ when you specify single-trial syntax.

The log likelihood, Akaike’s information criterion (AIC), and Schwarz criterion (SC) are described in the section “[Model Fitting Information](#)” on page 4245. The full log likelihood is displayed for models specified with events/trials syntax, and the constant term is described in the section “[Model Fitting Information](#)” on page 4245. The AICC is a small-sample bias-corrected version of the AIC (Hurvich and Tsai 1993; Burnham and Anderson 1998). The Bayesian information criterion (BIC) is the same as the SC except when events/trials syntax is specified. The area under the ROC curve for binary response models is defined in the section “[ROC Computations](#)” on page 4261. The R-square and maximum-rescaled R-square statistics, defined in “[Generalized Coefficient of Determination](#)” on page 4246, are not computed when you specify both an **OFFSET=** variable and the **INMODEL=** data set. The Brier score (Brier 1950) is the weighted squared difference between the predicted probabilities and their observed response levels. For events/trials syntax, the Brier reliability is the weighted squared difference between the predicted probabilities and the observed proportions (Murphy 1973).

Posterior Probabilities and Confidence Limits

Let F be the inverse link function. That is,

$$F(t) = \begin{cases} \frac{1}{1+\exp(-t)} & \text{logistic} \\ \Phi(t) & \text{normal} \\ 1 - \exp(-\exp(t)) & \text{complementary log-log} \end{cases}$$

The first derivative of F is given by

$$F'(t) = \begin{cases} \frac{\exp(-t)}{(1+\exp(-t))^2} & \text{logistic} \\ \phi(t) & \text{normal} \\ \exp(t) \exp(-\exp(t)) & \text{complementary log-log} \end{cases}$$

Suppose there are $k + 1$ response categories. Let Y be the response variable with levels $1, \dots, k + 1$. Let $\mathbf{x} = (x_0, x_1, \dots, x_s)'$ be a $(s + 1)$ -vector of covariates, with $x_0 \equiv 1$. Let $\boldsymbol{\beta}$ be the vector of intercept and slope regression parameters.

Posterior probabilities are given by

$$p(Y = i | \mathbf{x}) = \frac{p_o(Y = i | \mathbf{x}) \frac{\tilde{p}(Y=i)}{p_o(Y=i)}}{\sum_j p_o(Y = j | \mathbf{x}) \frac{\tilde{p}(Y=j)}{p_o(Y=j)}} \quad i = 1, \dots, k + 1$$

where the old posterior probabilities ($p_o(Y = i | \mathbf{x}), i = 1, \dots, k + 1$) are the conditional probabilities of the response categories given \mathbf{x} , the old priors ($p_o(Y = i), i = 1, \dots, k + 1$) are the sample proportions of response categories of the training data, and the new priors ($\tilde{p}(Y = i), i = 1, \dots, k + 1$) are specified in the **PRIOR=** or **PRIOREVENT=** option. To simplify notation, absorb the old priors into the new priors; that is

$$p(Y = i) = \frac{\tilde{p}(Y = i)}{p_o(Y = i)} \quad i = 1, \dots, k + 1$$

Note if the **PRIOR=** and **PRIOREVENT=** options are not specified, then $p(Y = i) = 1$.

The posterior probabilities are functions of $\boldsymbol{\beta}$ and their estimates are obtained by substituting $\boldsymbol{\beta}$ by its MLE $\hat{\boldsymbol{\beta}}$. The variances of the estimated posterior probabilities are given by the *delta method* as follows:

$$\text{Var}(\hat{p}(Y = i | \mathbf{x})) = \left[\frac{\partial p(Y = i | \mathbf{x})}{\partial \boldsymbol{\beta}} \right]' \text{Var}(\hat{\boldsymbol{\beta}}) \left[\frac{\partial p(Y = i | \mathbf{x})}{\partial \boldsymbol{\beta}} \right]$$

where

$$\frac{\partial p(Y = i | \mathbf{x})}{\partial \boldsymbol{\beta}} = \frac{\frac{\partial p_o(Y=i|\mathbf{x})}{\partial \boldsymbol{\beta}} p(Y = i)}{\sum_j p_o(Y = j | \mathbf{x}) p(Y = j)} - \frac{p_o(Y = i | \mathbf{x}) p(Y = i) \sum_j \frac{\partial p_o(Y=j|\mathbf{x})}{\partial \boldsymbol{\beta}} p(Y = j)}{[\sum_j p_o(Y = j | \mathbf{x}) p(Y = j)]^2}$$

and the old posterior probabilities $p_o(Y = i | \mathbf{x})$ are described in the following sections.

A $100(1 - \alpha)\%$ confidence interval for $p(Y = i | \mathbf{x})$ is

$$\hat{p}(Y = i | \mathbf{x}) \pm z_{1-\alpha/2} \sqrt{\widehat{\text{Var}}(\hat{p}(Y = i | \mathbf{x}))}$$

where z_τ is the upper 100τ percentile of the standard normal distribution.

Binary and Cumulative Response Models

Let $\alpha_1, \dots, \alpha_k$ be the intercept parameters and let β_s be the vector of slope parameters. Denote $\beta = (\alpha_1, \dots, \alpha_k, \beta_s')'$. Let

$$\eta_i = \eta_i(\beta) = \alpha_i + \mathbf{x}'\beta_s, i = 1, \dots, k$$

Estimates of η_1, \dots, η_k are obtained by substituting the maximum likelihood estimate $\hat{\beta}$ for β .

The predicted probabilities of the responses are

$$\widehat{p}_o(Y = i|\mathbf{x}) = \widehat{\Pr}(Y = i) = \begin{cases} F(\hat{\eta}_1) & i = 1 \\ F(\hat{\eta}_i) - F(\hat{\eta}_{i-1}) & i = 2, \dots, k \\ 1 - F(\hat{\eta}_k) & i = k + 1 \end{cases}$$

For $i = 1, \dots, k$, let $\delta_i(\mathbf{x})$ be a $(k + 1)$ column vector with i th entry equal to 1, $k + 1$ entry equal to \mathbf{x} , and all other entries 0. The derivative of $p_o(Y = i|\mathbf{x})$ with respect to β are

$$\frac{\partial p_o(Y = i|\mathbf{x})}{\partial \beta} = \begin{cases} F'(\alpha_1 + \mathbf{x}'\beta_s)\delta_1(\mathbf{x}) & i = 1 \\ F'(\alpha_i + \mathbf{x}'\beta_s)\delta_i(\mathbf{x}) - F'(\alpha_{i-1} + \mathbf{x}'\beta_s)\delta_{i-1}(\mathbf{x}) & i = 2, \dots, k \\ -F'(\alpha_k + \mathbf{x}'\beta_s)\delta_k(\mathbf{x}) & i = k + 1 \end{cases}$$

The cumulative posterior probabilities are

$$p(Y \leq i|\mathbf{x}) = \frac{\sum_{j=1}^i p_o(Y = j|\mathbf{x})p(Y = j)}{\sum_{j=1}^{k+1} p_o(Y = j|\mathbf{x})p(Y = j)} = \sum_{j=1}^i p(Y = j|\mathbf{x}) \quad i = 1, \dots, k + 1$$

Their derivatives are

$$\frac{\partial p(Y \leq i|\mathbf{x})}{\partial \beta} = \sum_{j=1}^i \frac{\partial p(Y = j|\mathbf{x})}{\partial \beta} \quad i = 1, \dots, k + 1$$

In the delta-method equation for the variance, replace $p(Y = \cdot|\mathbf{x})$ with $p(Y \leq \cdot|\mathbf{x})$.

Finally, for the cumulative response model, use

$$\begin{aligned} \widehat{p}_o(Y \leq i|\mathbf{x}) &= F(\hat{\eta}_i) \quad i = 1, \dots, k \\ \widehat{p}_o(Y \leq k + 1|\mathbf{x}) &= 1 \\ \frac{\partial p_o(Y \leq i|\mathbf{x})}{\partial \beta} &= F'(\alpha_i + \mathbf{x}'\beta_s)\delta_i(\mathbf{x}) \quad i = 1, \dots, k \\ \frac{\partial p_o(Y \leq k + 1|\mathbf{x})}{\partial \beta} &= 0 \end{aligned}$$

Generalized Logit Model

Consider the last response level ($Y=k+1$) as the reference. Let β_1, \dots, β_k be the (intercept and slope) parameter vectors for the first k logits, respectively. Denote $\beta = (\beta'_1, \dots, \beta'_k)'$. Let $\eta = (\eta_1, \dots, \eta_k)'$ with

$$\eta_i = \eta_i(\beta) = \mathbf{x}'\beta_i \quad i = 1, \dots, k$$

Estimates of η_1, \dots, η_k are obtained by substituting the maximum likelihood estimate $\hat{\beta}$ for β .

The predicted probabilities are

$$\begin{aligned} \widehat{p}_o(Y = k + 1 | \mathbf{x}) &\equiv \Pr(Y = k + 1 | \mathbf{x}) = \frac{1}{1 + \sum_{l=1}^k \exp(\hat{\eta}_l)} \\ \widehat{p}_o(Y = i | \mathbf{x}) &\equiv \Pr(Y = i | \mathbf{x}) = \widehat{p}_o(Y = k + 1 | \mathbf{x}) \exp(\eta_i), i = 1, \dots, k \end{aligned}$$

The derivative of $p_o(Y = i | \mathbf{x})$ with respect to β are

$$\begin{aligned} \frac{\partial p_o(Y = i | \mathbf{x})}{\partial \beta} &= \frac{\partial \eta}{\partial \beta} \frac{\partial p_o(Y = i | \mathbf{x})}{\partial \eta} \\ &= (I_k \otimes \mathbf{x}) \left(\frac{\partial p_o(Y = i | \mathbf{x})}{\partial \eta_1}, \dots, \frac{\partial p_o(Y = i | \mathbf{x})}{\partial \eta_k} \right)' \end{aligned}$$

where

$$\frac{\partial p_o(Y = i | \mathbf{x})}{\partial \eta_j} = \begin{cases} p_o(Y = i | \mathbf{x})(1 - p_o(Y = i | \mathbf{x})) & j = i \\ -p_o(Y = i | \mathbf{x})p_o(Y = j | \mathbf{x}) & \text{otherwise} \end{cases}$$

Special Case of Binary Response Model with No Priors

Let β be the vector of regression parameters. Let

$$\eta = \eta(\beta) = \mathbf{x}'\beta$$

The variance of $\hat{\eta}$ is given by

$$\text{Var}(\hat{\eta}) = \mathbf{x}'\text{Var}(\hat{\beta})\mathbf{x}$$

A $100(1 - \alpha)$ percent confidence interval for η is

$$\hat{\eta} \pm z_{1-\alpha/2} \sqrt{\widehat{\text{Var}}(\hat{\eta})}$$

Estimates of $p_o(Y = 1 | \mathbf{x})$ and confidence intervals for the $p_o(Y = 1 | \mathbf{x})$ are obtained by back-transforming $\hat{\eta}$ and the confidence intervals for η , respectively. That is,

$$\widehat{p}_o(Y = 1 | \mathbf{x}) = F(\hat{\eta})$$

and the confidence intervals are

$$F \left(\hat{\eta} \pm z_{1-\alpha/2} \sqrt{\widehat{\text{Var}}(\hat{\eta})} \right)$$

Conditional Logistic Regression

The method of maximum likelihood described in the preceding sections relies on large-sample asymptotic normality for the validity of estimates and especially of their standard errors. When you do not have a large sample size compared to the number of parameters, this approach might be inappropriate and might result in biased inferences. This situation typically arises when your data are stratified and you fit intercepts to each stratum so that the number of parameters is of the same order as the sample size. For example, in a 1:1 matched pairs study with n pairs and p covariates, you would estimate $n - 1$ intercept parameters and p slope parameters. Taking the stratification into account by “conditioning out” (and not estimating) the stratum-specific intercepts gives consistent and asymptotically normal MLEs for the slope coefficients. See Breslow and Day (1980) and Stokes, Davis, and Koch (2012) for more information. If your nuisance parameters are not just stratum-specific intercepts, you can perform an [exact conditional logistic regression](#).

Computational Details

For each stratum h , $h = 1, \dots, H$, number the observations as $i = 1, \dots, n_h$ so that hi indexes the i th observation in stratum h . Denote the p covariates for the hi th observation as \mathbf{x}_{hi} and its binary response as y_{hi} , and let $\mathbf{y} = (y_{11}, \dots, y_{1n_1}, \dots, y_{H1}, \dots, y_{Hn_H})'$, $\mathbf{X}_h = (\mathbf{x}_{h1} \dots \mathbf{x}_{hn_h})'$, and $\mathbf{X} = (\mathbf{X}'_1 \dots \mathbf{X}'_H)'$. Let the dummy variables z_h , $h = 1, \dots, H$, be indicator functions for the strata ($z_h = 1$ if the observation is in stratum h), and denote $\mathbf{z}_{hi} = (z_1, \dots, z_H)$ for the hi th observation, $\mathbf{Z}_h = (\mathbf{z}_{h1} \dots \mathbf{z}_{hn_h})'$, and $\mathbf{Z} = (\mathbf{Z}'_1 \dots \mathbf{Z}'_H)'$. Denote $\mathbf{X}^* = (\mathbf{Z}|\mathbf{X})$ and $\mathbf{x}^*_{hi} = (\mathbf{z}'_{hi}|\mathbf{x}'_{hi})'$. Arrange the observations in each stratum h so that $y_{hi} = 1$ for $i = 1, \dots, m_h$, and $y_{hi} = 0$ for $i = m_h + 1, \dots, n_h$. Suppose all observations have unit frequency.

Consider the [binary logistic regression model](#) on page 4163 written as

$$\text{logit}(\pi) = \mathbf{X}^* \boldsymbol{\theta}$$

where the parameter vector $\boldsymbol{\theta} = (\boldsymbol{\alpha}', \boldsymbol{\beta}')'$ consists of $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_H)'$, α_h is the intercept for stratum h , $h = 1, \dots, H$, and $\boldsymbol{\beta}$ is the parameter vector for the p covariates.

From the section “[Determining Observations for Likelihood Contributions](#)” on page 4239, you can write the likelihood contribution of observation hi , $i = 1, \dots, n_h$, $h = 1, \dots, H$, as

$$L_{hi}(\boldsymbol{\theta}) = \frac{e^{y_{hi}\mathbf{x}^*_{hi}'\boldsymbol{\theta}}}{1 + e^{\mathbf{x}^*_{hi}'\boldsymbol{\theta}}}$$

where $y_{hi} = 1$ when the response takes Ordered Value 1, and $y_{hi} = 0$ otherwise.

The full likelihood is

$$L(\boldsymbol{\theta}) = \prod_{h=1}^H \prod_{i=1}^{n_h} L_{hi}(\boldsymbol{\theta}) = \frac{e^{\mathbf{y}'\mathbf{X}^*\boldsymbol{\theta}}}{\prod_{h=1}^H \prod_{i=1}^{n_h} (1 + e^{\mathbf{x}^*_{hi}'\boldsymbol{\theta}})}$$

Unconditional likelihood inference is based on maximizing this likelihood function.

When your nuisance parameters are the stratum-specific intercepts $(\alpha_1, \dots, \alpha_H)'$, and the slopes $\boldsymbol{\beta}$ are your parameters of interest, “conditioning out” the nuisance parameters produces the conditional likelihood (Lachin 2000)

$$L(\boldsymbol{\beta}) = \prod_{h=1}^H L_h(\boldsymbol{\beta}) = \prod_{h=1}^H \frac{\prod_{i=1}^{m_h} \exp(\mathbf{x}'_{hi}\boldsymbol{\beta})}{\sum \prod_{j=j_1}^{j_{m_h}} \exp(\mathbf{x}'_{hj}\boldsymbol{\beta})}$$

where the summation is over all $\binom{n_h}{m_h}$ subsets $\{j_1, \dots, j_{m_h}\}$ of m_h observations chosen from the n_h observations in stratum h . Note that the nuisance parameters have been factored out of this equation.

For conditional asymptotic inference, maximum likelihood estimates $\hat{\beta}$ of the regression parameters are obtained by maximizing the conditional likelihood, and asymptotic results are applied to the conditional likelihood function and the maximum likelihood estimators. A relatively fast method of computing this conditional likelihood and its derivatives is given by Gail, Lubin, and Rubinstein (1981) and Howard (1972). The optimization techniques can be controlled by specifying the **NLOPTIONS** statement.

Sometimes the log likelihood converges but the estimates diverge. This condition is flagged by having inordinately large standard errors for some of your parameter estimates, and can be monitored by specifying the **ITPRINT** option. Unfortunately, broad existence criteria such as those discussed in the section “**Existence of Maximum Likelihood Estimates**” on page 4242 do not exist for this model. It might be possible to circumvent such a problem by standardizing your independent variables before fitting the model.

Regression Diagnostic Details

Diagnostics are used to indicate observations that might have undue influence on the model fit or that might be outliers. Further investigation should be performed before removing such an observation from the data set.

The derivations in this section use an augmentation method described by Storer and Crowley (1985), which provides an estimate of the “one-step” DFBETAS estimates advocated by Pregibon (1984). The method also provides estimates of conditional stratum-specific predicted values, residuals, and leverage for each observation. The augmentation method can take a lot of time and memory.

Following Storer and Crowley (1985), the log-likelihood contribution can be written as

$$l_h = \log(L_h) = \mathbf{y}_h' \boldsymbol{\gamma}_h - a(\boldsymbol{\gamma}_h) \quad \text{where}$$

$$a(\boldsymbol{\gamma}_h) = \log \left[\sum_{j=j_1}^{j_{m_h}} \prod \exp(\boldsymbol{\gamma}_{hj}) \right]$$

and the h subscript on matrices indicates the submatrix for the stratum, $\boldsymbol{\gamma}_h = (\gamma_{h1}, \dots, \gamma_{hn_h})'$, and $\gamma_{hi} = \mathbf{x}_{hi}' \boldsymbol{\beta}$. Then the gradient and information matrix are

$$\mathbf{g}(\boldsymbol{\beta}) = \left\{ \frac{\partial l_h}{\partial \boldsymbol{\beta}} \right\}_{h=1}^H = \mathbf{X}'(\mathbf{y} - \boldsymbol{\pi})$$

$$\boldsymbol{\Lambda}(\boldsymbol{\beta}) = \left\{ \frac{\partial^2 l_h}{\partial \boldsymbol{\beta}^2} \right\}_{h=1}^H = \mathbf{X}' \text{diag}(\mathbf{U}_1, \dots, \mathbf{U}_H) \mathbf{X}$$

where

$$\begin{aligned}\pi_{hi} &= \frac{\partial a(\boldsymbol{\gamma}_h)}{\partial \gamma_{hi}} = \frac{\sum_{j(i)} \prod_{j=j_1}^{j_{m_h}} \exp(\gamma_{hj})}{\sum \prod_{j=j_1}^{j_{m_h}} \exp(\gamma_{hj})} \\ \boldsymbol{\pi}_h &= (\pi_{h1}, \dots, \pi_{hn_h}) \\ \mathbf{U}_h &= \frac{\partial^2 a(\boldsymbol{\gamma}_h)}{\partial \boldsymbol{\gamma}_h^2} = \left\{ \frac{\partial^2 a(\boldsymbol{\gamma}_h)}{\partial \gamma_{hi} \partial \gamma_{hj}} \right\} = \{a_{ij}\} \\ a_{ij} &= \frac{\sum_{k(i,j)} \prod_{k=k_1}^{k_{m_h}} \exp(\gamma_{hk})}{\sum \prod_{k=k_1}^{k_{m_h}} \exp(\gamma_{hk})} - \frac{\partial a(\boldsymbol{\gamma}_h)}{\partial \gamma_{hi}} \frac{\partial a(\boldsymbol{\gamma}_h)}{\partial \gamma_{hj}} = \pi_{hij} - \pi_{hi} \pi_{hj}\end{aligned}$$

and where π_{hi} is the conditional stratum-specific probability that subject i in stratum h is a case, the summation on $j(i)$ is over all subsets from $\{1, \dots, n_h\}$ of size m_h that contain the index i , and the summation on $k(i, j)$ is over all subsets from $\{1, \dots, n_h\}$ of size m_h that contain the indices i and j .

To produce the true one-step estimate $\boldsymbol{\beta}_{hi}^1$, start at the MLE $\hat{\boldsymbol{\beta}}$, delete the h th observation, and use this reduced data set to compute the next Newton-Raphson step. Note that if there is only one event or one nonevent in a stratum, deletion of that single observation is equivalent to deletion of the entire stratum. The augmentation method does not take this into account.

The augmented model is

$$\text{logit}(\Pr(y_{hi} = 1 | \mathbf{x}_{hi})) = \mathbf{x}'_{hi} \boldsymbol{\beta} + \mathbf{z}'_{hi} \gamma$$

where $\mathbf{z}_{hi} = (0, \dots, 0, 1, 0, \dots, 0)'$ has a 1 in the h th coordinate, and use $\boldsymbol{\beta}^0 = (\hat{\boldsymbol{\beta}}', 0)'$ as the initial estimate for $(\boldsymbol{\beta}', \gamma)'$. The gradient and information matrix before the step are

$$\begin{aligned}\mathbf{g}(\boldsymbol{\beta}^0) &= \begin{bmatrix} \mathbf{X}' \\ \mathbf{z}'_{hi} \end{bmatrix} (\mathbf{y} - \boldsymbol{\pi}) = \begin{bmatrix} \mathbf{0} \\ y_{hi} - \pi_{hi} \end{bmatrix} \\ \boldsymbol{\Lambda}(\boldsymbol{\beta}^0) &= \begin{bmatrix} \mathbf{X}' \\ \mathbf{z}'_{hi} \end{bmatrix} \mathbf{U} [\mathbf{X} \quad \mathbf{z}_{hi}] = \begin{bmatrix} \boldsymbol{\Lambda}(\boldsymbol{\beta}) & \mathbf{X}' \mathbf{U} \mathbf{z}_{hi} \\ \mathbf{z}'_{hi} \mathbf{U} \mathbf{X} & \mathbf{z}'_{hi} \mathbf{U} \mathbf{z}_{hi} \end{bmatrix}\end{aligned}$$

Inserting the $\boldsymbol{\beta}^0$ and $(\mathbf{X}', \mathbf{z}'_{hi})'$ into the Gail, Lubin, and Rubinstein (1981) algorithm provides the appropriate estimates of $\mathbf{g}(\boldsymbol{\beta}^0)$ and $\boldsymbol{\Lambda}(\boldsymbol{\beta}^0)$. Indicate these estimates with $\hat{\boldsymbol{\pi}} = \boldsymbol{\pi}(\hat{\boldsymbol{\beta}})$, $\hat{\mathbf{U}} = \mathbf{U}(\hat{\boldsymbol{\beta}})$, $\hat{\mathbf{g}}$, and $\hat{\boldsymbol{\Lambda}}$.

DFBETA is computed from the information matrix as

$$\begin{aligned}\Delta_{hi} \boldsymbol{\beta} &= \boldsymbol{\beta}^0 - \boldsymbol{\beta}_{hi}^1 \\ &= -\hat{\boldsymbol{\Lambda}}^{-1}(\boldsymbol{\beta}^0) \hat{\mathbf{g}}(\boldsymbol{\beta}^0) \\ &= -\hat{\boldsymbol{\Lambda}}^{-1}(\hat{\boldsymbol{\beta}}) (\mathbf{X}' \hat{\mathbf{U}} \mathbf{z}_{hi}) \mathbf{M}^{-1} \mathbf{z}'_{hi} (\mathbf{y} - \hat{\boldsymbol{\pi}})\end{aligned}$$

where

$$\mathbf{M} = (\mathbf{z}'_{hi} \hat{\mathbf{U}} \mathbf{z}_{hi}) - (\mathbf{z}'_{hi} \hat{\mathbf{U}} \mathbf{X}) \hat{\boldsymbol{\Lambda}}^{-1}(\hat{\boldsymbol{\beta}}) (\mathbf{X}' \hat{\mathbf{U}} \mathbf{z}_{hi})$$

For each observation in the data set, a DFBETA statistic is computed for each parameter β_j , $1 \leq j \leq p$, and standardized by the standard error of β_j from the full data set to produce the estimate of DFBETAS.

The estimated leverage is defined as

$$h_{hi} = \frac{\text{trace}\{(\mathbf{z}'_{hi}\hat{\mathbf{U}}\mathbf{X})\hat{\mathbf{\Lambda}}^{-1}(\hat{\boldsymbol{\beta}})(\mathbf{X}'\hat{\mathbf{U}}\mathbf{z}_{hi})\}}{\text{trace}\{\mathbf{z}'_{hi}\hat{\mathbf{U}}\mathbf{z}_{hi}\}}$$

This definition of leverage produces different values from those defined by Pregibon (1984); Moolgavkar, Lustbader, and Venzon (1985); Hosmer and Lemeshow (2000); however, it has the advantage that no extra computations beyond those for the DFBETAS are required.

The estimated residuals $e_{hi} = y_{hi} - \hat{\pi}_{hi}$ are obtained from $\hat{\mathbf{g}}(\boldsymbol{\beta}^0)$, and the weights, or predicted probabilities, are then $\hat{\pi}_{hi} = y_{hi} - e_{hi}$. The residuals are standardized and reported as (estimated) Pearson residuals:

$$\frac{r_{hi} - n_{hi}\hat{\pi}_{hi}}{\sqrt{n_{hi}\hat{\pi}_{hi}(1 - \hat{\pi}_{hi})}}$$

where r_{hi} is the number of events in the observation and n_{hi} is the number of trials.

The STDRES option in the **INFLUENCE** and **PLOTS=INFLUENCE** options computes the standardized Pearson residual:

$$e_{s,hi} = \frac{e_{hi}}{\sqrt{1 - h_{hi}}}$$

For events/trials MODEL statement syntax, treat each observation as two observations (the first for the nonevents and the second for the events) with frequencies $f_{h,2i-1} = n_{hi} - r_{hi}$ and $f_{h,2i} = r_{hi}$, and augment the model with a matrix $\mathbf{Z}_{hi} = [\mathbf{z}_{h,2i-1} \mathbf{z}_{h,2i}]$ instead of a single \mathbf{z}_{hi} vector. Writing $\gamma_{hi} = \mathbf{x}'_{hi}\boldsymbol{\beta} f_{hi}$ in the preceding section results in the following gradient and information matrix:

$$\begin{aligned} \mathbf{g}(\boldsymbol{\beta}^0) &= \begin{bmatrix} \mathbf{0} \\ f_{h,2i-1}(y_{h,2i-1} - \pi_{h,2i-1}) \\ f_{h,2i}(y_{h,2i} - \pi_{h,2i}) \end{bmatrix} \\ \mathbf{\Lambda}(\boldsymbol{\beta}^0) &= \begin{bmatrix} \mathbf{\Lambda}(\boldsymbol{\beta}) & \mathbf{X}'\text{diag}(\mathbf{f})\text{Udiag}(\mathbf{f})\mathbf{Z}_{hi} \\ \mathbf{Z}'_{hi}\text{diag}(\mathbf{f})\text{Udiag}(\mathbf{f})\mathbf{X} & \mathbf{Z}'_{hi}\text{diag}(\mathbf{f})\text{Udiag}(\mathbf{f})\mathbf{Z}_{hi} \end{bmatrix} \end{aligned}$$

The predicted probabilities are then $\hat{\pi}_{hi} = y_{h,2i} - e_{h,2i}/r_{h,2i}$, while the leverage and the DFBETAS are produced from $\mathbf{\Lambda}(\boldsymbol{\beta}^0)$ in a fashion similar to that for the preceding single-trial equations.

Exact Conditional Logistic Regression

The theory of exact logistic regression, also known as exact conditional logistic regression, was originally laid out by Cox (1970), and the computational methods employed in PROC LOGISTIC are described in Hirji, Mehta, and Patel (1987); Hirji (1992); Mehta, Patel, and Senchaudhuri (1992). Other useful references for the derivations include Cox and Snell (1989); Agresti (1990); Mehta and Patel (1995).

Exact conditional inference is based on generating the conditional distribution for the sufficient statistics of the parameters of interest. This distribution is called the *permutation* or *exact conditional* distribution. Using the notation in the section “[Computational Details](#)” on page 4271, follow Mehta and Patel (1995) and

first note that the sufficient statistics $\mathbf{T} = (T_1, \dots, T_p)$ for the parameter vector of intercepts and slopes, $\boldsymbol{\beta}$, are

$$T_j = \sum_{i=1}^n y_i x_{ij}, \quad j = 1, \dots, p$$

Denote a vector of observable sufficient statistics as $\mathbf{t} = (t_1, \dots, t_p)'$.

The probability density function (PDF) for \mathbf{T} can be created by summing over all binary sequences \mathbf{y} that generate an observable \mathbf{t} and letting $C(\mathbf{t}) = ||\{\mathbf{y} : \mathbf{y}'\mathbf{X} = \mathbf{t}'\}||$ denote the number of sequences \mathbf{y} that generate \mathbf{t}

$$\Pr(\mathbf{T} = \mathbf{t}) = \frac{C(\mathbf{t}) \exp(\mathbf{t}'\boldsymbol{\beta})}{\prod_{i=1}^n [1 + \exp(\mathbf{x}_i'\boldsymbol{\beta})]}$$

In order to condition out the nuisance parameters, partition the parameter vector $\boldsymbol{\beta} = (\boldsymbol{\beta}'_N, \boldsymbol{\beta}'_I)'$, where $\boldsymbol{\beta}_N$ is a $p_N \times 1$ vector of the nuisance parameters, and $\boldsymbol{\beta}_I$ is the parameter vector for the remaining $p_I = p - p_N$ parameters of interest. Likewise, partition \mathbf{X} into \mathbf{X}_N and \mathbf{X}_I , \mathbf{T} into \mathbf{T}_N and \mathbf{T}_I , and \mathbf{t} into \mathbf{t}_N and \mathbf{t}_I . The nuisance parameters can be removed from the analysis by conditioning on their sufficient statistics to create the conditional likelihood of \mathbf{T}_I given $\mathbf{T}_N = \mathbf{t}_N$,

$$\begin{aligned} \Pr(\mathbf{T}_I = \mathbf{t}_I | \mathbf{T}_N = \mathbf{t}_N) &= \frac{\Pr(\mathbf{T} = \mathbf{t})}{\Pr(\mathbf{T}_N = \mathbf{t}_N)} \\ &= f_{\boldsymbol{\beta}_I}(\mathbf{t}_I | \mathbf{t}_N) = \frac{C(\mathbf{t}_N, \mathbf{t}_I) \exp(\mathbf{t}_I'\boldsymbol{\beta}_I)}{\sum_{\mathbf{u}} C(\mathbf{t}_N, \mathbf{u}) \exp(\mathbf{u}'\boldsymbol{\beta}_I)} \end{aligned}$$

where $C(\mathbf{t}_N, \mathbf{u})$ is the number of vectors \mathbf{y} such that $\mathbf{y}'\mathbf{X}_N = \mathbf{t}_N$ and $\mathbf{y}'\mathbf{X}_I = \mathbf{u}$. Note that the nuisance parameters have factored out of this equation, and that $C(\mathbf{t}_N, \mathbf{t}_I)$ is a constant.

The goal of the exact conditional analysis is to determine how likely the observed response \mathbf{y}_0 is with respect to all 2^n possible responses $\mathbf{y} = (y_1, \dots, y_n)'$. One way to proceed is to generate every \mathbf{y} vector for which $\mathbf{y}'\mathbf{X}_N = \mathbf{t}_N$, and count the number of vectors \mathbf{y} for which $\mathbf{y}'\mathbf{X}_I$ is equal to each unique \mathbf{t}_I . Generating the conditional distribution from complete enumeration of the joint distribution is conceptually simple; however, this method becomes computationally infeasible very quickly. For example, if you had only 30 observations, you would have to scan through 2^{30} different \mathbf{y} vectors.

Several algorithms are available in PROC LOGISTIC to generate the exact distribution. All of the algorithms are based on the following observation. Given any $\mathbf{y} = (y_1, \dots, y_n)'$ and a design $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)'$, let $\mathbf{y}_{(i)} = (y_1, \dots, y_i)'$ and $\mathbf{X}_{(i)} = (\mathbf{x}_1, \dots, \mathbf{x}_i)'$ be the first i rows of each matrix. Write the sufficient statistic based on these i rows as $\mathbf{t}_{(i)} = \mathbf{y}_{(i)}'\mathbf{X}_{(i)}$. A recursion relation results: $\mathbf{t}_{(i+1)} = \mathbf{t}_{(i)} + y_{i+1}\mathbf{x}_{i+1}$.

The following methods are available:

- The *multivariate shift algorithm* developed by Hirji, Mehta, and Patel (1987), which steps through the recursion relation by adding one observation at a time and building an intermediate distribution at each step. If it determines that $\mathbf{t}_{(i)}$ for the nuisance parameters could eventually equal \mathbf{t} , then $\mathbf{t}_{(i)}$ is added to the intermediate distribution.
- An extension of the multivariate shift algorithm to generalized logit models by Hirji (1992). Since the generalized logit model fits a new set of parameters to each logit, the number of parameters in the

model can easily get too large for this algorithm to handle. Note for these models that the hypothesis tests for each effect are computed across the logit functions, while individual parameters are estimated for each logit function.

- A network algorithm described in Mehta, Patel, and Senchaudhuri (1992), which builds a network for each parameter that you are conditioning out in order to identify feasible y_i for the \mathbf{y} vector. These networks are combined and the set of feasible y_i is further reduced, and then the multivariate shift algorithm uses this knowledge to build the exact distribution without adding as many intermediate $t_{(i+1)}$ as the multivariate shift algorithm does.
- A hybrid Monte Carlo and network algorithm described by Mehta, Patel, and Senchaudhuri (2000), which extends their 1992 algorithm by sampling from the combined network to build the exact distribution.

The bulk of the computation time and memory for these algorithms is consumed by the creation of the networks and the exact joint distribution. After the joint distribution for a set of effects is created, the computational effort required to produce hypothesis tests and parameter estimates for any subset of the effects is (relatively) trivial. See the section “[Computational Resources for Exact Logistic Regression](#)” on page 4284 for more computational notes about exact analyses.

NOTE: An alternative to using these exact conditional methods is to perform Firth’s bias-reducing penalized likelihood method (see the [FIRTH](#) option in the [MODEL](#) statement); this method has the advantage of being much faster and less memory intensive than exact algorithms, but it might not converge to a solution.

Hypothesis Tests

Consider testing the null hypothesis $H_0: \beta_I = \mathbf{0}$ against the alternative $H_A: \beta_I \neq \mathbf{0}$, conditional on $\mathbf{T}_N = \mathbf{t}_N$. Under the null hypothesis, the test statistic for the *exact probability test* is just $f_{\beta_I=\mathbf{0}}(\mathbf{t}_I|\mathbf{t}_N)$, while the corresponding p -value is the probability of getting a less likely (more extreme) statistic,

$$p(\mathbf{t}_I|\mathbf{t}_N) = \sum_{\mathbf{u} \in \Omega_p} f_0(\mathbf{u}|\mathbf{t}_N)$$

where $\Omega_p = \{\mathbf{u}: \text{there exist } \mathbf{y} \text{ with } \mathbf{y}'\mathbf{X}_I = \mathbf{u}, \mathbf{y}'\mathbf{X}_N = \mathbf{t}_N, \text{ and } f_0(\mathbf{u}|\mathbf{t}_N) \leq f_0(\mathbf{t}_I|\mathbf{t}_N)\}$.

For the *exact conditional scores test*, the conditional mean μ_I and variance matrix Σ_I of the \mathbf{T}_I (conditional on $\mathbf{T}_N = \mathbf{t}_N$) are calculated, and the score statistic for the observed value,

$$s = (\mathbf{t}_I - \mu_I)' \Sigma_I^{-1} (\mathbf{t}_I - \mu_I)$$

is compared to the score for each member of the distribution

$$S(\mathbf{T}_I) = (\mathbf{T}_I - \mu_I)' \Sigma_I^{-1} (\mathbf{T}_I - \mu_I)$$

The resulting p -value is

$$p(\mathbf{t}_I|\mathbf{t}_N) = \Pr(S \geq s) = \sum_{\mathbf{u} \in \Omega_s} f_0(\mathbf{u}|\mathbf{t}_N)$$

where $\Omega_s = \{\mathbf{u}: \text{there exist } \mathbf{y} \text{ with } \mathbf{y}'\mathbf{X}_I = \mathbf{u}, \mathbf{y}'\mathbf{X}_N = \mathbf{t}_N, \text{ and } S(\mathbf{u}) \geq s\}$.

The mid- p statistic, defined as

$$p(\mathbf{t}_I|\mathbf{t}_N) - \frac{1}{2}f_0(\mathbf{t}_I|\mathbf{t}_N)$$

was proposed by Lancaster (1961) to compensate for the discreteness of a distribution. See Agresti (1992) for more information. However, to allow for more flexibility in handling ties, you can write the mid- p statistic as (based on a suggestion by Lamotte (2002) and generalizing Vollset, Hirji, and Afifi (1991))

$$\sum_{\mathbf{u} \in \Omega_{<}} f_0(\mathbf{u}|\mathbf{t}_N) + \delta_1 f_0(\mathbf{t}_I|\mathbf{t}_N) + \delta_2 \sum_{\mathbf{u} \in \Omega_{=}} f_0(\mathbf{u}|\mathbf{t}_N)$$

where, for $i \in \{p, s\}$, $\Omega_{<}$ is Ω_i using strict inequalities, and $\Omega_{=}$ is Ω_i using equalities with the added restriction that $\mathbf{u} \neq \mathbf{t}_I$. Letting $(\delta_1, \delta_2) = (0.5, 1.0)$ yields Lancaster's mid- p .

CAUTION: When the exact distribution has ties and **METHOD=NETWORKMCMC** is specified, the Monte Carlo algorithm estimates $p(\mathbf{t}|\mathbf{t}_N)$ with error, and hence it cannot determine precisely which values contribute to the reported p -values. For example, if the exact distribution has densities $\{0.2, 0.2, 0.2, 0.4\}$ and if the observed statistic has probability 0.2, then the exact probability p -value is exactly 0.6. Under Monte Carlo sampling, if the densities after N samples are $\{0.18, 0.21, 0.23, 0.38\}$ and the observed probability is 0.21, then the resulting p -value is 0.39. Therefore, the exact probability test p -value for this example fluctuates between 0.2, 0.4, and 0.6, and the reported p -values are actually lower bounds for the true p -values. If you need more precise values, you can specify the **OUTDIST=** option, determine appropriate cutoff values for the observed probability and score, and then construct the true p -value estimates from the **OUTDIST=** data set and display them in the SAS log by using the following statements:

```
data _null_;
  set outdist end=end;
  retain pvalueProb 0 pvalueScore 0;
  if prob < ProbCutOff then pvalueProb+prob;
  if score > ScoreCutOff then pvalueScore+prob;
  if end then put pvalueProb= pvalueScore=;
run;
```

Inference for a Single Parameter

Exact parameter estimates are derived for a single parameter β_i by regarding all the other parameters $\beta_N = (\beta_1, \dots, \beta_{i-1}, \beta_{i+1}, \dots, \beta_{p_N+p_I})'$ as nuisance parameters. The appropriate sufficient statistics are $\mathbf{T}_I = T_i$ and $\mathbf{T}_N = (T_1, \dots, T_{i-1}, T_{i+1}, \dots, T_{p_N+p_I})'$, with their observed values denoted by the lowercase t . Hence, the conditional PDF used to create the parameter estimate for β_i is

$$f_{\beta_i}(t_i|\mathbf{t}_N) = \frac{C(\mathbf{t}_N, t_i) \exp(t_i \beta_i)}{\sum_{\mathbf{u} \in \Omega} C(\mathbf{t}_N, u) \exp(u \beta_i)}$$

for $\Omega = \{u: \text{there exist } \mathbf{y} \text{ with } T_i = u \text{ and } \mathbf{T}_N = \mathbf{t}_N\}$.

The maximum exact conditional likelihood estimate is the quantity $\hat{\beta}_i$, which maximizes the conditional PDF. A Newton-Raphson algorithm is used to perform this search. However, if the observed t_i attains either its maximum or minimum value in the exact distribution (that is, either $t_i = \min\{u : u \in \Omega\}$ or $t_i = \max\{u : u \in \Omega\}$), then the conditional PDF is monotonically increasing in β_i and cannot be maximized. In this case, a median unbiased estimate (Hirji, Tsiatis, and Mehta 1989) $\hat{\beta}_i$ is produced that satisfies $f_{\hat{\beta}_i}(t_i|\mathbf{t}_N) = 0.5$, and a Newton-Raphson algorithm is used to perform the search.

The standard error of the exact conditional likelihood estimate is just the negative of the inverse of the second derivative of the exact conditional log likelihood (Agresti 2002).

Likelihood ratio tests based on the conditional PDF are used to test the null $H_0: \beta_i = 0$ against the alternative $H_A: \beta_i > 0$. The critical region for this UMP test consists of the upper tail of values for T_i in the exact distribution. Thus, the one-sided significance level $p_+(t_i; 0)$ is

$$p_+(t_i; 0) = \sum_{u \geq t_i} f_0(u | \mathbf{t}_N)$$

Similarly, the one-sided significance level $p_-(t_i; 0)$ against $H_A: \beta_i < 0$ is

$$p_-(t_i; 0) = \sum_{u \leq t_i} f_0(u | \mathbf{t}_N)$$

The two-sided significance level $p(t_i; 0)$ against $H_A: \beta_i \neq 0$ is calculated as

$$p(t_i; 0) = 2 \min[p_-(t_i; 0), p_+(t_i; 0)]$$

An upper $100(1 - 2\epsilon)\%$ exact confidence limit for $\hat{\beta}_i$ corresponding to the observed t_i is the solution $\beta_U(t_i)$ of $\epsilon = p_-(t_i, \beta_U(t_i))$, while the lower exact confidence limit is the solution $\beta_L(t_i)$ of $\epsilon = p_+(t_i, \beta_L(t_i))$. Again, a Newton-Raphson procedure is used to search for the solutions. Note that one of the confidence limits for a median unbiased estimate is set to infinity, but the other is still computed at ϵ . This results in the display of a one-sided $100(1 - \epsilon)\%$ confidence interval; if you want the 2ϵ limit instead, you can specify the **ONESIDED** option.

Specifying the **ONESIDED** option displays only one p -value and one confidence interval, because small values of $p_+(t_i; 0)$ and $p_-(t_i; 0)$ support different alternative hypotheses and only one of these p -values can be less than 0.50.

The mid- p confidence limits are the solutions to $\min\{p_-(t_i, \beta(t_i)), p_+(t_i, \beta(t_i))\} - (1 - \delta_1) f_{\beta(t_i)}(t_i | \mathbf{t}_N) = \epsilon$ for $\epsilon = \alpha/2, 1 - \alpha/2$ (Vollset, Hirji, and Afifi 1991). $\delta_1 = 1$ produces the usual exact (or *max-p*) confidence interval, $\delta_1 = 0.5$ yields the mid- p interval, and $\delta_1 = 0$ gives the *min-p* interval. The mean of the endpoints of the *max-p* and *min-p* intervals provides the *mean-p* interval as defined by Hirji, Mehta, and Patel (1988).

Estimates and confidence intervals for the odds ratios are produced by exponentiating the estimates and interval endpoints for the parameters.

Notes about Exact p -Values

In the “Conditional Exact Tests” table, the exact probability test is not necessarily a sum of tail areas and can be inflated if the distribution is skewed. The more robust exact conditional scores test is a sum of tail areas and is generally preferred over the exact probability test.

The p -value reported for a single parameter in the “Exact Parameter Estimates” table is twice the one-sided tail area of a likelihood ratio test against the null hypothesis of the parameter equaling zero.

Input and Output Data Sets

OUTEST= Output Data Set

The **OUTEST=** data set contains one observation for each BY group containing the maximum likelihood estimates of the regression coefficients. If you also use the **COVOUT** option in the PROC LOGISTIC statement, there are additional observations containing the rows of the estimated covariance matrix. If you specify **SELECTION=FORWARD**, **BACKWARD**, or **STEPWISE**, only the estimates of the parameters and covariance matrix for the final model are output to the OUTEST= data set.

Variables in the OUTEST= Data Set

The OUTEST= data set contains the following variables:

- any BY variables specified
- **_LINK_**, a character variable of length 8 with four possible values: CLOGLOG for the complementary log-log function, LOGIT for the logit function, NORMIT for the probit (alias normit) function, and GLOGIT for the generalized logit function
- **_TYPE_**, a character variable of length 8 with two possible values: PARMS for parameter estimates or COV for covariance estimates. If an EXACT statement is also specified, then two other values are possible: EPARMMLE for the exact maximum likelihood estimates and EPARMMUE for the exact median unbiased estimates.
- **_NAME_**, a character variable containing the name of the response variable when **_TYPE_=PARMS**, EPARMMLE, and EPARMMUE, or the name of a model parameter when **_TYPE_=COV**
- **_STATUS_**, a character variable that indicates whether the estimates have converged
- one variable for each intercept parameter
- one variable for each slope parameter and one variable for the offset variable if the **OFFSET=** option is specified. If an effect is not included in the final model in a model building process, the corresponding parameter estimates and covariances are set to missing values.
- **_LNLIKE_**, the log likelihood

Parameter Names in the OUTEST= Data Set

If there are only two response categories in the entire data set, the intercept parameter is named Intercept. If there are more than two response categories in the entire data set, the intercept parameters are named Intercept_xxx, where xxx is the value (formatted if a format is applied) of the corresponding response category.

For continuous explanatory variables, the names of the parameters are the same as the corresponding variables. For CLASS variables, the parameter names are obtained by concatenating the corresponding CLASS variable name with the CLASS category; see the section “[Class Variable Naming Convention](#)” on page 4189 for more details. For interaction and nested effects, the parameter names are created by concatenating the names of each effect.

For the generalized logit model, names of parameters corresponding to each nonreference category contain _xxx as the suffix, where xxx is the value (formatted if a format is applied) of the corresponding nonreference

category. For example, suppose the variable Net3 represents the television network (ABC, CBS, and NBC) viewed at a certain time. The following statements fit a generalized logit model with Age and Gender (a CLASS variable with values Female and Male) as explanatory variables:

```
proc logistic;
  class Gender;
  model Net3 = Age Gender / link=glogit;
run;
```

There are two logit functions, one contrasting ABC with NBC and the other contrasting CBS with NBC. For each logit, there are three parameters: an intercept parameter, a slope parameter for Age, and a slope parameter for Gender (since there are only two gender levels and the EFFECT parameterization is used by default). The names of the parameters and their descriptions are as follows:

Intercept_ABC	intercept parameter for the logit contrasting ABC with NBC
Intercept_CBS	intercept parameter for the logit contrasting CBS with NBC
Age_ABC	Age slope parameter for the logit contrasting ABC with NBC
Age_CBS	Age slope parameter for the logit contrasting CBS with NBC
GenderFemale_ABC	Gender=Female slope parameter for the logit contrasting ABC with NBC
GenderFemale_CBS	Gender=Female slope parameter for the logit contrasting CBS with NBC

INEST= Input Data Set

You can specify starting values for the iterative algorithm in the **INEST=** data set. The **INEST=** data set has the same structure as the **OUTEST=** data set but is not required to have all the variables or observations that appear in the **OUTEST=** data set. A previous **OUTEST=** data set can be used as, or modified for use as, an **INEST=** data set.

The **INEST=** data set must contain the intercept variables (named Intercept for binary response models and Intercept, Intercept_2, Intercept_3, and so forth, for ordinal and nominal response models) and all explanatory variables in the **MODEL** statement. If BY processing is used, the **INEST=** data set should also include the BY variables, and there must be one observation for each BY group. If the **INEST=** data set also contains the **_TYPE_** variable, only observations with **_TYPE_** value 'PARMS' are used as starting values.

OUT= Output Data Set in the OUTPUT Statement

The **OUT=** data set in the **OUTPUT** statement contains all the variables in the input data set along with statistics you request by specifying *keyword=name* options or the **PREDPROBS=** option in the **OUTPUT** statement. In addition, if you use the single-trial syntax and you request any of the **XBETA=**, **STDXBETA=**, **PREDICTED=**, **LCL=**, and **UCL=** options, the **OUT=** data set contains the automatic variable **_LEVEL_**. The value of **_LEVEL_** identifies the response category upon which the computed values of **XBETA=**, **STDXBETA=**, **PREDICTED=**, **LCL=**, and **UCL=** are based.

When there are more than two response levels, only variables named by the **XBETA=**, **STDXBETA=**, **PREDICTED=**, **LOWER=**, and **UPPER=** options and the variables given by **PREDPROBS=(INDIVIDUAL CUMULATIVE)** have their values computed; the other variables have missing values. If you fit a generalized logit model, the cumulative predicted probabilities are not computed.

When there are only two response categories, each input observation produces one observation in the OUT= data set.

If there are more than two response categories and you specify only the PREDPROBS= option, then each input observation produces one observation in the OUT= data set. However, if you fit an ordinal (cumulative) model and specify options other than the PREDPROBS= options, each input observation generates as many output observations as one fewer than the number of response levels, and the predicted probabilities and their confidence limits correspond to the cumulative predicted probabilities. If you fit a generalized logit model and specify options other than the PREDPROBS= options, each input observation generates as many output observations as the number of response categories; the predicted probabilities and their confidence limits correspond to the probabilities of individual response categories.

For observations in which only the response variable is missing, values of the XBETA=, STDXBETA=, PREDICTED=, UPPER=, LOWER=, and the PREDPROBS= options are computed even though these observations do not affect the model fit. This enables, for instance, predicted probabilities to be computed for new observations.

OUT= Output Data Set in a SCORE Statement

The OUT= data set in a SCORE statement contains all the variables in the data set being scored. The data set being scored can be either the input DATA= data set in the PROC LOGISTIC statement or the DATA= data set in the SCORE statement. The DATA= data set in the SCORE statement does not need to contain the response variable.

If the data set being scored contains the response variable, then denote the *normalized* levels (left-justified, formatted values of 16 characters or less) of your response variable Y by Y_1, \dots, Y_{k+1} . For each response level, the OUT= data set also contains the following:

- F_Y, the normalized levels of the response variable Y in the data set being scored. If the events/trials syntax is used, the F_Y variable is not created.
- I_Y, the normalized levels that the observations are classified into. Note that an observation is classified into the level with the largest probability. If the events/trials syntax is used, the _INTO_ variable is created instead, and it contains the values EVENT and NONEVENT.
- P_Y_i, the posterior probabilities of the normalized response level Y_i
- If the CLM option is specified in the SCORE statement, the OUT= data set also includes the following:
 - LCL_Y_i, the lower 100(1 – α)% confidence limits for P_Y_i
 - UCL_Y_i, the upper 100(1 – α)% confidence limits for P_Y_i

OUTDIST= Output Data Set

The OUTDIST= data set contains every exact conditional distribution necessary to process the corresponding EXACT statement. For example, the following statements create one distribution for the x1 parameter and another for the x2 parameters, and produce the data set dist shown in Table 54.12:

```

data test;
  input y x1 x2 count;
  datalines;
0 0 0 1
1 0 0 1
0 1 1 2
1 1 1 1
1 0 2 3
1 1 2 1
1 2 0 3
1 2 1 2
1 2 2 1
;

proc logistic data=test exactonly;
  class x2 / param=ref;
  model y=x1 x2;
  exact x1 x2/ outdist=dist;
run;
proc print data=dist;
run;

```

Table 54.12 OUTDIST= Data Set

Obs	x1	x20	x21	Count	Score	Prob
1	.	0	0	3	5.81151	0.03333
2	.	0	1	15	1.66031	0.16667
3	.	0	2	9	3.12728	0.10000
4	.	1	0	15	1.46523	0.16667
5	.	1	1	18	0.21675	0.20000
6	.	1	2	6	4.58644	0.06667
7	.	2	0	19	1.61869	0.21111
8	.	2	1	2	3.27293	0.02222
9	.	3	0	3	6.27189	0.03333
10	2	.	.	6	3.03030	0.12000
11	3	.	.	12	0.75758	0.24000
12	4	.	.	11	0.00000	0.22000
13	5	.	.	18	0.75758	0.36000
14	6	.	.	3	3.03030	0.06000

The first nine observations in the dist data set contain an exact distribution for the parameters of the x2 effect (hence the values for the x1 parameter are missing), and the remaining five observations are for the x1 parameter. If a joint distribution was created, there would be observations with values for both the x1 and x2 parameters. For **CLASS** variables, the corresponding parameters in the dist data set are identified by concatenating the variable name with the appropriate classification level.

The data set contains the possible sufficient statistics of the parameters for the effects specified in the **EXACT** statement, and the Count variable contains the number of different responses that yield these statistics. In particular, there are six possible response vectors y for which the dot product $y'x_1$ was equal to 2, and

for which $y'x_{20}$, $y'x_{21}$, and $y'1$ were equal to their actual observed values (displayed in the “Sufficient Statistics” table).

When hypothesis tests are performed on the parameters, the **Prob** variable contains the probability of obtaining that statistic (which is just the count divided by the total count), and the **Score** variable contains the score for that statistic.

The **OUTDIST=** data set can contain a different exact conditional distribution for each specified **EXACT** statement. For example, consider the following **EXACT** statements:

```
exact 'O1'    x1    /          outdist=o1;
exact 'OJ12' x1 x2 / jointonly outdist=oj12;
exact 'OA12' x1 x2 / joint     outdist=oa12;
exact 'OE12' x1 x2 / estimate  outdist=oe12;
```

The **O1** statement outputs a single exact conditional distribution. The **OJ12** statement outputs only the joint distribution for x_1 and x_2 . The **OA12** statement outputs three conditional distributions: one for x_1 , one for x_2 , and one jointly for x_1 and x_2 . The **OE12** statement outputs two conditional distributions: one for x_1 and the other for x_2 . Data set **oe12** contains both the x_1 and x_2 variables; the distribution for x_1 has missing values in the x_2 column while the distribution for x_2 has missing values in the x_1 column.

OUTROC= Output Data Set

The **OUTROC=** data set contains data necessary for producing the ROC curve, and can be created by specifying the **OUTROC=** option in the **MODEL** statement or the **OUTROC=** option in the **SCORE** statement: It has the following variables:

- any **BY** variables specified
- **_STEP_**, the model step number. This variable is not included if model selection is not requested.
- **_PROB_**, the estimated probability of an event. These estimated probabilities serve as cutpoints for predicting the response. Any observation with an estimated event probability that exceeds or equals **_PROB_** is predicted to be an event; otherwise, it is predicted to be a nonevent. Predicted probabilities that are close to each other are grouped together, with the maximum allowable difference between the largest and smallest values less than a constant that is specified by the **ROCEPS=** option. The smallest estimated probability is used to represent the group.
- **_POS_**, the number of correctly predicted event responses
- **_NEG_**, the number of correctly predicted nonevent responses
- **_FALPOS_**, the number of falsely predicted event responses
- **_FALNEG_**, the number of falsely predicted nonevent responses
- **_SENSIT_**, the sensitivity, which is the proportion of event observations that were predicted to have an event response
- **_1MSPEC_**, one minus specificity, which is the proportion of nonevent observations that were predicted to have an event response

Note that none of these statistics are affected by the bias-correction method discussed in the section “[Classification Table](#)” on page 4255. An ROC curve is obtained by plotting `_SENSIT_` against `_1MSPEC_`.

For more information, see the section “[Receiver Operating Characteristic Curves](#)” on page 4260.

Computational Resources

The memory needed to fit an unconditional model is approximately $8n(p + 2) + 24(p + 2)^2$ bytes, where p is the number of parameters estimated and n is the number of observations in the data set. For cumulative response models with more than two response levels, a test of the parallel lines assumption requires an additional memory of approximately $4k^2(m + 1)^2 + 24(m + 2)^2$ bytes, where k is the number of response levels and m is the number of slope parameters. However, if this additional memory is not available, the procedure skips the test and finishes the other computations. You might need more memory if you use the `SELECTION=` option for model building.

The data that consist of relevant variables (including the design variables for model effects) and observations for fitting the model are stored in a temporary utility file. If sufficient memory is available, such data will also be kept in memory; otherwise, the data are reread from the utility file for each evaluation of the likelihood function and its derivatives, with the resulting execution time of the procedure substantially increased. Specifying the `MULTIPASS` option in the `MODEL` statement avoids creating this utility file and also does not store the data in memory; instead, the `DATA=` data set is reread when needed. This saves approximately $8n(p + 2)$ bytes of memory but increases the execution time.

If a conditional logistic regression is performed, then approximately $4(m^2 + m + 4) \max_h(m_h) + (8s_H + 36)H + 12s_H$ additional bytes of memory are needed, where m_h is the number of events in stratum h , H is the total number of strata, and s_H is the number of variables used to define the strata. If the `CHECK-DEPENDENCY=ALL` option is specified in the `STRATA` statement, then an extra $4(m + H)(m + H + 1)$ bytes are required, and the resulting execution time of the procedure might be substantially increased.

Computational Resources for Exact Logistic Regression

Many problems require a prohibitive amount of time and memory for exact computations, depending on the speed and memory available on your computer. For such problems, consider whether exact methods are really necessary. Stokes, Davis, and Koch (2012) suggest looking at exact p -values when the sample size is small and the approximate p -values from the unconditional analysis are less than 0.10, and they provide *rules of thumb* for determining when various models are valid.

A formula does not exist that can predict the amount of time and memory necessary to generate the exact conditional distributions for a particular problem. The time and memory required depends on several factors, including the total sample size, the number of parameters of interest, the number of nuisance parameters, and the order in which the parameters are processed. To provide a feel for how these factors affect performance, 19 data sets containing $\text{Nobs} \in \{10, \dots, 500\}$ observations consisting of up to 10 independent uniform binary covariates (X_1, \dots, X_N) and a binary response variable (Y), are generated, and the following statements create exact conditional distributions for X_1 conditional on the other covariates by using the default `METHOD=NETWORK`. [Figure 54.11](#) displays results obtained on a 400Mhz PC with 768MB RAM running Microsoft Windows NT.

```
data one;
  do obs=1 to HalfNobs;
```

```

do Y=0 to 1;
  X1=round(ranuni(0));
  ...
  XN=round(ranuni(0));
  output;
end;
end;
options fullstimer;
proc logistic exactonly;
  exactoptions method=network maxtime=1200;
  class X1...XN / param=ref;
  model Y=X1...XN;
  exact X1 / outdist=dist;
run;

```

Figure 54.11 Mean Time and Memory Required

At any time while PROC LOGISTIC is deriving the distributions, you can terminate the computations by pressing the system interrupt key sequence (see the SAS Companion for your system) and choosing to stop computations. If you run out of memory, see the SAS Companion for your system to see how to allocate more.

You can use the [EXACTOPTIONS](#) option [MAXTIME=](#) to limit the total amount of time PROC LOGISTIC uses to derive all of the exact distributions. If PROC LOGISTIC does not finish within that time, the procedure terminates.

Calculation of frequencies are performed in the log scale by default. This reduces the need to check for excessively large frequencies but can be slower than not scaling. You can turn off the log scaling by specifying the [NOLOGSCALE](#) option in the [EXACTOPTIONS](#) statement. If a frequency in the exact distribution is larger than the largest integer that can be held in double precision, a warning is printed to the SAS log. But

since inaccuracies due to adding small numbers to these large frequencies might have little or no effect on the statistics, the exact computations continue.

You can monitor the progress of the procedure by submitting your program with the **EXACTOPTIONS** option **STATUSTIME=**. If the procedure is too slow, you can try another method by specifying the **EXACTOPTIONS** option **METHOD=**, you can try reordering the variables in the **MODEL** statement (note that **CLASS** variables are always processed before continuous covariates), or you can try reparameterizing your classification variables as in the following statement:

```
class class-variables / param=ref ref=first order=freq;
```

Displayed Output

If you use the **NOPRINT** option in the **PROC LOGISTIC** statement, the procedure does not display any output. Otherwise, the tables displayed by the LOGISTIC procedure are discussed in the following section in the order in which they appear in the output. Some of the tables appear only in conjunction with certain options or statements; see the section “**ODS Table Names**” on page 4291 for details.

NOTE: The **EFFECT**, **ESTIMATE**, **LSMEANS**, **LSMESTIMATE**, and **SLICE** statements also create tables, which are not listed in this section. For information about these tables, see the corresponding sections of Chapter 19, “**Shared Concepts and Topics**.”

Table Summary

Model Information and the Number of Observations

See the section “**Missing Values**” on page 4237 for information about missing-value handling, and the sections “**FREQ Statement**” on page 4203 and “**WEIGHT Statement**” on page 4236 for information about valid frequencies and weights.

Response Profile

Displays the Ordered Value assigned to each response level. See the section “**Response Level Ordering**” on page 4237 for details.

Class Level Information

Displays the design values for each **CLASS** explanatory variable. See the section “**Other Parameterizations**” on page 387 in Chapter 19, “**Shared Concepts and Topics**,” for details.

Simple Statistics Tables

The following tables are displayed if you specify the **SIMPLE** option in the **PROC LOGISTIC** statement:

- **Descriptive Statistics for Continuous Explanatory Variables**
- **Frequency Distribution of Class Variables**
- **Weight Distribution of Class Variables**
Displays if you also specify a **WEIGHT** statement.

Strata Tables for (Exact) Conditional Logistic Regression

The following tables are displayed if you specify a **STRATA** statement:

- **Strata Summary**
Shows the pattern of the number of events and the number of nonevents in a stratum. See the section “**STRATA Statement**” on page 4233 for more information.
- **Strata Information**
Displays if you specify the **INFO** option in a **STRATA** statement.

Maximum Likelihood Iteration History

Displays if you specify the **ITPRINT** option in the **MODEL** statement. See the sections “**Iterative Algorithms for Model Fitting**” on page 4240, “**Convergence Criteria**” on page 4242, and “**Existence of Maximum Likelihood Estimates**” on page 4242 for details.

Deviance and Pearson Goodness-of-Fit Statistics

Displays if you specify the **SCALE=** option in the **MODEL** statement. Small p -values reject the null hypothesis that the fitted model is adequate. See the section “**Overdispersion**” on page 4257 for details.

Score Test for the Equal Slopes (Proportional Odds) Assumption

Tests the parallel lines assumption if you fit an ordinal response model with the **LINK=CLOGLOG** or **LINK=PROBIT** options. If you specify **LINK=LOGIT**, this is called the “Proportional Odds” assumption. The table is not displayed if you specify the **UNEQUALSLOPES** option in the **MODEL** statement. Small p -values reject the null hypothesis that the slope parameters for each explanatory variable are constant across all the response functions. See the section “**Testing the Parallel Lines Assumption**” on page 4248 for details.

Model Fit Statistics

Computes various fit criteria based on a model with intercepts only and a model with intercepts and explanatory variables. If you specify the **NOINT** option in the **MODEL** statement, these statistics are calculated without considering the intercept parameters. See the section “**Model Fitting Information**” on page 4245 for details.

Testing Global Null Hypothesis: BETA=0

Tests the joint effect of the explanatory variables included in the model. Small p -values reject the null hypothesis that all slope parameters are equal to zero, $H_0: \beta = \mathbf{0}$. See the sections “**Model Fitting Information**” on page 4245, “**Residual Chi-Square**” on page 4247, and “**Testing Linear Hypotheses about the Regression Coefficients**” on page 4262 for details. If you also specify the **RSQUARE** option in the **MODEL** statement, two generalized R Square measures are included; see the section “**Generalized Coefficient of Determination**” on page 4246 for details.

Score Test for Global Null Hypothesis

Displays instead of the “Testing Global Null Hypothesis: BETA=0” table if the **NOFIT** option is specified in the **MODEL** statement. The global score test evaluates the joint significance of the effects in the **MODEL** statement. Small p -values reject the null hypothesis that all slope parameters are equal to zero, $H_0: \beta = \mathbf{0}$. See the section “**Residual Chi-Square**” on page 4247 for details.

Model Selection Tables

The tables in this section are produced when the **SELECTION=** option is specified in the **MODEL** statement. See the section “[Effect-Selection Methods](#)” on page 4244 for more information.

- **Residual Chi-Square Test**

Displays if you specify **SELECTION=FORWARD**, **BACKWARD**, or **STEPWISE** in the **MODEL** statement. Small p -values reject the null hypothesis that the reduced model is adequate. See the section “[Residual Chi-Square](#)” on page 4247 for details.

- **Analysis of Effects Eligible for Entry**

Displays if you specify the **DETAILS** option and the **SELECTION=FORWARD** or **STEPWISE** option in the **MODEL** statement. Small p -values reject $H_0: \beta_i \neq 0$. The score chi-square is used to determine entry; see the section “[Testing Individual Effects Not in the Model](#)” on page 4247 for details.

- **Analysis of Effects Eligible for Removal**

Displays if you specify the **SELECTION=BACKWARD** or **STEPWISE** option in the **MODEL** statement. Small p -values reject $H_0: \beta_i = 0$. The Wald chi-square is used to determine removal; see the section “[Testing Linear Hypotheses about the Regression Coefficients](#)” on page 4262 for details.

- **Analysis of Effects Removed by Fast Backward Elimination**

Displays if you specify the **FAST** option and the **SELECTION=BACKWARD** or **STEPWISE** option in the **MODEL** statement. This table gives the approximate chi-square statistic for the variable removed, the corresponding p -value with respect to a chi-square distribution with one degree of freedom, the residual chi-square statistic for testing the joint significance of the variable and the preceding ones, the degrees of freedom, and the p -value of the residual chi-square with respect to a chi-square distribution with the corresponding degrees of freedom.

- **Summary of Forward, Backward, and Stepwise Selection**

Displays if you specify **SELECTION=FORWARD**, **BACKWARD**, or **STEPWISE** in the **MODEL** statement. The score chi-square is used to determine entry; see the section “[Testing Individual Effects Not in the Model](#)” on page 4247 for details. The Wald chi-square is used to determine removal; see the section “[Testing Linear Hypotheses about the Regression Coefficients](#)” on page 4262 for details.

- **Regression Models Selected by Score Criterion**

Displays the score chi-square for all models if you specify the **SELECTION=SCORE** option in the **MODEL** statement. Small p -values reject the null hypothesis that the fitted model is adequate. See the section “[Effect-Selection Methods](#)” on page 4244 for details.

Type 3 Analysis of Effect

Displays if the model contains a **CLASS** variable. Performs Wald chi-square tests of the joint effect of the parameters for each **CLASS** variable in the model. Small p -values reject $H_0: \beta_i = 0$. See the section “[Testing Linear Hypotheses about the Regression Coefficients](#)” on page 4262 for details.

Analysis of Maximum Likelihood Estimates

CLASS effects are identified by their (nonreference) level. For generalized logit models, a response variable column displays the nonreference level of the logit. The table includes the following:

- the estimated standard error of the parameter estimate, computed as the square root of the corresponding diagonal element of the estimated covariance matrix
- the Wald chi-square statistic, computed by squaring the ratio of the parameter estimate divided by its standard error estimate. See the section “[Testing Linear Hypotheses about the Regression Coefficients](#)” on page 4262 for details.
- the p -value tests the null hypothesis $H_0: \beta_i = 0$; small values reject the null.
- the standardized estimate for the slope parameter, if you specify the **STB** option in the **MODEL** statement. See the **STB** option on page 4220 for details.
- exponentiated values of the estimates of the slope parameters, if you specify the **EXPB** option in the **MODEL** statement. See the **EXPB** option on page 4212 for details.
- the label of the variable, if you specify the **PARMLABEL** option in the **MODEL** statement and if space permits. Due to constraints on the line size, the variable label might be suppressed in order to display the table in one panel. Use the SAS system option **LINESIZE=** to specify a larger line size to accommodate variable labels. A shorter line size can break the table into two panels allowing labels to be displayed.

Odds Ratio Estimates

Displays the odds ratio estimates and the corresponding 95% Wald confidence intervals for variables that are not involved in nestings or interactions. For continuous explanatory variables, these odds ratios correspond to a unit increase in the risk factors. See the section “[Odds Ratio Estimation](#)” on page 4250 for details.

Association of Predicted Probabilities and Observed Responses

See the section “[Rank Correlation of Observed Responses and Predicted Probabilities](#)” on page 4253 for details.

Parameter Estimates and Profile-Likelihood or Wald Confidence Intervals

Displays if you specify the **CLPARM=** option in the **MODEL** statement. See the section “[Confidence Intervals for Parameters](#)” on page 4248 for details.

Odds Ratio Estimates and Profile-Likelihood or Wald Confidence Intervals

Displays if you specify the **ODDSRATIO** statement for any effects with any class parameterizations. Also displays if you specify the **CLODDS=** option in the **MODEL** statement, except odds ratios are computed only for main effects not involved in interactions or nestings, and if the main effect is a **CLASS** variable, the parameterization must be **EFFECT**, **REFERENCE**, or **GLM**. See the section “[Odds Ratio Estimation](#)” on page 4250 for details.

Estimated Covariance or Correlation Matrix

Displays if you specify the **COVB** or **CORRB** option in the **MODEL** statement. See the section “[Iterative Algorithms for Model Fitting](#)” on page 4240 for details.

Contrast Test Results

Displays the Wald test for each specified **CONTRAST** statement. Small p -values reject $H_0: \mathbf{L}\boldsymbol{\beta} = \mathbf{0}$. The “Coefficients of Contrast” table displays the contrast matrix if you specify the **E** option, and the “Contrast Estimation and Testing Results by Row” table displays estimates and Wald tests for each row of the contrast matrix if you specify the **ESTIMATE=** option. See the sections “**CONTRAST Statement**” on page 4190, “**Testing Linear Hypotheses about the Regression Coefficients**” on page 4262, and “**Linear Predictor, Predicted Probability, and Confidence Limits**” on page 4253 for details.

Linear Hypotheses Testing Results

Displays the Wald test for each specified **TEST** statement. See the sections “**Testing Linear Hypotheses about the Regression Coefficients**” on page 4262 and “**TEST Statement**” on page 4234 for details.

Hosmer and Lemeshow Goodness-of-Fit Test

Displays if you specify the **LACKFIT** option in the **MODEL** statement. Small p -values reject the null hypothesis that the fitted model is adequate. The “Partition for the Hosmer and Lemeshow Test” table displays the grouping used in the test. See the section “**The Hosmer-Lemeshow Goodness-of-Fit Test**” on page 4259 for details.

Classification Table

Displays if you use the **CTABLE** option in the **MODEL** statement. If you specify a list of cutpoints with the **PPROB=** option, then the cutpoints are displayed in the Prob Level column. If you specify the prior event probabilities with the **PEVENT=** option, then the probabilities are displayed in the Prob Event column. The Correct column displays the number of correctly classified events and nonevents, the Incorrect Event column displays the number of nonevents incorrectly classified as events, and the Incorrect Nonevent column gives the number of nonevents incorrectly classified as events. See the section “**Classification Table**” on page 4255 for more details.

Regression Diagnostics

Displays if you specify the **INFLUENCE** option in the **MODEL** statement. See the section “**Regression Diagnostics**” on page 4263 for more information about diagnostics from an unconditional analysis, and the section “**Regression Diagnostic Details**” on page 4272 for information about diagnostics from a conditional analysis.

Fit Statistics for SCORE Data

Displays if you specify the **FITSTAT** option in the **SCORE** statement. See the section “**Scoring Data Sets**” on page 4266 for details.

ROC Association Statistic and Contrast Tables

Displayed if a **ROC** statement or a **ROCONTRAST** statement is specified. See the section “**ROC Computations**” on page 4261 for details about the Mann-Whitney statistics and the test and estimation computations, and see the section “**Rank Correlation of Observed Responses and Predicted Probabilities**” on page 4253 for details about the other statistics.

Exact Conditional Logistic Regression Tables

The tables in this section are produced when the **EXACT** statement is specified. If the **METHOD=NETWORKMC** option is specified, the test and estimate tables are renamed “Monte Carlo” tables and a Monte Carlo standard error column ($\sqrt{p(1-p)/n}$) is displayed.

- **Sufficient Statistics**

Displays if you request an **OUTDIST=** data set in an **EXACT** statement. The table lists the parameters and their observed sufficient statistics.

- **(Monte Carlo) Conditional Exact Tests**

See the section “[Hypothesis Tests](#)” on page 4276 for details.

- **(Monte Carlo) Exact Parameter Estimates**

Displays if you specify the **ESTIMATE** option in the **EXACT** statement. This table gives individual parameter estimates for each variable (conditional on the values of all the other parameters in the model), confidence limits, and a two-sided p -value (twice the one-sided p -value) for testing that the parameter is zero. See the section “[Inference for a Single Parameter](#)” on page 4277 for details.

- **(Monte Carlo) Exact Odds Ratios**

Displays if you specify the **ESTIMATE=ODDS** or **ESTIMATE=BOTH** option in the **EXACT** statement. See the section “[Inference for a Single Parameter](#)” on page 4277 for details.

ODS Table Names

PROC LOGISTIC assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 54.13](#). For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

The EFFECT, ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements also create tables, which are not listed in [Table 54.13](#). For information about these tables, see the corresponding sections of Chapter 19, “[Shared Concepts and Topics](#).”

Table 54.13 ODS Tables Produced by PROC LOGISTIC

ODS Table Name	Description	Statement	Option
Association	Association of predicted probabilities and observed responses	MODEL (without STRATA)	Default
BestSubsets	Best subset selection	MODEL	SELECTION=SCORE
ClassFreq	Frequency breakdown of CLASS variables	PROC	Simple (with CLASS vars)
ClassLevelInfo	CLASS variable levels and design variables	MODEL	Default (with CLASS vars)
Classification	Classification table	MODEL	CTABLE
ClassWgt	Weight breakdown of CLASS variables	PROC, WEIGHT	Simple (with CLASS vars)
CLOddsPL	Odds ratio estimates and profile-likelihood confidence intervals	MODEL	CLODDS=PL
CLOddsWald	Odds ratio estimates and Wald confidence intervals	MODEL	CLODDS=WALD

Table 54.13 continued

ODS Table Name	Description	Statement	Option
CLParmPL	Parameter estimates and profile-likelihood confidence intervals	MODEL	CLPARM=PL
CLParmWald	Parameter estimates and Wald confidence intervals	MODEL	CLPARM=WALD
ContrastCoeff	L matrix from CONTRAST	CONTRAST	E
ContrastEstimate	Estimates from CONTRAST	CONTRAST	ESTIMATE=
ContrastTest	Wald test for CONTRAST	CONTRAST	Default
ConvergenceStatus	Convergence status	MODEL	Default
CorrB	Estimated correlation matrix of parameter estimators	MODEL	CORRB
CovB	Estimated covariance matrix of parameter estimators	MODEL	COVB
CumulativeModelTest	Test of the cumulative model assumption	MODEL	(Ordinal response)
EffectNotInModel	Test for effects not in model	MODEL	SELECTION=SIF
ExactOddsRatio	Exact odds ratios	EXACT	ESTIMATE=ODDS, ESTIMATE=BOTH
ExactParmEst	Parameter estimates	EXACT	ESTIMATE, ESTIMATE=PARM, ESTIMATE=BOTH
ExactTests	Conditional exact tests	EXACT	Default
FastElimination	Fast backward elimination	MODEL	SELECTION=B,FAST
FitStatistics	Model fit statistics	MODEL	Default
GlobalScore	Global score test	MODEL	NOFIT
GlobalTests	Test for global null hypothesis	MODEL	Default
GoodnessOfFit	Pearson and deviance goodness-of-fit tests	MODEL	SCALE
IndexPlots	Batch capture of the index plots	MODEL	IPLOTS
Influence	Regression diagnostics	MODEL	INFLUENCE
IterHistory	Iteration history	MODEL	ITPRINT
LackFitChiSq	Hosmer-Lemeshow chi-square test results	MODEL	LACKFIT
LackFitPartition	Partition for the Hosmer-Lemeshow test	MODEL	LACKFIT
LastGradient	Last evaluation of gradient	MODEL	ITPRINT
Linear	Linear combination	PROC	Default
LogLikeChange	Final change in the log likelihood	MODEL	ITPRINT
ModelBuildingSummary	Summary of model building	MODEL	SELECTION=BIFIS
ModelInfo	Model information	PROC	Default
NObs	Number of observations	PROC	Default

Table 54.13 continued

ODS Table Name	Description	Statement	Option
OddsEst	Adjusted odds ratios	UNITS	Default
OddsRatios	Odds ratio estimates	MODEL	Default
OddsRatiosWald	Odds ratio estimates and Wald confidence intervals	ODDSRATIOS	CL=WALD
OddsRatiosPL	Odds ratio estimates and PL confidence intervals	ODDSRATIOS	CL=PL
ParameterEstimates	Maximum likelihood estimates of model parameters	MODEL	Default
RSquare	R-square	MODEL	RSQUARE
ResidualChiSq	Residual chi-square	MODEL	SELECTION=FIB
ResponseProfile	Response profile	PROC	Default
ROCAssociation	Association table for ROC models	ROC	Default
ROCContrastCoeff	L matrix from ROCCONTRAST	ROCCONTRAST	E
ROCContrastCov	Covariance of ROCCONTRAST rows	ROCCONTRAST	COV
ROCContrastEstimate	Estimates from ROCCONTRAST	ROCCONTRAST	ESTIMATE=
ROCContrastTest	Wald test from ROCCONTRAST	ROCCONTRAST	Default
ROCCov	Covariance between ROC curves	ROCCONTRAST	COV
ScoreFitStat	Fit statistics for Scored data	SCORE	FITSTAT
SimpleStatistics	Summary statistics for explanatory variables	PROC	SIMPLE
StrataSummary	Number of strata with specific response frequencies	STRATA	Default
StrataInfo	Event and nonevent frequencies for each stratum	STRATA	INFO
SuffStats	Sufficient statistics	EXACT	OUTDIST=
TestPrint1	$L[Cov(\mathbf{b})]L'$ and $L\mathbf{b}-\mathbf{c}$	TEST	PRINT
TestPrint2	$G_{inv}(L[Cov(\mathbf{b})]L')$ and $G_{inv}(L[Cov(\mathbf{b})]L')(\mathbf{Lb}-\mathbf{c})$	TEST	PRINT
TestStmts	Linear hypotheses testing results	TEST	Default
Type3	Type 3 tests of effects	MODEL	Default (with CLASS variables)

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

You must also specify the options in the PROC LOGISTIC statement that are indicated in [Table 54.14](#).

When ODS Graphics is enabled, then the EFFECT, EFFECTPLOT, ESTIMATE, LSMEANS, LSMESTIMATE, and SLICE statements can produce plots that are associated with their analyses. For information about these plots, see the corresponding sections of Chapter 19, “[Shared Concepts and Topics](#).”

PROC LOGISTIC assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in [Table 54.14](#).

Table 54.14 Graphs Produced by PROC LOGISTIC

ODS Graph Name	Plot Description	Statement or Option
DfBetasPlot	Panel of dfbetas by case number	PLOTS=DFBETAS or MODEL / INFLUENCE or IPLOTS

Examples: LOGISTIC Procedure

Example 54.1: Stepwise Logistic Regression and Predicted Values

Consider a study on cancer remission (Lee 1974). The data consist of patient characteristics and whether or not cancer remission occurred. The following DATA step creates the data set Remission containing seven variables. The variable remiss is the cancer remission indicator variable with a value of 1 for remission and a value of 0 for nonremission. The other six variables are the risk factors thought to be related to cancer remission.

```
data Remission;
  input remiss cell smear infil li blast temp;
  label remiss='Complete Remission';
  datalines;
1   .8   .83   .66   1.9   1.1       .996
1   .9   .36   .32   1.4   .74       .992
```

```

0   .8   .88   .7   .8   .176   .982
0  1     .87   .87   .7  1.053   .986
1   .9   .75   .68  1.3   .519   .98
0  1     .65   .65   .6   .519   .982
1   .95   .97   .92  1     1.23   .992
0   .95   .87   .83  1.9  1.354  1.02
0  1     .45   .45   .8   .322   .999
0   .95   .36   .34   .5  0       1.038
0   .85   .39   .33   .7   .279   .988
0   .7   .76   .53  1.2   .146   .982
0   .8   .46   .37   .4   .38   1.006
0   .2   .39   .08   .8   .114   .99
0  1     .9   .9   1.1  1.037   .99
1  1     .84   .84  1.9  2.064  1.02
0   .65   .42   .27   .5   .114  1.014
0  1     .75   .75  1     1.322  1.004
0   .5   .44   .22   .6   .114   .99
1  1     .63   .63  1.1  1.072   .986
0  1     .33   .33   .4   .176  1.01
0   .9   .93   .84   .6  1.591  1.02
1  1     .58   .58  1     .531  1.002
0   .95   .32   .3   1.6   .886   .988
1  1     .6   .6   1.7   .964   .99
1  1     .69   .69   .9   .398   .986
0  1     .73   .73   .7   .398   .986
;

```

The following invocation of PROC LOGISTIC illustrates the use of [stepwise selection](#) to identify the prognostic factors for cancer remission. A significance level of 0.3 is required to allow a variable into the model ([SLENTRY=0.3](#)), and a significance level of 0.35 is required for a variable to stay in the model ([SLSTAY=0.35](#)). A detailed account of the variable selection process is requested by specifying the [DETAILS](#) option. The Hosmer and Lemeshow goodness-of-fit test for the final selected model is requested by specifying the [LACKFIT](#) option. The [OUTEST=](#) and [COVOUT](#) options in the PROC LOGISTIC statement create a data set that contains parameter estimates and their covariances for the final selected model. The response variable option [EVENT=](#) chooses remiss=1 (remission) as the event so that the probability of remission is modeled. The [OUTPUT](#) statement creates a data set that contains the cumulative predicted probabilities and the corresponding confidence limits, and the individual and cross validated predicted probabilities for each observation.

```

  title2 'Parameter Estimates and Covariance Matrix';
run;

proc print data=pred;
  title2 'Predicted Probabilities and 95% Confidence Limits';
run;

```

In stepwise selection, an attempt is made to remove any insignificant variables from the model before adding a significant variable to the model. Each addition or deletion of a variable to or from a model is listed as a separate step in the displayed output, and at each step a new model is fitted. Details of the model selection steps are shown in Outputs 54.1.1 through 54.1.5.

Prior to the first step, the intercept-only model is fit and individual score statistics for the potential variables are evaluated (Output 54.1.1).

Output 54.1.1 Startup Model

Stepwise Regression on Cancer Remission Data					
The LOGISTIC Procedure					
Step 0. Intercept entered:					
Model Convergence Status					
Convergence criterion (GCONV=1E-8) satisfied.					
-2 Log L = 34.372					
Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	1	-0.6931	0.4082	2.8827	0.0895
Residual Chi-Square Test					
		Chi-Square	DF	Pr > ChiSq	
		9.4609	6	0.1493	

Output 54.1.1 *continued*

Analysis of Effects Eligible for Entry			
Effect	DF	Score	
		Chi-Square	Pr > ChiSq
cell	1	1.8893	0.1693
smear	1	1.0745	0.2999
infil	1	1.8817	0.1701
li	1	7.9311	0.0049
blast	1	3.5258	0.0604
temp	1	0.6591	0.4169

In Step 1 (Output 54.1.2), the variable *li* is selected into the model since it is the most significant variable among those to be chosen ($p = 0.0049 < 0.3$). The intermediate model that contains an intercept and *li* is then fitted. *li* remains significant ($p = 0.0146 < 0.35$) and is not removed.

Output 54.1.2 Step 1 of the Stepwise Analysis

```

Step 1. Effect li entered:

Model Convergence Status

Convergence criterion (GCONV=1E-8) satisfied.

The data set `pred` created by the `OUTPUT` statement is displayed in [Output 54.1.8](#). It contains all the variables in the input data set, the variable `phat` for the (cumulative) predicted probability, the variables `lcl` and `ucl` for the lower and upper confidence limits for the probability, and four other variables (`IP_1`, `IP_0`, `XP_1`, and `XP_0`) for the `PREDPROBS=` option. The data set also contains the variable `_LEVEL_`, indicating the response value to which `phat`, `lcl`, and `ucl` refer. For instance, for the first row of the `OUTPUT` data set, the values of `_LEVEL_` and `phat`, `lcl`, and `ucl` are 1, 0.72265, 0.16892, and 0.97093, respectively; this means that the estimated probability that `remiss=1` is 0.723 for the given explanatory variable values, and the corresponding 95% confidence interval is (0.16892, 0.97093). The variables `IP_1` and `IP_0` contain the predicted probabilities that `remiss=1` and `remiss=0`, respectively. Note that values of `phat` and `IP_1` are identical since they both contain the probabilities that `remiss=1`. The variables `XP_1` and `XP_0` contain the cross validated predicted probabilities that `remiss=1` and `remiss=0`, respectively.

Output 54.1.8 Predicted Probabilities and Confidence Intervals

Next, a different variable selection method is used to select prognostic factors for cancer remission, and an efficient algorithm is employed to eliminate insignificant variables from a model. The following statements invoke PROC LOGISTIC to perform the backward elimination analysis:

```

title 'Backward Elimination on Cancer Remission Data';
proc logistic data=Remission;
    model remiss(event='1')=temp cell li smear blast
        / selection=backward fast slstay=0.2 ctable;
run;

```

The backward elimination analysis (**SELECTION=BACKWARD**) starts with a model that contains all explanatory variables given in the **MODEL** statement. By specifying the **FAST** option, PROC LOGISTIC eliminates insignificant variables without refitting the model repeatedly. This analysis uses a significance level of 0.2 to retain variables in the model (**SLSTAY=0.2**), which is different from the previous stepwise analysis where **SLSTAY=.35**. The **CTABLE** option is specified to produce classifications of input observations based on the final selected model.

Results of the fast elimination analysis are shown in [Output 54.1.9](#) and [Output 54.1.10](#). Initially, a full model containing all six risk factors is fit to the data ([Output 54.1.9](#)). In the next step ([Output 54.1.10](#)), PROC LOGISTIC removes blast, smear, cell, and temp from the model all at once. This leaves li and the intercept as the only variables in the final model. Note that in this analysis, only parameter estimates for the final model are displayed because the **DETAILS** option has not been specified.

Output 54.1.9 Initial Step in Backward Elimination

Note that you can also use the FAST option when **SELECTION=STEPWISE**. However, the FAST option operates only on backward elimination steps. In this example, the stepwise process only adds variables, so the FAST option would not be useful.

Results of the **CTABLE** option are shown in [Output 54.1.11](#).

Output 54.1.11 Classifying Input Observations

Each row of the “Classification Table” corresponds to a cutpoint applied to the predicted probabilities, which is given in the Prob Level column. The 2×2 frequency tables of observed and predicted responses are given by the next four columns. For example, with a cutpoint of 0.5, 4 events and 16 nonevents were classified correctly. On the other hand, 2 nonevents were incorrectly classified as events and 5 events were incorrectly classified as nonevents. For this cutpoint, the correct classification rate is 20/27 (=74.1%), which is given in the sixth column. Accuracy of the classification is summarized by the sensitivity, specificity, and false positive and negative rates, which are displayed in the last four columns. You can control the number of cutpoints used, and their values, by using the `PPROB=` option.

Example 54.2: Logistic Modeling with Categorical Predictors

Consider a study of the analgesic effects of treatments on elderly patients with neuralgia. Two test treatments and a placebo are compared. The response variable is whether the patient reported pain or not. Researchers recorded the age and gender of 60 patients and the duration of complaint before the treatment began. The following DATA step creates the data set Neuralgia:

```
data Neuralgia;
  input Treatment $ Sex $ Age Duration Pain $ @@;
  datalines;
P F 68 1 No B M 74 16 No P F 67 30 No
P M 66 26 Yes B F 67 28 No B F 77 16 No
A F 71 12 No B F 72 50 No B F 76 9 Yes

P F 67 1 Yes A M 67 10 No P F 72 11 Yes
A F 74 1 No B M 80 21 Yes A F 69 3 No
;
```

The data set Neuralgia contains five variables: Treatment, Sex, Age, Duration, and Pain. The last variable, Pain, is the response variable. A specification of Pain=Yes indicates there was pain, and Pain=No indicates no pain. The variable Treatment is a categorical variable with three levels: A and B represent the two test treatments, and P represents the placebo treatment. The gender of the patients is given by the categorical variable Sex. The variable Age is the age of the patients, in years, when treatment began. The duration of complaint, in months, before the treatment began is given by the variable Duration.

The following statements use the LOGISTIC procedure to fit a two-way logit with interaction model for the effect of Treatment and Sex, with Age and Duration as covariates. The categorical variables Treatment and

Sex are declared in the **CLASS** statement.

```
proc logistic data=Neuralgia;
  class Treatment Sex;
  model Pain= Treatment Sex Treatment*Sex Age Duration / expb;
run;
```

In this analysis, PROC LOGISTIC models the probability of no pain (Pain=No). By default, effect coding is used to represent the CLASS variables. Two design variables are created for Treatment and one for Sex, as shown in [Output 54.2.1](#).

Output 54.2.1 Effect Coding of CLASS Variables

The LOGISTIC Procedure			
Class Level Information			
Class	Value	Design Variables	
Treatment	A	1	0
	B	0	1
	P	-1	-1
Sex	F	1	
	M	-1	

PROC LOGISTIC displays a table of the Type 3 analysis of effects based on the Wald test ([Output 54.2.2](#)). Note that the Treatment*Sex interaction and the duration of complaint are not statistically significant ($p = 0.9318$ and $p = 0.8752$, respectively). This indicates that there is no evidence that the treatments affect pain differently in men and women, and no evidence that the pain outcome is related to the duration of pain.

Output 54.2.2 Wald Tests of Individual Effects

Type 3 Analysis of Effects			
Effect	DF	Wald	
		Chi-Square	Pr > ChiSq
Treatment	2	11.9886	0.0025
Sex	1	5.3104	0.0212
Treatment*Sex	2	0.1412	0.9318
Age	1	7.2744	0.0070
Duration	1	0.0247	0.8752

Parameter estimates are displayed in [Output 54.2.3](#). The Exp(Est) column contains the exponentiated parameter estimates requested with the **EXPB** option. These values can, but do not necessarily, represent odds ratios for the corresponding variables. For continuous explanatory variables, the Exp(Est) value corresponds to the odds ratio for a unit increase of the corresponding variable. For CLASS variables that use effect coding, the Exp(Est) values have no direct interpretation as a comparison of levels. However, when

the reference coding is used, the Exp(Est) values represent the odds ratio between the corresponding level and the reference level. Following the parameter estimates table, PROC LOGISTIC displays the odds ratio estimates for those variables that are not involved in any interaction terms. If the variable is a CLASS variable, the odds ratio estimate comparing each level with the reference level is computed regardless of the coding scheme. In this analysis, since the model contains the Treatment*Sex interaction term, the odds ratios for Treatment and Sex were not computed. The odds ratio estimates for Age and Duration are precisely the values given in the Exp(Est) column in the parameter estimates table.

Output 54.2.3 Parameter Estimates with Effect Coding

Analysis of Maximum Likelihood Estimates							
Parameter		DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq	Exp(Est)
Intercept		1	19.2236	7.1315	7.2661	0.0070	2.232E8
Treatment	A	1	0.8483	0.5502	2.3773	0.1231	2.336
Treatment	B	1	1.4949	0.6622	5.0956	0.0240	4.459

Odds Ratio Estimates			
Effect	Point Estimate	95% Wald Confidence Limits	
Age	0.764	0.629	0.929
Duration	1.005	0.942	1.073

The following PROC LOGISTIC statements illustrate the use of forward selection on the data set Neuralgia to identify the effects that differentiate the two Pain responses. The option **SELECTION=FORWARD** is specified to carry out the forward selection. The term Treatment|Sex@2 illustrates another way to specify main effects and two-way interactions. (Note that, in this case, the “@2” is unnecessary because no interactions besides the two-way interaction are possible).

```
proc logistic data=Neuralgia;
  class Treatment Sex;
  model Pain=Treatment|Sex@2 Age Duration
    /selection=forward expb;
run;
```

Results of the forward selection process are summarized in [Output 54.2.4](#). The variable Treatment is selected first, followed by Age and then Sex. The results are consistent with the previous analysis ([Output 54.2.2](#)) in which the Treatment*Sex interaction and Duration are not statistically significant.

Output 54.2.4 Effects Selected into the Model

The LOGISTIC Procedure					
Summary of Forward Selection					
Step	Effect Entered	DF	Number In	Score Chi-Square	Pr > ChiSq
1	Treatment	2	1	13.7143	0.0011
2	Age	1	2	10.6038	0.0011
3	Sex	1	3	5.9959	0.0143

Output 54.2.5 shows the Type 3 analysis of effects, the parameter estimates, and the odds ratio estimates for the selected model. All three variables, Treatment, Age, and Sex, are statistically significant at the 0.05 level ($p=0.0018$, $p=0.0213$, and $p=0.0057$, respectively). Since the selected model does not contain the Treatment*Sex interaction, odds ratios for Treatment and Sex are computed. The estimated odds ratio is 24.022 for treatment A versus placebo, 41.528 for Treatment B versus placebo, and 6.194 for female patients versus male patients. Note that these odds ratio estimates are not the same as the corresponding values in the Exp(Est) column in the parameter estimates table because effect coding was used. From Output 54.2.5, it is evident that both Treatment A and Treatment B are better than the placebo in reducing pain; females tend to have better improvement than males; and younger patients are faring better than older patients.

Output 54.2.5 Type 3 Effects and Parameter Estimates with Effect Coding

Type 3 Analysis of Effects						
Effect	DF		Wald Chi-Square	Pr > ChiSq		
Treatment	2		12.6928	0.0018

Sex F	1	0.9118	0.3960	5.3013	0.0213	2.489
Age	1	-0.2650	0.0959	7.6314	0.0057	0.767

Output 54.2.5 continued

Odds Ratio Estimates			
Effect	Point Estimate	95% Wald Confidence Limits	
Treatment A vs P	24.022	3.295	175.121
Treatment B vs P	41.528	4.500	383.262
Sex F vs M	6.194	1.312	29.248
Age	0.767	0.636	0.926

Finally, the following statements refit the previously selected model, except that reference coding is used for the CLASS variables instead of effect coding:

```
ods graphics on;
proc logistic data=Neuralgia plots(only)=(oddsratio(range=clip));
  class Treatment Sex /param=ref;
  model Pain= Treatment Sex Age;
  oddsratio Treatment;
  oddsratio Sex;
  oddsratio Age;
  contrast 'Pairwise A vs P' Treatment 1 0 / estimate=exp;
  contrast 'Pairwise B vs P' Treatment 0 1 / estimate=exp;
  contrast 'Pairwise A vs B' Treatment 1 -1 / estimate=exp;
  contrast 'Female vs Male' Sex 1 / estimate=exp;
  effectplot / at(Sex=all) noobs;
  effectplot slicefit(sliceby=Sex plotby=Treatment) / noobs;
run;
ods graphics off;
```

The **ODDSRATIO** statements compute the odds ratios for the covariates. Four **CONTRAST** statements are specified; they provide another method of producing the odds ratios. The three contrasts labeled 'Pairwise' specify a contrast vector, L , for each of the pairwise comparisons between the three levels of Treatment. The contrast labeled 'Female vs Male' compares female to male patients. The option **ESTIMATE=EXP** is specified in all **CONTRAST** statements to exponentiate the estimates of $L'\beta$. With the given specification of contrast coefficients, the first of the 'Pairwise' **CONTRAST** statements corresponds to the odds ratio of A versus P, the second corresponds to B versus P, and the third corresponds to A versus B. You can also specify the 'Pairwise' contrasts in a single contrast statement with three rows. The 'Female vs Male' **CONTRAST** statement corresponds to the odds ratio that compares female to male patients.

The **PLOTS(ONLY)=** option displays only the requested odds ratio plot when ODS Graphics is enabled. The **EFFECTPLOT** statements do not honor the **ONLY** option, and display the fitted model. The first **EFFECTPLOT** statement by default produces a plot of the predicted values against the continuous Age variable, grouped by the Treatment levels. The **AT** option produces one plot for males and another for females; the **NOOBS** option suppresses the display of the observations. In the second **EFFECTPLOT** statement, a **SLICEFIT** plot is specified to display the Age variable on the X axis, the fits are grouped by the Sex levels, and the **PLOTBY=** option produces a panel of plots that displays each level of the Treatment variable.

The reference coding is shown in [Output 54.2.6](#). The Type 3 analysis of effects, the parameter estimates for the reference coding, and the odds ratio estimates are displayed in [Output 54.2.7](#). Although the parameter

estimates are different because of the different parameterizations, the “Type 3 Analysis of Effects” table and the “Odds Ratio” table remain the same as in [Output 54.2.5](#). With effect coding, the treatment A parameter estimate (0.8772) estimates the effect of treatment A compared to the average effect of treatments A, B, and placebo. The treatment A estimate (3.1790) under the reference coding estimates the difference in effect of treatment A and the placebo treatment.

Output 54.2.6 Reference Coding of CLASS Variables

The LOGISTIC Procedure			
Class Level Information			
Class	Value	Design Variables	
Treatment	A	1	0
	B	0	1
	P	0	0
Sex	F	1	
	M	0	

Output 54.2.7 Type 3 Effects and Parameter Estimates with Reference Coding

Type 3 Analysis of Effects			
Effect	DF	Wald Chi-Square	Pr > ChiSq
Treatment	2	12.6928	0.0018
Sex	1	5.3013	0.0213
Age	1	7.6314	0.0057

Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	1	15.8669	6.4056	6.1357	0.0132
Treatment A	1	3.1790	1.0135	9.8375	0.0017
Treatment B	1	3.7264	1.1339	10.8006	0.0010
Sex F	1	1.8235	0.7920	5.3013	0.0213
Age	1	-0.2650	0.0959	7.6314	0.0057

The **ODDSRATIO** statement results are shown in [Output 54.2.8](#), and the resulting plot is displayed in [Output 54.2.9](#). Note in [Output 54.2.9](#) that the odds ratio confidence limits are truncated due to specifying the **RANGE=CLIP** option; this enables you to see which intervals contain “1” more clearly. The odds ratios are identical to those shown in the “Odds Ratio Estimates” table in [Output 54.2.7](#) with the addition of the odds ratio for “Treatment A vs B”. Both treatments A and B are highly effective over placebo in reducing pain, as can be seen from the odds ratios comparing treatment A against P and treatment B against P (the second

and third rows in the table). However, the 95% confidence interval for the odds ratio comparing treatment A to B is (0.0932, 3.5889), indicating that the pain reduction effects of these two test treatments are not very different. Again, the 'Sex F vs M' odds ratio shows that female patients fared better in obtaining relief from pain than male patients. The odds ratio for Age shows that a patient one year older is 0.77 times as likely to show no pain; that is, younger patients have more improvement than older patients.

Output 54.2.8 Results from the ODDSRATIO Statements

Odds Ratio Estimates and Wald Confidence Intervals			
Label	Estimate	95% Confidence Limits	
Treatment A vs B	0.578	0.093	3.589
Treatment A vs P	24.022	3.295	175.121
Treatment B vs P	41.528	4.500	383.262
Sex F vs M	6.194	1.312	29.248
Age	0.767	0.636	0.926

Output 54.2.9 Plot of the ODDSRATIO Statement Results

Output 54.2.10 contains two tables: the “Contrast Test Results” table and the “Contrast Estimation and Testing Results by Row” table. The former contains the overall Wald test for each CONTRAST statement. The latter table contains estimates and tests of individual contrast rows. The estimates for the first two rows of the ‘Pairwise’ CONTRAST statements are the same as those given in the two preceding odds ratio tables (Output 54.2.7 and Output 54.2.8). The third row estimates the odds ratio comparing A to B, agreeing with Output 54.2.8, and the last row computes the odds ratio comparing pain relief for females to that for males.

Output 54.2.10 Results of CONTRAST Statements

Contrast Test Results

ANCOVA-style plots of the model-predicted probabilities against the Age variable for each combination of Treatment and Sex are displayed in Output 54.2.11 and Output 54.2.12. These plots confirm that females always have a higher probability of pain reduction in each treatment group, the placebo treatment has a lower probability of success than the other treatments, and younger patients respond to treatment better than older patients.

Output 54.2.11 Model-Predicted Probabilities by Sex

Output 54.2.12 Model-Predicted Probabilities by Treatment

Example 54.3: Ordinal Logistic Regression

Consider a study of the effects on taste of various cheese additives. Researchers tested four cheese additives and obtained 52 response ratings for each additive. Each response was measured on a scale of nine categories ranging from strong dislike (1) to excellent taste (9). The data, given in McCullagh and Nelder (1989, p. 175) in the form of a two-way frequency table of additive by rating, are saved in the data set `Cheese` by using the following program. The variable `y` contains the response rating. The variable `Additive` specifies the cheese additive (1, 2, 3, or 4). The variable `freq` gives the frequency with which each additive received each rating.

```
data Cheese;
  do Additive = 1 to 4;
    do y = 1 to 9;
      input freq @@;
      output;
    end;
  end;
  label y='Taste Rating';
  datalines;
```

```

0 0 1 7 8 8 19 8 1
6 9 12 11 7 6 1 0 0
1 1 6 8 23 7 5 1 0
0 0 0 1 3 7 14 16 11
;

```

The response variable y is ordinally scaled. A cumulative logit model is used to investigate the effects of the cheese additives on taste. The following statements invoke PROC LOGISTIC to fit this model with y as the response variable and three indicator variables as explanatory variables, with the fourth additive as the reference level. With this parameterization, each Additive parameter compares an additive to the fourth additive. The COVB option displays the estimated covariance matrix. The ODDSRATIO statement computes odds ratios for all combinations of the Additive levels. The PLOTS option produces a graphical display of the odds ratios, and the EFFECTPLOT statement displays the predicted probabilities.

```

ods graphics on;
proc logistic data=Cheese plots(only)=oddsratio(range=clip);
  freq freq;
  class Additive (param=ref ref='4');
  model y=Additive / covb;
  oddsratio Additive;
  effectplot / polybar;
  title 'Multiple Response Cheese Tasting Experiment';
run;
ods graphics off;

```

The “Response Profile” table in [Output 54.3.1](#) shows that the strong dislike ($y=1$) end of the rating scale is associated with lower Ordered Values in the “Response Profile” table; hence the probability of disliking the additives is modeled.

The score chi-square for testing the proportional odds assumption is 17.287, which is not significant with respect to a chi-square distribution with 21 degrees of freedom ($p = 0.694$). This indicates that the proportional odds assumption is reasonable. The positive value (1.6128) for the parameter estimate for Additive1 indicates a tendency toward the lower-numbered categories of the first cheese additive relative to the fourth. In other words, the fourth additive tastes better than the first additive. The second and third additives are both less favorable than the fourth additive. The relative magnitudes of these slope estimates imply the preference ordering: fourth, first, third, second.

The odds ratio results in [Output 54.3.2](#) show the preferences more clearly. For example, the “Additive 1 vs 4” odds ratio says that the first additive has 5.017 times the odds of receiving a lower score than the fourth

additive; that is, the first additive is 5.017 times more likely than the fourth additive to receive a lower score. [Output 54.3.3](#) displays the odds ratios graphically; the range of the confidence limits is truncated by the `RANGE=CLIP` option, so you can see that “1” is not contained in any of the intervals.

Output 54.3.2 Odds Ratios of All Pairs of Additive Levels

Additive3	-0.09122	-0.05802	-0.04143	0.092128	0.132877	0.180709

Output 54.3.5 displays the probability of each taste rating y within each additive. You can see that Additive=1 mostly receives ratings of 5 to 7, Additive=2 mostly receives ratings of 2 to 5, Additive=3 mostly receives ratings of 4 to 6, and Additive=4 mostly receives ratings of 7 to 9, which also confirms the previously discussed preference orderings.

Output 54.3.5 Model-Predicted Probabilities

Example 54.4: Nominal Response Data: Generalized Logits Model

Over the course of one school year, third graders from three different schools are exposed to three different styles of mathematics instruction: a self-paced computer-learning style, a team approach, and a traditional class approach. The students are asked which style they prefer and their responses, classified by the type of program they are in (a regular school day versus a regular day supplemented with an afternoon school program), are displayed in [Table 54.15](#). The data set is from Stokes, Davis, and Koch (2012), and is also analyzed in the section “Generalized Logits Model” on page 1784 of Chapter 30, “The CATMOD Procedure.”

Table 54.15 School Program Data

School	Program	Learning Style Preference		
		Self	Team	Class
1	Regular	10	17	26
1	Afternoon	5	12	50
2	Regular	21	17	26
2	Afternoon	16	12	36
3	Regular	15	15	16
3	Afternoon	12	12	20

The levels of the response variable (self, team, and class) have no essential ordering, so a logistic regression is performed on the generalized logits. The model to be fit is

$$\log\left(\frac{\pi_{hij}}{\pi_{hir}}\right) = \alpha_j + \mathbf{x}_{hi}'\boldsymbol{\beta}_j$$

where π_{hij} is the probability that a student in school h and program i prefers teaching style j , $j \neq r$, and style r is the baseline style (in this case, class). There are separate sets of intercept parameters α_j and regression parameters $\boldsymbol{\beta}_j$ for each logit, and the vector \mathbf{x}_{hi} is the set of explanatory variables for the h th population. Thus, two logits are modeled for each school and program combination: the logit comparing self to class and the logit comparing team to class.

The following statements create the data set `school` and request the analysis. The `LINK=GLOGIT` option forms the generalized logits. The response variable option `ORDER=DATA` means that the response variable levels are ordered as they exist in the data set: self, team, and class; thus, the logits are formed by comparing self to class and by comparing team to class. The `ODDSRATIO` statement produces odds ratios in the presence of interactions, and a graphical display of the requested odds ratios is produced when ODS Graphics is enabled.

The table produced by the **ODDSRATIO** statement is displayed in [Output 54.4.4](#). The differences between the program preferences are small across all the styles (logits) compared to their variability as displayed by the confidence limits in [Output 54.4.5](#), confirming that the interaction effect is nonsignificant.

Output 54.4.4 Odds Ratios for Style

Odds Ratio Estimates and Wald Confidence Intervals			
Label	Estimate	95% Confidence Limits	
Style self: Program regular vs afternoon at School=1	3.846	1.190	12.435
Style team: Program regular vs afternoon at School=1	2.724	1.132	6.554
Style self: Program regular vs afternoon at School=2	1.817	0.798	4.139
Style team: Program regular vs afternoon at School=2	1.962	0.802	4.799
Style self: Program regular vs afternoon at School=3	1.562	0.572	4.265
Style team: Program regular vs afternoon at School=3	1.562	0.572	4.265

Output 54.4.5 Plot of Odds Ratios for Style

Since the interaction effect is clearly nonsignificant, a main-effects model is fit with the following statements. The **EFFECTPLOT** statement creates a plot of the predicted values versus the levels of the School

variable at each level of the Program variables. The **CLM** option adds confidence bars, and the **NOOBS** option suppresses the display of the observations.

```
ods graphics on;
proc logistic data=school;
  freq Count;
  class School Program(ref=first);
  model Style(order=data)=School Program / link=glogit;
  effectplot interaction(plotby=Program) / clm noobs;
run;
ods graphics off;
```

All of the global fit tests in [Output 54.4.6](#) suggest the model is significant, and the Type 3 tests show that the school and program effects are also significant.

Output 54.4.6 Analysis of Main-Effects Model

The LOGISTIC Procedure			
Model Convergence Status			
Convergence criterion (GCONV=1E-8) satisfied.

Program	2	10.9160	0.0043

The parameter estimates, tests for individual parameters, and odds ratios are displayed in [Output 54.4.7](#). The Program variable has nearly the same effect on both logits, while School=1 has the largest effect of the schools.

Output 54.4.7 Estimates

Analysis of Maximum Likelihood Estimates						
Parameter	Style	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	self	1	-0.7978	0.1465	29.6502	<.0001
Intercept	team	1	-0.6589	0.1367	23.2300	<.0001
School 1	self	1	-0.7992	0.2198	13.2241	0.0003
School 1	team	1	-0.2786	0.1867	2.2269	0.1356
School 2	self	1	0.2836	0.1899	2.2316	0.1352
School 2	team	1	-0.0985	0.1892	0.2708	0.6028
Program regular	self	1	0.3737	0.1410	7.0272	0.0080
Program regular	team	1	0.3713	0.1353	7.5332	0.0061

Odds Ratio Estimates				
Effect	Style	Point Estimate	95% Wald Confidence Limits	
School 1 vs 3	self	0.269	0.127	0.570
School 1 vs 3	team	0.519	0.267	1.010
School 2 vs 3	self	0.793	0.413	1.522
School 2 vs 3	team	0.622	0.317	1.219
Program regular vs afternoon	self	2.112	1.215	3.670
Program regular vs afternoon	team	2.101	1.237	3.571

The interaction plots in [Output 54.4.8](#) show that School=1 and Program=afternoon have a preference for the traditional classroom style. Of course, since these are not simultaneous confidence intervals, the nonoverlapping 95% confidence limits do not take the place of an actual test.

Output 54.4.8 Model-Predicted Probabilities

Example 54.5: Stratified Sampling

Consider the hypothetical example in Fleiss (1981, pp. 6–7), in which a test is applied to a sample of 1,000 people known to have a disease and to another sample of 1,000 people known not to have the same disease. In the diseased sample, 950 test positive; in the nondiseased sample, only 10 test positive. If the true disease rate in the population is 1 in 100, specifying **PEVENT=0.01** results in the correct false positive and negative rates for the stratified sampling scheme. Omitting the **PEVENT=** option is equivalent to using the overall sample disease rate ($1000/2000 = 0.5$) as the value of the **PEVENT=** option, which would ignore the stratified sampling.

The statements to create the data set and perform the analysis are as follows:

```
data Screen;
  do Disease='Present', 'Absent';
    do Test=1,0;
      input Count @@;
      output;
    end;
  end;
```

```

    datalines;
950  50
10  990
;

proc logistic data=Screen;
    freq Count;
    model Disease(event='Present')=Test
        / pevent=.5 .01 ctable pprob=.5;
run;

```

The response variable option **EVENT=** indicates that `Disease='Present'` is the event. The **CTABLE** option is specified to produce a classification table. Specifying **PPROB=0.5** indicates a cutoff probability of 0.5. A list of two probabilities, 0.5 and 0.01, is specified for the **PEVENT=** option; 0.5 corresponds to the overall sample disease rate, and 0.01 corresponds to a true disease rate of 1 in 100.

The classification table is shown in [Output 54.5.1](#).

Output 54.5.1 False Positive and False Negative Rates

The LOGISTIC Procedure										
Classification Table										
Prob Event	Prob Level	Correct		Incorrect		Correct	Percentages			
		Event	Non- Event	Event	Non- Event		Sensi- tivity	Speci- ficity	False POS	False NEG
0.500	0.500	950	990	10	50	97.0	95.0	99.0	1.0	4.8
0.010	0.500	950	990	10	50	99.0	95.0	99.0	51.0	0.1

In the classification table, the column “Prob Level” represents the cutoff values (the settings of the **PPROB=** option) for predicting whether an observation is an event. The “Correct” columns list the numbers of subjects that are correctly predicted as events and nonevents, respectively, and the “Incorrect” columns list the number of nonevents incorrectly predicted as events and the number of events incorrectly predicted as nonevents, respectively. For **PEVENT=0.5**, the false positive rate is 1% and the false negative rate is 4.8%. These results ignore the fact that the samples were stratified and incorrectly assume that the overall sample proportion of disease (which is 0.5) estimates the true disease rate. For a true disease rate of 0.01, the false positive rate and the false negative rate are 51% and 0.1%, respectively, as shown in the second line of the classification table.

Example 54.6: Logistic Regression Diagnostics

In a controlled experiment to study the effect of the rate and volume of air intake on a transient reflex vasoconstriction in the skin of the digits, 39 tests under various combinations of rate and volume of air intake were obtained (Finney 1947). The endpoint of each test is whether or not vasoconstriction occurred. Pregibon (1981) uses this set of data to illustrate the diagnostic measures he proposes for detecting influential observations and to quantify their effects on various aspects of the maximum likelihood fit.

The vasoconstriction data are saved in the data set vaso:

```

;
```

In the data set vaso, the variable Response represents the outcome of a test. The variable LogVolume represents the log of the volume of air intake, and the variable LogRate represents the log of the rate of air intake.

The following statements invoke PROC LOGISTIC to fit a logistic regression model to the vasoconstriction data, where Response is the response variable, and LogRate and LogVolume are the explanatory variables. Regression diagnostics are displayed when ODS Graphics is enabled, and the [INFLUENCE](#) option is specified to display a table of the regression diagnostics.

```
ods graphics on;
title 'Occurrence of Vasoconstriction';
proc logistic data=vaso;
  model Response=LogRate LogVolume/influence iplots;
run;
ods graphics off;
```

Results of the model fit are shown in [Output 54.6.1](#). Both LogRate and LogVolume are statistically significant to the occurrence of vasoconstriction ($p = 0.0131$ and $p = 0.0055$, respectively). Their positive parameter estimates indicate that a higher inspiration rate or a larger volume of air intake is likely to increase the probability of vasoconstriction.

The index plots produced by the IPLOTS option are essentially the same line-printer plots as those produced by the INFLUENCE option, but with a 90-degree rotation and perhaps on a more refined scale. Since ODS Graphics is enabled, the line-printer plots from the INFLUENCE and IPLOTS options are suppressed and ODS Graphics versions of the plots are displayed in Outputs 54.6.3 through 54.6.5. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For specific information about the graphics available in the LOGISTIC procedure, see the section “[ODS Graphics](#)” on page 4294. The vertical axis of an index plot represents the value of the diagnostic, and the horizontal axis represents the sequence (case number) of the observation. The index plots are useful for identification of extreme values.

The index plots of the Pearson residuals and the deviance residuals ([Output 54.6.3](#)) indicate that case 4 and case 18 are poorly accounted for by the model. The index plot of the diagonal elements of the hat matrix ([Output 54.6.3](#)) suggests that case 31 is an extreme point in the design space. The index plots of DFBETAS ([Output 54.6.5](#)) indicate that case 4 and case 18 are causing instability in all three parameter estimates. The other four index plots in Outputs 54.6.3 and 54.6.4 also point to these two cases as having a large impact on the coefficients and goodness of fit.

Output 54.6.3 Residuals, Hat Matrix, and CI Displacement C

Output 54.6.4 CI Displacement CBar, Change in Deviance and Pearson Chi-Square**Output 54.6.5** DFBETAS Plots

Other versions of diagnostic plots can be requested by specifying the appropriate options in the **PLOTS=** option. For example, the following statements produce three other sets of influence diagnostic plots: the **PHAT** option plots several diagnostics against the predicted probabilities ([Output 54.6.6](#)), the **LEVERAGE** option plots several diagnostics against the leverage ([Output 54.6.7](#)), and the **DPC** option plots the deletion diagnostics against the predicted probabilities and colors the observations according to the confidence interval displacement diagnostic ([Output 54.6.8](#)). The **LABEL** option displays the observation numbers on the plots. In all plots, you are looking for the outlying observations, and again cases 4 and 18 are noted.

```
ods graphics on;
proc logistic data=vaso plots(only label)=(phat leverage dpc);
  model Response=LogRate LogVolume;
run;
ods graphics off;
```

Output 54.6.6 Diagnostics versus Predicted Probability

Output 54.6.7 Diagnostics versus Leverage**Output 54.6.8** Three Diagnostics

Example 54.7: ROC Curve, Customized Odds Ratios, Goodness-of-Fit Statistics, R-Square, and Confidence Limits

This example plots an ROC curve, estimates a customized odds ratio, produces the traditional goodness-of-fit analysis, displays the generalized R Square measures for the fitted model, calculates the normal confidence intervals for the regression parameters, and produces a display of the probability function and prediction curves for the fitted model. The data consist of three variables: *n* (number of subjects in the sample), *disease* (number of diseased subjects in the sample), and *age* (age for the sample). A linear logistic regression model is used to study the effect of age on the probability of contracting the disease. The statements to produce the data set and perform the analysis are as follows:

```
data Data1;
  input disease n age;
  datalines;
0 14 25
0 20 35
0 19 45
7 18 55
6 12 65
17 17 75
;

ods graphics on;
proc logistic data=Data1 plots(only)=roc(id=obs);
  model disease/n=age / scale=none
                        clparm=wald
                        clodds=pl
                        rsquare;

  units age=10;
  effectplot;
run;
ods graphics off;
```

The option **SCALE=NONE** is specified to produce the deviance and Pearson goodness-of-fit analysis without adjusting for overdispersion. The **RSQUARE** option is specified to produce generalized R Square measures of the fitted model. The **CLPARM=WALD** option is specified to produce the Wald confidence intervals for the regression parameters. The **UNITS** statement is specified to produce customized odds ratio estimates for a change of 10 years in the age variable, and the **CLODDS=PL** option is specified to produce profile-likelihood confidence limits for the odds ratio. The **PLOTS=** option with ODS Graphics enabled produces a graphical display of the ROC curve, and the **EFFECTPLOT** statement displays the model fit.

The results in [Output 54.7.1](#) show that the deviance and Pearson statistics indicate no lack of fit in the model.

Output 54.7.1 Deviance and Pearson Goodness-of-Fit Analysis

The LOGISTIC Procedure				
Deviance and Pearson Goodness-of-Fit Statistics				
Criterion	Value	DF	Value/DF	Pr > ChiSq
Deviance	7.7756	4	1.9439	0.1002
Pearson	6.6020	4	1.6505	0.1585
Number of events/trials observations: 6				

Output 54.7.2 shows that the R-square for the model is 0.74. The odds of an event increases by a factor of 7.9 for each 10-year increase in age.

Output 54.7.2 R-Square, Confidence Intervals, and Customized Odds Ratio

Since ODS Graphics is enabled, a graphical display of the ROC curve is produced as shown in [Output 54.7.3](#).

Output 54.7.3 Receiver Operating Characteristic Curve

Note that the area under the ROC curve is estimated by the statistic c in the “Association of Predicted Probabilities and Observed Responses” table. In this example, the area under the ROC curve is 0.953.

Since there is only one continuous covariate and since ODS Graphics is enabled, the [EFFECTPLOT](#) statement produces a graphical display of the predicted probability curve with bounding 95% confidence limits as shown in [Output 54.7.4](#).

Output 54.7.4 Predicted Probability and 95% Prediction Limits

Example 54.8: Comparing Receiver Operating Characteristic Curves

DeLong, DeLong, and Clarke-Pearson (1988) report on 49 patients with ovarian cancer who also suffer from an intestinal obstruction. Three (correlated) screening tests are measured to determine whether a patient will benefit from surgery. The three tests are the K-G score and two measures of nutritional status: total protein and albumin. The data are as follows:

```
data roc;
  input alb tp totscore popind @@;
  totscore = 10 - totscore;
  datalines;

In the following statements, the **NOFIT** option is specified in the **MODEL** statement to prevent PROC LOGISTIC from fitting the model with three covariates. Each **ROC** statement lists one of the covariates, and PROC LOGISTIC then fits the model with that single covariate. Note that the original data set contains six more records with missing values for one of the tests, but PROC LOGISTIC ignores all records with missing values; hence there is a common sample size for each of the three models. The **ROCCONTRAST** statement implements the nonparametric approach of DeLong, DeLong, and Clarke-Pearson (1988) to compare the three ROC curves, the **REFERENCE** option specifies that the K-G Score curve is used as the reference curve in the contrast, the **E** option displays the contrast coefficients, and the **ESTIMATE** option computes and tests each comparison. With ODS Graphics enabled, the **plots=roc(id=prob)** specification in the PROC LOGISTIC statement displays several plots, and the plots of individual ROC curves have certain points labeled with their predicted probabilities.

```

ods graphics on;
proc logistic data=roc plots=roc(id=prob);
  model popind(event='0') = alb tp totscore / nofit;
  roc 'Albumin' alb;
  roc 'K-G Score' totscore;
  roc 'Total Protein' tp;
  roccontrast reference('K-G Score') / estimate e;
run;
ods graphics off;

```

The initial model information is displayed in [Output 54.8.1](#).

Example 54.9: Goodness-of-Fit Tests and Subpopulations

A study is done to investigate the effects of two binary factors, A and B, on a binary response, Y. Subjects are randomly selected from subpopulations defined by the four possible combinations of levels of A and B. The number of subjects responding with each level of Y is recorded, and the following DATA step creates the data set One:

```

data One;
  do A=0,1;
    do B=0,1;
      do Y=1,2;
        input F @@;
        output;
      end;
    end;
  end;
  datalines;
23 63 31 70 67 100 70 104
;

```

The following statements fit a full model to examine the main effects of A and B as well as the interaction effect of A and B:

```

proc logistic data=One;
  freq F;
  model Y=A B A*B;
run;

```

Results of the model fit are shown in [Output 54.9.1](#). Notice that neither the A*B interaction nor the B main effect is significant.

Output 54.9.1 Full Model Fit

Score	6.9921	3	0.0721		
Wald	6.9118	3	0.0748		
Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	1	-1.0074	0.2436	17.1015	<.0001
A	1	0.6069	0.2903	4.3714	0.0365
B	1	0.1929	0.3254	0.3515	0.5533
A*B	1	-0.1883	0.3933	0.2293	0.6321

Pearson and deviance goodness-of-fit tests cannot be obtained for this model since a full model containing four parameters is fit, leaving no residual degrees of freedom. For a binary response model, the goodness-of-fit tests have $m - q$ degrees of freedom, where m is the number of subpopulations and q is the number of model parameters. In the preceding model, $m = q = 4$, resulting in zero degrees of freedom for the tests.

The following statements fit a reduced model containing only the A effect, so two degrees of freedom become available for testing goodness of fit. Specifying the **SCALE=NONE** option requests the Pearson and deviance statistics. With single-trial syntax, the **AGGREGATE=** option is needed to define the subpopulations in the study. Specifying **AGGREGATE=(A B)** creates subpopulations of the four combinations of levels of A and B. Although the B effect is being dropped from the model, it is still needed to define the original subpopulations in the study. If **AGGREGATE=(A)** were specified, only two subpopulations would be created from the levels of A, resulting in $m = q = 2$ and zero degrees of freedom for the tests.

```
proc logistic data=One;
  freq F;
  model Y=A / scale=none aggregate=(A B);
run;
```

The goodness-of-fit tests in [Output 54.9.2](#) show that dropping the B main effect and the A*B interaction simultaneously does not result in significant lack of fit of the model. The tests' large p -values indicate insufficient evidence for rejecting the null hypothesis that the model fits.

Output 54.9.2 Reduced Model Fit

The LOGISTIC Procedure

Example 54.10: Overdispersion

In a seed germination test, seeds of two cultivars were planted in pots of two soil conditions. The following statements create the data set `seeds`, which contains the observed proportion of seeds that germinated for various combinations of cultivar and soil condition. The variable `n` represents the number of seeds planted in a pot, and the variable `r` represents the number germinated. The indicator variables `cult` and `soil` represent the cultivar and soil condition, respectively.

```
data seeds;
  input pot n r cult soil;
  datalines;
1 16      8      0      0
2 51     26      0      0
3 45     23      0      0
4 39     10      0      0
5 36      9      0      0
6 81     23      1      0
7 30     10      1      0
8 39     17      1      0
9 28      8      1      0
10 62     23      1      0
11 51     32      0      1
12 72     55      0      1
13 41     22      0      1
14 12      3      0      1
15 13     10      0      1
16 79     46      1      1

19 74     53      1      1
20 56     12      1      1
;
```

PROC LOGISTIC is used as follows to fit a logit model to the data, with cult, soil, and cult \times soil interaction as explanatory variables. The option **SCALE=NONE** is specified to display goodness-of-fit statistics.

```
proc logistic data=seeds;
  model r/n=cult soil cult*soil/scale=none;
  title 'Full Model With SCALE=NONE';
run;
```

Results of fitting the full factorial model are shown in [Output 54.10.1](#). Both Pearson χ^2 and deviance are highly significant ($p < 0.0001$), suggesting that the model does not fit well.

Output 54.10.1 Results of the Model Fit for the Two-Way Layout

Full Model With SCALE=NONE

cult*soil	1	-0.1239	0.2790	0.1973	0.6569

If the link function and the model specification are correct and if there are no outliers, then the lack of fit might be due to overdispersion. Without adjusting for the overdispersion, the standard errors are likely to be underestimated, causing the Wald tests to be too sensitive. In PROC LOGISTIC, there are three `SCALE=` options to accommodate overdispersion. With unequal sample sizes for the observations, `SCALE=WILLIAMS` is preferred. The Williams model estimates a scale parameter ϕ by equating the value of Pearson χ^2 for the full model to its approximate expected value. The full model considered in the following statements is the model with cultivar, soil condition, and their interaction. Using a full model reduces the risk of contaminating ϕ with lack of fit due to incorrect model specification.

```
proc logistic data=seeds;
  model r/n=cult soil cult*soil / scale=williams;
  title 'Full Model With SCALE=WILLIAMS';
run;
```

Results of using Williams' method are shown in [Output 54.10.2](#). The estimate of ϕ is 0.075941 and is given in the formula for the Weight Variable at the beginning of the displayed output.

Output 54.10.2 Williams' Model for Overdispersion

Deviance and Pearson Goodness-of-Fit Statistics					
Criterion	Value	DF	Value/DF	Pr > ChiSq	
Deviance	16.4402	16	1.0275	0.4227	
Pearson	16.0000	16	1.0000	0.4530	
Number of events/trials observations: 20					
NOTE: Since the Williams method was used to accommodate overdispersion, the Pearson chi-squared statistic and the deviance can no longer be used to assess the goodness of fit of the model.					
Model Fit Statistics					
		Intercept and Covariates			
	Intercept	Log	Full Log		
Criterion	Only	Likelihood	Likelihood		
AIC	276.155	273.586	44.579		
SC	280.964	292.822	63.815		
-2 Log L	274.155	265.586	36.579		
Testing Global Null Hypothesis: BETA=0					
Test	Chi-Square	DF	Pr > ChiSq		
Likelihood Ratio	8.5687	3	0.0356		
Score	8.4856	3	0.0370		
Wald	8.3069	3	0.0401		
Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	1	-0.3926	0.2932	1.7932	0.1805
cult	1	-0.2618	0.4160	0.3963	0.5290
soil	1	0.8309	0.4223	3.8704	0.0491
cult*soil	1	-0.0532	0.5835	0.0083	0.9274

Since neither cult nor cult \times soil is statistically significant ($p = 0.5290$ and $p = 0.9274$, respectively), a reduced model that contains only the soil condition factor is fitted, with the observations weighted by $1/(1 + 0.075941(N - 1))$. This can be done conveniently in PROC LOGISTIC by including the scale estimate in the SCALE=WILLIAMS option as follows:

```
proc logistic data=seeds;
  model r/n=soil / scale=williams(0.075941);
  title 'Reduced Model With SCALE=WILLIAMS(0.075941)';
run;
```

Results of the reduced model fit are shown in [Output 54.10.3](#). Soil condition remains a significant factor ($p = 0.0064$) for the seed germination.

Output 54.10.3 Reduced Model with Overdispersion Controlled

Reduced Model With SCALE=WILLIAMS(0.075941)

soil	1	0.7910	0.2902	7.4284	0.0064

Example 54.11: Conditional Logistic Regression for Matched Pairs Data

In matched pairs, or *case-control*, studies, conditional logistic regression is used to investigate the relationship between an outcome of being an event (case) or a nonevent (control) and a set of prognostic factors.

The following data are a subset of the data from the Los Angeles Study of the Endometrial Cancer Data in Breslow and Day (1980). There are 63 matched pairs, each consisting of a case of endometrial cancer (Outcome=1) and a control (Outcome=0). The case and corresponding control have the same ID. Two prognostic factors are included: Gall (an indicator variable for gall bladder disease) and Hyper (an indicator variable for hypertension). The goal of the case-control analysis is to determine the relative risk for gall bladder disease, controlling for the effect of hypertension.

```
data Data1;
  do ID=1 to 63;
    do Outcome = 1 to 0 by -1;
      input Gall Hyper @@;
      output;
    end;
  end;
  datalines;
0 0 0 0    0 0 0 0    0 1 0 1    0 0 1 0    1 0 0 1

0 0 0 0    1 1 0 0    0 1 0 0    0 0 0 0    0 1 0 1
0 0 0 0    0 1 0 1    0 1 0 0    0 1 0 0    1 0 0 0
0 0 0 0    1 1 1 0    0 0 0 0    0 0 0 0    1 1 0 0
1 0 1 0    0 1 0 0    1 0 0 0
```

There are several ways to approach this problem with PROC LOGISTIC:

- Specify the **STRATA** statement to perform a conditional logistic regression.
- Specify **EXACT** and **STRATA** statements to perform an exact logistic regression on the original data set, if you believe the data set is too small or too sparse for the usual asymptotics to hold.
- Transform each matched pair into a single observation, and then specify a PROC LOGISTIC statement on this transformed data without a STRATA statement; this also performs a conditional logistic regression and produces essentially the same results.
- Specify an **EXACT** statement on the transformed data.

SAS statements and selected results for these four approaches are given in the remainder of this example.

Conditional Analysis Using the STRATA Statement

In the following statements, PROC LOGISTIC is invoked with the ID variable declared in the **STRATA** statement to obtain the conditional logistic model estimates for a model containing Gall as the only predictor variable:

```
proc logistic data=Data1;
  strata ID;
  model outcome(event='1')=Gall;
run;
```

Results from the conditional logistic analysis are shown in [Output 54.11.1](#). Note that there is no intercept term in the “Analysis of Maximum Likelihood Estimates” tables.

The odds ratio estimate for Gall is 2.60, which is marginally significant ($p = 0.0694$) and which is an estimate of the relative risk for gall bladder disease. A 95% confidence interval for this relative risk is (0.927, 7.293).

Output 54.11.1 Conditional Logistic Regression (Gall as Risk Factor)

Gall	2.600	0.927	7.293

Exact Analysis Using the STRATA Statement

When you believe there are not enough data or that the data are too sparse, you can perform a stratified exact logistic regression. The following statements perform stratified exact logistic regressions on the original data set by specifying both the **STRATA** and **EXACT** statements:

```
proc logistic data=Data1 exactonly;
  strata ID;
  model outcome(event='1')=Gall;
  exact Gall / estimate=both;
run;
```

Output 54.11.2 Exact Logistic Regression (Gall as Risk Factor)

The LOGISTIC Procedure					
Exact Conditional Analysis					
Exact Conditional Tests					
Effect	Test	Statistic	--- p-Value ---		
			Exact	Mid	
Gall	Score	3.5556	0.0963	0.0799	
	Probability	0.0327	0.0963	0.0799	
Exact Parameter Estimates					
Parameter	Estimate	Standard Error	95% Confidence Limits		Two-sided p-Value
Gall	0.9555	0.5262	-0.1394	2.2316	0.0963
Exact Odds Ratios					
Parameter	Estimate	95% Confidence Limits		Two-sided p-Value	
Gall	2.600	0.870	9.315	0.0963	

Note that the score statistic in the “Conditional Exact Tests” table in [Output 54.11.2](#) is identical to the score statistic in [Output 54.11.1](#) from the conditional analysis. The exact odds ratio confidence interval is much wider than its conditional analysis counterpart, but the parameter estimates are similar. The exact analysis confirms the marginal significance of Gall as a predictor variable.

Conditional Analysis Using Transformed Data

When each matched set consists of one event and one nonevent, the conditional likelihood is given by

$$\prod_i (1 + \exp(-\beta'(\mathbf{x}_{i1} - \mathbf{x}_{i0})))^{-1}$$

where \mathbf{x}_{i1} and \mathbf{x}_{i0} are vectors representing the prognostic factors for the event and nonevent, respectively, of the i th matched set. This likelihood is identical to the likelihood of fitting a logistic regression model to a set of data with constant response, where the model contains no intercept term and has explanatory variables given by $\mathbf{d}_i = \mathbf{x}_{i1} - \mathbf{x}_{i0}$ (Breslow 1982).

To apply this method, the following DATA step transforms each matched pair into a single observation, where the variables Gall and Hyper contain the differences between the corresponding values for the case and the control (case-control). The variable Outcome, which will be used as the response variable in the logistic regression model, is given a constant value of 0 (which is the Outcome value for the control, although any constant, numeric or character, will suffice).

```
data Data2;
    set Data1;
    drop id1 gall1 hyper1;
    retain id1 gall1 hyper1 0;
    if (ID = id1) then do;
        Gall=gall1-Gall; Hyper=hyper1-Hyper;
        output;
    end;
    else do;
        id1=ID; gall1=Gall; hyper1=Hyper;
    end;
run;
```

Note that there are 63 observations in the data set, one for each matched pair. Since the number of observations n is halved, statistics that depend on n such as R Square (see the “[Generalized Coefficient of Determination](#)” on page 4246 section) will be incorrect. The variable Outcome has a constant value of 0.

In the following statements, PROC LOGISTIC is invoked with the **NOINT** option to obtain the conditional logistic model estimates. Because the option **CLODDS=PL** is specified, PROC LOGISTIC computes a 95% profile-likelihood confidence interval for the odds ratio for each predictor variable; note that profile-likelihood confidence intervals are not currently available when a **STRATA** statement is specified.

```
proc logistic data=Data2;
    model outcome=Gall / noint clodds=PL;
run;
```

The results are not displayed here.

Exact Analysis Using Transformed Data

Sometimes the original data set in a matched-pairs study is too large for the exact methods to handle. In such cases it might be possible to use the transformed data set. The following statements perform exact logistic regressions on the transformed data set. The results are not displayed here.

```
proc logistic data=Data2 exactonly;
  model outcome=Gall / noint;
  exact Gall / estimate=both;
run;
```

Example 54.12: Firth's Penalized Likelihood Compared with Other Approaches

Firth's penalized likelihood approach is a method of addressing issues of separability, small sample sizes, and bias of the parameter estimates. This example performs some comparisons between results from using the **FIRTH** option to results from the usual unconditional, conditional, and exact logistic regression analyses. When the sample size is large enough, the unconditional estimates and the Firth penalized-likelihood estimates should be nearly the same. These examples show that Firth's penalized likelihood approach compares favorably with unconditional, conditional, and exact logistic regression; however, this is not an exhaustive analysis of Firth's method. For more detailed analyses with separable data sets, see Heinze (2006, 1999) and Heinze and Schemper (2002).

Comparison on 2x2 Tables with One Zero Cell

A 2×2 table with one cell having zero frequency, where the rows of the table are the levels of a covariate while the columns are the levels of the response variable, is an example of a quasi-completely separated data set. The parameter estimate for the covariate under unconditional logistic regression will move off to infinity, although PROC LOGISTIC will stop the iterations at an earlier point in the process. An exact logistic regression is sometimes performed to determine the importance of the covariate in describing the variation in the data, but the median-unbiased parameter estimate, while finite, might not be near the true value, and one confidence limit (for this example, the upper) is always infinite.

The following DATA step produces 1000 different 2×2 tables, all following an underlying probability structure, with one cell having a near zero probability of being observed:

```
%let beta0=-15;
%let beta1=16;
data one;
  keep sample X y pry;
  do sample=1 to 1000;
    do i=1 to 100;
      X=rantrb1(987987, .4, .6)-1;
      xb= &beta0 + X*&beta1;
      exb=exp(xb);
      pry= exb/(1+exb);
      cut= ranuni(393993);
      if (pry < cut) then y=1; else y=0;
      output;
    end;
  end;
```

```
end;
run;
```

The following statements perform the bias-corrected and exact logistic regression on each of the 1000 different data sets, output the odds ratio tables by using the ODS OUTPUT statement, and compute various statistics across the data sets by using the MEANS procedure:

```
ods exclude all;
proc logistic data=one;
  by sample;
  class X(param=ref);
  model y(event='1')=X / firth clodds=pl;
  ods output cloddspl=firth;
run;
proc logistic data=one exactonly;
  by sample;
  class X(param=ref);
  model y(event='1')=X;
  exact X / estimate=odds;
  ods output exactoddsratio=exact;
run;
ods select all;
proc means data=firth;
  var LowerCL OddsRatioEst UpperCL;
run;
proc means data=exact;
  var LowerCL Estimate UpperCL;
run;
```

The results of the PROC MEANS statements are summarized in [Table 54.16](#). You can see that the odds ratios are all quite large; the confidence limits on every table suggest that the covariate X is a significant factor in explaining the variability in the data.

Table 54.16 Odds Ratio Results

Method	Mean Estimate	Standard Error	Minimum Lower CL	Maximum Upper CL
Firth	231.59	83.57	10.40	111317
Exact	152.02	52.30	11.16	∞

Comparison on Case-Control Data

Case-control models contain an intercept term for every case-control pair in the data set. This means that there are a large number of parameters compared to the number of observations. Breslow and Day (1980) note that the estimates from unconditional logistic regression are biased with the corresponding odds ratios off by a power of 2 from the true value; conditional logistic regression was developed to remedy this.

The following DATA step produces 1000 case-control data sets, with pair indicating the strata:

```

%let beta0=1;
%let beta1=2;
data one;
  do sample=1 to 1000;
    do pair=1 to 20;
      ran=ranuni(939393);
      a=3*ranuni(9384984)-1;
      pdf0= pdf('NORMAL',a,.4,1);
      pdf1= pdf('NORMAL',a,1,1);
      pry0= pdf0/(pdf0+pdf1);
      pry1= 1-pry0;
      xb= log(pry0/pry1);
      x= (xb-&beta0*pair/100) / &beta1;
      y=0;
      output;
      x= (-xb-&beta0*pair/100) / &beta1;
      y=1;
      output;
    end;
  end;
run;

```

Unconditional, conditional, exact, and Firth-adjusted analyses are performed on the data sets, and the mean, minimum, and maximum odds ratios and the mean upper and lower limits for the odds ratios are displayed in [Table 54.17](#). **CAUTION:** Due to the exact analyses, this program takes a long time and a lot of resources to run. You might want to reduce the number of samples generated.

```

ods exclude all;
proc logistic data=one;
  by sample;
  class pair / param=ref;
  model y=x pair / clodds=pl;
  ods output cloddspl=oru;
run;
data oru;
  set oru;
  if Effect='x';
  rename lowercl=lclu uppercl=uclu oddsratioest=orestu;
run;
proc logistic data=one;
  by sample;
  strata pair;
  model y=x / clodds=wald;
  ods output cloddswald=orc;
run;
data orc;
  set orc;
  if Effect='x';
  rename lowercl=lclc uppercl=uclc oddsratioest=orestc;
run;
proc logistic data=one exactonly;
  by sample;
  strata pair;

```

```

model y=x;
exact x / estimate=both;
ods output ExactOddsRatio=ore;
run;
proc logistic data=one;
  by sample;
  class pair / param=ref;
  model y=x pair / firth clodds=pl;
  ods output cloddspl=orf;
run;
data orf;
  set orf;
  if Effect='x';
  rename lowercl=lclf uppercl=uclf oddsratioest=orestf;
run;
data all;
  merge oru orc ore orf;
run;
ods select all;
proc means data=all;
run;

```

You can see from Table 54.17 that the conditional, exact, and Firth-adjusted results are all comparable, while the unconditional results are several orders of magnitude different.

Table 54.17 Odds Ratio Estimates

Method	N	Minimum	Mean	Maximum
Unconditional	1000	0.00045	112.09	38038
Conditional	1000	0.021	4.20	195
Exact	1000	0.021	4.20	195
Firth	1000	0.018	4.89	71

Further examination of the data set all shows that the differences between the square root of the unconditional odds ratio estimates and the conditional estimates have mean -0.00019 and standard deviation 0.0008 , verifying that the unconditional odds ratio is about the square of the conditional odds ratio. The conditional and exact conditional odds ratios are also nearly equal, with their differences having mean $3E-7$ and standard deviation $6E-6$. The differences between the Firth and the conditional odds ratios can be large (mean 0.69 , standard deviation 5.40), but their relative differences, $\frac{Firth - Conditional}{Conditional}$, have mean 0.20 with standard deviation 0.19 , so the largest differences occur with the larger estimates.

Example 54.13: Complementary Log-Log Model for Infection Rates

Antibodies produced in response to an infectious disease like malaria remain in the body after the individual has recovered from the disease. A serological test detects the presence or absence of such antibodies. An individual with such antibodies is called seropositive. In geographic areas where the disease is endemic, the inhabitants are at fairly constant risk of infection. The probability of an individual never having been

infected in Y years is $\exp(-\mu Y)$, where μ is the mean number of infections per year (see the appendix of Draper, Voller, and Carpenter 1972). Rather than estimating the unknown μ , epidemiologists want to estimate the probability of a person living in the area being infected in one year. This infection rate γ is given by

$$\gamma = 1 - e^{-\mu}$$

The following statements create the data set `sero`, which contains the results of a serological survey of malarial infection. Individuals of nine age groups (Group) were tested. The variable `A` represents the midpoint of the age range for each age group. The variable `N` represents the number of individuals tested in each age group, and the variable `R` represents the number of individuals that are seropositive.

```
data sero;
  input Group A N R;
  X=log(A);
  label X='Log of Midpoint of Age Range';
  datalines;
1  1.5  123  8
2  4.0  132  6
3  7.5  182 18
4 12.5  140 14
5 17.5  138 20
6 25.0  161 39
7 35.0  133 19
8 47.0   92 25
9 60.0   74 44
;
```

For the i th group with the age midpoint A_i , the probability of being seropositive is $p_i = 1 - \exp(-\mu A_i)$. It follows that

$$\log(-\log(1 - p_i)) = \log(\mu) + \log(A_i)$$

By fitting a binomial model with a complementary log-log link function and by using `X=log(A)` as an offset term, you can estimate $\alpha = \log(\mu)$ as an intercept parameter. The following statements invoke PROC LOGISTIC to compute the maximum likelihood estimate of α . The `LINK=CLOGLOG` option is specified to request the complementary log-log link function. Also specified is the `CLPARM=PL` option, which requests the profile-likelihood confidence limits for α .

X	0	1.0000	0	.	.

Parameter Estimates and Profile-Likelihood Confidence Intervals			
Parameter	Estimate	95% Confidence Limits	
Intercept	-4.6605	-4.8057	-4.5219

Output 54.13.1 shows that the maximum likelihood estimate of $\alpha = \log(\mu)$ and its estimated standard error are $\hat{\alpha} = -4.6605$ and $\hat{\sigma}_{\hat{\alpha}} = 0.0725$, respectively. The infection rate is estimated as

$$\hat{\gamma} = 1 - e^{-\hat{\mu}} = 1 - e^{-e^{\hat{\alpha}}} = 1 - e^{-e^{-4.6605}} = 0.00942$$

The 95% confidence interval for γ , obtained by back-transforming the 95% confidence interval for α , is (0.0082, 0.0108); that is, there is a 95% chance that, in repeated sampling, the interval of 8 to 11 infections per thousand individuals contains the true infection rate.

The goodness-of-fit statistics for the constant risk model are statistically significant ($p < 0.0001$), indicating that the assumption of constant risk of infection is not correct. You can fit a more extensive model by allowing a separate risk of infection for each age group. Suppose μ_i is the mean number of infections per year for the i th age group. The probability of seropositive for the i th group with the age midpoint A_i is $p_i = 1 - \exp(-\mu_i A_i)$, so that

$$\log(-\log(1 - p_i)) = \log(\mu_i) + \log(A_i)$$

In the following statements, a complementary log-log model is fit containing Group as an explanatory classification variable with the GLM coding (so that a dummy variable is created for each age group), no intercept term, and $X = \log(A)$ as an offset term. The ODS OUTPUT statement saves the estimates and their 95% profile-likelihood confidence limits to the ClparmPL data set. Note that $\log(\mu_i)$ is the regression parameter associated with $\text{Group} = i$.

```
proc logistic data=sero;
  ods output ClparmPL=ClparmPL;
  class Group / param=glm;
  model R/N=Group / noint
        offset=X
        link=cloglog
        clparm=pl;
  title 'Infectious Rates and 95% Confidence Intervals';
run;
```

Results of fitting the model with a separate risk of infection are shown in Output 54.13.2.

Group 8	1	-4.9987	-5.4195	-4.6289
Group 9	1	-4.1965	-4.5164	-3.9037

For the first age group (Group=1), the point estimate of $\log(\mu_1)$ is -3.1048, which transforms into an infection rate of $1 - \exp(-\exp(-3.1048)) = 0.0438$. A 95% confidence interval for this infection rate is obtained by transforming the 95% confidence interval for $\log(\mu_1)$. For the first age group, the lower and upper confidence limits are $1 - \exp(-\exp(-3.8880)) = 0.0203$ and $1 - \exp(-\exp(-2.4833)) = 0.0801$, respectively; that is, there is a 95% chance that, in repeated sampling, the interval of 20 to 80 infections per thousand individuals contains the true infection rate. The following statements perform this transformation on the estimates and confidence limits saved in the ClparmPL data set; the resulting estimated infection rates in one year's time for each age group are displayed in [Table 54.18](#). Note that the infection rate for the first age group is high compared to that of the other age groups.

```
data ClparmPL;
  set ClparmPL;
  Estimate=round( 1000*( 1-exp(-exp(Estimate)) ) );
  LowerCL =round( 1000*( 1-exp(-exp(LowerCL)) ) );
  UpperCL =round( 1000*( 1-exp(-exp(UpperCL)) ) );
run;
```

Table 54.18 Infection Rate in One Year

Example 54.14: Complementary Log-Log Model for Interval-Censored Survival Times

Often survival times are not observed more precisely than the interval (for instance, a day) within which the event occurred. Survival data of this form are known as grouped or interval-censored data. A discrete analog of the continuous proportional hazards model (Prentice and Gloeckler 1978; Allison 1982) is used to investigate the relationship between these survival times and a set of explanatory variables.

Suppose T_i is the discrete survival time variable of the i th subject with covariates \mathbf{x}_i . The discrete-time hazard rate λ_{it} is defined as

$$\lambda_{it} = \Pr(T_i = t \mid T_i \geq t, \mathbf{x}_i), \quad t = 1, 2, \dots$$

Using elementary properties of conditional probabilities, it can be shown that

$$\Pr(T_i = t) = \lambda_{it} \prod_{j=1}^{t-1} (1 - \lambda_{ij}) \quad \text{and} \quad \Pr(T_i > t) = \prod_{j=1}^t (1 - \lambda_{ij})$$

Suppose t_i is the observed survival time of the i th subject. Suppose $\delta_i = 1$ if $T_i = t_i$ is an event time and 0 otherwise. The likelihood for the grouped survival data is given by

$$\begin{aligned}
 L &= \prod_i [\Pr(T_i = t_i)]^{\delta_i} [\Pr(T_i > t_i)]^{1-\delta_i} \\
 &= \prod_i \left(\frac{\lambda_{it_i}}{1 - \lambda_{it_i}} \right)^{\delta_i} \prod_{j=1}^{t_i} (1 - \lambda_{ij}) \\
 &= \prod_i \prod_{j=1}^{t_i} \left(\frac{\lambda_{ij}}{1 - \lambda_{ij}} \right)^{y_{ij}} (1 - \lambda_{ij})
 \end{aligned}$$

where $y_{ij} = 1$ if the i th subject experienced an event at time $T_i = j$ and 0 otherwise.

Note that the likelihood L for the grouped survival data is the same as the likelihood of a binary response model with event probabilities λ_{ij} . If the data are generated by a continuous-time proportional hazards model, Prentice and Gloeckler (1978) have shown that

$$\lambda_{ij} = 1 - \exp(-\exp(\alpha_j + \beta'x_i))$$

which can be rewritten as

$$\log(-\log(1 - \lambda_{ij})) = \alpha_j + \beta'x_i$$

where the coefficient vector β is identical to that of the continuous-time proportional hazards model, and α_j is a constant related to the conditional survival probability in the interval defined by $T_i = j$ at $x_i = \mathbf{0}$. The grouped data survival model is therefore equivalent to the binary response model with complementary log-log link function. To fit the grouped survival model by using PROC LOGISTIC, you must treat each discrete time unit for each subject as a separate observation. For each of these observations, the response is dichotomous, corresponding to whether or not the subject died in the time unit.

Consider a study of the effect of insecticide on flour beetles. Four different concentrations of an insecticide were sprayed on separate groups of flour beetles. The following DATA step saves the number of male and female flour beetles dying in successive intervals in the data set Beetles:

```
data Beetles(keep=time sex conc freq);
  input time m20 f20 m32 f32 m50 f50 m80 f80;
  conc=.20; freq= m20; sex=1; output;
           freq= f20; sex=2; output;
  conc=.32; freq= m32; sex=1; output;
           freq= f32; sex=2; output;
  conc=.50; freq= m50; sex=1; output;
           freq= f50; sex=2; output;
  conc=.80; freq= m80; sex=1; output;
           freq= f80; sex=2; output;
  datalines;
1   3   0   7   1   5   0   4   2
2  11   2  10   5   8   4  10   7
3  10   4  11  11  11   6   8  15
4   7   8  16  10  15   6  14   9
5   4   9   3   5   4   3   8   3
6   3   3   2   1   2   1   2   4

12  1   0   0   0   0   1   0   0
13  1   0   0   0   0   1   0   0
14 101 126 19 47   7  17   2   4
;
```

The data set Beetles contains four variables: time, sex, conc, and freq. The variable time represents the interval death time; for example, time=2 is the interval between day 1 and day 2. Insects surviving the duration (13 days) of the experiment are given a time value of 14. The variable sex represents the sex of the insects (1=male, 2=female), conc represents the concentration of the insecticide (mg/cm²), and freq represents the frequency of the observations.

To use PROC LOGISTIC with the grouped survival data, you must expand the data so that each beetle has a separate record for each day of survival. A beetle that died in the third day (time=3) would contribute three observations to the analysis, one for each day it was alive at the beginning of the day. A beetle that survives the 13-day duration of the experiment (time=14) would contribute 13 observations.

The following DATA step creates a new data set named Days containing the beetle-day observations from the data set Beetles. In addition to the variables sex, conc, and freq, the data set contains an outcome variable y and a classification variable day. The variable y has a value of 1 if the observation corresponds to the day that the beetle died, and it has a value of 0 otherwise. An observation for the first day will have a value of 1 for day; an observation for the second day will have a value of 2 for day, and so on. For instance, [Output 54.14.1](#) shows an observation in the Beetles data set with time=3, and [Output 54.14.2](#) shows the corresponding beetle-day observations in the data set Days.

```
data Days;
  set Beetles;
  do day=1 to time;
    if (day < 14) then do;
      y= (day=time);
      output;
    end;
  end;
run;
```

Output 54.14.1 An Observation with Time=3 in Beetles Data Set

Obs	time	conc	freq	sex
17	3	0.2	10	1

Output 54.14.2 Corresponding Beetle-Day Observations in Days

Obs	time	conc	freq	sex	day	y
25	3	0.2	10	1	1	0
26	3	0.2	10	1	2	0
27	3	0.2	10	1	3	1

The following statements invoke PROC LOGISTIC to fit a complementary log-log model for binary data with the response variable Y and the explanatory variables day, sex, and Variableconc. Specifying the **EVENT=** option ensures that the event (y=1) probability is modeled. The GLM coding in the **CLASS** statement creates an indicator column in the design matrix for each level of day. The coefficients of the indicator effects for day can be used to estimate the baseline survival function. The **NOINT** option is specified to prevent any redundancy in estimating the coefficients of day. The Newton-Raphson algorithm is used for the maximum likelihood estimation of the parameters.

```
proc logistic data=Days outest=est1;
  class day / param=glm;
  model y(event='1')= day sex conc
    / noint link=cloglog technique=newton;
  freq freq;
run;
```

Results of the model fit are given in [Output 54.14.3](#). Both sex and conc are statistically significant for the survival of beetles sprayed by the insecticide. Female beetles are more resilient to the chemical than male beetles, and increased concentration of the insecticide increases its effectiveness.

Output 54.14.3 Parameter Estimates for the Grouped Proportional Hazards Model

Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq	
day	1	-3.9314	0.2934	179.5602	<.0001	
day	2	-2.8751	0.2412	142.0596	<.0001	
day	3	-2.3985	0.2299	108.8833	<.0001	
day	4	-1.9953	0.2239	79.3960	<.0001	
day	5	-2.4920	0.2515	98.1470	<.0001	
day	6	-3.1060	0.3037	104.5799	<.0001	
day	7	-3.9704	0.4230	88.1107	<.0001	
day	8	-3.7917	0.4007	89.5233	<.0001	
day	9	-5.1540	0.7316	49.6329	<.0001	
day	10	-5.1350	0.7315	49.2805	<.0001	
day	11	-5.1131	0.7313	48.8834	<.0001	
day	12	-5.1029	0.7313	48.6920	<.0001	
day	13	-5.0951	0.7313	48.5467	<.0001	
sex	1	-0.5651	0.1141	24.5477	<.0001	
conc	1	3.0918	0.2288	182.5665	<.0001	

The coefficients of parameters for the day variable are the maximum likelihood estimates of $\alpha_1, \dots, \alpha_{13}$, respectively. The baseline survivor function $S_0(t)$ is estimated by

$$\hat{S}_0(t) = \hat{\Pr}(T > t) = \prod_{j \leq t} \exp(-\exp(\hat{\alpha}_j))$$

and the survivor function for a given covariate pattern (sex= x_1 and conc= x_2) is estimated by

$$\hat{S}(t) = [\hat{S}_0(t)]^{\exp(-0.5651x_1 + 3.0918x_2)}$$

The following statements compute the survival curves for male and female flour beetles exposed to the insecticide in concentrations of 0.20 mg/cm² and 0.80 mg/cm²:

```

data one (keep=day survival element s_m20 s_f20 s_m80 s_f80);
  array dd day1-day13;
  array sc[4] m20 f20 m80 f80;
  array s_sc[4] s_m20 s_f20 s_m80 s_f80 (1 1 1 1);
  set est1;
  m20= exp(sex + .20 * conc);
  f20= exp(2 * sex + .20 * conc);
  m80= exp(sex + .80 * conc);
  f80= exp(2 * sex + .80 * conc);
  survival=1;
  day=0;
  output;
  do over dd;
    element= exp(-exp(dd));
    survival= survival * element;
    do i=1 to 4;
      s_sc[i] = survival ** sc[i];
    end;
    day + 1;
    output;
  end;
run;

```

Instead of plotting the curves as step functions, the following statements use the PBSPLINE statement in the SGPLOT procedure to smooth the curves with a penalized B-spline. See Chapter 97, “[The TRANSREG Procedure](#),” for details about the implementation of the penalized B-spline method. The SAS autocall macro %MODSTYLE is specified to change the marker symbols for the plot. For more information about the %MODSTYLE macro, see the section “[Style Template Modification Macro](#)” on page 667 in Chapter 21, “[Statistical Graphics Using ODS](#).” The smoothed survival curves are displayed in [Output 54.14.4](#).

```

%modstyle(name=LogiStyle,parent=htmlblue,markers=circlefilled);
ods listing style=LogiStyle;
proc sgplot data=one;
  title 'Flour Beetles Sprayed with Insecticide';
  xaxis grid integer;
  yaxis grid label='Survival Function';
  pbspline y=s_m20 x=day /
    legendlabel = "Male at 0.20 conc." name="pred1";
  pbspline y=s_m80 x=day /
    legendlabel = "Male at 0.80 conc." name="pred2";
  pbspline y=s_f20 x=day /
    legendlabel = "Female at 0.20 conc." name="pred3";
  pbspline y=s_f80 x=day /
    legendlabel = "Female at 0.80 conc." name="pred4";
  discretelegend "pred1" "pred2" "pred3" "pred4" / across=2;
run;

```

Output 54.14.4 Predicted Survival at Insecticide Concentrations of 0.20 and 0.80 mg/cm²

The probability of survival is displayed on the vertical axis. Notice that most of the insecticide effect occurs by day 6 for both the high and low concentrations.

Example 54.15: Scoring Data Sets

This example first illustrates the syntax used for scoring data sets, then uses a previously scored data set to score a new data set. A generalized logit model is fit to the remote-sensing data set used in the section “[Example 33.4: Linear Discriminant Analysis of Remote-Sensing Data on Crops](#)” on page 2146 of Chapter 33, “[The DISCRIM Procedure](#),” to illustrate discrimination and classification methods. In the following DATA step, the response variable is Crop and the prognostic factors are x1 through x4:

```
data Crops;
  length Crop $ 10;
  infile datalines truncover;
  input Crop $ @@;
  do i=1 to 3;
    input x1-x4 @@;
    if (x1 ^= .) then output;
```

```

end;
input;
datalines;
Corn      16 27 31 33  15 23 30 30  16 27 27 26
Corn      18 20 25 23  15 15 31 32  15 32 32 15
Corn      12 15 16 73
Soybeans  20 23 23 25  24 24 25 32  21 25 23 24
Soybeans  27 45 24 12  12 13 15 42  22 32 31 43
Cotton    31 32 33 34  29 24 26 28  34 32 28 45
Cotton    26 25 23 24  53 48 75 26  34 35 25 78
Sugarbeets 22 23 25 42  25 25 24 26  34 25 16 52
Sugarbeets 54 23 21 54  25 43 32 15  26 54  2 54
Clover    12 45 32 54  24 58 25 34  87 54 61 21
Clover    51 31 31 16  96 48 54 62  31 31 11 11
Clover    56 13 13 71  32 13 27 32  36 26 54 32
Clover    53 08 06 54  32 32 62 16
;

```

In the following statements, you specify a **SCORE** statement to use the fitted model to score the Crops data. The data together with the predicted values are saved in the data set **Score1**. The output from the **EFFECTPLOT** statement is discussed at the end of this section.

```

ods graphics on;
proc logistic data=Crops;
  model Crop=x1-x4 / link=glogit;
  score out=Score1;
  effectplot slicefit(x=x3);
run;
ods graphics off;

```

In the following statements, the model is fit again, and the data and the predicted values are saved into the data set **Score2**. The **OUTMODEL=** option saves the fitted model information in the permanent SAS data set **sasuser.CropModel**, and the **STORE** statement saves the fitted model information into the SAS data set **CropModel2**. Both the **OUTMODEL=** option and the **STORE** statement are specified to illustrate their use; you would usually specify only one of these model-storing methods.

```

proc logistic data=Crops outmodel=sasuser.CropModel;
  model Crop=x1-x4 / link=glogit;
  score data=Crops out=Score2;
  store CropModel2;
run;

```

To score data without refitting the model, specify the **INMODEL=** option to identify a previously saved SAS data set of model information. In the following statements, the model is read from the **sasuser.CropModel** data set, and the data and the predicted values are saved in the data set **Score3**. Note that the data set being scored does not have to include the response variable.

```

proc logistic inmodel=sasuser.CropModel;
  score data=Crops out=Score3;
run;

```

Another method available to score the data without refitting the model is to invoke the **PLM** procedure. In the following statements, the stored model is named in the **SOURCE=** option. The **PREDICTED=** option computes the linear predictors, and the **ILINK** option transforms the linear predictors to the probability

scale. The SCORE statement scores the Crops data set, and the predicted probabilities are saved in the data set ScorePLM. See Chapter 69, “[The PLM Procedure](#),” for more information.

```
proc plm source=CropModel2;
    score data=Crops out=ScorePLM predicted=p / ilink;
run;
```

For each observation in the Crops data set, the ScorePLM data set contains 5 observations—one for each level of the response variable. The following statements transform this data set into a form that is similar to the other scored data sets in this example:

```
proc transpose data=ScorePLM out=Score4 prefix=P_ let;
    id _LEVEL_;
    var p;
    by x1-x4 notsorted;
run;
data Score4(drop=_NAME_ _LABEL_);
    merge Score4 Crops(keep=Crop x1-x4);
    F_Crop=Crop;
run;
proc summary data=ScorePLM nway;
    by x1-x4 notsorted;
    var p;
    output out=into maxid(p(_LEVEL_))=I_Crop;
run;
data Score4;
    merge Score4 into(keep=I_Crop);
run;
```

To set prior probabilities on the responses, specify the **PRIOR=** option to identify a SAS data set containing the response levels and their priors. In the following statements, the Prior data set contains the values of the response variable (because this example uses single-trial MODEL statement syntax) and a **_PRIOR_** variable containing values proportional to the default priors. The data and the predicted values are saved in the data set Score5.

```
data Prior;
    length Crop $10.;
    input Crop _PRIOR_;
    datalines;
Clover      11
Corn        7
Cotton      6
Soybeans    6
Sugarbeets  6
;

proc logistic inmodel=sasuser.CropModel;
    score data=Crops prior=prior out=Score5 fitstat;
run;
```

The “Fit Statistics for SCORE Data” table displayed in [Output 54.15.1](#) shows that 47.22% of the observations are misclassified.

Output 54.15.1 Fit Statistics for Data Set Prior

Fit Statistics for SCORE Data						
Data Set	Total Frequency	Log Likelihood	Error Rate	AIC	AICC	BIC
WORK.CROPS	36	-32.2247	0.4722	104.4493	160.4493	136.1197

0.43649	0.00033	0.01631

The **EFFECTPLOT** statement that is specified in the first PROC LOGISTIC invocation produces a plot of the model-predicted probabilities versus X3 while holding the other three covariates at their means (Output 54.15.4). This plot shows how the value of X3 affects the probabilities of the various crops when the other prognostic factors are fixed at their means. If you are interested in the effect of X3 when the other covariates are fixed at a certain level—say, 10—specify the following EFFECTPLOT statement.

```
effectplot slicefit(x=x3) / at (x1=10 x2=10 x4=10)
```

Output 54.15.4 Model-Predicted Probabilities

Example 54.16: Using the LSMEANS Statement

Recall the main-effects model fit to the Neuralgia data set in [Example 54.2](#). The Treatment*Sex interaction, which was previously shown to be nonsignificant, is added back into the model for this discussion.

In the following statements, the **ODDSRATIO** statement is specified to produce odds ratios of pairwise differences of the Treatment parameters in the presence of the Sex interaction. The **LSMEANS** statement is specified with several options: the **E** option displays the coefficients that are used to compute the LS-means for each Treatment level, the **DIFF** option takes all pairwise differences of the LS-means for the levels of the Treatment variable, the **ODDSRATIO** option computes odds ratios of these differences, the **CL** option produces confidence intervals for the differences and odds ratios, and the **ADJUST=BON** option performs a very conservative adjustment of the *p*-values and confidence intervals.

```

proc logistic data=Neuralgia;
  class Treatment Sex / param=glm;
  model Pain= Treatment|Sex Age;
  oddsratio Treatment;
  lsmeans Treatment / e diff oddsratio cl adjust=bon;
run;

```

The results from the **ODDSRATIO** statement are displayed in [Output 54.16.1](#). All pairwise differences of levels of the Treatment effect are compared. However, because of the interaction between the Treatment and Sex variables, each difference is computed at each of the two levels of the Sex variable. These results show that the difference between Treatment levels A and B is insignificant for both genders.

To compute these odds ratios, you must first construct a linear combination of the parameters, $l'\beta$, for each level that is compared with all other levels fixed at some value. For example, to compare Treatment=A with B for Sex=F, you fix the Age variable at its mean, 70.05, and construct the following l vectors:

	Intercept	Treatment			Sex		Treatment*Sex						Age
		A	B	P	F	M	AF	AM	BF	BM	PF	PM	
l'_A	1	1	0	0	1	0	1	0	0	0	0	0	70.05
l'_B	1	0	1	0	1	0	0	0	1	0	0	0	70.05
$l'_A - l'_B$	0	1	-1	0	0	0	1	0	-1	0	0	0	0

Then the odds ratio for Treatment A versus B at Sex=F is computed as $\exp((l'_A - l'_B)\beta)$. Different l vectors must be similarly constructed when Sex=M because the resulting odds ratio will be different due to the interaction.

Output 54.16.1 Odds Ratios from the ODDSRATIO Statement

Odds Ratio Estimates and Wald Confidence Intervals			
Label	Estimate	95% Confidence Limits	
Treatment A vs B at Sex=F	0.398	0.016	9.722
Treatment A vs P at Sex=F	16.892	1.269	224.838
Treatment B vs P at Sex=F	42.492	2.276	793.254
Treatment A vs B at Sex=M	0.663	0.078	5.623
Treatment A vs P at Sex=M	34.766	1.807	668.724
Treatment B vs P at Sex=M	52.458	2.258	>999.999

The results from the **LSMEANS** statement are displayed in [Output 54.16.2](#) through [Output 54.16.4](#).

The LS-means are computed by constructing each of the l coefficient vectors shown in [Output 54.16.2](#), and then computing $l'\beta$. The LS-means are not estimates of the event probabilities; they are estimates of the linear predictors on the logit scale. In order to obtain event probabilities, you need to apply the inverse-link transformation by specifying the **ILINK** option in the **LSMEANS** statement. Notice in [Output 54.16.2](#) that the Sex rows do not indicate either Sex=F or Sex=M. Instead, the LS-means are computed at an average of these two levels, so only one result needs to be reported. For more information about the construction of LS-means, see the section “[Construction of Least Squares Means](#)” on page 3363 of Chapter 42, “[The GLM Procedure](#).”

Output 54.16.2 Treatment LS-Means Coefficients

Coefficients for Treatment Least Squares Means					
Parameter	Treatment	Sex	Row1	Row2	Row3
Intercept: Pain=No			1	1	1
Treatment A	A		1		
Treatment B	B			1	
Treatment P	P				1
Sex F		F	0.5	0.5	0.5
Sex M		M	0.5	0.5	0.5
Treatment A * Sex F	A	F	0.5		
Treatment A * Sex M	A	M	0.5		
Treatment B * Sex F	B	F		0.5	
Treatment B * Sex M	B	M		0.5	
Treatment P * Sex F	P	F			0.5
Treatment P * Sex M	P	M			0.5
Age			70.05	70.05	70.05

The Treatment LS-means shown in [Output 54.16.3](#) are all significantly nonzero at the 0.05 level. These LS-means are *predicted population margins* of the logits; that is, they estimate the marginal means over a balanced population, and they are effectively the within-Treatment means appropriately adjusted for the other effects in the model. The LS-means are not event probabilities; in order to obtain event probabilities, you need to apply the inverse-link transformation by specifying the ILINK option in the **LSMEANS** statement. For more information about LS-means, see the section “**LSMEANS Statement**” on page 453 of Chapter 19, “**Shared Concepts and Topics**.”

Output 54.16.3 Treatment LS-Means

Treatment Least Squares Means							
Treatment	Estimate	Standard Error	z Value	Pr > z	Alpha	Lower	Upper
A	1.3195	0.6664	1.98	0.0477	0.05	0.01331	2.6257
B	1.9864	0.7874	2.52	0.0116	0.05	0.4431	3.5297
P	-1.8682	0.7620	-2.45	0.0142	0.05	-3.3618	-0.3747

Pairwise differences between the Treatment LS-means, requested with the **DIFF** option, are displayed in [Output 54.16.4](#). The LS-mean for the level that is displayed in the `_Treatment` column is subtracted from the LS-mean for the level in the `Treatment` column, so the first row displays the LS-mean for Treatment level A minus the LS-mean for Treatment level B. The `Pr > |z|` column indicates that the A and B levels are not significantly different; however, both of these levels are different from level P. If the inverse-link transformation is specified with the **ILINK** option, then these differences do not transform back to differences in probabilities.

There are two odds ratios for Treatment level A versus B in [Output 54.16.1](#); these are constructed at each level of the interacting covariate Sex. In contrast, there is only one LS-means odds ratio for Treatment level A versus B in [Output 54.16.4](#). This odds ratio is computed at an average of the interacting effects by creating the \mathbf{l} vectors shown in [Output 54.16.2](#) (the Row1 column corresponds to \mathbf{l}_A and the Row2 column corresponds to \mathbf{l}_B) and computing $\exp(\mathbf{l}_A'\boldsymbol{\beta} - \mathbf{l}_B'\boldsymbol{\beta})$.

Since multiple tests are performed, you can protect yourself from falsely significant results by adjusting your p -values for multiplicity. The **ADJUST=BON** option performs the very conservative Bonferroni adjustment, and adds the columns labeled with ‘Adj’ to [Output 54.16.4](#). Comparing the $\text{Pr} > |z|$ column to the Adj P column, you can see that the p -values are adjusted upwards; in this case, there is no change in your conclusions. The confidence intervals are also adjusted for multiplicity—all adjusted intervals are wider than the unadjusted intervals, but again your conclusions in this example are unchanged.

Output 54.16.4 Differences and Odds Ratios for the Treatment LS-Means

Differences of Treatment Least Squares Means Adjustment for Multiple Comparisons: Bonferroni							
Treatment	_Treatment	Estimate	Standard Error	z Value	Pr > z	Adj P	Alpha

B	P	4.384	508.441	2.590	860.612		

If you want to jointly test whether the active treatments are different from the placebo, you can specify a custom hypothesis test with the **LSMESTIMATE** statement. In the following statements, the LS-means for the two treatments are contrasted against the LS-mean of the placebo, and the **JOINT** option performs a joint test that the two treatments are not different from placebo.

```
proc logistic data=Neuralgia;
  class Treatment Sex / param=glm;
  model Pain= Treatment|Sex Age;
  lsmestimate treatment 1 0 -1, 0 1 -1 / joint;
run;
```

[Output 54.16.5](#) displays the results from the **LSMESTIMATE** statement. The “Least Squares Means Es-

imate” table displays the differences of the two active treatments against the placebo, and the results are identical to the second and third rows of [Output 54.16.3](#). The “Chi-Square Test for Least Squares Means Estimates” table displays the joint test. In all of these tests, you reject the null hypothesis that the treatment has the same effect as the placebo.

Output 54.16.5 Custom LS-Mean Tests

Least Squares Means Estimates					
Effect	Label	Estimate	Standard Error	z Value	Pr > z
Treatment	Row 1	3.1877	1.0376	3.07	0.0021
Treatment	Row 2	3.8547	1.2126	3.18	0.0015
Chi-Square Test for Least Squares Means Estimates					
Effect	Num DF	Chi-Square	Pr > ChiSq		
Treatment	2	12.13	0.0023		

If you want to work with LS-means but you prefer to compute the Treatment odds ratios within the Sex levels in the same fashion as the [ODDSRATIO](#) statement does, you can specify the [SLICE](#) statement. In the following statements, you specify the same options in the [SLICE](#) statement as you do in the [LSMEANS](#) statement, except that you also specify the [SLICEBY=](#) option to perform an LS-means analysis partitioned into sets that are defined by the Sex variable:

```
proc logistic data=Neuralgia;
  class Treatment Sex / param=glm;
  model Pain= Treatment|Sex Age;
  slice Treatment*Sex / sliceby=Sex diff oddsratio cl adjust=bon;
run;
```

The results for Sex=F are displayed in [Output 54.16.6](#) and [Output 54.16.7](#). The joint test in [Output 54.16.6](#) tests the equality of the LS-means of the levels of Treatment for Sex=F, and rejects equality at level 0.05. In [Output 54.16.7](#), the odds ratios and confidence intervals match those reported for Sex=F in [Output 54.16.1](#), and multiplicity adjustments are performed.

Example 54.17: Partial Proportional Odds Model

Cameron and Trivedi (1998, p. 68) studied the number of doctor visits from the Australian Health Survey 1977–78. The data set contains a dependent variable, `dvisits`, which contains the number of doctor visits in the past two weeks (0, 1, or 2, where 2 represents two or more visits) and the following explanatory variables: `sex`, which indicates whether the patient is female; `age`, which contains the patient's age in years divided by 100; `income`, which contains the patient's annual income (in units of \$10,000); `levyplus`, which indicates whether the patient has private health insurance; `freepoor`, which indicates that the patient has free government health insurance due to low income; `freerepa`, which indicates that the patient has free government health insurance for other reasons; `illness`, which contains the number of illnesses in the past two weeks; `actdays`, which contains the number of days the illness caused reduced activity; `hscore`, which is a questionnaire score; `chcond1`, which indicates a chronic condition that does not limit activity; and `chcond2`, which indicates a chronic condition that limits activity.

```
data docvisit;
  input sex age agesq income levyplus freepoor freerepa
        illness actdays hscore chcond1 chcond2 dvisits;
  if ( dvisits > 2) then dvisits = 2;
datalines;
1 0.19 0.0361 0.55 1 0 0 1 4 1 0 0 1
1 0.19 0.0361 0.45 1 0 0 1 2 1 0 0 1
0 0.19 0.0361 0.90 0 0 0 3 0 0 0 0 1

... more lines ...

1 0.37 0.1369 0.25 0 0 1 1 0 1 0 0 0
1 0.52 0.2704 0.65 0 0 0 0 0 0 0 0 0
0 0.72 0.5184 0.25 0 0 1 0 0 0 0 0 0
;
```

Because the response variable `dvisits` has three levels, the proportional odds model constructs two response functions. There is an intercept parameter for each of the two response functions, $\alpha_1 < \alpha_2$, and common slope parameters $\beta = (\beta_1, \dots, \beta_{12})$ across the functions. The model can be written as

$$\text{logit}(\Pr(Y \leq i \mid \mathbf{x})) = \alpha_i + \beta' \mathbf{x}, \quad i = 1, 2$$

The following statements fit a proportional odds model to this data:

```
proc logistic data=docvisit;
  model dvisits = sex age agesq income levyplus
                freepoor freerepa illness actdays hscore
                chcond1 chcond2;
run;
```

Selected results are displayed in [Output 54.17.1](#).

Output 54.17.1 Test of Proportional Odds Assumption

Score Test for the Proportional Odds Assumption			
Chi-Square	DF	Pr > ChiSq	
27.4256	12	0.0067	
Testing Global Null Hypothesis: BETA=0			
Test	Chi-Square	DF	Pr > ChiSq
Likelihood Ratio	734.2971	12	<.0001
Score	811.8964	12	<.0001
Wald	690.7156	12	<.0001

The test of the proportional odds assumption in [Output 54.17.1](#) rejects the null hypothesis that all the slopes are equal across the two response functions. This test is very anticonservative; that is, it tends to reject the null hypothesis even when the proportional odds assumption is reasonable.

The proportional odds assumption for ordinal response models can be relaxed by specifying the [UNEQUALSLOPES](#) option in the MODEL statement. A fully nonproportional odds model has different slope parameters $\beta_i = (\beta_{1,i}, \dots, \beta_{12,i})$ for every logit i :

$$\text{logit}(\Pr(Y \leq i | \mathbf{x})) = \alpha_i + \beta'_i \mathbf{x}, \quad i = 1, 2$$

The nonproportional odds model is fit with the following statements. The [TEST](#) statements test the proportional odds assumption for each of the covariates in the model.

```
proc logistic data=docvisit;
  model dvisits = sex age agesq income levyplus
               freepoor freerepa illness actdays hscore
               chcond1 chcond2 / unequalslopes;

The preceding nonproportional odds model fits $12 \times 2 = 24$ slope parameters, and the model seems to overfit the data. You can obtain a more parsimonious model by specifying a subset of the parameters to have nonproportional odds. The following statements allow the parameters for the variables in the “Linear Hypotheses Testing Results” table that have p -values less than 0.1 (actdays, agesq, and income) to vary across the response functions:

```
proc logistic data=docvisit;
  model dvisits= sex age agesq income levyplus freepoor
    freerepa illness actdays hscore chcond1 chcond2
    / unequalslopes=(actdays agesq income);
run;
```

Selected results from fitting this partial proportional odds model are displayed in [Output 54.17.3](#).

The partial proportional odds model can be written in the same form as the nonproportional odds model by letting $\mathbf{x} = (x_1, \dots, x_q, x_{q+1}, \dots, x_{12})$ and $\boldsymbol{\beta}_i = (\beta_1, \dots, \beta_q, \beta_{q+1,i}, \dots, \beta_{12,i})$, so the first q parameters have proportional odds and the remaining parameters do not. The last $12-q$ parameters can be rewritten to have a common slope: $\beta_{q+j} + \gamma_{q+j,i}$, $j = 1, \dots, 12-q$, where the new parameters γ_i contain the increments from the common slopes. The model in this form makes it obvious that the proportional odds model is a submodel of the partial proportional odds models, and both of these are submodels of the nonproportional odds model. This means that you can use likelihood ratio tests to compare models.

You can use the following statements to compute the likelihood ratio tests from the Likelihood Ratio row of the “Testing Global Null hypothesis: BETA=0” tables in the preceding outputs:

```
data a;
  label p='Pr>ChiSq';
  format p 8.6;
  input Test $10. ChiSq1 DF1 ChiSq2 DF2;
  ChiSq= ChiSq1-ChiSq2;
  DF= DF1-DF2;
  p=1-probchi(ChiSq,DF);
  keep Test ChiSq DF p;
  datalines;

PPO vs PO      752.5512 15      734.2971 12
Non vs PPO      761.4797 24      752.5512 15
;

proc print data=a label noobs;
  var Test ChiSq DF p;
run;
```

Output 54.17.4 Likelihood Ratio Tests

Test	ChiSq	DF	Pr>ChiSq
Non vs PO	27.1826	12	0.007273
PPO vs PO	18.2541	3	0.000390
Non vs PPO	8.9285	9	0.443900

Therefore, you reject the proportional odds model in favor of both the nonproportional odds model and the partial proportional odds model, and the partial proportional odds model fits as well as the nonproportional odds model. The likelihood ratio test of the nonproportional odds model versus the proportional odds model is very similar to the score test of the proportional odds assumption in [Output 54.17.1](#) because of the large sample size (Stokes, Davis, and Koch 2000, p. 249).

NOTE: The proportional odds model has increasing intercepts, which ensures the increasing nature of the cumulative response functions. However, none of the parameters in the partial or nonproportional odds models are constrained. Because of this, sometimes during the optimization process a predicted individual probability can be negative; the optimization continues because it might recover from this situation. Sometimes your final model will predict negative individual probabilities for some of the observations; in this case a message is displayed, and you should check your data for outliers and possibly redefine your model. Other times the model fits your data well, but if you try to score new data you can get negative individual probabilities. This means the model is not appropriate for the data you are trying to score, a message is displayed, and the estimates are set to missing.

Overview: MCMC Procedure

The MCMC procedure is a general purpose Markov chain Monte Carlo (MCMC) simulation procedure that is designed to fit Bayesian models. Bayesian statistics is different from traditional statistical methods such as frequentist or classical methods. For a short introduction to Bayesian analysis and related basic concepts, see Chapter 7, “[Introduction to Bayesian Analysis Procedures](#).” Also see the section “[A Bayesian Reading List](#)” on page 156 for a guide to Bayesian textbooks of varying degrees of difficulty.

In essence, Bayesian statistics treats parameters as unknown random variables, and it makes inferences based on the posterior distributions of the parameters. There are several advantages associated with this approach to statistical inference. Some of the advantages include its ability to use prior information and to directly answer specific scientific questions that can be easily understood. For further discussions of the relative advantages and disadvantages of Bayesian analysis, see the section “[Bayesian Analysis: Advantages and Disadvantages](#)” on page 132.

It follows from Bayes’ theorem that a posterior distribution is the product of the likelihood function and the prior distribution of the parameter. In all but the simplest cases, it is very difficult to obtain the posterior distribution directly and analytically. Often, Bayesian methods rely on simulations to generate sample from the desired posterior distribution and use the simulated draws to approximate the distribution and to make all of the inferences.

PROC MCMC is a flexible, simulation-based procedure that is suitable for fitting a wide range of Bayesian models. To use PROC MCMC, you need to specify a likelihood function for the data and a prior distribution for the parameters. If you are fitting hierarchical models, you can specify a hyperprior distribution or distributions for the random-effects parameters. PROC MCMC then obtains samples from the corresponding posterior distributions, produces summary and diagnostic statistics, and saves the posterior samples in an output data set that can be used for further analysis. Although PROC MCMC supports a suite of standard distributions, you can analyze data that have any likelihood, prior, or hyperprior, as long as these functions are programmable using the SAS DATA step functions. There are no constraints on how the parameters can enter the model, in either linear or any nonlinear functional form.

The **MODEL** statement in PROC MCMC can automatically model missing data, response variables, or covariates. In releases before SAS/STAT 12.1, observations with missing values were discarded prior to the analysis. Now, PROC MCMC treats the missing values as unknown parameters and incorporates the sampling of the missing values as part of the simulation.

PROC MCMC selects a sampling method for each parameter or a block of parameters. For example, when conjugacy is available, samples are drawn directly from the full conditional distribution by using standard random number generators. In other cases, PROC MCMC uses an adaptive blocked random walk Metropolis algorithm that uses a normal proposal distribution. You can also choose alternative sampling algorithms, such as the slice sampler.

PROC MCMC Compared with Other SAS Procedures

PROC MCMC is unlike most other SAS/STAT procedures in that the nature of the statistical inference is Bayesian. You specify prior distributions for the parameters with **PRIOR** statements and the likelihood function for the data with **MODEL** statements. PROC MCMC derives inferences from simulation rather than through analytic or numerical methods. You should expect slightly different answers from each run

for the same problem, unless the same random number seed is used. The model specification is similar to PROC NLIN, and PROC MCMC shares some of the syntax of PROC NLMIXED.

You can also carry out a Bayesian analysis with the GENMOD, PHREG, LIFEREG, and FMM procedures for generalized linear models, accelerated life failure models, Cox regression models, piecewise constant baseline hazard models (also known as piecewise exponential models), and finite mixture models. See Chapter 40, “[The GENMOD Procedure](#),” Chapter 67, “[The PHREG Procedure](#),” Chapter 51, “[The LIFEREG Procedure](#),” and Chapter 37, “[The FMM Procedure](#).”

Getting Started: MCMC Procedure

There are three examples in this “Getting Started” section: a simple linear regression, the Behrens-Fisher estimation problem, and a random-effects model. The regression model is chosen for its simplicity; the Behrens-Fisher problem illustrates some advantages of the Bayesian approach; and the random-effects model is one of the most prevalently used models.

Keep in mind that **PARMS** statements declare the parameters in the model, **PRIOR** statements declare the prior distributions, **MODEL** statements declare the likelihood for the data, and **RANDOM** statements declare the random effects. In most cases, you do not need to supply initial values. PROC MCMC advises you if it is unable to generate starting values for the Markov chain.

Simple Linear Regression

This section illustrates some basic features of PROC MCMC by using a linear regression model. The model is as follows:

$$Y_i = \beta_0 + \beta_1 X_i + \epsilon_i$$

for the observations $i = 1, 2, \dots, n$.

The following statements create a SAS data set with measurements of Height and Weight for a group of children:

```

title 'Simple Linear Regression';

data Class;
  input Name $ Height Weight @@;
  datalines;
Alfred 69.0 112.5   Alice 56.5 84.0   Barbara 65.3 98.0
Carol 62.8 102.5   Henry 63.5 102.5   James 57.3 83.0
Jane 59.8 84.5    Janet 62.5 112.5   Jeffrey 62.5 84.0
John 59.0 99.5    Joyce 51.3 50.5    Judy 64.3 90.0
Louise 56.3 77.0   Mary 66.5 112.0   Philip 72.0 150.0
Robert 64.8 128.0  Ronald 67.0 133.0  Thomas 57.5 85.0
William 66.5 112.0
;

```

The equation of interest is as follows:

$$\text{Weight}_i = \beta_0 + \beta_1 \text{Height}_i + \epsilon_i$$

The observation errors, ϵ_i , are assumed to be independent and identically distributed with a normal distribution with mean zero and variance σ^2 .

$$\text{Weight}_i \sim \text{normal}(\beta_0 + \beta_1 \text{Height}_i, \sigma^2)$$

The likelihood function for each of the `Weight`, which is specified in the `MODEL` statement, is as follows:

$$p(\text{Weight}|\beta_0, \beta_1, \sigma^2, \text{Height}_i) = \phi(\beta_0 + \beta_1 \text{Height}_i, \sigma^2)$$

where $p(\cdot|\cdot)$ denotes a conditional probability density and ϕ is the normal density. There are three parameters in the likelihood: β_0 , β_1 , and σ^2 . You use the `PARMS` statement to indicate that these are the parameters in the model.

Suppose you want to use the following three prior distributions on each of the parameters:

$$\begin{aligned}\pi(\beta_0) &= \phi(0, \text{var} = 1e6) \\ \pi(\beta_1) &= \phi(0, \text{var} = 1e6) \\ \pi(\sigma^2) &= f_{i\Gamma}(\text{shape} = 3/10, \text{scale} = 10/3)\end{aligned}$$

where $\pi(\cdot)$ indicates a prior distribution and $f_{i\Gamma}$ is the density function for the inverse-gamma distribution. The normal priors on β_0 and β_1 have large variances, expressing your lack of knowledge about the regression coefficients. The priors correspond to an equal-tail 95% credible intervals of approximately (-2000, 2000) for β_0 and β_1 . Priors of this type are often called *vague* or *diffuse* priors. See the section “[Prior Distributions](#)” on page 127 for more information. Typically diffuse prior distributions have little influence on the posterior distribution and are appropriate when stronger prior information about the parameters is not available.

A frequently used prior for the variance parameter σ^2 is the inverse-gamma distribution. See [Table 55.22](#) in the section “[Standard Distributions](#)” on page 4476 for the density definition. The inverse-gamma distribution is a conjugate prior (see the section “[Conjugate Sampling](#)” on page 4472) for the variance parameter in a normal distribution. Also see the section “[Gamma and Inverse-Gamma Distributions](#)” on page 4512 for typical usages of the gamma and inverse-gamma prior distributions. With a shape parameter of 3/10 and a scale parameter of 10/3, this prior corresponds to an equal-tail 95% credible interval of (1.7, 1E6), with the mode at 2.5641 for σ^2 . Alternatively, you can use any other prior distribution with positive support on this variance component. For example, you can use the gamma prior.

According to Bayes’ theorem, the likelihood function and prior distributions determine the posterior (joint) distribution of β_0 , β_1 , and σ^2 as follows:

$$\pi(\beta_0, \beta_1, \sigma^2 | \text{Weight}, \text{Height}) \propto \pi(\beta_0)\pi(\beta_1)\pi(\sigma^2)p(\text{Weight}|\beta_0, \beta_1, \sigma^2, \text{Height})$$

You do not need to know the form of the posterior distribution when you use PROC MCMC. PROC MCMC automatically obtains samples from the desired posterior distribution, which is determined by the prior and likelihood you supply.

The following statements fit this linear regression model with diffuse prior information:

```
ods graphics on;
proc mcmc data=class outpost=classout nmc=10000 thin=2 seed=246810;
  parms beta0 0 beta1 0;
  parms sigma2 1;
  prior beta0 beta1 ~ normal(mean = 0, var = 1e6);
  prior sigma2 ~ igamma(shape = 3/10, scale = 10/3);
  mu = beta0 + beta1*height;
  model weight ~ n(mu, var = sigma2);
run;
ods graphics off;
```

When ODS Graphics is enabled, diagnostic plots, such as the trace and autocorrelation function plots of the posterior samples, are displayed. For more information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).”

The PROC MCMC statement invokes the procedure and specifies the input data set `Class`. The output data set `Classout` contains the posterior samples for all of the model parameters. The `NMC=` option specifies the number of posterior simulation iterations. The `THIN=` option controls the thinning of the Markov chain and specifies that one of every 2 samples is kept. Thinning is often used to reduce the correlations among posterior sample draws. In this example, 5,000 simulated values are saved in the `Classout` data set. The `SEED=` option specifies a seed for the random number generator, which guarantees the reproducibility of the random stream. For more information about Markov chain sample size, burn-in, and thinning, see the section “[Burn-in, Thinning, and Markov Chain Samples](#)” on page 138.

The `PARMS` statements identify the three parameters in the model: `beta0`, `beta1`, and `sigma2`. Each statement also forms a block of parameters, where the parameters are updated simultaneously in each iteration. In this example, `beta0` and `beta1` are sampled jointly, conditional on `sigma2`; and `sigma2` is sampled conditional on fixed values of `beta0` and `beta1`. In simple regression models such as this, you expect the parameters `beta0` and `beta1` to have high posterior correlations, and placing them both in the same block improves the mixing of the chain—that is, the efficiency that the posterior parameter space is explored by the Markov chain. For more information, see the section “[Blocking of Parameters](#)” on page 4466. The `PARMS` statements also assign initial values to the parameters (see the section “[Initial Values of the Markov Chains](#)” on page 4474). The regression parameters are given 0 as their initial values, and the scale parameter `sigma2` starts at value 1. If you do not provide initial values, PROC MCMC chooses starting values for every parameter.

The `PRIOR` statements specify prior distributions for the parameters. The parameters `beta0` and `beta1` both share the same prior—a normal prior with mean 0 and variance 1e6. The parameter `sigma2` has an inverse-gamma distribution with a shape parameter of 3/10 and a scale parameter of 10/3. For a list of standard distributions that PROC MCMC supports, see the section “[Standard Distributions](#)” on page 4476.

The `MU` assignment statement calculates the expected value of `Weight` as a linear function of `Height`. The `MODEL` statement uses the shorthand notation, `n`, for the normal distribution to indicate that the response variable, `Weight`, is normally distributed with parameters `mu` and `sigma2`. The functional argument `MEAN=` in the normal distribution is optional, but you have to indicate whether `sigma2` is a variance (`VAR=`), a standard deviation (`SD=`), or a precision (`PRECISION=`) parameter. See [Table 55.2](#) in the section “[MODEL Statement](#)” on page 4443 for distribution specifications.

The distribution parameters can contain expressions. For example, you can write the `MODEL` statement as follows:

```
model weight ~ n(beta0 + betal*height, var = sigma2);
```

Before you do any posterior inference, it is essential that you examine the convergence of the Markov chain (see the section “[Assessing Markov Chain Convergence](#)” on page 139). You cannot make valid inferences if the Markov chain has not converged. A very effective convergence diagnostic tool is the trace plot. Although PROC MCMC produces graphs at the end of the procedure output (see [Figure 55.5](#)), you should visually examine the convergence graph first.

The first table that PROC MCMC produces is the “Number of Observations” table, as shown in [Figure 55.1](#). This table lists the number of observations read from the `DATA=` data set and the number of observations used in the analysis.

Figure 55.1 Observation Information

Simple Linear Regression	
The MCMC Procedure	
Number of Observations Read	19
Number of Observations Used	19

The “Parameters” table, shown in [Figure 55.2](#), lists the names of the parameters, the blocking information, the sampling method used, the starting values, and the prior distributions. For more information about blocking information, see the section “[Blocking of Parameters](#)” on page 4466; for more information about starting values, see the section “[Initial Values of the Markov Chains](#)” on page 4474. The first block, which consists of the parameters `beta0` and `beta1`, uses a random walk Metropolis algorithm. The second block, which consists of the parameter `sigma2`, is updated via its full conditional distribution in conjugacy. You should check this table to ensure that you have specified the parameters correctly, especially for complicated models.

Figure 55.2 Parameter Information

Parameters				
Block	Parameter	Sampling Method	Initial Value	Prior Distribution
1	<code>beta0</code>	N-Metropolis	0	<code>normal(mean = 0, var = 1e6)</code>
	<code>beta1</code>		0	<code>normal(mean = 0, var = 1e6)</code>
2	<code>sigma2</code>	Conjugate	1.0000	<code>igamma(shape = 3/10, scale = 10/3)</code>

For each posterior distribution, PROC MCMC also reports summary statistics (posterior means, standard deviations, and quantiles) and interval statistics (95% equal-tail and highest posterior density credible intervals), as shown in [Figure 55.3](#). For more information about posterior statistics, see the section “[Summary Statistics](#)” on page 153.

Figure 55.3 MCMC Summary and Interval Statistics

Simple Linear Regression						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
beta0	5000	-142.8	33.4326	-164.8	-142.3	-120.0
beta1	5000	3.8924	0.5333	3.5361	3.8826	4.2395
sigma2	5000	137.3	51.1030	101.9	127.2	161.2
Posterior Intervals						
Parameter	Alpha	Equal-Tail Interval		HPD Interval		
beta0	0.050	-208.9	-78.7305	-210.8	-81.6714	
beta1	0.050	2.8790	4.9449	2.9056	4.9545	
sigma2	0.050	69.1351	259.8	59.2362	236.3	

By default, PROC MCMC also computes a number of convergence diagnostics to help you determine whether the chain has converged. These are the Monte Carlo standard errors, the autocorrelations at selected lags, the Geweke diagnostics, and the effective sample sizes. These statistics are shown in [Figure 55.4](#). For details and interpretations of these diagnostics, see the section “[Assessing Markov Chain Convergence](#)” on page 139.

The “Monte Carlo Standard Errors” table indicates that the standard errors of the mean estimates for each of the parameters are relatively small, with respect to the posterior standard deviations. The values in the “MCSE/SD” column (ratios of the standard errors and the standard deviations) are small, around 0.03. This means that only a fraction of the posterior variability is due to the simulation. The “Autocorrelations of the Posterior Samples” table shows that the autocorrelations among posterior samples reduce quickly and become almost nonexistent after a few lags. The “Geweke Diagnostics” table indicates that no parameter failed the test, and the “Effective Sample Sizes” table reports the number of effective sample sizes of the Markov chain.

Figure 55.4 MCMC Convergence Diagnostics

Simple Linear Regression			
The MCMC Procedure			
Monte Carlo Standard Errors			
Parameter	MCSE	Standard Deviation	MCSE/SD
beta0	1.0070	33.4326	0.0301
beta1	0.0159	0.5333	0.0299
sigma2	0.9473	51.1030	0.0185

Figure 55.4 *continued*

Posterior Autocorrelations				
Parameter	Lag 1	Lag 5	Lag 10	Lag 50
beta0	0.6177	0.1083	0.0250	-0.0007
beta1	0.6162	0.1052	0.0217	0.0029
sigma2	0.1224	0.0216	0.0098	0.0197

Geweke Diagnostics		
Parameter	z	Pr > z
beta0	1.0267	0.3046
beta1	-0.9305	0.3521
sigma2	-0.3578	0.7205

Effective Sample Sizes			
Parameter	ESS	Autocorrelation	
		Time	Efficiency
beta0	1102.2	4.5366	0.2204
beta1	1119.0	4.4684	0.2238
sigma2	2910.1	1.7182	0.5820

PROC MCMC produces a number of graphs, shown in [Figure 55.5](#), which also aid convergence diagnostic checks. With the trace plots, there are two important aspects to examine. First, you want to check whether the mean of the Markov chain has stabilized and appears constant over the graph. Second, you want to check whether the chain has good mixing and is “dense,” in the sense that it quickly traverses the support of the distribution to explore both the tails and the mode areas efficiently. The plots show that the chains appear to have reached their stationary distributions.

Next, you should examine the autocorrelation plots, which indicate the degree of autocorrelation for each of the posterior samples. High correlations usually imply slow mixing. Finally, the kernel density plots estimate the posterior marginal distributions for each parameter.

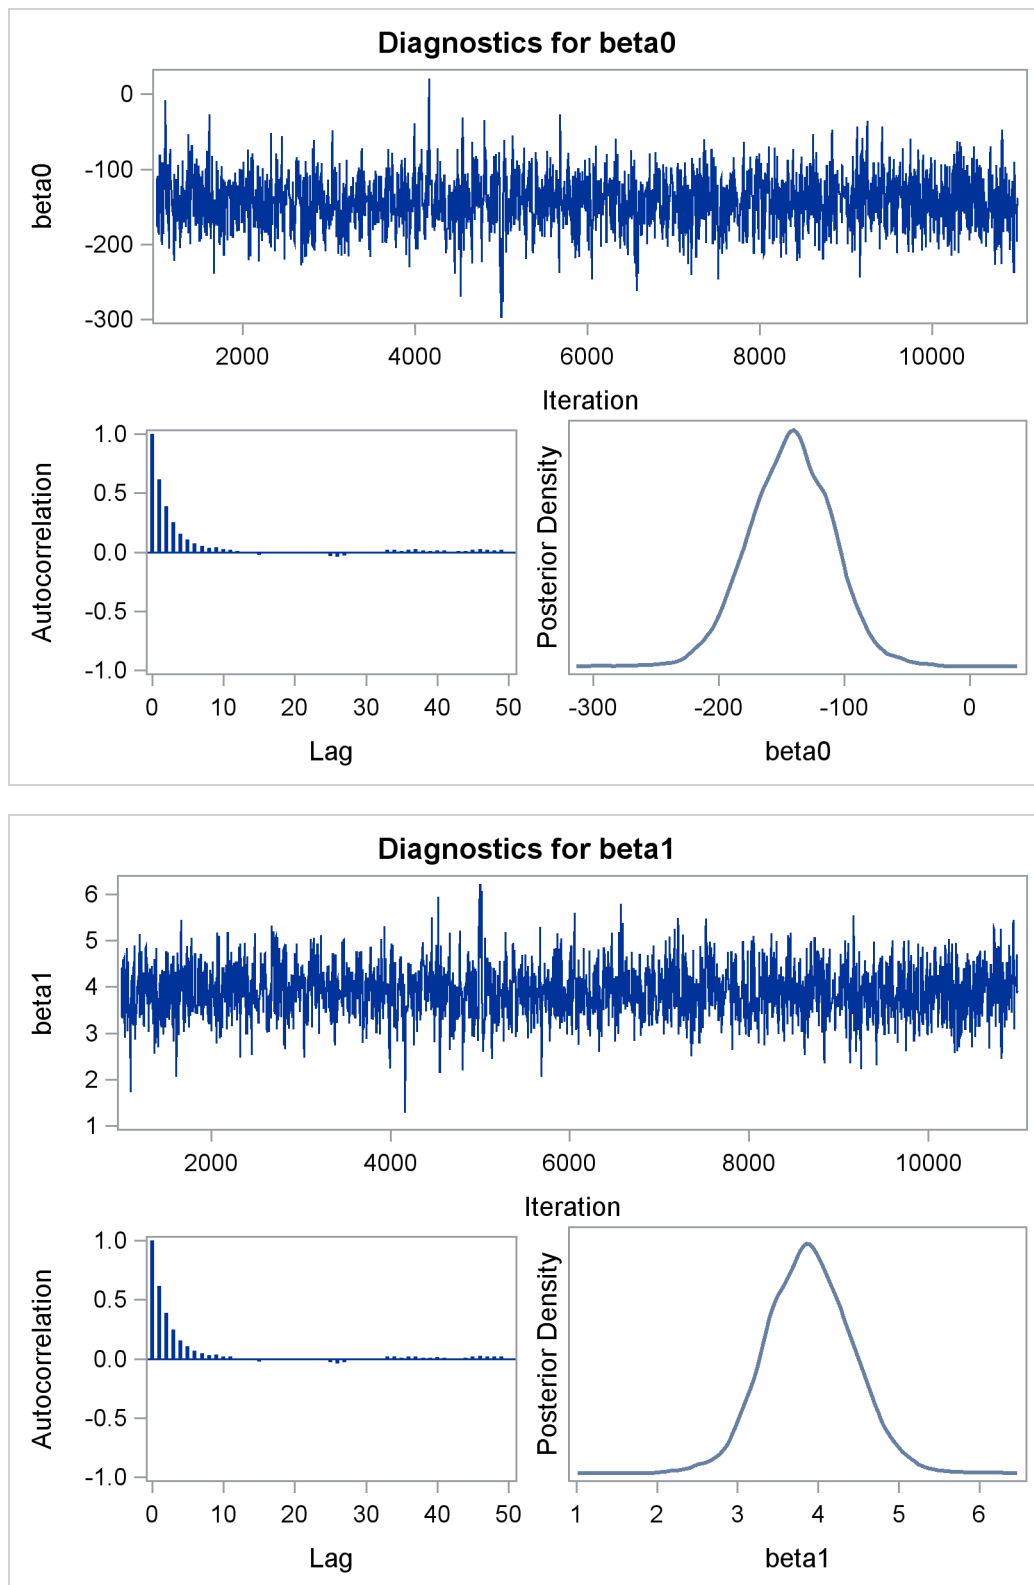

Figure 55.5 Diagnostic Plots for β_0 , β_1 and σ^2 

Figure 55.5 continued

In regression models such as this, you expect the posterior estimates to be very similar to the maximum likelihood estimators with noninformative priors on the parameters. The REG procedure produces the following fitted model (code not shown):

$$\text{Weight} = -143.0 + 3.9 \times \text{Height}$$

These are very similar to the means shown in Figure 55.3. With PROC MCMC, you can carry out informative analysis that uses specifications to indicate prior knowledge on the parameters. Informative analysis is likely to produce different posterior estimates, which are the result of information from both the likelihood and the prior distributions. Incorporating additional information in the analysis is one major difference between the classical and Bayesian approaches to statistical inference.

The Behrens-Fisher Problem

One of the famous examples in the history of statistics is the Behrens-Fisher problem (Fisher 1935). Consider the situation where there are two independent samples from two different normal distributions:

$$\begin{aligned} y_{11}, y_{12}, \dots, y_{1n_1} &\sim \text{normal}(\mu_1, \sigma_1^2) \\ y_{21}, y_{22}, \dots, y_{2n_2} &\sim \text{normal}(\mu_2, \sigma_2^2) \end{aligned}$$

Note that $n_1 \neq n_2$. When you do not want to assume that the variances are equal, testing the hypothesis $H_0 : \mu_1 = \mu_2$ is a difficult problem in the classical statistics framework, because the distribution under H_0

is not known. Within the Bayesian framework, this problem is straightforward because you can estimate the posterior distribution of $\mu_1 - \mu_2$ while taking into account the uncertainties in all of parameters by treating them as random variables.

Suppose you have the following set of data:

```

title 'The Behrens-Fisher Problem';

data behrens;
    input y ind @@;
    datalines;
121 1  94 1 119 1 122 1 142 1 168 1 116 1
172 1 155 1 107 1 180 1 119 1 157 1 101 1
145 1 148 1 120 1 147 1 125 1 126 2 125 2
130 2 130 2 122 2 118 2 118 2 111 2 123 2
126 2 127 2 111 2 112 2 121 2
;

```

The response variable is y , and the ind variable is the group indicator, which takes two values: 1 and 2. There are 19 observations that belong to group 1 and 14 that belong to group 2.

The likelihood functions for the two samples are as follows:

$$\begin{aligned}
 p(y_{1i}|\mu_1, \sigma_1^2) &= \phi(y_{1i}; \mu_1, \sigma_1^2) \text{ for } i = 1, \dots, 19 \\
 p(y_{2j}|\mu_2, \sigma_2^2) &= \phi(y_{2j}; \mu_2, \sigma_2^2) \text{ for } j = 1, \dots, 14
 \end{aligned}$$

Berger (1985) showed that a uniform prior on the support of the location parameter is a noninformative prior. The distribution is invariant under location transformations—that is, $\theta = \mu + c$. You can use this prior for the mean parameters in the model:

$$\begin{aligned}
 \pi(\mu_1) &\propto 1 \\
 \pi(\mu_2) &\propto 1
 \end{aligned}$$

In addition, Berger (1985) showed that a prior of the form $1/\sigma^2$ is noninformative for the scale parameter, and it is invariant under scale transformations (that is $\tau = c\sigma^2$). You can use this prior for the variance parameters in the model:

$$\begin{aligned}
 \pi(\sigma_1^2) &\propto 1/\sigma_1^2 \\
 \pi(\sigma_2^2) &\propto 1/\sigma_2^2
 \end{aligned}$$

The log densities of the prior distributions on σ_1^2 and σ_2^2 are:

$$\begin{aligned}
 \log(\pi(\sigma_1^2)) &= -\log(\sigma_1^2) \\
 \log(\pi(\sigma_2^2)) &= -\log(\sigma_2^2)
 \end{aligned}$$

The following statements generate posterior samples of $\mu_1, \mu_2, \sigma_1^2, \sigma_2^2$, and the difference in the means: $\mu_1 - \mu_2$:

```

proc mcmc data=behrens outpost=postout seed=123
    nmc=40000 thin=10 monitor=(_parms_ mudif)
    statistics(alpha=0.01)=(summary interval);
    ods select PostSummaries PostIntervals;
    parm mu1 0 mu2 0;
    parm sig21 1;
    parm sig22 1;
    prior mu: ~ general(0);
    prior sig21 ~ general(-log(sig21), lower=0);
    prior sig22 ~ general(-log(sig22), lower=0);
    mudif = mu1 - mu2;
    if ind = 1 then do;
        mu = mu1;
        s2 = sig21;
    end;
    else do;
        mu = mu2;
        s2 = sig22;
    end;
    model y ~ normal(mu, var=s2);
run;

```

The PROC MCMC statement specifies an input data set (Behrens), an output data set containing the posterior samples (Postout), a random number seed, the simulation size, and the thinning rate. The **MONITOR=** option specifies a list of symbols, which can be either parameters or functions of the parameters in the model, for which inference is to be done. The symbol _parms_ is a shorthand for all model parameters—in this case, μ_1 , μ_2 , sig21 , and sig22 . The symbol `mudif` is defined in the program as the difference between μ_1 and μ_2 .

The **STATISTICS=** option requests the calculation of summary and interval statistics. The global suboption `ALPHA=0.01` specifies 99% equal-tail and highest posterior density (HPD) credible intervals for all parameters.

The ODS SELECT statement displays the summary statistics and interval statistics tables while excluding all other output. For a complete list of ODS tables that PROC MCMC can produce, see the sections “[Displayed Output](#)” on page 4533 and “[ODS Table Names](#)” on page 4537.

The **PARMS** statements assign the parameters μ_1 and μ_2 to the same block, and sig21 and sig22 each to their own separate blocks. There are a total of three blocks. The **PARMS** statements also assign an initial value to each parameter.

The **PRIOR** statements specify prior distributions for the parameters. Because the priors are all nonstandard (uniform on the real axis for μ_1 and μ_2 and $1/\sigma^2$ for σ_1^2 and σ_2^2), you must use the **GENERAL** function here. The argument in the **GENERAL** function is an expression for the log of the distribution, up to an additive constant. This distribution can have any functional form, as long as it is programmable using SAS functions and expressions. The function specifies a distribution on the log scale, not on the original scale. The log of the prior on μ_1 and μ_2 is 0, and the log of the priors on sig21 and sig22 are $-\log(\text{sig21})$ and $-\log(\text{sig22})$ respectively. See the section “[Specifying a New Distribution](#)” on page 4490 for more information about how to specify an arbitrary distribution. The **LOWER=** option indicates that both variance terms must be strictly positive.

The MUDIF assignment statement calculates the difference between μ_1 and μ_2 . The IF-ELSE statements enable different y 's to have different mean and variance, depending on their group indicator ind . The **MODEL** statement specifies the normal likelihood function for each observation in the model.

Figure 55.6 displays the posterior summary and interval statistics.

Figure 55.6 Posterior Summary and Interval Statistics

The Behrens-Fisher Problem						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
mu1	4000	134.8	6.0065	130.9	134.7	138.7
mu2	4000	121.4	1.9150	120.2	121.4	122.7
sig21	4000	683.2	259.9	507.8	630.1	792.3
sig22	4000	51.3975	24.2881	35.0212	45.7449	61.2582
mudif	4000	13.3596	6.3335	9.1732	13.4078	17.6332
Posterior Intervals						
Parameter	Alpha	Equal-Tail Interval		HPD Interval		
mu1	0.010	118.7	150.6	119.3	151.0	
mu2	0.010	115.9	126.6	116.2	126.7	
sig21	0.010	292.0	1821.1	272.8	1643.7	
sig22	0.010	18.5883	158.8	16.3730	140.5	
mudif	0.010	-3.2537	29.9987	-3.1915	30.0558	

The mean difference has a posterior mean value of 13.36, and the lower endpoints of the 99% credible intervals are negative. This suggests that the mean difference is positive with a high probability. However, if you want to estimate the probability that $\mu_1 - \mu_2 > 0$, you can do so as follows.

The following statements produce Figure 55.7:

```
proc format;
  value diffmt low=0 = 'mu1 - mu2 <= 0' 0<-high = 'mu1 - mu2 > 0';
run;

proc freq data = postout;
  tables mudif /nocum;
  format mudif diffmt.;
run;
```

The sample estimate of the posterior probability that $\mu_1 - \mu_2 > 0$ is 0.98. This example illustrates an advantage of Bayesian analysis. You are not limited to making inferences based on model parameters only. You can accurately quantify uncertainties with respect to any function of the parameters, and this allows for flexibility and easy interpretations in answering many scientific questions.

Figure 55.7 Estimated Probability of $\mu_1 - \mu_2 > 0$.

The Behrens-Fisher Problem		
The FREQ Procedure		
mudif	Frequency	Percent

mu1 - mu2 <= 0	77	1.93
mu1 - mu2 > 0	3923	98.08

Random-Effects Model

This example illustrates how you can fit a normal likelihood random-effects model in PROC MCMC. PROC MCMC offers you the ability to model beyond the normal likelihood (see “[Example 55.7: Logistic Regression Random-Effects Model](#)” on page 4579, “[Example 55.8: Nonlinear Poisson Regression Multilevel Random-Effects Model](#)” on page 4581, and “[Example 55.16: Piecewise Exponential Frailty Model](#)” on page 4631).

Consider a scenario in which data are collected in groups and you want to model group-specific effects. You can use a random-effects model (sometimes also known as a variance-components model):

$$y_{ij} = \beta_0 + \beta_1 x_{ij} + \gamma_i + e_{ij}, \quad e_{ij} \sim \text{normal}(0, \sigma^2)$$

where $i = 1, 2, \dots, I$ is the group index and $j = 1, 2, \dots, n_i$ indexes the observations in the i th group. In the regression model, the fixed effects β_0 and β_1 are the intercept and the coefficient for variable x_{ij} , respectively. The random effect γ_i is the mean for the i th group, and e_{ij} are the error term.

Consider the following SAS data set:

```

title 'Random-Effects Model';

data heights;
  input Family G$ Height @@;
  datalines;
1 F 67   1 F 66   1 F 64   1 M 71   1 M 72   2 F 63
2 F 63   2 F 67   2 M 69   2 M 68   2 M 70   3 F 63
3 M 64   4 F 67   4 F 66   4 M 67   4 M 67   4 M 69
;

```

The response variable Height measures the heights (in inches) of 18 individuals. The covariate x is the gender (variable G), and the individuals are grouped according to Family (group index). Since the variable G is a character variable and PROC MCMC does not support a CLASS statement, you need to create the corresponding design matrix. In this example, the design matrix for a factor variable of level 2 (M and F) can be constructed using the following statement:

```

data input;
  set heights;
  if g eq 'F' then gf = 1;
  else gf = 0;
  drop g;
run;

```

The data set variable `gf` is a numeric variable and can be used in the regression model in PROC MCMC.

In data sets with factor variables that have more levels, you can consider using PROC TRANSREG to construct the design matrix. See the section “[Create Design Matrix](#)” on page 4502 for more information.

To model the data, you can assume that `Height` is normally distributed:

$$y_{ij} \sim \text{normal}(\mu_{ij}, \sigma^2), \quad \mu_{ij} = \beta_0 + \beta_1 \text{gf}_{ij} + \gamma_i$$

The priors on the parameters β_0 , β_1 , γ_i are also assumed to be normal:

$$\begin{aligned} \beta_0 &\sim \text{normal}(0, \text{var} = 1e5) \\ \beta_1 &\sim \text{normal}(0, \text{var} = 1e5) \\ \gamma_i &\sim \text{normal}(0, \text{var} = \sigma_\gamma^2) \end{aligned}$$

Priors on the variance terms, σ^2 and σ_γ^2 , are inverse-gamma:

$$\begin{aligned} \sigma^2 &\sim \text{igamma}(\text{shape} = 0.01, \text{scale} = 0.01) \\ \sigma_\gamma^2 &\sim \text{igamma}(\text{shape} = 0.01, \text{scale} = 0.01) \end{aligned}$$

The inverse-gamma distribution is a conjugate prior for the variance in the normal likelihood and the variance in the prior distribution of the random effect.

The following statements fit a linear random-effects model to the data and produce the output shown in [Figure 55.9](#) and [Figure 55.10](#):

```

ods graphics on;
proc mcmc data=input outpost=postout nmc=50000 thin=5 seed=7893 plots=trace;
  ods select Parameters REparameters PostSummaries PostIntervals
    tracepanel;
  parms b0 0 b1 0 s2 1 s2g 1;

  prior b: ~ normal(0, var = 10000);
  prior s: ~ igamma(0.01, scale = 0.01);
  random gamma ~ normal(0, var = s2g) subject=family monitor=(gamma);
  mu = b0 + b1 * gf + gamma;
  model height ~ normal(mu, var = s2);
run;
ods graphics off;

```

Some of the statements are very similar to those shown in the previous two examples. The ODS GRAPHICS ON statement enables ODS Graphics. The PROC MCMC statement specifies the input and output data sets, the simulation size, the thinning rate, and a random number seed. The ODS SELECT statement displays

the model parameter and random-effects parameter information tables, summary statistics table, the interval statistics table, and the trace plots.

The **PARMS** statement lumps all four model parameters in a single block. They are **b0** (overall intercept), **b1** (main effect for **gf**), **s2** (variance of the likelihood function), and **s2g** (variance of the random effect). If a random walk Metropolis sampler is the only applicable sampler for all parameters, then these four parameters are updated in a single block. However, because PROC MCMC updates the parameters **s2** and **s2g** via conjugacy, these parameters are separated into individual blocks. (See the Block column in “Parameters” table in Figure 55.8.)

The **PRIOR** statements specify priors for all the parameters. The notation **b:** is a shorthand for all symbols that start with the letter ‘b’. In this example, **b:** includes **b0** and **b1**. Similarly, **s:** stands for both **s2** and **s2g**. This shorthand notation can save you some typing, and it keeps your statements tidy.

The **RANDOM** statement specifies a single random effect to be **gamma**, and specifies that it has a normal prior centered at 0 with variance **s2g**. The **SUBJECT=** argument in the **RANDOM** statement defines a group index (family) in the model, where all observations from the same family should have the same group indicator value. The **MONITOR=** option outputs analysis for all the random-effects parameters.

Finally, the **MU** assignment statement calculates the expected value of the height of the model. The calculation includes the random-effects term **gamma**. The **MODEL** statement specifies the likelihood function for height.

The “Parameters” and “Random-Effects Parameters” tables, shown in Figure 55.8, contain information about the model parameters and the four random-effects parameters.

Figure 55.8 Model and Random-Effects Parameter Information

Random-Effects Model					
The MCMC Procedure					
Parameters					
Block	Parameter	Sampling Method	Initial Value	Prior Distribution	
1	s2	Conjugate	1.0000	igamma(0.01, scale = 0.01)	
2	s2g	Conjugate	1.0000	igamma(0.01, scale = 0.01)	
3	b0	N-Metropolis	0	normal(0, var = 10000)	
	b1		0	normal(0, var = 10000)	
Random Effect Parameters					
Parameter	Sampling Method	Subject	Number of Subjects	Subject Values	Prior Distribution
gamma	N-Metropolis	Family	4	1 2 3 4	normal(0, var = s2g)

The posterior summary and interval statistics for the model parameters and the random-effects parameters are shown in Figure 55.9.

Figure 55.9 Posterior Summary and Interval Statistics

Random-Effects Model						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
b0	10000	68.4717	1.2735	67.7757	68.4495	69.1213
b1	10000	-3.5533	0.9740	-4.1829	-3.5381	-2.9375
s2	10000	4.1334	1.9372	2.8024	3.7093	4.9790
s2g	10000	5.1508	23.4698	0.2312	1.3104	4.2433
gamma_1	10000	0.9404	1.3219	0.0860	0.6963	1.6322
gamma_2	10000	0.0131	1.1935	-0.4020	0.0214	0.4878
gamma_3	10000	-1.3481	1.6535	-2.1852	-0.9346	-0.1252
gamma_4	10000	0.0945	1.1931	-0.3323	0.0528	0.5643

Posterior Intervals					
Parameter	Alpha	Equal-Tail Interval		HPD Interval	
b0	0.050	65.8646	71.1331	65.9097	71.1712
b1	0.050	-5.5058	-1.6127	-5.4201	-1.5651
s2	0.050	1.7166	9.0766	1.3678	7.8796
s2g	0.050	0.00983	32.7002	0.00105	19.0298
gamma_1	0.050	-1.0884	4.0560	-1.0160	4.0923
gamma_2	0.050	-2.5942	2.5279	-2.5357	2.5636
gamma_3	0.050	-5.4957	0.6638	-4.7168	1.0677
gamma_4	0.050	-2.4901	2.7349	-2.5895	2.5888

Trace plots for all the parameters are shown in [Figure 55.10](#). The mixing looks very reasonable, suggesting convergence.

Figure 55.10 Plots for b_1 and Log of the Posterior Density

Figure 55.10 continued

From the interval statistics table, you see that both the equal-tail and HPD intervals for β_0 are positive, strongly indicating the positive effect of the parameter. On the other hand, both intervals for β_1 cover the value zero, indicating that *gf* does not have a strong impact on predicting height in this model.

Syntax: MCMC Procedure

The following statements are available in the MCMC procedure. Items within *< >* are optional.

```

PROC MCMC < options > ;
  ARRAY arrayname [ dimensions ] < $ > < variables-and-constants > ;
  BEGINCNST/ENDCNST ;
  BEGINNODATA/ENDNODATA ;
  BY variables ;
  MODEL variable ~ distribution < options > ;
  PARMS parameter < = > number < / options > ;
  PREDDIST < 'label' > OUTPRED=SAS-data-set < options > ;
  PRIOR/HYPERPRIOR parameter ~ distribution ;
  Programming statements ;
  RANDOM random-effects-specification < / options > ;
  UDS subroutine-name (subroutine-argument-list) ;

```

The **PARMS** statements declare parameters in the model and assign optional starting values for the Markov chain. The **PRIOR/HYPERPRIOR** statements specify the prior distributions of the parameters. The **MODEL** statements specify the log-likelihood functions for the response variables. These statements form the basis of most Bayesian models.

In addition, you can use the **ARRAY** statement to define constant or parameter arrays, the **BEGINNST/ENDCNST** and **BEGINNODATA/ENDNODATA** statements to omit unnecessary evaluation and reduce simulation time, the **PREDDIST** statement to generate samples from the posterior predictive distribution, the **program statements** to specify more complicated models that you want to fit, the **RANDOM** statement to specify random effects and their prior distributions, and the **UDS** statement to define your own Gibbs samplers to sample parameters in the model.

The following sections provide a description of each of these statements.

PROC MCMC Statement

PROC MCMC *options* ;

The PROC MCMC statement invokes the MCMC procedure. [Table 55.1](#) summarizes the options available in the PROC MCMC statement.

Table 55.1 PROC MCMC Statement Options

Option	Description
Basic options	
DATA=	Names the input data set
OUTPOST=	Names the output data set for posterior samples of parameters
Debugging output	
LIST	Displays model program and variables
LISTCODE	Displays compiled model program
TRACE	Displays detailed model execution messages
Frequently used MCMC options	
MAXTUNE=	Specifies the maximum number of tuning loops
MINTUNE=	Specifies the minimum number of tuning loops
NBI=	Specifies the number of burn-in iterations
NMC=	Specifies the number of MCMC iterations, excluding the burn-in iterations
NTU=	Specifies the number of tuning iterations
PROPCOV=	Controls options for constructing the initial proposal covariance matrix
SEED=	Specifies the random seed for simulation
THIN=	Specifies the thinning rate
Less frequently used MCMC options	
ACCEPTTOL=	Specifies the acceptance rate tolerance
DISCRETE=	Controls sampling discrete parameters
INIT=	Controls generating initial values
MCHISTORY=	Displays Markov chain sampling history
MAXINDEXPRINT=	Specifies the maximum number of observation indices to print in models with missing data

Table 55.1 (continued)

Option	Description
MAXSUBVALUEPRINT=	Specifies the maximum number of subject values to print in the “Random Effects Parameters” table
PROPDIST=	Specifies the proposal distribution
REOBSINFO	Displays more detailed information about each random effect
SCALE=	Specifies the initial scale applied to the proposal distribution
TARGACCEPT=	Specifies the target acceptance rate for random walk sampler
TARGACCEPTI=	Specifies the target acceptance rate for independence sampler
TUNEW=	Specifies the weight used in covariance updating
Summary, diagnostics, and plotting options	
AUTOCORLAG=	Specifies the number of autocorrelation lags used to compute effective sample sizes and Monte Carlo errors
DIAGNOSTICS=	Controls the convergence diagnostics
DIC	Computes deviance information criterion (DIC)
MONITOR=	Outputs analysis for a list of symbols of interest
PLOTS=	Controls plotting
STATISTICS=	Controls posterior statistics
Other Options	
INF=	Specifies the machine numerical limit for infinity
JOINTMODEL	Specifies joint log-likelihood function
MISSING=	Indicates how missing values are handled.
NOLOGDIST	Omits the calculation of the logarithm of the joint distribution of the parameters
SIMREPORT=	Controls the frequency of report for expected run time
SINGDEN=	Specifies the singularity tolerance

These options are described in alphabetical order.

ACCEPTTOL=*n*

specifies a tolerance for acceptance probabilities. By default, ACCEPTTOL=0.075.

AUTOCORLAG=*n***ACLAG=*n***

specifies the maximum number of autocorrelation lags used in computing the effective sample size; see the section “Effective Sample Size” on page 152 for more details. The value is used in the calculation of the Monte Carlo standard error; see the section “Standard Error of the Mean Estimate” on page 153. By default, AUTOCORLAG=MIN(500, MCsample/4), where MCsample is the Markov chain sample size kept after thinning—that is, $MCsample = \left\lceil \frac{NMC}{NTHIN} \right\rceil$. If AUTOCORLAG= is set too low, you might observe significant lags, and the effective sample size cannot be calculated accurately. A WARNING message appears, and you can either increase AUTOCORLAG= or NMC=, accordingly.

DISCRETE=*keyword*

specifies the proposal distribution used in sampling discrete parameters. The default is DISCRETE=BINNING.

The *keyword* values are as follows:

BINNING

uses continuous proposal distributions for all discrete parameter blocks. The proposed sample is then discretized (binned) before further calculations. This sampling method approximates the correlation structure among the discrete parameters in the block and could improve mixing in some cases.

GEO

uses independent symmetric geometric proposal distributions for all discrete parameter blocks. This proposal does not take parameter correlations into account. However, it can work better than the BINNING option in cases where the range of the parameters is relatively small and a normal approximation can perform poorly.

DIAGNOSTICS=NONE | (*keyword-list*)**DIAG=NONE** | (*keyword-list*)

specifies options for MCMC convergence diagnostics. By default, PROC MCMC computes the Geweke test, sample autocorrelations, effective sample sizes, and Monte Carlo errors. The Raftery-Lewis and Heidelberger-Welch tests are also available. See the section “[Assessing Markov Chain Convergence](#)” on page 139 for more details on convergence diagnostics. You can request all of the diagnostic tests by specifying DIAGNOSTICS=ALL. You can suppress all the tests by specifying DIAGNOSTICS=NONE.

You can use postprocessing autocall macros to calculate convergence diagnostics of the posterior samples after PROC MCMC has exited. See the section “[Autocall Macros for Postprocessing](#)” on page 4510.

The following *options* are available.

ALL

computes all diagnostic tests and statistics. You can combine the option ALL with any other specific tests to modify test options. For example DIAGNOSTICS=(ALL AUTOCORR(LAGS=(1 5 35))) computes all tests with default settings and autocorrelations at lags 1, 5, and 35.

AUTOCORR < (*autocorr-options*) >

computes default autocorrelations at lags 1, 5, 10, and 50 for each variable. You can choose other lags by using the following *autocorr-options*:

LAGS | **AC=***numeric-list*

specifies autocorrelation lags. The *numeric-list* must take positive integer values.

ESS

computes the effective sample sizes (Kass et al. (1998)) of the posterior samples of each parameter. It also computes the correlation time and the efficiency of the chain for each parameter. Small values of ESS might indicate a lack of convergence. See the section “[Effective Sample Size](#)” on page 152 for more details.

GEWEKE < (*Geweke-options*) >

computes the Geweke spectral density diagnostics; this is a two-sample t -test between the first f_1 portion and the last f_2 portion of the chain. See the section “[Geweke Diagnostics](#)” on page 146 for more details. The default is $\text{FRAC1}=0.1$ and $\text{FRAC2}=0.5$, but you can choose other fractions by using the following *Geweke-options*:

FRAC1 | **F1**=*value*

specifies the beginning FRAC1 proportion of the Markov chain. By default, $\text{FRAC1}=0.1$.

FRAC2 | **F2**=*value*

specifies the end FRAC2 proportion of the Markov chain. By default, $\text{FRAC2}=0.5$.

HEIDELBERGER | **HEIDEL** < (*Heidel-options*) >

computes the Heidelberg and Welch diagnostic (which consists of a stationarity test and a halfwidth test) for each variable. The stationary diagnostic test tests the null hypothesis that the posterior samples are generated from a stationary process. If the stationarity test is passed, a halfwidth test is then carried out. See the section “[Heidelberg and Welch Diagnostics](#)” on page 148 for more details.

These diagnostics are not performed by default. You can specify the `DIAGNOSTICS=HEIDELBERGER` option to request these diagnostics, and you can also specify suboptions, such as `DIAGNOSTICS=HEIDELBERGER(EPS=0.05)`, as follows:

SALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the stationarity test. By default, $\text{SALPHA}=0.05$.

HALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the halfwidth test. By default, $\text{HALPHA}=0.05$.

EPS=*value*

specifies a small positive number ϵ such that if the halfwidth is less than ϵ times the sample mean of the retaining iterates, the halfwidth test is passed. By default, $\text{EPS}=0.1$.

MCSE**MCERROR**

computes the Monte Carlo standard error for the posterior samples of each parameter.

NONE

suppresses all of the diagnostic tests and statistics. This is not recommended.

RAFTERY | **RL** < (*Raftery-options*) >

computes the Raftery and Lewis diagnostics, which evaluate the accuracy of the estimated quantile ($\hat{\theta}_Q$ for a given $Q \in (0, 1)$) of a chain. $\hat{\theta}_Q$ can achieve any degree of accuracy when the chain is allowed to run for a long time. The algorithm stops when the estimated probability $\hat{P}_Q = \Pr(\theta \leq \hat{\theta}_Q)$ reaches within $\pm R$ of the value Q with probability S ; that is, $\Pr(Q - R \leq \hat{P}_Q \leq Q + R) = S$. See the section “[Raftery and Lewis Diagnostics](#)” on page 149

for more details. The *Raftery-options* enable you to specify Q, R, S, and a precision level ϵ for a stationary test.

These diagnostics are not performed by default. You can specify the `DIAGNOSTICS=RAFERTY` option to request these diagnostics, and you can also specify suboptions, such as `DIAGNOSTICS=RAFERTY(QUANTILE=0.05)`, as follows:

QUANTILE | Q=value

specifies the order (a value between 0 and 1) of the quantile of interest. By default, `QUANTILE=0.025`.

ACCURACY | R=value

specifies a small positive number as the margin of error for measuring the accuracy of estimation of the quantile. By default, `ACCURACY=0.005`.

PROB | S=value

specifies the probability of attaining the accuracy of the estimation of the quantile. By default, `PROB=0.95`.

EPS=value

specifies the tolerance level (a small positive number) for the stationary test. By default, `EPS=0.001`.

DIC

computes the Deviance Information Criterion (DIC). DIC is calculated using the posterior mean estimates of the parameters. See the section “[Deviance Information Criterion \(DIC\)](#)” on page 155 for more details.

DATA=SAS-data-set

specifies the input data set. Observations in this data set are used to compute the log-likelihood function that you specify with PROC MCMC statements.

INF=value

specifies the numerical definition of infinity in PROC MCMC. The default is `INF=1E15`. For example, PROC MCMC considers `1E16` to be outside of the support of the normal distribution and assigns a missing value to the log density evaluation. You can select a larger value with the `INF=` option. The minimum value allowed is `1E10`.

INIT=(keyword-list)

specifies options for generating the initial values for the parameters. These options apply only to prior distributions that are recognized by PROC MCMC. See the section “[Standard Distributions](#)” on page 4476 for a list of these distributions. If either of the functions `GENERAL` or `DGENERAL` is used, you must supply explicit initial values for the parameters. By default, `INIT=MODE`. The following keywords are used:

MODE

uses the mode of the prior density as the initial value of the parameter, if you did not provide one. If the mode does not exist or if it is on the boundary of the support of the density, the mean value is used. If the mean is outside of the support or on the boundary, which can happen if the prior distribution is truncated, a random number drawn from the prior is used as the initial value.

PINIT

tabulates parameter values after the tuning phase. This option also tabulates the tuned proposal parameters used by the Metropolis algorithm. These proposal parameters include covariance matrices for continuous parameters and probability vectors for discrete parameters for each block. By default, PROC MCMC does not display the initial values or the tuned proposal parameters after the tuning phase.

RANDOM

generates a random number from the prior density and uses it as the initial value of the parameter, if you did not provide one.

REINIT

resets the parameters, after the tuning phase, with the initial values that you provided explicitly or that were assigned by PROC MCMC. By default, PROC MCMC does not reset the parameters because the tuning phase usually moves the Markov chains to a more favorable place in the posterior distribution.

LIST

displays the model program and variable lists. The LIST option is a debugging feature and is not normally needed.

LISTCODE

displays the compiled program code. The LISTCODE option is a debugging feature and is not normally needed.

JOINTMODEL**JOINTLLIKE**

specifies how the likelihood function is calculated. By default, PROC MCMC assumes that the observations in the data set are independent so that the joint log-likelihood function is the sum of the individual log-likelihood functions for the observations, where the individual log-likelihood function is specified in the [MODEL](#) statement. When your data are not independent, you can specify the JOINTMODEL option to modify the way that PROC MCMC computes the joint log-likelihood function. In this situation, PROC MCMC no longer steps through the input data set to sum the individual log likelihood.

To use this option correctly, you need to do the following two things:

- create ARRAY symbols to store all data set variables that are used in the program. This can be accomplished with the [BEGINCNST](#) and [ENDCNST](#) statements.
- program the joint log-likelihood function by using these ARRAY symbols only. The [MODEL](#) statement specifies the joint log-likelihood function for the entire data set. Typically, you use the function [GENERAL](#) in the [MODEL](#) statement.

See the sections “[BEGINCNST/ENDCNST Statement](#)” on page 4441 and “[Modeling Joint Likelihood](#)” on page 4504 for details.

MAXTUNE=*n*

specifies an upper limit for the number of proposal tuning loops. By default, MAXTUNE=24. See the section “[Covariance Tuning](#)” on page 4470 for more details.

MAXINDEXPRINT=*number* | ALL**MAXIPRINT=*number* | ALL**

specifies the maximum number of observation indices to print in the ODS tables “Missing Response Information” table and “Missing Covariates Information” table. This option applies only to programs that model missing data. The default value is 20. MAXINDEXPRINT=ALL prints all observation indices for every missing variable that is modeled in PROC MCMC.

MAXSUBVALUEPRINT=*number* | ALL**MAXSVPRINT=*number* | ALL**

specifies the maximum number of subject values to display in the “Subject Values” column of the ODS table “Random Effects Parameters.” This option applies only to programs that have RANDOM statements. The default value is 20. MAXSUBVALUEPRINT=ALL prints all subject values for every random effect in the program.

MCHISTORY=*keyword***MCHIST=*keyword***

controls the display of the Markov chain sampling history.

BRIEF

produces a summary output for the tuning, burn-in, and sampling history tables. The tables show the following when applicable:

- “RWM Scale” shows the scale, or the range of the scales, used in each random walk Metropolis block that is normal or is based on a *t* distribution.
- “Probability” shows the proposal probability parameter, or the range of the parameters, used in each random walk Metropolis block that is based on a geometric distribution.
- “RWM Acceptance Rate” shows the acceptance rate, or the range of the acceptance rates, for each random walk Metropolis block.
- “IM Acceptance Rate” shows the acceptance rate, or the range of the acceptance rates, for each independent Metropolis block.

DETAILED

produces detailed output of the tuning, burn-in, and sampling history tables, including scale values, acceptance probabilities, blocking information, and so on. Use this option with caution, especially in random-effects models that have a large number of random-effects groups. This option can produce copious output.

NONE

produces none of the tuning history, burn-in history, and sampling history tables.

The default is MCHISTORY=NONE.

MINTUNE=*n*

specifies a lower limit for the number of proposal tuning loops. By default, MINTUNE=2. See the section “[Covariance Tuning](#)” on page 4470 for more details.

MISSING=*keyword*

MISS=*keyword*

specifies how missing values are handled (see the section “[Handling of Missing Data](#)” on page 4518 for more details). The default is MISSING=COMPLETECASE.

ALLCASE | AC

gives you the option to model the missing values in an all-case analysis. You can use any techniques that you see fit, for example, fully Bayesian or multiple imputation.

COMPLETECASE | CC

assumes a complete case analysis, so all observations with missing variable values are discarded prior to the simulation.

MONITOR= (*symbol-list*)

outputs analysis for selected symbols of interest in the program. The symbols can be any of the following: model parameters (symbols in the [PARMS](#) statement), secondary parameters (assigned using the operator “=”), the log of the posterior density (LOGPOST), the log of the prior density (LOGPRIOR), the log of the hyperprior density (LOGHYPER) if the [HYPER](#) statement is used, or the log of the likelihood function (LOGLIKE). You can use the keyword `_PARMS_` as a shorthand for all of the model parameters. PROC MCMC performs only posterior analyses (such as plotting, diagnostics, and summaries) on the symbols selected with the MONITOR= option. You can also choose to monitor an entire array by specifying the name of the array. By default MONITOR=`_PARMS_`.

Posterior samples of any secondary parameters listed in the MONITOR= option are saved in the [OUTPOST=](#) data set. Posterior samples of model parameters are always saved to the [OUTPOST=](#) data set, regardless of whether they appear in the MONITOR= option.

NBI=*n*

specifies the number of burn-in iterations to perform before beginning to save parameter estimate chains. By default, NBI=1000. See the section “[Burn-in, Thinning, and Markov Chain Samples](#)” on page 138 for more details.

NMC=*n*

specifies the number of iterations in the main simulation loop. This is the MCMC sample size if [THIN=1](#). By default, NMC=1000.

NOLOGDIST

omits the calculation of the logarithm of the joint distribution of the model parameters at each iteration. The option applies only if all parameters in the model are updated directly from their target distribution, either from the full conditional posterior via conjugacy or from the marginal distribution. Such algorithms do not require the calculation of the joint posterior distribution; hence PROC MCMC runs faster by avoiding these unnecessary calculations. As a result, the [OUTPOST=](#) data set does not contain the LOGPRIOR, LOGLIKE, and LOGPOST variables.

NTU=*n*

specifies the number of iterations to use in each proposal tuning phase. By default, NTU=500.

OUTPOST=*SAS-data-set*

specifies an output data set that contains the posterior samples of all model parameters, the iteration numbers (variable name ITERATION), the log of the posterior density (LOGPOST), the log of the

prior density (LOGPRIOR), the log of the hyperprior density (LOGHYPER), if the [HYPER](#) statement is used, and the log likelihood (LOGLIKE). Any secondary parameters (assigned using the operator “=”) listed in the [MONITOR=](#) option are saved to this data set. By default, no OUTPOST= data set is created.

PLOTS< (*global-plot-options*)>= (*plot-request* <...*plot-request*>)

PLOT< (*global-plot-options*)>= (*plot-request* <...*plot-request*>)

controls the display of diagnostic plots. Three types of plots can be requested: trace plots, autocorrelation function plots, and kernel density plots. By default, the plots are displayed in panels unless the global plot option UNPACK is specified. Also when more than one type of plot is specified, the plots are grouped by parameter unless the global plot option GROUPBY=TYPE is specified. When you specify only one plot request, you can omit the parentheses around the plot-request, as shown in the following example:

```
plots=none
plots(unpack)=trace
plots=(trace density)
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc mcmc data=exi seed=7 outpost=p1 plots=all;
  parm mu;
  prior mu ~ normal(0, sd=10);
  model y ~ normal(mu, sd=1);
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

If ODS Graphics is enabled but do not specify the PLOTS= option, then PROC MCMC produces, for each parameter, a panel that contains the trace plot, the autocorrelation function plot, and the density plot. This is equivalent to specifying PLOTS=(TRACE AUTOCORR DENSITY).

The *global-plot-options* include the following:

FRINGE

adds a fringe plot to the horizontal axis of the density plot.

GROUPBY|GROUP=PARAMETER | TYPE

specifies how the plots are grouped when there is more than one type of plot. GROUPBY=PARAMETER is the default. The choices are as follows:

TYPE

specifies that the plots are grouped by type.

PARAMETER

specifies that the plots are grouped by parameter.

LAGS=*n*

specifies the number of autocorrelation lags used in plotting the ACF graph. By default, LAGS=50.

SMOOTH

smooths the trace plot with a fitted penalized B-spline curve (Eilers and Marx 1996).

UNPACKPANEL

UNPACK

specifies that all paneled plots are to be unpacked, so that each plot in a panel is displayed separately.

The *plot-requests* are as follows:

ALL

requests all types of plots. PLOTS=ALL is equivalent to specifying PLOTS=(TRACE AUTOCORR DENSITY).

AUTOCORR | ACF

displays the autocorrelation function plots for the parameters.

DENSITY | D | KERNEL | K

displays the kernel density plots for the parameters.

NONE

suppresses the display of all plots.

TRACE | T

displays the trace plots for the parameters.

Consider a model with four parameters, X1–X4. Displays for various specifications are depicted as follows.

- PLOTS=(TRACE AUTOCORR) displays the trace and autocorrelation plots for each parameter side by side with two parameters per panel:

Display 1	Trace(X1)	Autocorr(X1)
	Trace(X2)	Autocorr(X2)
Display 2	Trace(X3)	Autocorr(X3)
	Trace(X4)	Autocorr(X4)

- PLOTS(GROUPBY=TYPE)=(TRACE AUTOCORR) displays all the paneled trace plots, followed by panels of autocorrelation plots:

Display 1	Trace(X1)	
	Trace(X2)	
Display 2	Trace(X3)	
	Trace(X4)	
Display 3	Autocorr(X1)	Autocorr(X2)
	Autocorr(X3)	Autocorr(X4)

- **PLOTS(UNPACK)=(TRACE AUTOCORR)** displays a separate trace plot and a separate correlation plot, parameter by parameter:

Display 1	Trace(X1)
Display 2	Autocorr(X1)
Display 3	Trace(X2)
Display 4	Autocorr(X2)
Display 5	Trace(X3)
Display 6	Autocorr(X3)
Display 7	Trace(X4)
Display 8	Autocorr(X4)

- **PLOTS(UNPACK GROUPBY=TYPE)=(TRACE AUTOCORR)** displays all the separate trace plots followed by the separate autocorrelation plots:

Display 1	Trace(X1)
Display 2	Trace(X2)
Display 3	Trace(X3)
Display 4	Trace(X4)
Display 5	Autocorr(X1)
Display 6	Autocorr(X2)
Display 7	Autocorr(X3)
Display 8	Autocorr(X4)

PROPCOV=*value*

specifies the method used in constructing the initial covariance matrix for the Metropolis-Hastings algorithm. The QUANEW and NMSIMP methods find numerically approximated covariance matrices at the optimum of the posterior density function with respect to all continuous parameters. The optimization does not apply to discrete parameters. The tuning phase starts at the optimized values; in some problems, this can greatly increase convergence performance. If the approximated covariance matrix is not positive definite, then an identity matrix is used instead. Valid values are as follows:

IND

uses the identity covariance matrix. This is the default. See the section “[Tuning the Proposal Distribution](#)” on page 4469.

CONGRA<(optimize-options)>

performs a conjugate-gradient optimization.

DBLDOG<(optimize-options)>

performs a double-dogleg optimization.

QUANEW<(optimize-options)>

performs a quasi-Newton optimization.

NMSIMP | SIMPLEX<(optimize-options)>

performs a Nelder-Mead simplex optimization.

The *optimize-options* are as follows:

ITPRINT

prints optimization iteration steps and results.

PROPDIST=value

specifies a proposal distribution for the Metropolis algorithm. See the section “[Metropolis and Metropolis-Hastings Algorithms](#)” on page 134. You can also use **PARMS** statement option (see the section “[PARMS Statement](#)” on page 4451) to change the proposal distribution for a particular block of parameters. Valid values are as follows:

NORMAL**N**

specifies a normal distribution as the proposal distribution. This is the default.

T<(df)>

specifies a t distribution with the degrees of freedom df . By default, $df = 3$. If $df > 100$, the normal distribution is used since the two distributions are almost identical.

REOBSINFO <(display-options)>

displays the ODS table “Random Effect Observation Information.” The table lists the name of each random effect, the unique values in the corresponding subject variable, the number of observations in each subject, and the observation indices for each subject value.

To understand how this option works, consider the following statements:

```
data input;
  array names{*} $ n1-n10 ("John" "Mary" "Chris" "Rob" "Greg"
                          "Jen" "Henry" "Alice" "James" "Toby");
  call streaminit(17);
  do i = 1 to 20;
    j = ceil(rand("uniform") * 10 );
    index = names[j];
    output;
  end;
```

```

drop n: j;
run;

proc print data=input;
run;

```

The input data set (Figure 55.11) contains the index variable, which indicates subjects in a hypothetical random-effects model.

Figure 55.11 Subject Variable in an Input Data Set

Obs	i	index
1	1	Mary
2	2	James
3	3	Mary
4	4	Greg
5	5	Chris
6	6	James
7	7	James
8	8	Chris
9	9	James
10	10	James
11	11	Chris
12	12	Rob
13	13	Rob
14	14	Greg
15	15	Greg
16	16	Alice
17	17	Jen
18	18	Alice
19	19	John
20	20	Chris

The following statements illustrate the use of the REOBSINFO option:

```

ods select reobsinfo;
proc mcmc data=input reobsinfo stats=none diag=none;
  random u ~ normal(0, sd=1) subject=index;
  model general(0);
run;

```

Figure 55.12 displays the “Random Effect Observation Information” table. The table contains the name of the random-effect parameter (u), the values of the subject variable index, the total number of observations, and the row index of these observations in each of the subject values.

Figure 55.12 Random Effect Observation Information

The MCMC Procedure			
Random Effect Observation Information			
Parameter	Subject Values	Number of Observations in Subject	Observation Indices
u	Mary	2	1 3
	James	5	2 6 7 9 10
	Greg	3	4 14 15
	Chris	4	5 8 11 20
	Rob	2	12 13
	Alice	2	16 18
	Jen	1	17
	John	1	19

The *display-options* are as follows:

MAXVALUEPRINT=*number* | **ALL**

MAXVPRINT=*number* | **ALL**

prints the number of subject values for each random effect (that is, the number of rows that are displayed in the “Random Effect Observation Information” table for each random effect). The default value is 20. MAXVALUEPRINT=ALL displays all subject values.

MAXOBSPRINT=*number* | **ALL**

MAXOPRINT=*number* | **ALL**

prints the number of observation indices for each subject value of every random effect (that is, the maximum number of indices that are displayed in the “Observation Indices” column in the “Random Effect Observation Information” table). The default value is 20. MAXOBSPRINT=ALL displays indices for every subject value.

SCALE=*value*

controls the initial multiplicative scale to the covariance matrix of the proposal distribution. By default, SCALE=2.38. See the section “[Scale Tuning](#)” on page 4470 for more details.

SEED=*n*

specifies the random number seed. By default, SEED=0, and PROC MCMC gets a random number seed from the clock.

SIMREPORT=*n*

controls the number of times that PROC MCMC reports the expected run time of the simulation. This can be useful for monitoring the progress of CPU-intensive programs. For example, with SIMREPORT=2, PROC MCMC reports the simulation progress twice. By default, SIMREPORT=0, and there is no reporting. The expected run times are displayed in the log file.

SINGDEN=*value*

defines the singularity criterion in PROC MCMC. By default, SINGDEN=1E-11. The *value* indicates the exclusion of an endpoint in an interval. The mathematical notation “(0)” is equivalent to “[*value*” in PROC MCMC—that is, $x < 0$ is treated as $x \leq \text{value}$ in PROC MCMC. The maximum SINGDEN allowed is 1E-6.

STATISTICS< (*global-stats-options*)> = **NONE** | **ALL** | *stats-request***STATS**< (*global-stats-options*)> = **NONE** | **ALL** | *stats-request*

specifies options for posterior statistics. By default, PROC MCMC computes the posterior mean, standard deviation, quantiles, and two 95% credible intervals: equal-tail and highest posterior density (HPD). Other available statistics include the posterior correlation and covariance. See the section “[Summary Statistics](#)” on page 153 for more details. You can request all of the posterior statistics by specifying STATS=ALL. You can suppress all the calculations by specifying STATS=NONE.

You can use postprocessing autocall macros to calculate posterior summary statistics of the posterior samples after PROC MCMC has exited. See the section “[Autocall Macros for Postprocessing](#)” on page 4510.

The *global-stats-options* includes the following:

ALPHA=*numeric-list*

specifies the α level for the equal-tail and HPD intervals. The value α must be between 0 and 0.5. By default, ALPHA=0.05.

PERCENTAGE | **PERCENT**=*numeric-list*

calculates the posterior percentages. The *numeric-list* contains values between 0 and 100. By default, PERCENTAGE=(25 50 75).

The *stats-requests* include the following:

ALL

computes all posterior statistics. You can combine the option ALL with any other options. For example STATS(ALPHA=(0.02 0.05 0.1))=ALL computes all statistics with the default settings and intervals at α levels of 0.02, 0.05, and 0.1.

CORR

computes the posterior correlation matrix.

COV

computes the posterior covariance matrix.

SUMMARY**SUM**

computes the posterior means, standard deviations, and percentile points for each variable. By default, the 25th, 50th, and 75th percentile points are produced, but you can use the global PERCENT= option to request specific percentile points.

INTERVAL**INT**

computes the $100(1 - \alpha)\%$ equal-tail and HPD credible intervals for each variable. See the sections “[Equal-Tail Credible Interval](#)” on page 154 and “[Highest Posterior Density \(HPD\) Interval](#)” on page 154 for details. By default, ALPHA=0.05, but you can use the global ALPHA= option to request other intervals of any probabilities.

NONE

suppresses all of the statistics.

TARGACCEPT=value

specifies the target acceptance rate for the random walk based Metropolis algorithm. See the section “[Metropolis and Metropolis-Hastings Algorithms](#)” on page 134. The numeric *value* must be between 0.01 and 0.99. By default, TARGACCEPT=0.45 for models with 1 parameter; TARGACCEPT=0.35 for models with 2, 3, or 4 parameters; and TARGACCEPT=0.234 for models with more than 4 parameters (Roberts, Gelman, and Gilks 1997; Roberts and Rosenthal 2001).

TARGACCEPTI=value

specifies the target acceptance rate for the independence sampler algorithm. The independence sampler is used for blocks of binary parameters. See the section “[Independence Sampler](#)” on page 137 for more details. The numeric *value* must be between 0 and 1. By default, TARGACCEPTI=0.6.

THIN=n**NTHIN=n**

controls the thinning rate of the simulation. PROC MCMC keeps every *n*th simulation sample and discards the rest. All of the posterior statistics and diagnostics are calculated using the thinned samples. By default, THIN=1. See the section “[Burn-in, Thinning, and Markov Chain Samples](#)” on page 138 for more details.

TRACE

displays the result of each operation in each statement in the model program as it is executed. This debugging option is very rarely needed, and it produces voluminous output. If you use this option, also use small NMC=, NBI=, MAXTUNE=, and NTU= numbers.

TUNEWT=value

specifies the multiplicative weight used in updating the covariance matrix of the proposal distribution. The numeric *value* must be between 0 and 1. By default, TUNEWT=0.75. See the section “[Covariance Tuning](#)” on page 4470 for more details.

ARRAY Statement

ARRAY *arrayname* [*dimensions*] < \$ > < *variables-and-constants* > ;

The ARRAY statement associates a name (of no more than eight characters) with a list of variables and constants. The ARRAY statement is similar to, but not the same as, the ARRAY statement in the DATA step, and it is the same as the ARRAY statements in the NLIN, NLP, NLMIXED, and MODEL procedures. The array name is used with subscripts in the program to refer to the array elements, as illustrated in the following statements:

```
array r[8] r1-r8;

do i = 1 to 8;
    r[i] = 0;
end;
```

The ARRAY statement does not support all the features of the ARRAY statement in the DATA step. Implicit indexing of variables cannot be used; all array references must have explicit subscript expressions. Only exact array dimensions are allowed; lower-bound specifications are not supported. A maximum of six dimensions is allowed.

Both variables and constants can be array elements. Constant array elements cannot have values assigned to them while variables can. Both the dimension specification and the list of elements are optional, but at least one must be specified. When the list of elements is not specified or fewer elements than the size of the array are listed, array variables are created by appending element numbers to the array name to complete the element list. You can index array elements by enclosing a subscript in braces ({ }) or brackets ([]), but not in parentheses (()). The parentheses are reserved for function calls only.

For example, the following statement names an array `day`:

```
array day[365];
```

By default, the variables names are `day1` to `day365`. However, since `day` is a SAS function, any subscript that uses parentheses gives you the wrong results. The expression `day(4)` returns the value 5 and does not reference the array element `day4`.

BEGINCNST/ENDCNST Statement

```
BEGINCNST ;
```

```
ENDCNST ;
```

The BEGINCNST and ENDCNST statements define a block within which PROC MCMC processes the programming statements only during the setup stage of the simulation. You can use the BEGINCNST and ENDCNST statements to define constants or import data set variables into arrays. Storing data in arrays enables you to work with data that are not identically distributed (see the section “[Modeling Joint Likelihood](#)” on page 4504) or to implement your own Markov chain sampler (see the section “[UDS Statement](#)” on page 4462). You can also use the BEGINCNST and ENDCNST statements to assign initial values to the parameters (see the section “[Assignments of Parameters](#)” on page 4474).

Assign Constants

Whenever you have programming statements that calculate constants that do not need to be evaluated multiple times throughout the simulation, you should put them within the BEGINCNST and ENDCNST statements. Using these statements can reduce redundant processing. For example, you can assign a constant to a symbol or fill in an array with numbers:

```
array cnst[17];
begincnst;
  offset = 17;
  do i = 1 to 17;
    cnst[i] = i * i;
  end;
endcnst;
```

During the setup process, PROC MCMC evaluates the programming statements within the BEGINCNST/ENDCNST once for each observation in the data set and ignores the statements in the rest of the simulation.

READ_ARRAY Function

Sometimes you might need to store variables, either from the current input data set or from a different data set, in arrays and use these arrays to specify your model. The READ_ARRAY function is convenient for that purpose.

The following two forms of the READ_ARRAY function are available:

```
rc = READ_ARRAY (data-set, array) ;
```

```
rc = READ_ARRAY (data-set, array < , "col-name1"> < , "col-name2"> < , ... > ) ;
```

where

- *rc* returns 0 if the function is able to successfully read the data set.
- *data-set* specifies the name of the data set from which the array data is read. The value specified for *data-set* must be a character literal or a variable that contains the member name (libname.memname) of the data set to be read from.
- *array* specifies the PROC MCMC array variable into which the data is read. The value specified for *array* must be a local temporary array variable because the function might need to grow or shrink its size to accommodate the size of the data set.
- *col-name* specifies optional names for the specific columns of the data set that are read. If specified, *col-name* must be a literal string enclosed in quotation marks. In addition, *col-name* cannot be a PROC MCMC variable. If column names are not specified, PROC MCMC reads all of the columns in the data set.

When SAS translates between an array and a data set, the array is indexed as [row,column].

The READ_ARRAY function attempts to dynamically resize the array to match the dimensions of the input data set. Therefore, the array must be dynamic; that is, the array must be declared with the /NOSYMBOLS option.

For examples that use the READ_ARRAY function, see “Modeling Joint Likelihood” on page 4504, “Example 55.14: Time Independent Cox Model” on page 4617, and “Example 55.19: Implement a New Sampling Algorithm” on page 4645.

BEGINNODATA/ENDNODATA Statements

```
BEGINNODATA ;
```

```
ENDNODATA ;
```

```
BEGINPRIOR ;
```

```
ENDPRIOR ;
```

The BEGINNODATA and ENDNODATA statements define a block within which PROC MCMC processes the programming statements without stepping through the entire data set. The programming statements are executed only twice: at the first and the last observation of the data set. The BEGINNODATA and ENDNODATA statements are best used to reduce unnecessary observation-level computations. Any computations that are identical to every observation, such as transformation of parameters, should be enclosed in these statements.

At the first observation, PROC MCMC executes all programming statements, including those that are enclosed by these two statements. This enables a quick update of all the symbols enclosed by the BEGINNODATA and ENDNODATA statements. The goal is to ensure that subsequent statements (for example, the **MODEL** statement) use symbol values that have been calculated correctly. At the last observation, PROC MCMC executes the enclosed programming statements again and adds the log of the prior density to the log of the posterior density.

The BEGINPRIOR and ENDPRIOR statements are aliases for the BEGINNODATA and ENDNODATA statements, respectively. You can enclose PRIOR statements in the BEGINNODATA and ENDNODATA statements.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC MCMC to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the MCMC procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

MODEL Statement

MODEL *dependent-variable-list* ~ *distribution* < options > ;

The MODEL statement specifies the conditional distribution of the data given the parameters (the likelihood function). You specify a single dependent variable or a list of dependent variables, a tilde ~, and then a

distribution with its arguments. The dependent variables can be variables from the input data set or functions of the symbols in the program. You must specify the dependent variables unless you use the [GENERAL](#) function or the [DGENERAL](#) function (see the section “[Specifying a New Distribution](#)” on page 4490 for more details).

The MODEL statement assumes that the observations are independent of each other, conditional on the model parameters. If you want to model dependent data—that is, $f(y_i|\theta, y_j)$ for $j \neq i$ —you can use the [JOINTMODEL](#) option in the PROC MCMC statement. See the section “[Modeling Joint Likelihood](#)” on page 4504 for more details. By default, the log-likelihood value is the sum of the individual log-likelihood value for each observation.

You can specify multiple MODEL statements. You can define likelihood functions that are independent of each other. For example, in the following statements, the dependent variables y1 and y2 are independent of each other:

```
model y1 ~ normal(alpha, var=s21);
model y2 ~ normal(beta, var=s22);
```

Alternatively, you can use marginal and conditional distributions to define a joint log-likelihood function for multiple dependent variables. For example, the following statements jointly define a distribution over (y1, y2). They specify a marginal distribution for the dependent variable y1 and a conditional distribution for the dependent variable y2:

```
model y1 ~ normal(alpha, var=s21);
model y2 ~ normal(beta * y1, var=s22);
```

Every program must have at least one MODEL statement. If you want to run a Monte Carlo simulation that does not require a response variable, use the [GENERAL](#) function in the MODEL statement:

```
model general(0);
```

PROC MCMC interprets the statement as a flat likelihood function with a constant log-likelihood value of 0.

PROC MCMC is a programming language that is similar to the DATA step, and the order of statement evaluation is important. For example, the MODEL statement must come after any SAS programming statements that define or modify arguments used in the construction of the log likelihood. In PROC MCMC, a symbol can be defined multiple times and used at different places. Using an expression out of order produces erroneous results that can also be hard to detect.

Do not embed the MODEL statement within programming statements. For example, suppose you have three response variables, y1, y2, and y3, and want to model each with a normal distribution. The following statements lead to erroneous output:

```
array Y[3] y1 y2 y3;
do i = 1 to 3;
  model y[i] ~ normal(mu, sd=s);
end;
```

Instead, you should do one of the following.

- Use separate MODEL statements:

```

model y1 ~ normal(mu, sd=s);
model y2 ~ normal(mu, sd=s);
model y3 ~ normal(mu, sd=s);

```

- Use the GENERAL function to construct a joint distribution of the three dependent variables and use a single MODEL statement to specify the log-likelihood function:

```

llike = logpdf("normal", y1, mu, s) +
        logpdf("normal", y2, mu, s) +
        logpdf("normal", y3, mu, s);
model y1 y2 y3 ~ general(llike);

```

See the section “[Specifying a New Distribution](#)” on page 4490 for more information about how to use the GENERAL function to specify an arbitrary distribution.

Missing data are allowed in the response variables; the MODEL statement augments missing data automatically. (In releases before SAS/STAT 12.1, observations with missing values were discarded prior to analysis and PROC MCMC did not attempt to model these values.) In each iteration, PROC MCMC samples missing values from their posterior distributions and incorporates them as part of the simulation. PROC MCMC creates one variable for each missing response value. There are two ways to create the missing value variable names; see the [NAMESUFFIX=](#) option for the naming convention of the variables.

Distributions in MODEL Statement

Standard distributions that the MODEL statement supports are listed in the [Table 55.2](#) (univariate) and [Table 55.3](#) (multivariate). See the section “[Standard Distributions](#)” on page 4476 for density specifications. You can also specify all distributions except the multinomial distribution in the [PRIOR](#) and [HYPERPRIOR](#) statements. The [RANDOM](#) statement supports only a subset of the distributions (see [Table 55.4](#)).

PROC MCMC allows some distributions to be parameterized in multiple ways. For example, you can specify a normal distribution with a variance, standard deviation, or precision parameter. For distributions that have different parameterizations, you must specify an option to clearly name the ambiguous parameter. For example, in the normal distribution, you must indicate whether the second argument represents variance, standard deviation, or precision.

All univariate distributions, with the exception of binary and uniform, can have the optional LOWER= and UPPER= arguments, which specify a truncated density. See the section “[Truncation and Censoring](#)” on page 4494 for more details. Truncation is not supported for multivariate distributions.

Table 55.2 Univariate Distributions

Distribution Name	Definition
beta (< a = α , < b = β)	Beta distribution with shape parameters α and β
binary (< prob p = p)	Binary (Bernoulli) distribution with probability of success p . You can use the alias bern for this distribution.
binomial (< n = n , < prob p = p)	Binomial distribution with count n and probability of success p

Table 55.2 (continued)

Distribution Name	Definition
cauchy (<location loc = > θ , <scale s = > λ)	Cauchy distribution with location θ and scale λ
chisq (<df= > ν)	χ^2 distribution with ν degrees of freedom
dgeneral (//)	General log-likelihood function that you construct using SAS programming statements for single or multiple discrete parameters. Also see the function general . The name dlogden is an alias for this function.
expchisq (<df= > ν)	Log transformation of a χ^2 distribution with ν degrees of freedom: $\theta \sim \mathbf{chisq}(\nu) \Leftrightarrow \log(\theta) \sim \mathbf{expchisq}(\nu)$. You can use the alias echisq for this distribution.
expexpon (scale s= λ) expexpon (iscale is= λ)	Log transformation of an exponential distribution with scale or inverse-scale parameter λ : $\theta \sim \mathbf{expon}(\lambda) \Leftrightarrow \log(\theta) \sim \mathbf{expexpon}(\lambda)$. You can use the alias eexpon for this distribution.
expGamma (<shape sp= > a , scale s= λ) expGamma (<shape sp= > a , iscale is= λ)	Log transformation of a gamma distribution with shape a and scale or inverse-scale λ : $\theta \sim \mathbf{gamma}(a, \lambda) \Leftrightarrow \log(\theta) \sim \mathbf{expgamma}(a, \lambda)$. You can use the alias egamma for this distribution.
expichisq (<df= > ν)	Log transformation of an inverse χ^2 distribution with ν degrees of freedom: $\theta \sim \mathbf{ichisq}(\nu) \Leftrightarrow \log(\theta) \sim \mathbf{expichisq}(\nu)$. You can use the alias eichisq for this distribution.
expiGamma (<shape sp= > a , scale s= λ) expiGamma (<shape sp= > a , iscale is= λ)	Log transformation of an inverse-gamma distribution with shape a and scale or inverse-scale λ : $\theta \sim \mathbf{igamma}(a, \lambda) \Leftrightarrow \log(\theta) \sim \mathbf{expigamma}(a, \lambda)$. You can use the alias eigamma for this distribution.
expsichisq (<df= > ν , <scale s= > s)	Log transformation of a scaled inverse χ^2 distribution with ν degrees of freedom and scale parameter s : $\theta \sim \mathbf{sichisq}(\nu) \Leftrightarrow \log(\theta) \sim \mathbf{expsichisq}(\nu)$. You can use the alias esichisq for this distribution.
expon (scale s= λ) expon (iscale is= λ)	Exponential distribution with scale or inverse-scale parameter λ
gamma (<shape sp= > a , scale s= λ) gamma (<shape sp= > a , iscale is= λ)	Gamma distribution with shape a and scale or inverse-scale λ

Table 55.2 (continued)

Distribution Name	Definition
geo (< prob p= > p)	Geometric distribution with probability p
general (<i>//</i>)	General log-likelihood function that you construct using SAS programming statements for a single or multiple continuous parameters. The argument <i>//</i> is an expression for the log of the distribution. If there are multiple variables specified before the tilde in a MODEL, PRIOR, or HYPERPRIOR statement, <i>//</i> is interpreted as the log of the joint distribution for these variables. Note that in the MODEL statement, the response variable specified before the tilde is just a place holder and is of no consequence; the variable must have appeared in the construction of <i>//</i> in the programming statements. general (<i>constant</i>) is equivalent to a uniform distribution on the real line. You can use the alias logden for this distribution.
ichisq (< df= > ν)	Inverse χ^2 distribution with ν degrees of freedom
igamma (< shape sp= > a, scale s= λ) igamma (< shape sp= > a, iscale is= λ)	Inverse-gamma distribution with shape a and scale or inverse-scale λ
laplace (< location loc = > θ, scale s= λ) laplace (< location loc = > θ, iscale is= λ)	Laplace distribution with location θ and scale or inverse-scale λ . This is also known as the <i>double exponential</i> distribution. You can use the alias dexpon for this distribution.
logistic (< location loc = > a, < scale s= > b)	Logistic distribution with location a and scale b
lognormal (< mean m= > μ, sd= λ) lognormal (< mean m= > μ, var v= λ) lognormal (< mean m= > μ, prec= λ)	Log-normal distribution with mean μ and a value of λ for the standard deviation, variance, or precision. You can use the aliases lognormal or lnorm for this distribution.
negbin (< n= > n, < prob p= > p)	Negative binomial distribution with count n and probability of success p . You can use the alias nb for this distribution.
normal (< mean m= > μ, sd= λ) normal (< mean m= > μ, var v= λ) normal (< mean m= > μ, prec= λ)	Normal (Gaussian) distribution with mean μ and a value of λ for the standard deviation, variance, or precision. You can use the aliases gaussian , norm , or n for this distribution.
pareto (< shape sp= > a, < scale s= > b)	Pareto distribution with shape a and scale b

Table 55.2 (continued)

Distribution Name	Definition
poisson (< mean m= > λ)	Poisson distribution with mean λ
sichisq (< df= > ν , < scale s= > s)	Scaled inverse χ^2 distribution with ν degrees of freedom and scale parameter s
t (< mean m= > μ , sd= λ , < df= > ν) t (< mean m= > μ , var v= λ , < df= > ν) t (< mean m= > μ , prec= λ , < df= > ν)	T distribution with mean μ , standard deviation or variance or precision λ , and ν degrees of freedom
uniform (< left l= > a , < right r= > b)	Uniform distribution with range a and b . You can use the alias unif for this distribution.
wald (< mean m= > μ , < iscale is= > λ)	Wald distribution with mean parameter μ and inverse scale parameter λ . This is also known as the <i>Inverse Gaussian</i> distribution. You can use the alias igaussian for this distribution.
weibull (μ, c, σ)	Weibull distribution with location (threshold) parameter μ , shape parameter c , and scale parameter σ .

Table 55.3 Multivariate Distributions

Distribution Name	Definition
dirichlet (< alpha= > α)	Dirichlet distribution with parameter vector α , where α must be a one-dimensional array of length greater than 1
iwish (< df= > ν , < scale= > S)	Inverse Wishart distribution with ν degrees of freedom and symmetric positive definite scale array S
mvn (< mu= > μ , < cov= > Σ)	Multivariate normal distribution with mean vector μ and covariance matrix Σ
mvnar (< mu= > μ , sd= λ , < rho= > ρ) mvnar (< mu= > μ , var= λ , < rho= > ρ) mvnar (< mu= > μ , prec= λ , < rho= > ρ)	Multivariate normal distribution with mean vector μ and a covariance matrix Σ . The covariance matrix Σ is a multiple of the scale and a matrix with a first-order autoregressive structure. When rho=0 , this distribution becomes a multivariate normal distribution with shared variance.
multinom (< p= > p)	Multinomial distribution with probability vector p

Options for the MODEL Statement

The *options* in the MODEL statement apply only when there are missing values in the response variable. You can specify the following options:

INITIAL=SAS-data-set | constant | numeric-list

specifies the initial values of the missing values. By default, PROC MCMC uses a sample average of the nonmissing values of a response variable as the starting values for all missing values in the simulation for that variable. You can use the INITIAL= option to start the Markov chain at a different place.

If you use a *SAS-data-set* to store initial values, the data set must consist of variable names that agree with the missing variable names that are used by PROC MCMC. The easiest way to find the names of the internally created variables is to run a default analysis with a very small number of simulations and check the variable names in the [OUTPOST=](#) data set. You can provide a subset of the initial values in the *SAS-data-set*, and PROC MCMC uses a default mechanism to fill in the rest of the missing initial values.

For example, the following statement creates a data set with initial values for the first three missing values of a response variable:

```
data RandomInit;
  input y_1 y_2 y_3;
  datalines;
  2.3 3 -3
;
```

The following MODEL statement uses the values in the RandomInit data set as the initial values of the corresponding missing values in the model:

```
model y ~ normal(0,var=s2u) init=randominit;
```

Specifying a *constant* assigns that constant as the initial value to all missing values in that response variable. For example, the following statement assigns the value 5 to be used as an initial value for all missing y_i in the model:

```
model y ~ normal(0,var=s2u) init=5;
```

If you have a multidimensional response variable, you can provide a list of numbers that have the same length as the dimension of your response array. Each number is then given to all corresponding missing variables in order. For example, the following statement assigns the value 2 to be used as an initial value for all missing w_{1i} and the value 3 to be used for all missing w_{2i} in the model:

```
array w[2] w1 w2;
model w ~ mvn(mu, cov) init=(2 3);
```

MONITOR= (symbol-list | number-list | RANDOM(number))

outputs analysis for selected missing data variables. You can choose to monitor the missing values by listing the response variable names, the missing data variable names, or indices, or you can have them randomly selected by PROC MCMC.

For example, suppose that the data set contains 10 observations and the response variable *y* has missing values in observations 2, 3, 7, 9, and 10. To monitor all missing data variables (five in total), you specify the response variable name in the **MONITOR=** option:

```
model y ~ normal(0,var=s2u) monitor=(y);
```

Suppose you want to monitor the missing data variables that correspond to the missing values in observations 2, 3, and 10. You have two options: provide either a list of variable names or a list of indices.

The following statement selects monitored variables by their variable names:

```
model y ~ normal(0,var=s2u) monitor=(y_2 y_3 y_10);
```

The variable names must match the internally created variable names for each missing value. See **NAMESUFFIX=** option for the naming convention of the variables. By default, the names are created by concatenating the response variable with the observation index; hence you use the **name_obs** format to construct the names. The numbers 2, 3, and 10 are the corresponding observation indices to the missing values in the input data set.

The following statement selects monitored variables by indices:

```
model y ~ normal(0,var=s2u) monitor=(1 2 5);
```

The indices are not a list of the observation numbers, but rather the order by which the missing values appear in the data set: PROC MCMC reports back the first, the second, and the fifth missing value variables that it creates. The actual variable names that appear in the output are still *y_2*, *y_3*, and *y_10*, honoring the control of the **NAMESUFFIX=** option.

Lastly, PROC MCMC can randomly choose a subset of the variables to monitor. The following statement randomly selects 3 variables to monitor:

```
model y ~ normal(0,var=s2u) monitor=(random(3));
```

The list of the random indices is controlled by the **SEED=** option in the PROC MCMC statement. Therefore, the selected variables will be the same when the **SEED=** option is the same.

NAMESUFFIX=OBSERVATION | POSITION | ORDER

specifies how the names of the missing data variables are created. By default, the names are created by concatenating the response variable symbol, an underscore (“_”), and the observation number of the missing value.

NAMESUFFIX=OBSERVATION constructs the parameter names by appending the observation number to the response variable symbol. This is the default. **NAMESUFFIX=POSITION** or **NAMESUFFIX=ORDER** construct the parameter names by appending the numbers 1, 2, 3, and so on, where the number indicates the order in which the missing values appear in the data set.

For example, suppose you have a response variable *y* with 10 observations in total, of which five are missing (observations 2, 3, 7, 9, and 10). By default, PROC MCMC creates five variable names *y_2*, *y_3*, *y_7*, *y_9*, and *y_10*. Using **NAMESUFFIX=POSITION** changes the names to *y_1*, *y_2*, *y_3*, *y_4*, and *y_5*.

NOOUTPOST

suppresses the output of the posterior samples of missing data variables to the posterior output data set (which is specified in the [OUTPOST=](#) option in the PROC MCMC statement). In models with a large number of missing values (for example, tens of thousands), PROC MCMC can run faster if it does not save the posterior samples.

When you specify both the NOOUTPOST option and the [MONITOR=](#) option, PROC MCMC outputs the list of variables that are monitored.

The maximum number of variables that can be saved to an [OUTPOST=](#) data set is 32,767. If the total number of parameters in your model, including the number of missing data variables, exceeds the limit, the NOOUTPOST option is evoked automatically and PROC MCMC does not save the missing value draws to the posterior output data set. You can use the [MONITOR=](#) option to select a subset of the parameters to store in the [OUTPOST=](#) data set.

PARMS Statement

```
PARMS  name |(name-list)<=><{> number | number-list <}>
        <name |(name-list)<=><{> number | number-list <}> ... >
        </options> ;
```

The PARMS statement lists the names of the parameters in the model and specifies optional initial values for these parameters. These parameters are referred to as the *model parameters*. You can specify multiple PARMS statements. Each PARMS statement defines a block of parameters, and the blocked Metropolis algorithm updates the parameters in each block simultaneously. See the section “[Blocking of Parameters](#)” on page 4466 for more details. PROC MCMC generates missing initial values from the prior distributions whenever needed, as long as they are the standard distributions and not the [GENERAL](#) or [DGENERAL](#) function.

If your model contains a multidimensional parameter (for example, a parameter with a multivariate normal prior distribution), you must declare the parameter as an array (using the [ARRAY](#) statement). You can use braces { } after the parameter name in the PARM statement to assign initial values. For example:

```
array mu[3];
parms mu {1 2 3};
```

You cannot use the [ARRAY](#) statement to assign initial values. If you use the [ARRAY](#) statement to store values in array elements, the declared array becomes a constant array and cannot be used as parameters in the PARMS statement. For example, the following statement assigns three numbers to mu:

```
array mu[3] (1 2 3);
```

The array mu can no longer be a model parameter.

Every parameter in the PARMS statement must have a corresponding prior distribution in the PRIOR statement. The program exits if this one-to-one requirement is not satisfied.

You can specify the following *options* to control different samplers explicitly for that block of parameters.

NORMAL | N

uses the normal proposal distribution in the random walk Metropolis. This is the default.

T <(df)>

uses the t distribution with df degrees of freedom as an alternative proposal distribution. A t distribution with a small number of degrees of freedom has thicker tails and can sometimes improve the mixing of the Markov chain. When $df > 100$, the normal distribution is used instead.

SLICE

applies the slice sampler to each parameter in the PARMS statement individually. See the section “[Slice Sampler](#)” on page 136 for details. PROC MCMC does not implement a multidimensional version of the slice sampler. Because the slice sampler usually requires multiple evaluations of the objective function (the posterior distribution) in each iteration, the associated computational cost could be potentially high with this sampling algorithm.

UDS

implements a user-defined sampler for any of the parameters in the block. See the section “[UDS Statement](#)” on page 4462 for details and “[Example 55.19: Implement a New Sampling Algorithm](#)” on page 4645 for a realistic example. When you specify the UDS option, PROC MCMC hands off the sampling of these parameters to you at each iteration and relies on your sampler to return a random draw from the conditional posterior distribution. This option is useful if you have a model-specific sampler that you want to implement or a new algorithm that can improve the convergence and mixing of the Markov chain. This functionality is for advanced users, and you should proceed with caution.

PREDDIST Statement

PREDDIST <'label'> **OUTPRED**=SAS-data-set <**NSIM**=n> <**COVARIATES**=SAS-data-set>
<**STATISTICS**=options> ;

The PREDDIST statement creates a new SAS data set that contains random samples from the posterior predictive distribution of the response variable. The posterior predictive distribution is the distribution of unobserved observations (prediction) conditional on the observed data. Let y be the observed data, X be the covariates, θ be the parameter, and y_{pred} be the unobserved data. The posterior predictive distribution is defined to be the following:

$$\begin{aligned} p(y_{\text{pred}}|y, X) &= \int p(y_{\text{pred}}, \theta|y, X) d\theta \\ &= \int p(y_{\text{pred}}|\theta, y, X) p(\theta|y, X) d\theta \end{aligned}$$

Given the assumption that the observed and unobserved data are conditional independent given θ , the posterior predictive distribution can be further simplified as the following:

$$p(y_{\text{pred}}|y, X) = \int p(y_{\text{pred}}|\theta) p(\theta|y, X) d\theta$$

The posterior predictive distribution is an integral of the likelihood function $p(y_{\text{pred}}|\theta)$ with respect to the posterior distribution $p(\theta|y)$. The PREDDIST statement generates samples from a posterior predictive distribution based on draws from the posterior distribution of θ .

The PREDDIST statement works only on response variables that have standard distributions, and it does not support either the GENERAL or DGENERAL functions. Multiple PREDDIST statements can be specified, and an optional label (specified as a quoted string) helps identify the output.

The following list explains specifications in the PREDDIST statement:

COVARIATES=SAS-data-set

names the SAS data set that contains the sets of explanatory variable values for which the predictions are established. This data set must contain data with the same variable names as are used in the likelihood function. If you omit the COVARIATES= option, the DATA= data set specified in the PROC MCMC statement is used instead.

NSIM=*n*

specifies the number of simulated predicted values. By default, NSIM= uses the NMC= option value specified in the PROC MCMC statement.

OUTPRED=SAS-data-set

creates an output data set to contain the samples from the posterior predictive distribution. The output variable names are listed as *resp_1*–*resp_m*, where *resp* is the name of the response variable and *m* is the number of observations in the COVARIATES= data set in the PREDDIST statement. If the COVARIATES= data set is not specified, *m* is the number of observations in the DATA= data set specified in the PROC statement.

STATISTICS<(global-stats-options)> = NONE | ALL |stats-request

STATS<(global-stats-options)> = NONE | ALL |stats-request

specifies options for calculating posterior statistics. This option works identically to the STATISTICS= option in the PROC statement. By default, this option takes the specification of the STATISTICS= option in the PROC MCMC statement.

For an example that uses the PREDDIST statement, see “[Posterior Predictive Distribution](#)” on page 4514.

PRIOR/HYPERPRIOR Statement

PRIOR *parameter-list* ~ *distribution* ;

HYPERPRIOR *parameter-list* ~ *distribution* ;

HYPER *parameter-list* ~ *distribution* ;

The PRIOR statement specifies the prior distribution of the model parameters. You must specify a single parameter or a list of parameters, a tilde ~, and then a distribution with its parameters.

You can specify multiple **PRIOR** statements to define models with multiple prior components. Your model can have as many hierarchical levels as you want. But in many cases, such as random-effects models, it is better to use the **RANDOM** statements to build up the model hierarchy. The log of the prior is the sum of the log prior values from each of the **PRIOR** statements. Similar to the **MODEL** statement, you can use the **PRIOR** statement to specify marginal or conditional prior distributions. See the section “**MODEL Statement**” on page 4443 for the names of the standard distributions and the section “**Standard Distributions**” on page 4476 for density specification.

The **PRIOR** statements are processed twice at every Markov chain simulation—that is, twice per pass through the data set. The statements are called at the first and the last observation of the data set, just as the **BEGINNODATA** and **ENDNODATA** statements are processed. If you run a Monte Carlo simulation that is data-independent, you can specify the **NOLOGDIST** option in the **PROC MCMC** statement to omit the calculation of the prior distribution. Omitting this calculation enables **PROC MCMC** to run faster.

The **HYPERPRIOR** statement is treated internally the same as the **PRIOR** statement. It provides a notational convenience in case you want to fit a multilevel hierarchical model. It specifies the hyperprior distribution of the prior distribution parameters. The log of the hyperprior is the sum of the log hyperprior values from each of the **HYPERPRIOR** statements.

Parameters in the **PRIOR** statements can appear as hyperparameters in the **RANDOM** statement. The reverse is not allowed: random-effects parameters cannot be hyperparameters in a **PRIOR** statement.

You can have a program that contains a **RANDOM** statement but no **PRIOR** statements. (In SAS 9.3 and earlier, each program had to contain a **PRIOR** statement.) A program that contains a **RANDOM** statement but no **PRIOR** statements could be a random-effects model with no fixed-effects parameters or hyperparameters to the random effects. A **MODEL** statement is still required in every program.

Programming Statements

This section lists the programming statements available in **PROC MCMC** to compute the priors and log-likelihood functions. This section also documents the differences between programming statements in **PROC MCMC** and programming statements in the **DATA** step. The syntax of programming statements used in **PROC MCMC** is identical to that used in the **NLMIXED** procedure (see Chapter 64, “**The NLMIXED Procedure**”) and the **MODEL** procedure (see Chapter 19, “**The MODEL Procedure**” (*SAS/ETS User’s Guide*)). Most of the programming statements that can be used in the **DATA** step can also be used in **PROC MCMC**. See *SAS Language Reference: Dictionary* for a description of SAS programming statements.

There are also a number of unique functions in **PROC MCMC** that calculate the log density of various distributions in the procedure. You can find them at the section “**Using Density Functions in the Programming Statements**” on page 4491.

For the list of matrix-based functions that is supported in **PROC MCMC**, see the section “**Matrix Functions in PROC MCMC**” on page 4498.

The following are valid statements:

```

ABORT;
ARRAY arrayname < [ dimensions ] > < $ > < variables-and-constants >;
CALL name < (expression < , expression ... >) >;
DELETE;
DO < variable = expression < TO expression > < BY expression > >
    < , expression < TO expression > < BY expression > > ...
    < WHILE expression > < UNTIL expression >;
END;
GOTO statement-label;
IF expression;
IF expression THEN program-statement;
    ELSE program-statement;
variable = expression;
variable + expression;
LINK statement-label;
PUT < variable > < = > ...;
RETURN;
SELECT < (expression) >;
STOP;
SUBSTR(variable, index, length) = expression;
WHEN (expression) program-statement;
    OTHERWISE program-statement;

```

For the most part, the SAS programming statements work the same as they do in the DATA step, as documented in *SAS Language Reference: Concepts*. However, there are several differences:

- The **ABORT** statement does not allow any arguments.
- The **DO** statement does not allow a character index variable. Thus

```
do i = 1, 2, 3;
```

is supported; however, the following statement is not supported:

```
do i = 'A', 'B', 'C';
```

- The **PUT** statement, used mostly for program debugging in PROC MCMC (see the section “[Handling Error Messages](#)” on page 4530), supports only some of the features of the DATA step **PUT** statement, and it has some features that are not available with the DATA step **PUT** statement:
 - The PROC MCMC **PUT** statement does not support line pointers, factored lists, iteration factors, overprinting, `_INFILE_`, `_OBS_`, the colon (:) format modifier, or “\$”.
 - The PROC MCMC **PUT** statement does support expressions, but the expression must be enclosed in parentheses. For example, the following statement displays the square root of x:

```
put (sqrt(x));
```

- The **WHEN** and **OTHERWISE** statements enable you to specify more than one target statement. That is, **DO/END** groups are not necessary for multiple statement **WHEN**s. For example, the following syntax is valid:

```

select;
  when (exp1) stmt1;
              stmt2;
  when (exp2) stmt3;
              stmt4;
end;

```

You should avoid defining variables that begin with an underscore (_). They might conflict with internal variables created by PROC MCMC. The **MODEL** statement must come after any SAS programming statements that define or modify terms used in the construction of the log likelihood.

RANDOM Statement

RANDOM *random-effect* ~ *distribution* **SUBJECT**=*variable* < *options* > ;

The **RANDOM** statement defines a single random effect and its prior distribution or an array of random effects and their prior distribution. The *random-effect* must be represented by either a symbol or an array. The **RANDOM** statement must consist of the *random-effect*, a tilde (~), the distribution for the random effect, and then a **SUBJECT**= variable.

SUBJECT=*variable* | **_OBS_**

identifies the subjects in the random-effects model. The *variable* must be part of the input data set, and it can be either a numeric variable or character literal. The *variable* does not need to be sorted, and the input data set does not need to be clustered according to it. **SUBJECT**=_OBS_ enables you fit an observation-level random-effects model (each observation has its own random effect) without specifying a subject variable in the input data set.

The random-effects parameters associated with each subject in the same **RANDOM** statement are assumed to be conditionally independent of each other, given other parameters and data set variables in the model. The other parameters include model parameters (declared in the **PARMS** statements), random-effects parameters (from other **RANDOM** statements), and missing data variables.

Table 55.4 shows the distributions that you can specify in the **RANDOM** statement.

Table 55.4 Valid Distributions in the **RANDOM** Statement

Distribution Name	Definition
beta (< a => α , < b => β)	Beta distribution with shape parameters α and β
binary (< prob p => p)	Binary (Bernoulli) distribution with probability of success p . You can use the alias bern for this distribution.
gamma (< shape sp => a , scale s => λ) gamma (< shape sp => a , iscale is => λ)	Gamma distribution with shape a and scale or inverse-scale λ

Table 55.4 (continued)

Distribution Name	Definition
dgeneral (//)	General log-prior function that you construct using SAS programming statements for univariate or multivariate discrete random effects. See the section “ Specifying a New Distribution ” on page 4490 for more details.
general (//)	General log-prior function that you construct using SAS programming statements for univariate or multivariate continuous random effects. See the section “ Specifying a New Distribution ” on page 4490 for more details.
igamma (< shape sp= > a , scale s= λ) igamma (< shape sp= > a , iscale is= λ)	Inverse-gamma distribution with shape a and scale or inverse-scale λ
laplace (< location loc = > θ , scale s= λ) laplace (< location loc = > θ , iscale is= λ)	Laplace distribution with location θ and scale or inverse-scale λ . This is also known as the <i>double exponential</i> distribution. You can use the alias dexpon for this distribution.
normal (< mean m= > μ , sd= λ) normal (< mean m= > μ , var v= λ) normal (< mean m= > μ , prec= λ)	Normal (Gaussian) distribution with mean μ and a value of λ for the standard deviation, variance, or precision. You can use the aliases gaussian , norm , or n for this distribution.
poisson (< mean m= > λ)	Poisson distribution with mean λ
mvn (< mu= > μ , < cov= > Σ)	Multivariate normal distribution with mean vector μ and covariance matrix Σ
mvnar (< mu= > μ , sd= λ , < rho= > ρ) mvnar (< mu= > μ , var= λ , < rho= > ρ) mvnar (< mu= > μ , prec= λ , < rho= > ρ)	Multivariate normal distribution with mean vector μ and a covariance matrix Σ . The covariance matrix Σ is a multiple of the scale and a matrix with a first-order autoregressive structure

The following RANDOM statement specifies a scale effect, where `s2u` can be a constant or a model parameter and `index` is a data set variable that indicates group membership of the random effect `u`:

```
random u ~ normal(0,var=s2u) subject=index;
```

The following statements specify multidimensional effects, where `mu` and `cov` can be either parameters in the model or constant arrays:

```
array w[2];
array mu[2];
array cov[2,2];
random w ~ mvn(mu, cov) subject=index;
```

You can specify multiple RANDOM statements. Hyperparameters in the prior distribution of a random effect can be other random effects in the model. For example, the following statements are allowed because the random effect *g* appears in the distribution for the random effect *u*:

```
random g ~ normal(0,var=s2g) subject=month;
random u ~ normal(g,var=s2u) subject=day;
```

These two RANDOM statements specify a nested hierarchical model in which the random-effects *g* is the hyperparameter of the random-effects *u*. You can build the hierarchical structure as deep as you want. You can also use multiple RANDOM statements to build non-nested random-effects models, where the effects could enter the model on different levels but not in the same hierarchy of each other.

The number of random-effects parameters in each RANDOM statement is determined by the number of unique values in the **SUBJECT=** variable, which can be either unsorted numeric or unsorted character literal. Unlike the model parameters that are explicitly declared in the **PARMS** statement (with therefore a fixed total number), the number of random-effects parameters in a program depends on the values of the **SUBJECT=** data set variable. That number can change from one BY group to another.

The names of the random-effects parameters are created internally. See the **NAMESUFFIX=** option for the naming convention of the random-effects parameters. The random-effects parameters are updated conditionally in the simulation. All posterior draws are saved to the **OUTPOST=** output data set by default, and you can use the **MONITOR=** option to monitor any of the parameters. For more information about available sampling algorithms, see the **ALGORITHM=** option. For more information about how to set a random-effects parameter to a constant (also known as corner-point constraint), see the **CONSTRAINT** option.

You can specify the following *options* in the RANDOM statement:

ALGORITHM=*option*

ALG=*option*

specifies the algorithm to use to sample the posterior distribution. The following *options* are available:

RWM

uses the random-walk Metropolis algorithm with normal proposal.

SLICE

uses the slice sampling algorithm.

GEO

uses the discrete random-walk Metropolis with symmetric geometric proposal.

When possible, PROC MCMC samples directly from the full conditional distribution. Otherwise, the default sampling algorithm is the RWM.

CONSTRAINT(VALUE=*value***) = FIRST | LAST | NONE | '***formatted-value***'**

ZERO=**FIRST | LAST | NONE | '***formatted-value***'**

sets one of the random-effects parameters to a fixed value. The default is ZERO=NONE, which does not fix any of the parameters to be a constant. This option enables you to eliminate one of the parameters.

For example, this option could be useful if you want to fit a regression model with categorical covariates and, instead of creating a design matrix, you treat the parameters as “random effects” and fit an equivalent random-effects model.

Suppose you have a regression that includes a categorical variable X with J levels. You can construct a full-rank design matrix with $J-1$ dummy variables ($X_2 \cdots X_J$ with X_1 being the base group) and fit a regression such as the following:

$$\mu_i = \beta_0 + \beta_2 \cdot X_2 \cdots \beta_J \cdot X_J$$

The following statements in a PROC MCMC step fit such a hypothetical regression model:

```
parms beta0 betax2 ... betaxJ;
prior beta: ~ n(0, sd=100);
mu = beta0 + betax2 * x2 + ... betaxJ * xJ;
...
```

Equivalently, you can also treat this model as a random-effects model such as the following, where β_j are random effects for each category in X :

$$\mu_i = \beta_0 + \beta_j \text{ for } j = 1, \dots, J$$

However, this random-effects model is over-parameterized. The ZERO= option rids the model with one random-effects parameter of choice and fixes it to be zero. The following example statements fit such a hypothetical random-effects model:

```
parms beta0;
prior beta0 ~ n(0, sd=100);
random beta ~ n(0, sd=100) subject=x zero=first;
mu = beta0 + beta;
...
```

The specification ZERO=FIRST sets the first random-effects parameter to 0, implying $\beta_1 = 0$. This random-effects parameter corresponds to the first category in the **SUBJECT=** variable. The category is what the first observation of the **SUBJECT=** variable takes.

The specification ZERO=LAST sets the last random-effects parameter to be 0, implying $\beta_J = 0$. This random-effects parameter corresponds to the last category in the **SUBJECT=** variable. The category is not necessarily the same category that the last observation of the **SUBJECT=** variable takes because the **SUBJECT=** variable does not need to be sorted.

The specification ZERO=*formatted-value* sets the random-effects parameter for the category (in the **SUBJECT=** variable) with a formatted value that matches *formatted-value* to 0. For example, ZERO='3' sets $\beta_3 = 0$.

The CONSTRAINT(VALUE=*value*) option works similarly to the ZERO= option. You can assign an arbitrary *value* to any one of the random-effects parameter. For example, the specification CONSTRAINT(VALUE=0)=FIRST is equivalent to ZERO=FIRST.

INITIAL=SAS-data-set | constant | numeric-list

specifies the initial values of the random-effects parameters. By default, PROC MCMC uses the same option as specified in the **INIT=** option to generate initial values for the random-effects parameter: either it uses the mode of the prior density or it randomly draws a sample from that distribution. You can start the Markov chain at different places by providing a *SAS-data-set*, a constant, or a *numeric-list* for multivariate random-effects parameters.

If you use a *SAS-data-set*, the data set must consist of variable names that agree with the random-effects parameters in the model (see the **NAMESUFFIX=** option for the naming convention of the random-effects parameters). The easiest way to find the names of the internally created parameter names is to run a default analysis with a very small number of simulations and check the variable names in the **OUTPOST=** data set. You can provide a subset of the initial values in the *SAS-data-set* and PROC MCMC will use the default mechanism to fill in the rest of the random-effects parameters.

For example, the following statement creates a data set with initial values for the random-effects parameters `u_1`, `u_2`, and `u_3`:

```
data RandomInit;
  input u_1 u_2 u_3;
  datalines;
  2.3 3 -3
;
```

The following **RANDOM** statement takes the values in the `RandomInit` data set to be the initial values of the corresponding random-effects parameters in the model:

```
random u ~ normal(0,var=s2u) subject=index init=randominit;
```

Specifying a *constant* assigns that constant as the initial value to all random-effects parameters in the statement. For example, the following statement assigns the value 5 to be used as an initial value for all u_i in the model:

```
random u ~ normal(0,var=s2u) subject=index init=5;
```

If you have multiple effects, you can provide a list of numbers, where the length of the list the same as the dimension of your random-effects array. Each number is then given to all corresponding random-effects parameters in order. For example, the following statement assigns the value 2 to be used as an initial value for all w_{1i} and the value 3 to be used for all w_{2i} in the model:

```
array w[2] w1 w2;
random w ~ mvn(mu, cov) subject=index init=(2 3);
```

If you use the **GENERAL** or **DGENERAL** functions in the **RANDOM** statement, you must provide initial values for these parameters.

MONITOR= (symbol-list | number-list | RANDOM(number))

outputs analysis for selected random-effects parameters. You can choose to monitor the random-effects parameters by listing the effect names or effect indices, or you can have them randomly selected by PROC MCMC.

To monitor all random-effects parameters, you specify the effect name in the **MONITOR=** option:

```
random u ~ normal(0,var=s2u) subject=index monitor=(u);
```

You have three options for monitoring a subset of the random-effects parameters. You can provide a list of the parameter names, you can provide a number list of the parameter indices, or you can have PROC MCMC randomly choose a subset of parameters for you.

For example, if you want to monitor analysis for parameters `u_1` through `u_10`, `u_23`, and `u_57`, you can provide the names as follows:

```
random u ~ normal(0,var=s2u) subject=index monitor=(u_1-u_10 u_23 u_57);
```

The naming convention in the *symbol-list* must agree with the `NAMESUFFIX=` option, which controls how the parameter names of the *random-effect* are created. By default, `NAMESUFFIX=SUBJECT`, and the *symbol-list* must use suffixes that correspond to the formatted values¹ in the `SUBJECT=` data set variable. With the `NAMESUFFIX=POSITION` option, the *symbol-list* must use suffixes that agree with the input order of the `SUBJECT=` variable. If the `SUBJECT=` variable has a character value, you cannot use the hyphen (-) in the *symbol-list* to indicate a range of variables.

To monitor the same list of random-effects parameters, you can provide their indices:

```
random u ~ normal(0,var=s2u) subject=index monitor=(1 to 10 by 1 23 57);
```

PROC MCMC can also randomly choose a subset of the parameters to monitor:

```
random u ~ normal(0,var=s2u) subject=index monitor=(random(12));
```

The sequence of the random indices is controlled by the `SEED=` option in the PROC MCMC statement.

By default, PROC MCMC does not monitor any random-effects parameters. When you specify this option, it takes the specification of the `STATISTICS=` and `PLOTS=` options in the PROC MCMC statement. By default, PROC MCMC outputs all the posterior samples of all random-effects parameters to the `OUTPOST=` output data set. You can use the `NOOUTPOST` option to suppress the saving of the random-effects parameters.

NAMESUFFIX=option

specifies how the names of the random-effects parameters are internally created from the `SUBJECT=variable` that is specified in the RANDOM statement. PROC MCMC creates the names by concatenating the *random-effect* symbol with an underscore and a series of numbers or characters. The following *options* control the type of methods that are used in such construction:

SUBJECT

constructs the parameter names by appending the formatted values of the `SUBJECT= variable` in the input data set¹.

¹In SAS/STAT 9.3, the random-effects parameters were created using the unformatted values of the `SUBJECT= variable`.

POSITION

constructs the parameter names by appending the numbers 1, 2, 3, and so on, where the number indicates the order in which the **SUBJECT=** *variable* appears in the data set.

For example, suppose you have an input data set with four observations and the **SUBJECT=** variable *zipcode* has four values (with three of them unique): 27513, 01440, 27513, and 15217. The following SAS statement creates three random-effects parameters named *u_27513*, *u_01440*, and *u_15217*:

```
random u ~ normal(0,var=10) subject=zipcode namesuffix=subject;
```

On the other hand, using **NAMESUFFIX=POSITION** creates three parameters named as *u_1*, *u_2*, and *u_3*:

```
random u ~ normal(0,var=10) subject=zipcode namesuffix=position;
```

By default, **NAMESUFFIX=SUBJECT**.

NOOUTPOST

suppresses the output of the posterior samples of random-effects parameters to the **OUTPOST=** data set. In models with a large number of random-effects parameters (for example, tens of thousands), PROC MCMC can run faster if it does not save the posterior samples of the random-effects parameters.

When you specify both the **NOOUTPOST** option and the **MONITOR=** option, PROC MCMC outputs the list of variables that are monitored.

The maximum number of variables that can be saved to an **OUTPOST=** data set is 32,767. If you run a large-scale random-effects model with the number of parameters exceeding the limit, the **NOOUTPOST** option is evoked automatically and PROC MCMC does not save the random-effects parameter draws to the posterior output data set. You can use the **MONITOR=** option to select a subset of the parameters to store in the **OUTPOST=** data set.

UDS Statement

UDS *subroutine-name* (*subroutine-argument-list*) ;

UDS stands for user defined sampler. The UDS statement enables you to use a separate algorithm, other than the default random walk Metropolis, to update parameters in the model. The purpose of the UDS statement is to give you a greater amount of flexibility and better control over the updating schemes of the Markov chain. Multiple UDS statements are allowed.

For the UDS statement to work properly, you have to do the following:

- write a subroutine by using PROC FCMP (see the FCMP Procedure in the *Base SAS Procedures Guide*) and save it to a SAS catalog (see the example in this section). The subroutine must update some parameters in the model. These are the UDS parameters. The subroutine is called the UDS subroutine.

- declare any UDS parameters in the **PARMS** statement with a sampling option, as in `</ UDS>` (see the section “**PARMS Statement**” on page 4451).
- specify the prior distributions for all UDS parameters, using the **PRIOR** statements.

NOTE: All UDS parameters must appear in three places: the UDS statement, the **PARMS** statement, and the **PRIOR** statement. Otherwise, PROC MCMC exits.

To obtain a valid Markov chain, a UDS subroutine must update a parameter from its full posterior conditional distribution and not the posterior marginal distribution. The posterior conditional is something that you need to provide. This conditional is implicitly based on a prior distribution. PROC MCMC has no means to verify that the implied prior in the UDS subroutine is the same as the prior that you specified in the **PRIOR** statement. You need to make sure that the two distributions agree; otherwise, you will get misleading results.

The priors in the **PRIOR** statements do not directly affect the sampling of the UDS parameters. They could affect the sampling of the other parameters in the model, which, in turn, changes the behavior of the Markov chain. You can see this by noting cases where the hyperparameters of the UDS parameters are model parameters; the priors should be part of the posterior conditional distributions of these hyperparameters, and they cannot be omitted.

Some additional information is listed to help you better understand the UDS statement:

- Most features of the SAS programming language can be used in subroutines processed by PROC FCMP (see the FCMP Procedure in the *Base SAS Procedures Guide*).
- The UDS statement does not support FCMP functions—a FCMP function returns a value, while a subroutine does not. A subroutine updates some of its subroutine arguments. These arguments are called OUTARGS arguments.
- The UDS parameters cannot be in the same block as other parameters. The optional argument `</ UDS>` in the **PARMS** statement prevents parameters that use the default Metropolis from being mixed with those that are updated by the UDS subroutines.
- You can put all the UDS parameters in the same **PARMS** statement or have a separate UDS statement for each of them.
- The same subroutine can be used in multiple UDS statements. This feature comes in handy if you have a generic sampler that can be applied to different parameters.
- PROC MCMC updates the UDS parameters by calling the UDS subroutines directly. At every iteration, PROC MCMC first samples parameters that use the Metropolis algorithm, then the UDS parameters. Sampling of the UDS parameters proceeds in the order in which the UDS statements are listed.
- A UDS subroutine accepts any symbols in the program as well as any input data set variables as its arguments.
- Only the OUTARGS arguments in a UDS subroutine are updated in PROC MCMC. You can modify other arguments in the subroutine, but the changes are not global in PROC MCMC.
- If a UDS subroutine has an argument that is a SAS data set variable, PROC MCMC steps through the data set while updating the UDS parameters. The subroutine is called once per observation in the data set for every iteration.

- If a UDS subroutine does not have any arguments that are data set variables, PROC MCMC does not access the data set while executing the subroutine. The subroutine is called once per iteration.
- To reduce the overhead in calling the UDS subroutine and accessing the data set repeatedly, you might consider reading all the input data set variables into arrays and using the arrays as the subroutine arguments. See the section “[BEGINCNST/ENDCNST Statement](#)” on page 4441 about how to use the [BEGINCNST](#) and [ENDCNST](#) statements to store data set variables.

For an example that uses the UDS statement, see “[Example 55.19: Implement a New Sampling Algorithm](#)” on page 4645.

Details: MCMC Procedure

How PROC MCMC Works

PROC MCMC is a simulation-based procedure that applies a variety of sampling algorithms to the program at hand. The default sampling methods include conjugate sampling (from full conditional), direct sampling from the marginal distribution, inverse cumulative distribution function, random walk Metropolis with normal proposal, and discretized random walk Metropolis with normal proposal. You can request alternate sampling algorithms, such as random walk Metropolis with t distribution proposal, discretized random walk Metropolis with symmetric geometric proposal, and the slice sampling algorithm.

PROC MCMC applies the more efficient sampling algorithms first, whenever possible. When a parameter does not appear in the conditional distributions of other random variables in the program, PROC MCMC generates samples directly from its prior distribution (which is also its marginal distribution). This usually occurs in data-independent Monte Carlo simulation programs (see “[Example 55.1: Simulating Samples From a Known Density](#)” on page 4540 for an example) or missing data problems, where the missing response variables are generated directly from the conditional sampling distribution (or the conditional likelihood). When conjugacy is detected, PROC MCMC uses random number generators to draw values from the full conditional distribution. (For information about detecting conjugacy, see the section “[Conjugate Sampling](#)” on page 4472.) In other situations, PROC MCMC resorts to the random walk Metropolis with normal proposal to generate posterior samples for continuous parameters and a discretized version for discrete parameters. See the section “[Metropolis and Metropolis-Hastings Algorithms](#)” on page 134 for details about the Metropolis algorithm. For the actual implementation details of the Metropolis algorithm in PROC MCMC, such as tuning of the covariance matrices, see the section “[Tuning the Proposal Distribution](#)” on page 4469.

A key component of the Metropolis algorithm is the calculation of the objective function. In most cases, the objective function that PROC MCMC uses in a Metropolis step is the logarithm of the joint posterior distribution, which is calculated with the inclusion of all data and parameters. The rest of this section describes how PROC MCMC calculates the objective function for parameters that use the Metropolis algorithm.

Model Parameters

To calculate the log of the posterior density, PROC MCMC assumes that all observations in the data set are independent,

$$\log(p(\theta|\mathbf{y})) = \log(\pi(\theta)) + \sum_{i=1}^n \log(f(y_i|\theta))$$

where θ is a parameter or a vector of parameters that are defined in the **PARMS** statements (referred to as the *model parameters*). The term $\log(\pi(\theta))$ is the sum of the log of the prior densities specified in the **PRIOR** and **HYPERPRIOR** statements. The term $\log(f(y_i|\theta))$ is the log likelihood specified in the **MODEL** statement. The **MODEL** statement specifies the log likelihood for a single observation in the data set.

If you want to model dependent data—that is, $\log(f(\mathbf{y}|\theta)) \neq \sum_i \log(f(y_i|\theta))$ —you can use the **JOINT-MODEL** option in the PROC MCMC statement. See the section “[Modeling Joint Likelihood](#)” on page 4504 for more details.

The statements in PROC MCMC are similar to DATA step statements; PROC MCMC evaluates every statement in order for each observation. At the beginning of the data set, the log likelihood is set to be 0. As PROC MCMC steps through the data set, it cumulatively adds the log likelihood for each observation. Statements between the **BEGINNODATA** and **ENDNODATA** statements are evaluated only at the first and the last observations. At the last observation, the log of the prior and hyperprior distributions is added to the sum of the log likelihood to obtain the log of the posterior distribution.

Calculation of the $\log(p(\theta|\mathbf{y}))$ objective function involves a complete pass through the data set, making it potentially computationally expensive. If $\theta = \{\theta_1, \theta_2\}$ is multidimensional, you can choose to update a portion of the parameters at each iteration step by declaring them in separate **PARMS** statements (see the section “[Blocking of Parameters](#)” on page 4466 for more information). PROC MCMC updates each block of parameters while holding others constant. The objective functions that are used in each update are the same as the log of the joint posterior density:

$$\log(p(\theta_1|\mathbf{y}, \theta_2)) = \log(p(\theta_2|\mathbf{y}, \theta_1)) = \log(p(\theta|\mathbf{y}))$$

In other words, PROC MCMC does not derive the conditional distribution explicitly for each block of parameters, and it uses the full joint distribution in the Metropolis step for every block update.

Random-Effects Models

For programs that require **RANDOM** statements, PROC MCMC includes the sum of the density evaluation of the random-effects parameters in the calculation of the objective function for θ ,

$$\log(p(\theta|\boldsymbol{\gamma}, \mathbf{y})) = \log(\pi(\theta)) + \sum_{j=1}^J \log(\pi(\gamma_j|\theta)) + \sum_{i=1}^n \log(f(y_i|\theta, \boldsymbol{\gamma}))$$

where $\boldsymbol{\gamma} = \{\gamma_1, \dots, \gamma_J\}$ are random-effects parameters and $\pi(\gamma_j|\theta)$ is the prior distribution of the random-effects parameters. The likelihood function can be conditional on $\boldsymbol{\gamma}$, but the prior distributions of θ , which must be independent of $\boldsymbol{\gamma}$, cannot.

The objective function used in the Metropolis step for the random-effects parameter γ_j contains only the portion of the data that belong to the j th cluster:

$$\log(p(\gamma_j|\theta, \mathbf{y})) = \log(\pi(\gamma_j|\theta)) + \sum_{i \in \{j\text{th cluster}\}} \log(f(y_i|\theta, \gamma_j))$$

The calculation does not include $\log(\theta)$, the prior density piece, because that is a known constant. Evaluation of this objective function involves only a portion of the data set, making it more computationally efficient. In fact, updating every random-effects parameters in a single **RANDOM** statement involves only one pass through the data set.

You can have multiple **RANDOM** statements in a program, which adds more pieces to the posterior calculation, such as

$$\log(p(\theta|\boldsymbol{\gamma}, \boldsymbol{\alpha}, \mathbf{y})) = \log(\pi(\theta)) + \sum_{j=1}^J \log(\pi(\gamma_j|\theta)) + \sum_{k=1}^K \log(\pi(\alpha_k|\theta)) + \sum_{i=1}^n \log(f(y_i|\theta, \boldsymbol{\gamma}, \boldsymbol{\alpha}))$$

where $\boldsymbol{\alpha} = \{\alpha_1, \dots, \alpha_K\}$ is another random effect. The random effects $\boldsymbol{\gamma}$ and $\boldsymbol{\alpha}$ can form their own hierarchy (as in a nested model), or they can enter the program in a non-nested fashion. The objective functions for γ_j and α_k are calculated using only observations that belong to their respective clusters.

Models with Missing Values

Missing values in the response variables of the **MODEL** statement are treated as random variables, and they add another layer in the conditional updates in the simulation. Suppose that

$$\mathbf{y} = \{\mathbf{y}_{\text{obs}}, \mathbf{y}_{\text{mis}}\}$$

The response variable \mathbf{y} consists of n_1 observed values \mathbf{y}_{obs} and n_2 missing values \mathbf{y}_{mis} . The log of the posterior distribution is thus formed by

$$\log(p(\theta|\boldsymbol{\gamma}, \mathbf{y}_{\text{mis}}, \mathbf{y}_{\text{obs}})) = \log(\pi(\theta)) + \sum_{j=1}^J \log(\pi(\gamma_j|\theta)) + \sum_{i=1}^{n_2} \log(f(\mathbf{y}_{\text{mis},i}|\theta, \boldsymbol{\gamma})) + \sum_{i=1}^{n_1} \log(f(\mathbf{y}_{\text{obs},i}|\theta, \boldsymbol{\gamma}))$$

where the expression is evaluated at the drawn $\boldsymbol{\gamma}$ and \mathbf{y}_{obs} values.

The conditional distribution of the random-effects parameter γ_j is

$$\log(p(\gamma_j|\theta, \mathbf{y})) = \log(\pi(\gamma_j|\theta)) + \sum_{i \in \{j\text{th cluster}\}} \log(f(y_i|\theta, \gamma_j))$$

where the y_i are either the observed or the imputed values of the response variable.

The missing values are usually sampled directly from the sampling distribution and do not require the Metropolis sampler. When a response variable takes on a **GENERAL** function, the objective function is simply the likelihood function: $\log(f(\mathbf{y}_{\text{mis},i}|\theta, \gamma_j))$.

Blocking of Parameters

In a multivariate parameter model, if all k parameters are proposed with one joint distribution $q(\cdot|\cdot)$, acceptance or rejection would occur for all of them. This can be rather inefficient, especially when parameters have vastly different scales. A way to avoid this difficulty is to allocate the k parameters into d blocks and update them separately. The **PARMS** statement puts model parameters in separate blocks, and each block of parameters is updated sequentially in the procedure.

Suppose you want to sample from a multivariate distribution with probability density function $p(\theta|\mathbf{y})$ where $\theta = \{\theta_1, \theta_2, \dots, \theta_k\}$. Now suppose that these k parameters are separated into d blocks—for example, $p(\theta|\mathbf{x}) = f_d(z)$ where $z = \{z_1, z_2, \dots, z_d\}$, where each z_j contains a nonempty subset of the $\{\theta_i\}$, and where each θ_i is contained in one and only one z_j . In the MCMC context, the z 's are blocks of parameters. In the blocked algorithm, a proposal consists of several parts. Instead of proposing a simultaneous move for all the θ 's, a proposal is made for the θ_i 's in z_1 only, then for the θ_i 's in z_2 , and so on for d subproposals. Any accepted proposal can involve any number of the blocks moving. The parameters do not necessarily all move at once as in the all-at-once Metropolis algorithm.

Formally, the blocked Metropolis algorithm is as follows. Let w_j be the collection of θ_i that are in block z_j , and let $q_j(\cdot|w_j)$ be a symmetric multivariate distribution that is centered at the current values of w_j .

1. Let $t = 0$. Choose points for all w_j^t . A point can be an arbitrary point as long as $p(w_j^t|\mathbf{y}) > 0$.
2. For $j = 1, \dots, d$:
 - a) Generate a new sample, $w_{j,\text{new}}$, using the proposal distribution $q_j(\cdot|w_j^t)$.
 - b) Calculate the following quantity:

$$r = \min \left\{ \frac{p(w_{j,\text{new}}|w_1^t, \dots, w_{j-1}^t, w_{j+1}^{t-1}, \dots, w_d^t, \mathbf{y})}{p(w_j^t|w_1^t, \dots, w_{j-1}^t, w_{j+1}^{t+1}, \dots, w_d^t, \mathbf{y})}, 1 \right\}.$$
 - c) Sample u from the uniform distribution $U(0, 1)$.
 - d) Set $w_j^{t+1} = w_{j,\text{new}}$ if $r < u$; $w_j^{t+1} = w_j^t$ otherwise.
3. Set $t = t + 1$. If $t < T$, the number of desired samples, go back to Step 2; otherwise, stop.

With PROC MCMC, you can sample all parameters simultaneously by putting them all in a single PARMS statement, you can sample parameters individually by putting each parameter in its own PARMS statement, or you can sample certain subsets of parameters together by grouping each subset in its own PARMS statements. For example, if the model you are interested in has five parameters, alpha, beta, gamma, phi, sigma, the all-at-once strategy is as follows:

```
parms alpha beta gamma phi sigma;
```

The one-at-a-time strategy is as follows:

```
parms alpha;
parms beta;
parms gamma;
parms phi;
parms sigma;
```

A two-block strategy could be as follows:

```
parms alpha beta gamma;
parms phi sigma;
```

The exceptions to the previously described blocking strategies are parameters that are sampled directly (either from their full conditional or marginal distributions) and parameters that are array-based (with multivariate prior distributions). In these cases, the parameters are taken out of an existing block and are updated individually. You can use the sampling options in the **PARMS** statement to override the default behavior.

One of the greatest challenges in MCMC sampling is achieving good mixing of the chains—the chains should quickly traverse the support of the stationary distribution. A number of factors determine the behavior of a Metropolis sampler; blocking is one of them, so you want to be extremely careful when you choose a good design. Generally speaking, forming blocks of parameters has its advantages, but it is not true that the larger the block the faster the convergence.

When simultaneously sampling a large number of parameters, the algorithm might find it difficult to achieve good mixing. As the number of parameters gets large, it is much more likely to have (proposal) samples that fall well into the tails of the target distribution, producing too small a test ratio. As a result, few proposed values are accepted and convergence is slow. On the other hand, when the algorithm samples each parameter individually, the computational cost increases linearly. Each block of Metropolis parameters requires one additional pass through the data set, so a five-block updating strategy could take five times longer than a single-block updating strategy. In addition, there is a chance that the chain might mix far too slowly because the conditional distributions (of θ_i given all other θ 's) might be very “narrow,” as a result of posterior correlation among the parameters. When that happens, it takes a long time for the chain to fully explore that dimension alone. There are no theoretical results that can help determine an optimal “blocking” for an arbitrary parametric model. A rule followed in practice is to form small groups of correlated parameters that belong to the same context in the formulation of the model. The best mixing is usually obtained with a blocking strategy somewhere between the all-at-once and one-at-a-time strategies.

Sampling Methods

When suitable, PROC MCMC chooses the optimal sampling method for each parameter. That involves direct sampling either from the conditional posterior via conjugacy (see the section “[Conjugate Sampling](#)” on page 4472) or via the marginal posterior (see the section “[Direct Sampling](#)” on page 4472). Alternatively, PROC MCMC samples according to [Table 55.5](#). Each block of parameters is classified by the nature of the prior distributions. “Continuous” means all priors of the parameters in the same block have a continuous distribution. “Discrete” means all priors are discrete. “Mixed” means that some parameters are continuous and others are discrete. Parameters that have binary priors are treated differently, as indicated in the table.

Table 55.5 Sampling Methods in PROC MCMC

Blocks	Default Method	Alternative Method
Continuous	Multivariate normal (MVN)	Multivariate t (MVT); slice sampler
Discrete (other than binary)	Binned MVN	Binned MVT or symmetric geometric
Mixed	MVN	MVT
Binary (single dimensional)	Inverse CDF	
Binary (multidimensional)	Independence sampler	

For a block of continuous parameters, PROC MCMC uses a multivariate normal distribution as the default proposal distribution. In the tuning phase, PROC MCMC finds an optimal scale c and a tuning covariance matrix Σ .

For a discrete block of parameters, PROC MCMC uses a discretized multivariate normal distribution as the default proposal distribution. The scale c and covariance matrix Σ are tuned. Alternatively, you can use an independent symmetric geometric proposal distribution. The density has form $\frac{p(1-p)^{|\theta|}}{2(1-p)}$ and has variance $\frac{(2-p)(1-p)}{p^2}$. In the tuning phase, the procedure finds an optimal proposal probability p for every parameter in the block.

You can change the proposal distribution, from the normal to a t distribution. You can either use the PROC option **PROPDIST=T(df)** or **PARMS** statement option **</ T(df)>** to make the change. The t distributions have thicker tails, and they can propose to the tail areas more efficiently than the normal distribution. It can help with the mixing of the Markov chain if some of the parameters have a skewed tails. See “[Example 55.6: Nonlinear Poisson Regression Models](#)” on page 4570. The independence sampler (see the section “[Independence Sampler](#)” on page 137) is used for a block of binary parameters. The inverse CDF method is used for a block that consists of a single binary parameter.

For parameters with continuous prior distributions, you can use the slice sampler as an alternative sampling algorithm. To do so, specify the **SLICE** option in the **PARMS**. When you specify the **SLICE** option, all parameters are updated individually. PROC MCMC does not support a multivariate version of the slice sampler. For more in information about the slice sampler, see the section “[Slice Sampler](#)” on page 136.

The sampling algorithms for the random-effects parameters are chosen in a similar fashion. The preferred algorithms are the direct method either from the full conditional or the marginal. When these are not attainable, Metropolis with normal proposal becomes the default for continuous random-effects parameters, and discrete Metropolis with normal proposal becomes the default for discrete random-effects parameters. You can use the **ALGORITHM=** option in the **RANDOM** statement to choose the slice sampler or discrete Metropolis with symmetric geometric as the alternatives.

The sampling preference of the missing data variables is the same as the random-effects parameters. The reserve sampling algorithm is the Metropolis. There is no alternative sampling method available for the missing data variables.

Tuning the Proposal Distribution

One key factor in achieving high efficiency of a Metropolis-based Markov chain is finding a good proposal distribution for each block of parameters. This process is referred to as tuning. The tuning phase consists of a number of loops. The minimum number of loops is controlled by the option **MINTUNE=**, with a default value of 2. The option **MAXTUNE=** controls the maximum number of tuning loops, with a default value of 24. Each loop lasts for **NTU=** iterations, where by default **NTU=** 500. At the end of every loop, PROC MCMC examines the acceptance probability for each block. The acceptance probability is the percentage of **NTU=** proposals that have been accepted. If the probability falls within the acceptance tolerance range (see the section “[Scale Tuning](#)” on page 4470), the current configuration of c/Σ or p is kept. Otherwise, these parameters are modified before the next tuning loop.

Continuous Distribution: Normal or t Distribution

A good proposal distribution should resemble the actual posterior distribution of the parameters. Large sample theory states that the posterior distribution of the parameters approaches a multivariate normal distribution (see Gelman et al. 2004, Appendix B, and Schervish 1995, Section 7.4). That is why a normal proposal distribution often works well in practice. The default proposal distribution in PROC MCMC is

the normal distribution: $q_j(\theta_{\text{new}}|\theta^t) = \text{MVN}(\theta_{\text{new}}|\theta^t, c^2\mathbf{\Sigma})$. As an alternative, you can choose a multivariate t distribution as the proposal distribution. It is a good distribution to use if you think that the posterior distribution has thick tails and a t distribution can improve the mixing of the Markov chain. See “[Example 55.6: Nonlinear Poisson Regression Models](#)” on page 4570.

Scale Tuning

The acceptance rate is closely related to the sampling efficiency of a Metropolis chain. For a random walk Metropolis, high acceptance rate means that most new samples occur right around the current data point. Their frequent acceptance means that the Markov chain is moving rather slowly and not exploring the parameter space fully. On the other hand, a low acceptance rate means that the proposed samples are often rejected; hence the chain is not moving much. An efficient Metropolis sampler has an acceptance rate that is neither too high nor too low. The scale c in the proposal distribution $q(\cdot|\cdot)$ effectively controls this acceptance probability. Roberts, Gelman, and Gilks (1997) showed that if both the target and proposal densities are normal, the optimal acceptance probability for the Markov chain should be around 0.45 in a single dimensional problem, and asymptotically approaches 0.234 in higher dimensions. The corresponding optimal scale is 2.38, which is the initial scale set for each block.

Due to the nature of stochastic simulations, it is impossible to fine-tune a set of variables such that the Metropolis chain has the exact desired acceptance rate. In addition, Roberts and Rosenthal (2001) empirically demonstrated that an acceptance rate between 0.15 and 0.5 is at least 80% efficient, so there is really no need to fine-tune the algorithms to reach acceptance probability that is within small tolerance of the optimal values. PROC MCMC works with a probability range, determined by the PROC options `TARGACCEPT ± ACCEPTTOL`. The default value of `TARGACCEPT` is a function of the number of parameters in the model, as outlined in Roberts, Gelman, and Gilks (1997). The default value of `ACCEPTTOL` is 0.075. If the observed acceptance rate in a given tuning loop is less than the lower bound of the range, the scale is reduced; if the observed acceptance rate is greater than the upper bound of the range, the scale is increased. During the tuning phase, a scale parameter in the normal distribution is adjusted as a function of the observed acceptance rate and the target acceptance rate. The following updating scheme is used in PROC MCMC ²:

$$c_{\text{new}} = \frac{c_{\text{cur}} \cdot \Phi^{-1}(p_{\text{opt}}/2)}{\Phi^{-1}(p_{\text{cur}}/2)}$$

where c_{cur} is the current scale, p_{cur} is the current acceptance rate, p_{opt} is the optimal acceptance probability.

Covariance Tuning

To tune a covariance matrix, PROC MCMC takes a weighted average of the old proposal covariance matrix and the recent observed covariance matrix, based on `NTU` samples in the current loop. The `TUNEWT=w` option determines how much weight is put on the recently observed covariance matrix. The formula used to update the covariance matrix is as follows:

$$\text{COV}_{\text{new}} = w \text{COV}_{\text{cur}} + (1 - w)\text{COV}_{\text{old}}$$

There are two ways to initialize the covariance matrix:

² Roberts, Gelman, and Gilks (1997) and Roberts and Rosenthal (2001) demonstrate that the relationship between acceptance probability and scale in a random walk Metropolis is $p = 2\Phi(-\sqrt{I}c/2)$, where c is the scale, p is the acceptance rate, Φ is the CDF of a standard normal, and $I \equiv E_f[(f'(x)/f(x))^2]$, $f(x)$ is the density function of samples. This relationship determines the updating scheme, with I being replaced by the identity matrix to simplify calculation.

- The default is an identity matrix multiplied by the initial scale of 2.38 (controlled by the PROC option `SCALE=`) and divided by the square root of the number of estimated parameters in the model. It can take a number of tuning phases before the proposal distribution is tuned to its optimal stage, since the Markov chain needs to spend time learning about the posterior covariance structure. If the posterior variances of your parameters vary by more than a few orders of magnitude, if the variances of your parameters are much different from 1, or if the posterior correlations are high, then the proposal tuning algorithm might have difficulty with forming an acceptable proposal distribution.
- Alternatively, you can use a numerical optimization routine, such as the quasi-Newton method, to find a starting covariance matrix. The optimization is performed on the joint posterior distribution, and the covariance matrix is a quadratic approximation at the posterior mode. In some cases this is a better and more efficient way of initializing the covariance matrix. However, there are cases, such as when the number of parameters is large, where the optimization could fail to find a matrix that is positive definite. In that case, the tuning covariance matrix is reset to the identity matrix.

A side product of the optimization routine is that it also finds the *maximum a posteriori* (MAP) estimates with respect to the posterior distribution. The MAP estimates are used as the initial values of the Markov chain.

If any of the parameters are discrete, then the optimization is performed conditional on these discrete parameters at their respective fixed initial values. On the other hand, if all parameters are continuous, you can in some cases skip the tuning phase (by setting `MAXTUNE=0`) or the burn-in phase (by setting `NBI=0`).

Discrete Distribution: Symmetric Geometric

By default, PROC MCMC uses the normal density as the proposal distribution in all Metropolis random walks. For parameters that have discrete prior distributions, PROC MCMC discretizes proposed samples. You can choose an alternative symmetric geometric proposal distribution by specifying the option `DIS-CREATE=GEO`.

The density of the symmetric geometric proposal distribution is as follows:

$$\frac{p_g(1 - p_g)^{|\theta|}}{2(1 - p_g)}$$

where the symmetry centers at θ . The distribution has a variance of

$$\sigma^2 = \frac{(2 - p_g)(1 - p_g)}{p_g^2}$$

Tuning for the proposal p_g uses the following formula:

$$\frac{\sigma_{\text{new}}}{\sigma_{\text{cur}}} = \frac{\Phi^{-1}(p_{\text{opt}}/2)}{\Phi^{-1}(p_{\text{cur}}/2)}$$

where σ_{new} is the standard deviation of the new proposal geometric distribution, σ_{cur} is the standard deviation of the current proposal distribution, p_{opt} is the target acceptance probability, and p_{cur} is the current acceptance probability for the discrete parameter block.

The updated p_g is the solution to the following equation that is between 0 and 1 :

$$\sqrt{\frac{(2 - p_g)(1 - p_g)}{p_g^2}} = \frac{\sigma_{\text{cur}} \cdot \Phi^{-1}(p_{\text{opt}}/2)}{\Phi^{-1}(p_{\text{cur}}/2)}$$

Binary Distribution: Independence Sampler

Blocks consisting of a single parameter with a binary prior do not require any tuning; the inverse-CDF method applies. Blocks that consist of multiple parameters with binary prior are sampled by using an independence sampler with binary proposal distributions. See the section “[Independence Sampler](#)” on page 137. During the tuning phase, the success probability p of the proposal distribution is taken to be the probability of acceptance in the current loop. Ideally, an independence sampler works best if the acceptance rate is 100%, but that is rarely achieved. The algorithm stops when the probability of success exceeds the `TARGACCEPTI=value`, which has a default value of 0.6.

Direct Sampling

The word “direct” is reserved for sampling that is done directly from the prior distribution of a model or a random-effects parameter or from the sampling distribution of a missing data variable. If the parameter is updated via sampling from its full conditional posterior distribution, the sampling method is referred to as conjugate sampling. (See the section “[Conjugate Sampling](#)” on page 4472.)

Whenever a parameter does not appear in the hierarchy of another parameter in the model, PROC MCMC samples directly from its distribution. For a model parameter or a random-effects parameter, this distribution is its prior distribution. For a missing data variable, this distribution is the sampling distribution of the response variable. Therefore, direct sampling takes place most frequently in data-independent Monte Carlo simulations or the sampling of missing response variables.

Conjugate Sampling

Conjugate prior is a family of prior distributions in which the prior and the posterior distributions are of the same family of distributions. For example, if you model an independently and identically distributed random variable y_i using a normal likelihood with known variance σ^2 ,

$$y_i \sim \text{normal}(\mu, \sigma^2)$$

a normal prior on μ

$$\mu \sim \text{normal}(\mu_0, \sigma_0^2)$$

is a conjugate prior because the posterior distribution of μ is also a normal distribution given $y = \{y_i\}$, σ^2 , μ_0 , and σ_0^2 :

$$\mu|y \sim \text{normal} \left(\left(\frac{1}{\sigma_0^2} + \frac{n}{\sigma^2} \right)^{-1} \cdot \left(\frac{\mu_0}{\sigma_0^2} + \frac{n \cdot \bar{y}}{\sigma^2} \right), \left(\frac{1}{\sigma_0^2} + \frac{n}{\sigma^2} \right)^{-1} \right)$$

Conjugate sampling is efficient because it enables the Markov chain to obtain samples from the target distribution directly. When appropriate, PROC MCMC uses conjugate sampling methods to draw conditional posterior samples. [Table 55.6](#) lists scenarios that lead to conjugate sampling in PROC MCMC.

Table 55.6 Conjugate Sampling in PROC MCMC

Family	Parameter	Prior
Normal with known μ	Variance σ^2	Inverse gamma family
Normal with known μ	Precision τ	Gamma family
Normal with known scale parameter (σ^2 , σ , or τ)	Mean μ	Normal
Multivariate normal with known Σ	Mean μ	Multivariate normal
Multivariate normal with known μ	Covariance Σ	Inverse Wishart
Multinomial	\mathbf{p}	Dirichlet
Binomial/binary	p	Beta
Poisson	λ	Gamma family

In most cases, Family in [Output 55.6](#) refers to the likelihood function. However, it does not necessarily have to be the case. The Family is a distribution that is conditional on the parameter of interest, and it can appear in any level of the hierarchical model, including on the random-effects level.

PROC MCMC can detect conjugacy only if the model parameter (not a function or a transformation of the model parameter) is used in the prior and Family distributions. For example, the following statements lead to a conjugate sampler being used on the parameter mu:

```
parm mu;
prior mu ~ n(0, sd=1000);
model y ~ n(mu, var=s2);
```

However, if you modify the program slightly in the following way, although the conjugacy still holds in theory, PROC MCMC cannot detect conjugacy on mu because the parameter enters the normal likelihood function through the symbol w:

```
parm mu;
prior mu ~ n(0, sd=1000);
w = mu;
model y ~ n(w, var=s2);
```

In this case, PROC MCMC resorts to the default sampling algorithm, which is a random walk Metropolis based on a normal kernel.

Similarly, the following statements also prevent PROC MCMC from detecting conjugacy on the parameter mu:

```
parm mu;
prior mu ~ n(0, sd=1000);
model y ~ n(mu + 2, var=s2);
```

In a normal family, an often-used and often-confused conjugate prior on the variance is the inverse gamma distribution, and a conjugate prior on the precision is the gamma distribution. See “[Gamma and Inverse-Gamma Distributions](#)” on page 4512 for typical usages of these prior distributions.

When conjugacy is detected in a model, PROC MCMC performs a numerical optimization on the joint posterior distribution at the start of the MCMC simulation. If the only sampling methods required in the program are conjugate samplers or direct samplers, PROC MCMC omits this optimization step. To turn off this optimization routine, use the [PROPCOV=IND](#) option in the PROC MCMC statement.

Initial Values of the Markov Chains

There are three types of parameters in a PROC MCMC program: the *model parameters* in the **PARMS** statement, the *random-effects parameters* in the **RANDOM** statement, and the *missing data variables* in the **MODEL** statement. The last category is used to model missing values in the input data set.

When the model parameters and random-effects parameters have missing initial values, PROC MCMC generates initial values based on the prior distributions. PROC MCMC either uses the mode value (the default) or draws a random number (if the **INIT=****RANDOM** option is specified). For distributions that do not have modes, such as the uniform distribution, PROC MCMC uses the mean instead. In general, PROC MCMC avoids using starting values that are close to the boundary of support of the prior distribution. For example, the exponential prior has a mode at 0, and PROC MCMC starts an initial value at the mean. This avoids some potential numerical problems. If you use the **GENERAL** or **DGENERAL** function in the **PRIOR** statements, you must provide initial values for those parameters.

With missing data variables, PROC MCMC uses the sample average of the nonmissing values (of the response variable) as the initial value. If all values of a particular variable are missing, PROC MCMC resorts to using the mode value or a random number from the sampling distribution (the likelihood), depending on the specification of the **INIT=** option.

To assign a different set of initial values to the model parameters, you use either the **PARMS** statements or programming statements within the **BEGINCNST** and **ENDCNST** statements. See the section “Assignments of Parameters” on page 4474 for more information about how to assign parameter values within the **BEGINCNST** and **ENDCNST** statements.

To assign initial values to the random-effects parameters, you can use the **INIT=** option in the **RANDOM** statement. Either you can give a constant value to all random-effects parameters that are associated with that statement (for example, use **init=3**), or you can assign values individually by providing a data set that stores different values for different parameters.

A mirroring **INIT=** option in the **MODEL** statement enables you to assign different initial values to the missing data variables.

If you use the **PROPCOV=** optimization option in the PROC MCMC statement, PROC MCMC starts the tuning at the optimized values. PROC MCMC overwrites the initial values that you might have provided at the beginning of the Markov chain unless you use the option **INIT=REINIT**.

Assignments of Parameters

In general, you cannot alter the values of any model parameters in PROC MCMC. For example, the following assignment statement produces an error:

```
parms alpha;  
alpha = 27;
```

This restriction prevents incorrect calculation of the posterior density—assignments of parameters in the program would override the parameter values generated by PROC MCMC and lead to an incorrect value of the density function.

However, you can modify parameter values and assign initial values to parameters within the block defined by the **BEGINCNST** and **ENDCNST** statements. The following syntax is allowed:

```
parms alpha;
begincnst;
  alpha = 27;
endcnst;
```

The initial value of alpha is 27. Assignments within the **BEGINCNST/ENDCNST** block override initial values specified in the **PARMS** statement. For example, with the following statements, the Markov chain starts at alpha = 27, not 23.

```
parms alpha 23;
begincnst;
  alpha = 27;
endcnst;
```

This feature enables you to systematically assign initial values. Suppose that z is an array parameter of the same length as the number of observations in the input data set. You want to start the Markov chain with each z_i having a different value depending on the data set variable y . The following statements set $z_i = |y|$ for the first half of the observations and $z_i = 2.3$ for the rest:

```
/* a rather artificial input data set. */
data inputdata;
  do ind = 1 to 10;
    y = rand('normal');
    output;
  end;
run;

proc mcmc data=inputdata;
  array z[10];
  begincnst;
    if ind <= 5 then z[ind] = abs(y);
    else z[ind] = 2.3;
  endcnst;
  parms z;;
  prior z: ~ normal(0, sd=1);
  model general(0);
run;
```

Elements of z are modified as PROC MCMC executes the programming statements between the **BEGINCNST** and **ENDCNST** statements. This feature could be useful when you use the **GENERAL** function and you find that the **PARMS** statements are too cumbersome for assigning starting values.

Standard Distributions

The section “Univariate Distributions” on page 4476 (Table 55.7 through Table 55.34) lists all univariate distributions that PROC MCMC recognizes. The section “Multivariate Distributions” on page 4486 (Table 55.35 through Table 55.39) lists all multivariate distributions that PROC MCMC recognizes. With the exception of the **multinomial** distribution, all these distributions can be used in the **MODEL**, **PRIOR**, and **HYPERPRIOR** statements. The **multinomial** distribution is supported only in the **MODEL** statement. The **RANDOM** statement supports a limited number of distributions; see Table 55.4 for the complete list.

See the section “Using Density Functions in the Programming Statements” on page 4491 for information about how to use distributions in the programming statements. To specify an arbitrary distribution, you can use the **GENERAL** and **DGENERAL** functions. See the section “Specifying a New Distribution” on page 4490 for more details. See the section “Truncation and Censoring” on page 4494 for tips about how to work with truncated distributions and censoring data.

Univariate Distributions

Table 55.7 Beta Distribution

PROC specification	beta (a, b)
Density	$\frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \theta^{a-1} (1-\theta)^{b-1}$
Parameter restriction	$a > 0, b > 0$
Range	$\begin{cases} [0, 1] & \text{when } a = 1, b = 1 \\ [0, 1) & \text{when } a = 1, b \neq 1 \\ (0, 1] & \text{when } a \neq 1, b = 1 \\ (0, 1) & \text{otherwise} \end{cases}$
Mean	$\frac{a}{a+b}$
Variance	$\frac{ab}{(a+b)^2(a+b+1)}$
Mode	$\begin{cases} \frac{a-1}{a+b-2} & a > 1, b > 1 \\ 0 \text{ and } 1 & a < 1, b < 1 \\ 0 & \begin{cases} a < 1, b \geq 1 \\ a = 1, b > 1 \end{cases} \\ 1 & \begin{cases} a \geq 1, b < 1 \\ a > 1, b = 1 \end{cases} \\ \text{does not exist uniquely} & a = b = 1 \end{cases}$
Random number	If $\min(a, b) > 1$, see (Cheng 1978); if $\max(a, b) < 1$, see (Atkinson and Whittaker 1976) and (Atkinson 1979); if $\min(a, b) < 1$ and $\max(a, b) > 1$, see (Cheng 1978); if $a = 1$ or $b = 1$, use the inversion method; if $a = b = 1$, use a uniform random number generator.

Table 55.8 Binary Distribution

PROC specification	binary (p)
Density	$p^\theta (1-p)^{1-\theta}$
Parameter restriction	$0 \leq p \leq 1$
Range	$\begin{cases} \{0\} & \text{when } p = 0 \\ \{1\} & \text{when } p = 1 \\ \{0, 1\} & \text{otherwise} \end{cases}$
Mean	$\text{round}(p)$
Variance	$p(1-p)$
Mode	$\begin{cases} \{1\} & \text{when } p = 1 \\ \{0\} & \text{otherwise} \end{cases}$
Random number	Generate $u \sim \text{uniform}(0, 1)$. If $u \leq p$, $\theta = 1$; else, $\theta = 0$.

Table 55.9 Binomial Distribution

PROC specification	binomial (n, p)
Density	$\binom{n}{\theta} p^\theta (1-p)^{n-\theta}$
Parameter restriction	$n = 0, 1, 2, \dots$ $0 \leq p \leq 1$
Range	$\theta \in \{0, \dots, n\}$
Mean	$\lfloor np \rfloor$
Variance	$np(1-p)$
Mode	$\lfloor (n+1)p \rfloor$

Table 55.10 Cauchy Distribution

PROC specification	cauchy (a, b)
Density	$\frac{1}{\pi} \left(\frac{b}{b^2 + (\theta - a)^2} \right)$
Parameter restriction	$b > 0$
Range	$\theta \in (-\infty, \infty)$
Mean	Does not exist.
Variance	Does not exist.
Mode	a
Random number	Generate $u_1, u_2 \sim \text{uniform}(0, 1)$; let $v = 2u_2 - 1$. Repeat the procedure until $u_1^2 + v^2 < 1$. $y = v/u_1$ is a draw from the standard Cauchy, and $\theta = a + by$ (Ripley 1987).

Table 55.11 χ^2 Distribution

PROC specification	chisq (ν)
Density	$\frac{1}{\Gamma(\nu/2)2^{\nu/2}} \theta^{(\nu/2)-1} e^{-\theta/2}$
Parameter restriction	$\nu > 0$
Range	$\theta \in [0, \infty)$ if $\nu = 2$; $(0, \infty)$ otherwise.
Mean	ν
Variance	2ν
Mode	$\nu - 2$ if $\nu \geq 2$; does not exist otherwise.
Random number	χ^2 is a special case of the gamma distribution: $\theta \sim \text{gamma}(\nu/2, \text{scale}=2)$ is a draw from the χ^2 distribution.

Table 55.12 Exponential χ^2 Distribution

PROC specification	expchisq (ν)
Density	$\frac{1}{\Gamma(\nu/2)2^{\nu/2}} \exp(\theta)^{\nu/2} \exp(-\exp(\theta)/2)$
Parameter restriction	$\nu > 0$
Range	$\theta \in (-\infty, \infty)$
Mode	$\log(\nu)$
Random number	Generate $x_1 \sim \chi^2(\nu)$, and $\theta = \log(x_1)$ is a draw from the exponential χ^2 distribution.
Relationship to the χ^2 distribution	$\theta \sim \chi^2(\nu) \Leftrightarrow \log(\theta) \sim \exp \chi^2(\nu)$

Table 55.13 Exponential Exponential Distribution

PROC specification	expexpon (scale = b)	expexpon (iscale = β)
Density	$\frac{1}{b} \exp(\theta) \exp(-\exp(\theta)/b)$	$\beta \exp(\theta) \exp(-\exp(\theta) \cdot \beta)$
Parameter restriction	$b > 0$	$\beta > 0$
Range	$\theta \in (-\infty, \infty)$	Same
Mode	$\log(b)$	$\log(1/\beta)$
Random number	Generate $x_1 \sim \text{expon}(\text{scale}=b)$, and $\theta = \log(x_1)$ is a draw from the exponential exponential distribution. Note that an exponential exponential distribution is not the same as the double exponential distribution.	
Relationship to the exponential distribution	$\theta \sim \text{expon}(b) \Leftrightarrow \log(\theta) \sim \text{expExpon}(b)$	

Table 55.14 Exponential Gamma Distribution

PROC specification	expgamma (a , scale = b)	expgamma (a , iscale = β)
Density	$\frac{1}{b^a \Gamma(a)} e^{a\theta} \exp(-e^\theta/b)$	$\frac{\beta^a}{\Gamma(a)} e^{a\theta} \exp(-e^\theta \cdot \beta)$
Parameter restriction	$a > 0, b > 0$	$a > 0, \beta > 0$
Range	$\theta \in (-\infty, \infty)$	Same
Mode	$\log(ab)$	$\log(a/\beta)$
Random number	Generate $x_1 \sim \text{gamma}(a, \text{scale} = b)$, and $\theta = \log(x_1)$ is a draw from the exponential gamma distribution.	
Relationship to the Γ distribution	$\theta \sim \text{gamma}(a, b) \Leftrightarrow \log(\theta) \sim \text{expGamma}(a, b)$	

Table 55.15 Exponential Inverse χ^2 Distribution

PROC specification	expichisq (v)
Density	$\frac{1}{\Gamma(\frac{v}{2}) 2^{v/2}} \exp(-v\theta/2) \exp(-1/(2 \exp(\theta)))$
Parameter restriction	$v > 0$
Range	$\theta \in (-\infty, \infty)$
Mode	$-\log(v)$
Random number	Generate $x_1 \sim i\chi^2(v)$, and $\theta = \log(x_1)$ is a draw from the exponential inverse χ^2 distribution.
Relationship to the $i\chi^2$ distribution	$\theta \sim i\chi^2(v) \Leftrightarrow \log(\theta) \sim \text{exp} i\chi^2(v)$

Table 55.16 Exponential Inverse-Gamma Distribution

PROC specification	expigamma (a , scale = b)	expigamma (a , iscale = β)
Density	$\frac{b^a}{\Gamma(a)} \exp(-\alpha\theta) \exp(-b/\exp(\theta))$	$\frac{1}{\beta^a \Gamma(a)} \exp(-\alpha\theta) \exp(-\frac{1}{\beta \exp(\theta)})$
Parameter restriction	$a > 0, b > 0$	$a > 0, \beta > 0$
Range	$\theta \in (-\infty, \infty)$	Same
Mode	$-\log(a/b)$	$-\log(a\beta)$
Random number	Generate $x_1 \sim \text{igamma}(a, \text{scale} = b)$, and $\theta = \log(x_1)$ is a draw from the exponential inverse-gamma distribution.	
Relationship to the $i\Gamma$ distribution	$\theta \sim \text{igamma}(a, b) \Leftrightarrow \log(\theta) \sim \text{eigamma}(a, b)$	

Table 55.17 Exponential Scaled Inverse χ^2 Distribution

PROC specification	expsichisq (ν, s)
Density	$\frac{(\frac{\nu}{2})^{\nu/2}}{\Gamma(\frac{\nu}{2})} s^\nu \exp(-\nu\theta/2) \exp(-\nu s^2/(2 \exp(\theta)))$
Parameter restriction	$\nu > 0, s > 0$
Range	$\theta \in (-\infty, \infty)$
Mode	$\log(s^2)$
Random number	Generate $x_1 \sim si\chi^2(\nu, s)$, and $\theta = \log(x_1)$ is a draw from the exponential scaled inverse χ^2 distribution.
Relationship to the $si\chi^2$ distribution	$\theta \sim si\chi^2(\nu, s) \Leftrightarrow \log(\theta) \sim \exp si\chi^2(\nu, s)$

Table 55.18 Exponential Distribution

PROC specification	expon (scale = b)	expon (iscale = β)
Density	$\frac{1}{b} e^{-\theta/b}$	$\beta e^{-\beta\theta}$
Parameter restriction	$b > 0$	$\beta > 0$
Range	$\theta \in [0, \infty)$	Same
Mean	b	$1/\beta$
Variance	b^2	$1/\beta^2$
Mode	0	0
Random number	The exponential distribution is a special case of the gamma distribution: $\theta \sim \text{gamma}(1, \text{scale} = b)$ is a draw from the exponential distribution.	

Table 55.19 Gamma Distribution

PROC specification	gamma ($a, \text{scale} = b$)	gamma ($a, \text{iscale} = \beta$)
Density	$\frac{1}{b^a \Gamma(a)} \theta^{a-1} e^{-\theta/b}$	$\frac{\beta^a}{\Gamma(a)} \theta^{a-1} e^{-\beta\theta}$
Parameter restriction	$a > 0, b > 0$	$a > 0, \beta > 0$
Range	$\theta \in [0, \infty)$ if $a = 1$; $(0, \infty)$ otherwise.	Same
Mean	ab	a/β
Variance	ab^2	a/β^2
Mode	$(a-1)b$ if $a \geq 1$	$(a-1)/\beta$ if $a \geq 1$
Random number	See (McGrath and Irving 1973).	

Table 55.20 Geometric Distribution

PROC specification	geo (p)
Density ³	$p(1 - p)^\theta$
Parameter restriction	$0 < p \leq 1$
Range	$\theta \in \begin{cases} \{0, 1, 2, \dots\} & 0 < p < 1 \\ \{0\} & p = 1 \end{cases}$
Mean	$\text{round}(\frac{1-p}{p})$
Variance	$\frac{1-p}{p^2}$
Mode	0
Random number	Based on samples obtained from a Bernoulli distribution with probability p until the first success.

Table 55.21 Inverse χ^2 Distribution

PROC specification	ichisq (ν)
Density	$\frac{1}{\Gamma(\nu/2)2^{\nu/2}} \theta^{-(\nu/2+1)} e^{-1/(2\theta)}$
Parameter restriction	$\nu > 0$
Range	$\theta \in (0, \infty)$
Mean	$\frac{1}{\nu-2}$ if $\nu > 2$
Variance	$\frac{2}{(\nu-2)^2(\nu-4)}$ if $\nu > 4$
Mode	$\frac{1}{\nu+2}$
Random number	Inverse χ^2 is a special case of the inverse-gamma distribution: $\theta \sim \text{igamma}(\nu/2, \text{iscale} = 2)$ is a draw from the inverse χ^2 distribution.

Table 55.22 Inverse-Gamma Distribution

PROC specification	igamma ($a, \text{scale} = b$)	igamma ($a, \text{iscale} = \beta$)
Density	$\frac{b^a}{\Gamma(a)} \theta^{-(a+1)} e^{-b/\theta}$	$\frac{1}{\beta^a \Gamma(a)} \theta^{-(a+1)} e^{-1/\beta\theta}$
Parameter restriction	$a > 0, b > 0$	$a > 0, \beta > 0$
Range	$\theta \in (0, \infty)$	Same
Mean	$\frac{b}{a-1}$ if $a > 1$	$\frac{1}{\beta(a-1)}$ if $a > 1$
Variance	$\frac{b^2}{(a-1)^2(a-2)}$	$\frac{1}{\beta^2(a-1)^2(a-2)}$
Mode	$\frac{b}{a+1}$	$\frac{1}{\beta(a+1)}$
Random number	Generate $x_1 \sim \text{gamma}(a, \text{scale} = b)$, and $\theta = 1/x_1$ is a draw from the $\text{igamma}(a, \text{iscale} = b)$ distribution.	

³The random variable θ is the total number of failures in an experiment *before* the first success. This density function is not to be confused with another popular formulation, $p(1 - p)^{\theta-1}$, which counts the total number of trials *until* the first success.

Relationship to the $\theta \sim \text{gamma}(a, \text{iscale} = b) \Leftrightarrow 1/\theta \sim \text{igamma}(a, \text{scale} = b)$
gamma distribution

Table 55.23 Laplace (Double Exponential) Distribution

PROC specification	laplace (a , scale = b)	laplace (a , iscale = β)
Density	$\frac{1}{2b} e^{- \theta-a /b}$	$\frac{\beta}{2} e^{-\beta \theta-a }$
Parameter restriction	$b > 0$	$\beta > 0$
Range	$\theta \in (-\infty, \infty)$	Same
Mean	a	a
Variance	$2b^2$	$2/\beta^2$
Mode	a	a
Random number	Inverse CDF. $F(\theta) = \begin{cases} \frac{1}{2} \exp\left(-\frac{a-\theta}{b}\right) & \theta < a \\ 1 - \frac{1}{2} \exp\left(-\frac{\theta-a}{b}\right) & \theta \geq a \end{cases}$ Generate $u_1, u_2 \sim \text{uniform}(0, 1)$. If $u_1 < 0.5$, $\theta = a + b \log(u_2)$; else $\theta = a - b \log(u_2)$. θ is a draw from the Laplace distribution.	

Table 55.24 Logistic Distribution

PROC specification	logistic (a , b)
Density	$\frac{\exp\left(-\frac{\theta-a}{b}\right)}{b(1+\exp\left(-\frac{\theta-a}{b}\right))^2}$
Parameter restriction	$b > 0$
Range	$\theta \in (-\infty, \infty)$
Mean	a
Variance	$\frac{\pi^2 b^2}{3}$
Mode	a
Random number	Inverse CDF method with $F(\theta) = \left(1 + \exp\left(-\frac{\theta-a}{b}\right)\right)^{-1}$. Generate $u \sim \text{uniform}(0, 1)$, and $\theta = a - b \log(1/u - 1)$ is a draw from the logistic distribution.

Table 55.25 Lognormal Distribution

PROC specification	lognormal (μ , sd = s)	lognormal (μ , var = v)	lognormal (μ , prec = τ)
Density	$\frac{1}{\theta s \sqrt{2\pi}} \exp\left(-\frac{(\log \theta - \mu)^2}{2s^2}\right)$	$\frac{1}{\theta \sqrt{2\pi v}} \exp\left(-\frac{(\log \theta - \mu)^2}{2v}\right)$	$\frac{1}{\theta} \sqrt{\frac{\tau}{2\pi}} \exp\left(-\frac{\tau(\log \theta - \mu)^2}{2}\right)$
Parameter restriction	$s > 0$	$v > 0$	$\tau > 0$

Range	$\theta \in (0, \infty)$	Same	Same
Mean	$\exp(\mu + s^2/2)$	$\exp(\mu + v/2)$	$\exp(\mu + 1/(2\tau))$
Variance	$\exp(2(\mu + s^2))$ $-\exp(2\mu + s^2)$	$\exp(2(\mu + v))$ $-\exp(2\mu + v)$	$\exp(2(\mu + 1/\tau))$ $-\exp(2\mu + 1/\tau)$
Mode	$\exp(\mu - s^2)$	$\exp(\mu - v)$	$\exp(\mu - 1/\tau)$
Random number	Generate $x_1 \sim \text{normal}(0, 1)$, and $\theta = \exp(\mu + sx_1)$ is a draw from the lognormal distribution.		

Table 55.26 Negative Binomial Distribution

PROC specification	negbin (n, p)
Density	$\binom{\theta + n - 1}{n - 1} p^n (1 - p)^\theta$
Parameter restriction	$n = 1, 2, \dots$, and $0 < p \leq 1$
Range	$\theta \in \begin{cases} \{0, 1, 2, \dots\} & 0 < p < 1 \\ \{0\} & p = 1 \end{cases}$
Mean	$\text{round}\left(\frac{n(1-p)}{p}\right)$
Variance	$\frac{n(1-p)}{p^2}$
Mode	$\begin{cases} 0 & n = 1 \\ \text{round}\left(\frac{(n-1)(1-p)}{p}\right) & n > 1 \end{cases}$
Random number	Generate $x_1 \sim \text{gamma}(n, 1)$, and $\theta \sim \text{Poisson}(x_1 \cdot (1 - p)/p)$ (Fishman 1996).

Table 55.27 Normal Distribution

PROC specification	normal ($\mu, \text{sd} = s$)	normal ($\mu, \text{var} = v$)	normal ($\mu, \text{prec} = \tau$)
Density	$\frac{1}{s\sqrt{2\pi}} \exp\left(-\frac{(\theta-\mu)^2}{2s^2}\right)$	$\frac{1}{\sqrt{2\pi v}} \exp\left(-\frac{(\theta-\mu)^2}{2v}\right)$	$\sqrt{\frac{\tau}{2\pi}} \exp\left(-\frac{\tau(\theta-\mu)^2}{2}\right)$
Parameter restriction	$s > 0$	$v > 0$	$\tau > 0$
Range	$\theta \in (-\infty, \infty)$	Same	Same
Mean	μ	Same	Same
Variance	s^2	v	$1/\tau$
Mode	μ	Same	Same

Table 55.28 Pareto Distribution

PROC specification	pareto (a, b)
Density	$\frac{a}{b} \left(\frac{b}{\theta}\right)^{a+1}$
Parameter restriction	$a > 0, b > 0$
Range	$\theta \in [b, \infty)$
Mean	$\frac{ab}{a-1}$ if $a > 1$
Variance	$\frac{b^2 a}{(a-1)^2(a-2)}$ if $a > 2$
Mode	b
Random number	Inverse CDF method with $F(\theta) = 1 - (b/\theta)^a$. Generate $u \sim \text{uniform}(0, 1)$, and $\theta = \frac{b}{u^{1/a}}$ is a draw from the Pareto distribution.
Useful transformation	$x = 1/\theta$ is $\text{Beta}(a, 1)\mathbf{I}\{x < 1/b\}$.

Table 55.29 Poisson Distribution

PROC specification	poisson (λ)
Density	$\frac{\lambda^\theta}{\theta!} \exp(-\lambda)$
Parameter restriction	$\lambda \geq 0$
Range	$\theta \in \begin{cases} \{0, 1, \dots\} & \text{if } \lambda > 0 \\ \{0\} & \text{if } \lambda = 0 \end{cases}$
Mean	λ
Variance	λ , if $\lambda > 0$
Mode	$\text{round}(\lambda)$

Table 55.30 Scaled Inverse χ^2 Distribution

PROC specification	sichisq (ν, s^2)
Density	$\frac{(s^2 \nu/2)^{\nu/2}}{\Gamma(\nu/2)} \theta^{-(\nu/2+1)} e^{-\nu s^2/(2\theta)}$
Parameter restriction	$\nu > 0, s > 0$
Range	$\theta \in (0, \infty)$
Mean	$\frac{\nu}{\nu-2} s^2$ if $\nu > 2$
Variance	$\frac{2\nu^2}{(\nu-2)^2(\nu-4)} s^4$ if $\nu > 4$
Mode	$\frac{\nu}{\nu+2} s^2$
Random number	Scaled inverse χ^2 is a special case of the inverse-gamma distribution: $\theta \sim \text{igamma}(\nu/2, \text{scale} = (\nu s^2)/2)$ is a draw from the scaled inverse χ^2 distribution.

Table 55.31 *t* Distribution

PROC specification	$\mathbf{t}(\mu, \text{sd} = s, \nu)$	$\mathbf{t}(\mu, \text{var} = v, \nu)$	$\mathbf{t}(\mu, \text{prec} = \tau, \nu)$
Density	$\frac{\Gamma(\frac{\nu+1}{2})}{\Gamma(\frac{\nu}{2})s\sqrt{\nu\pi}}(1 + \frac{(\theta-\mu)^2}{\nu s^2})^{-\frac{\nu+1}{2}}$	$\frac{\Gamma(\frac{\nu+1}{2})}{\Gamma(\frac{\nu}{2})\sqrt{\nu\pi v}}(1 + \frac{(\theta-\mu)^2}{\nu v})^{-\frac{\nu+1}{2}}$	$\frac{\Gamma(\frac{\nu+1}{2})\sqrt{\tau}}{\Gamma(\frac{\nu}{2})\sqrt{\nu\pi}}(1 + \frac{\tau(\theta-\mu)^2}{\nu})^{-\frac{\nu+1}{2}}$
Parm restriction	$s > 0, \nu > 0$	$v > 0, \nu > 0$	$\tau > 0, \nu > 0$
Range	$\theta \in (-\infty, \infty)$	Same	Same
Mean	μ if $\nu > 1$	Same	Same
Variance	$\frac{\nu}{\nu-2}s^2$ if $\nu > 2$	$\frac{\nu}{\nu-2}v$ if $\nu > 2$	$\frac{\nu}{\nu-2}\frac{1}{\tau}$ if $\nu > 2$
Mode	μ	Same	Same
Random number	$x_1 \sim \text{normal}(0, 1), x_2 \sim \chi^2(d)$, and $\theta = m + \sigma x_1 \sqrt{d/x_2}$ is a draw from the t distribution.		

Table 55.32 Uniform Distribution

PROC specification	$\mathbf{uniform}(a, b)$
Density	$\begin{cases} \frac{1}{a-b} & \text{if } a > b \\ \frac{1}{b-a} & \text{if } b > a \\ 1 & \text{if } a = b \end{cases}$
Parameter restriction	none
Range	$\theta \in [a, b]$
Mean	$\frac{a+b}{2}$
Variance	$\frac{ b-a ^2}{12}$
Mode	Does not exist
Random number	Mersenne Twister (Matsumoto and Kurita 1992, 1994; Matsumoto and Nishimura 1998)

Table 55.33 Wald Distribution

PROC specification	$\mathbf{wald}(\mu, \lambda)$
Density	$\sqrt{\frac{\lambda}{2\pi\theta^3}} \exp\left(\frac{-\lambda(\theta-\mu)^2}{2\mu^2\theta}\right)$
Parameter restriction	$\mu > 0, \lambda > 0$
Range	$\theta \in (0, \infty)$
Mean	μ
Variance	μ^3/λ
Mode	$\mu \left[\left(1 + \frac{9\mu^2}{4\lambda^2}\right)^{1/2} - \frac{3\mu}{2\lambda} \right]$

Random number	Generate $v_0 \sim \chi^2_{(1)}$. Let $x_1 = \mu + \frac{\mu^2 v_0}{2\lambda} - \frac{\mu}{2\lambda} \sqrt{4\mu\lambda v_0 + \mu^2 v_0^2}$ and $x_2 = \mu^2/x_1$. Perform a Bernoulli trial, $w \sim \text{Bernoulli}(\frac{\mu}{\mu+x_1})$. If $w = 1$, choose $\theta = x_1$; otherwise, choose $\theta = x_2$ (Michael, Schucany, and Haas 1976).
---------------	---

Table 55.34 Weibull Distribution

PROC specification	weibull (μ, c, σ)
Density	$\exp\left(-\left(\frac{\theta-\mu}{\sigma}\right)^c\right) \frac{c}{\sigma} \left(\frac{\theta-\mu}{\sigma}\right)^{c-1}$
Parameter restriction	$c > 0, \sigma > 0$
Range	$\theta \in [\mu, \infty)$ if $c = 1$; (μ, ∞) otherwise
Mean	$\mu + \sigma \Gamma(1 + 1/c)$
Variance	$\sigma^2[\Gamma(1 + 2/c) - \Gamma^2(1 + 1/c)]$
Mode	$\mu + \sigma(1 - 1/c)^{1/c}$ if $c > 1$
Random number	Inverse CDF method with $F(\theta) = 1 - \exp\left(-\left(\frac{\theta-\mu}{\sigma}\right)^c\right)$. Generate $u \sim \text{uniform}(0, 1)$, and $\theta = \mu + \sigma \cdot (-\ln u)^{1/c}$ is a draw from the Weibull distribution.

Multivariate Distributions

Table 55.35 Dirichlet Distribution

PROC specification	$\boldsymbol{\theta} \sim \text{dirich}(\boldsymbol{\alpha})$, where $\boldsymbol{\theta} = \{\theta_i\}$, $\boldsymbol{\alpha} = \{\alpha_i\}$, for $i = 1 \dots k$
Density	$\frac{\Gamma(\alpha_0)}{\prod_{i=1}^k \Gamma(\alpha_i)} \prod_{i=1}^k \theta_i^{\alpha_i-1}$, where $\alpha_0 = \sum_{i=1}^k \alpha_i$
Parameter restriction	$\alpha_i > 0$
Range	$\theta_i > 0, \sum_{i=1}^k \theta_i = 1$
Mean	α_j / α_0
Mode	$(\alpha_j - 1) / (\alpha_0 - k)$

Table 55.36 Inverse Wishart Distribution

PROC specification	$\boldsymbol{\theta} \sim \text{iwishart}(\nu, \mathbf{S})$, both $\boldsymbol{\theta}$ and \mathbf{S} are $k \times k$ matrices
Density	$\left(2^{\frac{\nu k}{2}} \pi^{\frac{k(k-1)}{4}} \prod_{i=1}^k \Gamma\left(\frac{\nu+1-i}{2}\right)\right)^{-1} \mathbf{S} ^{\frac{\nu}{2}} \boldsymbol{\theta} ^{-\frac{\nu+k+1}{2}} \exp\left(-\frac{1}{2} \text{tr}(\mathbf{S}\boldsymbol{\theta}^{-1})\right)$
Parameter restriction	\mathbf{S} must be symmetric and positive definite; $\nu > k - 1$
Range	$\boldsymbol{\theta}$ is symmetric and positive definite
Mean	$\mathbf{S} / (\nu - k - 1)$
Mode	$\mathbf{S} / (\nu + k + 1)$

Table 55.37 Multivariate Normal Distribution

PROC specification	$\boldsymbol{\theta} \sim \mathbf{mvn}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, where $\boldsymbol{\theta} = \{\theta_k\}$, $\boldsymbol{\mu} = \{\mu_k\}$, for $i = 1 \cdots k$, and $\boldsymbol{\Sigma}$ is a $k \times k$ variance matrix
Density	$\exp\left(-\frac{1}{2}(\boldsymbol{\theta} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1}(\boldsymbol{\theta} - \boldsymbol{\mu})\right) / \sqrt{(2\pi)^k \boldsymbol{\Sigma} }$
Parameter restriction	$\boldsymbol{\Sigma}$ must be symmetric and positive definite
Range	$-\infty < \theta_i < \infty$
Mean	$\boldsymbol{\mu}$
Mode	$\boldsymbol{\mu}$

Table 55.38 Autoregressive Multivariate Normal Distribution

PROC specification	$\boldsymbol{\theta} \sim \mathbf{mvn}(\boldsymbol{\mu}, \text{sd}=\sigma, \rho)$	$\boldsymbol{\theta} \sim \mathbf{mvn}(\boldsymbol{\mu}, \text{var}=\sigma^2, \rho)$	$\boldsymbol{\theta} \sim \mathbf{mvn}(\boldsymbol{\mu}, \text{prec}=1/\sigma^2, \rho)$
Density	$\exp\left(-\frac{1}{2}(\boldsymbol{\theta} - \boldsymbol{\mu})'(\sigma^2 \boldsymbol{\Sigma})^{-1}(\boldsymbol{\theta} - \boldsymbol{\mu})\right) / \sqrt{(2\pi)^k (\sigma^2 \boldsymbol{\Sigma}) }$ where $\boldsymbol{\Sigma} = \begin{bmatrix} 1 & \rho & \rho^2 & \rho^3 & \cdots & \rho^k \\ \rho & 1 & \rho & \rho^2 & \cdots & \rho^{k-1} \\ \rho^2 & \rho & 1 & \rho & \cdots & \rho^{k-2} \\ \rho^3 & \rho^2 & \rho & 1 & \cdots & \rho^{k-3} \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \rho^k & \rho^{k-1} & \rho^{k-2} & \rho^{k-3} & \cdots & 1 \end{bmatrix}$		
Parameter restriction	$\sigma > 0$ and $-1 < \rho < 1$		
Range	$-\infty < \theta_i < \infty$		
Mean	$\boldsymbol{\mu}$		
Mode	$\boldsymbol{\mu}$		
Special Case	When $\rho = 0$, the distribution simplifies to $\mathbf{mvn}(\boldsymbol{\mu}, \sigma^2 \cdot \mathbf{I}_k)$, where \mathbf{I}_k denotes the $k \times k$ identity matrix		

Table 55.39 Multinomial Distribution

PROC specification	$\boldsymbol{\theta} \sim \mathbf{multinom}(\mathbf{p})$, where $\boldsymbol{\theta} = \{\theta_i\}$ and $\mathbf{p} = \{p_i\}$, for $i = 1 \cdots k$
Density	$\frac{n!}{\theta_1! \cdots \theta_k!} p_1^{\theta_1} \cdots p_k^{\theta_k}$, where $\sum_i \theta_i = n$
Parameter restriction	$\sum_i p_i = 1$ with all $p_i > 0$
Range	$\theta_i \in \{0, \dots, n\}$, nonnegative integers
Mean	$n \cdot \mathbf{p}$

Usage of Multivariate Distributions

The following simple example illustrates the usage of the multivariate distributions in PROC MCMC. Suppose you are interested in estimating the mean and covariance of multivariate data using this multivariate normal model:

$$\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \sim \text{MVN} \left(\boldsymbol{\mu} = \begin{pmatrix} \mu_1 \\ \mu_2 \end{pmatrix}, \boldsymbol{\Sigma} = \begin{pmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{21} & \sigma_{22} \end{pmatrix} \right)$$

where

$$\begin{aligned} \boldsymbol{\mu} &= \begin{pmatrix} 1 \\ 2 \end{pmatrix} \\ \boldsymbol{\Sigma} &= \begin{pmatrix} 2.4 & 3 \\ 3 & 8.1 \end{pmatrix} \end{aligned}$$

You can use the following independent prior on $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$:

$$\begin{aligned} \boldsymbol{\mu} &\sim \text{MVN} \left(\boldsymbol{\mu}_0 = \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \boldsymbol{\Sigma}_0 = \begin{pmatrix} 100 & 0 \\ 0 & 100 \end{pmatrix} \right) \\ \boldsymbol{\Sigma} &\sim \text{iWishart} \left(\nu = 2, \mathbf{S} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \right) \end{aligned}$$

The following IML procedure statements simulate 100 random multivariate normal samples:

```
title 'An Example that Uses Multivariate Distributions';
proc iml;
  N = 100;
  Mean = {1 2};
  Cov = {2.4 3, 3 8.1};
  call randseed(1);
  x = RANDNORMAL( N, Mean, Cov );

  SampleMean = x[, ];
  n = nrow(x);
  y = x - repeat( SampleMean, n );
  SampleCov = y`*y / (n-1);
  print SampleMean Mean, SampleCov Cov;

  cname = {"x1", "x2"};
  create inputdata from x [colname = cname];
  append from x;
  close inputdata;
quit;
```

Figure 55.13 prints the sample mean and covariance of the simulated data, in addition to the true mean and covariance matrix.

Figure 55.13 Simulated Multivariate Normal Data

An Example that Uses Multivariate Distributions			
SampleMean		Mean	
0.9987751	2.115693	1	2
SampleCov		Cov	
2.8252975	3.7190704	2.4	3
3.7190704	9.2916805	3	8.1

The following PROC MCMC statements estimate the posterior mean and covariance of the multivariate normal data:

```
proc mcmc data=inputdata seed=17 nmc=3000 diag=none;
  ods select PostSummaries PostIntervals;
  array data[2] x1 x2;
  array mu[2];
  array Sigma[2,2];
  array mu0[2] (0 0);
  array Sigma0[2,2] (100 0 0 100);
  array S[2,2] (1 0 0 1);
  parm mu Sigma;
  prior mu ~ mvn(mu0, Sigma0);
  prior Sigma ~ iwish(2, S);
  model data ~ mvn(mu, Sigma);
run;
```

To use the multivariate distribution, you must specify parameters (or random variables in the MODEL statement) in an array form. The first **ARRAY** statement creates an one-dimensional array `data`, which contains two numeric variables, `x1` and `x2`, from the input data set. The `data` variable is your response variable. The subsequent statements defines two array-parameters (`mu` and `Sigma`) and three constant array-hyperparameters (`mu0`, `Sigma0`, and `S`). The **PARMS** statement declares `mu` and `Sigma` to be model parameters. The two **PRIOR** statements specify the multivariate normal and inverse Wishart distributions as the prior for `mu` and `Sigma`, respectively. The **MODEL** statement specifies the multivariate normal likelihood with `data` as the random variable, `mu` as the mean, and `Sigma` as the covariance matrix.

Figure 55.14 lists the estimated posterior mean and covariance matrix.

Figure 55.14 Estimated Mean and Covariance

The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
mu1	3000	0.9941	0.1763	0.8761	0.9958	1.1136
mu2	3000	2.1135	0.3112	1.9075	2.1056	2.3254
Sigma1	3000	2.8726	0.4084	2.5799	2.8347	3.1205

Sigma4	0.050	7.1260	12.3763	7.0155	12.0969

Specifying a New Distribution

To work with a new density that is not listed in the section “[Standard Distributions](#)” on page 4476, you can use the `GENERAL` and `DGENERAL` functions. The letter “D” stands for discrete. The new distributions have to be specified on the logarithm scale.

Suppose you want to use the inverse-beta distribution:

$$p(\alpha|a, b) = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \cdot \alpha^{(a-1)} \cdot (1+\alpha)^{-(a+b)}$$

The following statements in PROC MCMC define the density on its log scale:

```
a = 3; b = 5;
const = lgamma(a + b) - lgamma(a) - lgamma(b);
lp = const + (a - 1) * log(alpha) - (a + b) * log(1 + alpha);
prior alpha ~ general(lp);
```

The symbol `lp` is the expression for the log of an inverse-beta ($a = 3$, $b = 5$). The function `general(lp)` assigns that distribution to `alpha`. The constant term, `const`, can be omitted because the Markov simulation requires only the log of the density kernel.

You can use the `GENERAL` function to specify a distribution for a single variable or for multiple variables. It is important to emphasize that the argument `lp` is an expression for the log of the joint distribution for

these variables. On the contrary, any standard distribution is applied separately to each random variable in the statement.

When you use the **GENERAL** function in the **MODEL** statement, you do not need to specify the dependent variable on the left of the tilde \sim . The log-likelihood function takes the dependent variable into account; hence, there is no need to explicitly state the dependent variable in the **MODEL** statement. However, in the **PRIOR** and **RANDOM** statements, you need to explicitly state the parameter names and a tilde with the **GENERAL** function.

You can specify any distribution function by using the **GENERAL** and **DGENERAL** functions as long as the distribution function is programmable with SAS statements. When the function is used in the **PRIOR** statements, you must supply initial values in either the **PARMS** statement or within the **BEGINCNST** and **ENDCNST** statements. See the sections “**PARMS Statement**” on page 4451 and “**BEGINCNST/ENDCNST Statement**” on page 4441. When the function is used in the **RANDOM** statement, you must use the **INITIAL=** option in the **RANDOM** statement to supply initial values

NOTE: PROC MCMC does not verify that the **GENERAL** function you specify is a valid distribution—that is, an integrable density. You must use the function with caution.

Using Density Functions in the Programming Statements

Density Functions in PROC MCMC

PROC MCMC has a number of internally defined log-density functions for univariate and multivariate distributions. These functions have the basic form of $\text{LPDF}_{\text{dist}}(x, \text{parm-list})$, where *dist* is the name of the distribution (see Table 55.40 for univariate distributions and Table 55.41 for multivariate distributions). The argument *x* is the random variable, and *parm-list* is the list of parameters.

In addition, the univariate functions allow for optional boundary arguments, such as $\text{LPDF}_{\text{dist}}(x, \text{parm-list}, <\text{lower}>, <\text{upper}>)$, where *lower* and *upper* are optional but positional boundary arguments. With the exception of the Bernoulli and uniform distribution, you can specify limits on all univariate distributions.

To set a lower bound on the normal density:

```
lpdfnorm(x, 0, 1, -2);
```

To set just an upper bound, specify a missing value for the lower bound argument:

```
lpdfnorm(x, 0, 1, ., 2);
```

Leaving both limits out gives you the unbounded density. You can also specify both bounds:

```
lpdfnorm(x, 0, 1);
lpdfnorm(x, 0, 1, -3, 4);
```

See Table 55.40 for the function names of univariate distributions and Table 55.41 for multivariate distributions.

Table 55.40 Logarithm of Univariate Density Functions in PROC MCMC

Distribution Name	Function Call
Beta	lpdfbeta (<i>x</i> , <i>a</i> , <i>b</i> , < lower >, < upper >);
Binary	lpdfbern (<i>x</i> , <i>p</i>);
Binomial	lpdfbin (<i>x</i> , <i>n</i> , <i>p</i> , < lower >, < upper >);
Cauchy	lpdfcau (<i>x</i> , <i>loc</i> , <i>scale</i> , < lower >, < upper >);
χ^2	lpdfchisq (<i>x</i> , <i>df</i> , < lower >, < upper >);
Exponential χ^2	lpdfechisq (<i>x</i> , <i>df</i> , < lower >, < upper >);
Exponential gamma	lpdfegamma (<i>x</i> , <i>sp</i> , <i>scale</i> , < lower >, < upper >);
Exponential exponential	lpdfeexpon (<i>x</i> , <i>scale</i> , < lower >, < upper >);
Exponential inverse χ^2	lpdfeichisq (<i>x</i> , <i>df</i> , < lower >, < upper >);
Exponential inverse-gamma	lpdfeigamma (<i>x</i> , <i>sp</i> , <i>scale</i> , < lower >, < upper >);
Exponential scaled inverse χ^2	lpdfesichisq (<i>x</i> , <i>df</i> , <i>scale</i> , < lower >, < upper >);
Exponential	lpdfexpon (<i>x</i> , <i>scale</i> , < lower >, < upper >);
Gamma	lpdfgamma (<i>x</i> , <i>sp</i> , <i>scale</i> , < lower >, < upper >);
Geometric	lpdfgeo (<i>x</i> , <i>p</i> , < lower >, < upper >);
Inverse χ^2	lpdfichisq (<i>x</i> , <i>df</i> , < lower >, < upper >);
Inverse-gamma	lpdfigamma (<i>x</i> , <i>sp</i> , <i>scale</i> , < lower >, < upper >);
Laplace	lpdfdexp (<i>x</i> , <i>loc</i> , <i>scale</i> , < lower >, < upper >);
Logistic	lpdflogis (<i>x</i> , <i>loc</i> , <i>scale</i> , < lower >, < upper >);
Lognormal	lpdflnorm (<i>x</i> , <i>loc</i> , <i>sd</i> , < lower >, < upper >);
Negative binomial	lpdfnegbin (<i>x</i> , <i>n</i> , <i>p</i> , < lower >, < upper >);
Normal	lpdfnorm (<i>x</i> , <i>mu</i> , <i>sd</i> , < lower >, < upper >);
Pareto	lpdfpareto (<i>x</i> , <i>sp</i> , <i>scale</i> , < lower >, < upper >);

Table 55.40 (continued)

Distribution Name	Function Call
Poisson	lpdfpoi (<i>x</i> , <i>mean</i> , < <i>lower</i> >, < <i>upper</i> >);
Scaled inverse χ^2	lpdfsichisq (<i>x</i> , <i>df</i> , <i>scale</i> , < <i>lower</i> >, < <i>upper</i> >);
<i>t</i>	lpdfft (<i>x</i> , <i>mu</i> , <i>sd</i> , <i>df</i> , < <i>lower</i> >, < <i>upper</i> >);
Uniform	lpdfunif (<i>x</i> , <i>a</i> , <i>b</i>);
Wald	lpdfwald (<i>x</i> , <i>mean</i> , <i>scale</i> , < <i>lower</i> >, < <i>upper</i> >);
Weibull	lpdfwei (<i>x</i> , <i>loc</i> , <i>sp</i> , <i>scale</i> , < <i>lower</i> >, < <i>upper</i> >);

In the multivariate log-density functions, arrays must be used in place for the random variable and parameters in the model.

Table 55.41 Logarithm of Multivariate Density Functions in PROC MCMC

Distribution Name	Function Call
Dirichlet	lpdfdirch (<i>x_array</i> , <i>alpha_array</i>);
Inverse Wishart	lpdfiwish (<i>x_array</i> , <i>df</i> , <i>S_array</i>);
Multivariate normal	lpdfmvn (<i>x_array</i> , <i>mu_array</i> , <i>cov_array</i>);
Multinomial	lpdfmnom (<i>x_array</i> , <i>p_array</i>);

Standard Distributions, the LOGPDF Functions, and the LPDF*dist* Functions

Standard distributions listed in the section “[Standard Distributions](#)” on page 4476 are *names* only, and they can be used only in the **MODEL**, **PRIOR**, and **HYPERPRIOR** statements to specify either a prior distribution or a conditional distribution of the data given parameters. They do not return any values, and you cannot use them in the programming statements.

The LOGPDF functions are DATA step functions that compute the logarithm of various probability density (mass) functions. For example,

```
logpdf("beta", x, 2, 15);
```

returns the log of a beta density with parameters *a* = 2 and *b* = 15, evaluated at *x*. All the LOGPDF functions are supported in PROC MCMC.

The LPDF*dist* functions are unique to PROC MCMC. They compute the logarithm of various probability density (mass) functions. The functions are the same as the LOGPDF functions when it comes to calculating

the log density. For example,

```
lpdfbeta(x, 2, 15);
```

returns the same value as

```
logpdf("beta", x, 2, 15);
```

The *LPDFdist* functions cover a greater class of probability density functions, and the univariate distribution functions take the optional but positional boundary arguments. There are no corresponding *LCDFdist* or *LSDFdist* functions in PROC MCMC. To work with the cumulative probability function or the survival functions, you need to use the LOGCDF and the LOGSDF DATA step functions.

Truncation and Censoring

Truncated Distributions

To specify a truncated distribution, you can use the LOWER= and/or UPPER= options. Almost all of the standard distributions, including the [GENERAL](#) and [DGENERAL](#) functions, take these optional truncation arguments. The exceptions are the binary and uniform distributions.

For example, you can specify the following:

```
prior alpha ~ normal(mean = 0, sd = 1, lower = 3, upper = 45);
```

or

```
parms beta;  
a = 3; b = 7;  
ll = (a + 1) * log(b / beta);  
prior beta ~ general(ll, upper = b + 17);
```

The preceding statements state that if beta is less than b+17, the log of the prior density is ll, as calculated by the equation; otherwise, the log of the prior density is missing—the log of zero.

When the same distribution is applied to multiple parameters in a [PRIOR](#) statement, the LOWER= and UPPER= truncations apply to all parameters in that statement. For example, the following statements define a Poisson density for theta and gamma:

```
parms theta gamma;  
lambda = 7;  
ll = theta * log(lambda) - lgamma(1 + theta);  
l2 = gamma * log(lambda) - lgamma(1 + gamma);  
ll = ll + l2;  
prior theta gamma ~ dgeneral(ll, lower = 1);
```

The LOWER=1 condition is applied to both theta and gamma, meaning that for the assignment to ll to be meaningful, both theta and gamma have to be greater than 1. If either of the parameters is less than 1, the log of the joint prior density becomes a missing value.

With the exceptions of the normal distribution and the [GENERAL](#) and [DGENERAL](#) functions, the LOWER= and UPPER= options cannot be parameters or functions of parameters. The reason is that most

of the truncated distributions are not normalized. Unnormalized densities do not lead to wrong MCMC answers as long as the bounds are constants. However if the bounds involve model parameters, then the normalizing constant, which is a function of these parameters, must be taken into account in the posterior. Without specifying the normalizing constant, inferences on these boundary parameters are incorrect.

It is not difficult to construct a truncated distribution with a normalizing constant. Any truncated distribution has the probability distribution:

$$p(\theta|a < \theta < b) = \frac{p(\theta)}{F(a) - F(b)}$$

where $p(\cdot)$ is the density function and $F(\cdot)$ is the cumulative distribution function. In SAS functions, $p(\cdot)$ is probability density function and $F(\cdot)$ is cumulative distribution function. The following example shows how to construct a truncated gamma prior on theta, with SHAPE = 3, SCALE = 2, LOWER = a, and UPPER = b:

```
lp = logpdf('gamma', theta, 3, 2)
      - log(cdf('gamma', a, 3, 2) - cdf('gamma', b, 3, 2));
prior theta ~ general(lp);
```

Note the difference from a naive definition of the density, without taking into account of the normalizing constant:

```
lp = logpdf('gamma', theta, 3, 2);
prior theta ~ general(lp, lower=a, upper=b);
```

If a or b are parameters, you get very different results from the two formulations.

Censoring

There is no built-in mechanism in PROC MCMC that models censoring automatically. You need to construct the density function (using a combination of the LOGPDF, LOGCDF, and LOGSDF functions and IF-ELSE statements) for the censored data.

Suppose you partition the data into four categories: uncensored (with observation x), left censored (with observation xl), right censored (with observation xr), and interval censored (with observations xl and xr). The likelihood is the normal with mean mu and standard deviation s. The following statements construct the corresponding log likelihood for the observed data:

```
if uncensored then
  ll = logpdf('normal', x, mu, s);
else if leftcensored then
  ll = logcdf('normal', xl, mu, s);
else if rightcensored then
  ll = logsdf('normal', xr, mu, s);
else /* this is the case of interval censored. */
  ll = log(cdf('normal', xr, mu, s) - cdf('normal', xl, mu, s));
model general(ll);
```

See “[Example 55.17: Normal Regression with Interval Censoring](#)” on page 4638.

Some Useful SAS Functions

Table 55.42 Some Useful SAS Functions

SAS Function	Definition
abs(x);	$ x $
airy(x);	Returns the value of the AIRY function.
beta(x1, x2);	$\int_0^1 z^{x1-1} (1-z)^{x2-1} dz$
call logistic(x);	$\frac{\exp(x)}{1+\exp(x)}$
call softmax(x1,...,xn);	Each element is replaced by $\exp(x_j) / \sum \exp(x_j)$
call stdize(x1,...,xn);	Standardize values
cdf();	Cumulative distribution function
cdf('normal', x, 0, 1);	Standard normal cumulative distribution function
comb(x1, x2);	$\frac{x1!}{x2!(x1-x2)!}$
constant('.');	Calculate commonly used constants
cos(x);	cosine(x)
css(x1, ..., xn);	$\sum_i (x_i - \bar{x})^2$
cv(x1, ..., xn);	$\text{std}(x) / \text{mean}(x) * 100$
dairy(x);	Derivative of the AIRY function
dimN(m);	Returns the numbers of elements in the Nth dim of array <i>m</i>
x1 eq x2	Returns 1 if $x1 = x2$; 0 otherwise
x1**x2	$x1^{x2}$
geomean(x1, ..., xn);	$\exp\left(\frac{\log(x1) + \dots + \log(xn)}{n}\right)$
difN(x);	Returns differences between the argument and its Nth lag
digamma(x1);	$\frac{\Gamma'(x1)}{\Gamma(x1)}$
erf(x);	$\frac{2}{\sqrt{\pi}} \int_0^x \exp(-z^2) dz$
erfc(x);	$1 - \text{erf}(x)$
fact(x);	$x!$
floor(x);	Greatest integer $\leq x$
gamma(x);	$\int_0^\infty z^{x-1} \exp(-1) dz$
harmean(x1, ..., xn);	$\frac{n}{1/x1 + \dots + 1/xn}$
ibessel(nu, x, kode);	Modified Bessel function of order <i>nu</i> evaluated at <i>x</i>
jbessel(nu, x);	Bessel function of order <i>nu</i> evaluated at <i>x</i>
lagN(x);	Returns values from a queue
largest(k, x1, ..., xn);	Returns the k^{th} largest element
lgamma(x);	$\ln(\Gamma(x))$
lgamma(x+1);	$\ln(x!)$
log(x, logN(x));	$\ln(x)$
logbeta(x1, x2);	$\text{lgamma}(x1) + \text{lgamma}(x2) - \text{lgamma}(x1 + x2)$
logcdf();	Log of a left cumulative distribution function
logpdf();	Log of a probability density (mass) function
logsdf();	Log of a survival function
max(x1, x2);	Returns $x1$ if $x1 > x2$; $x2$ otherwise
mean(of x1-xn);	$\sum_i x_i / n$

Table 55.42 (continued)

SAS Function	Definition
median (of x_1 - x_n);	Returns the median of nonmissing values
min (x_1 , x_2);	Returns x_1 if $x_1 < x_2$; x_2 otherwise
missing (x);	Returns 1 if x is missing; 0 otherwise
mod (x_1 , x_2);	Returns the remainder from x_1/x_2
n (x_1 , ..., x_n);	Returns number of nonmissing values
nmiss (of y_1 - y_n);	Number of missing values
quantile ();	Computes the quantile from a specific distribution
pdf ();	Probability density (mass) functions
perm (n , r);	$\frac{n!}{(n-r)!}$
put ();	Returns a value that uses a specified format
round (x);	Rounds x
rms (of x_1 - x_n);	$\sqrt{\frac{x_1^2 + \dots + x_n^2}{n}}$
sdf ();	Survival function
sign (x);	Returns -1 if $x < 0$; 0 if $x = 0$; 1 if $x > 0$
sin (x);	sine(x)
smallest (s , x_1 , ..., x_n);	Returns the s^{th} smallest component of x_1, \dots, x_n
sortn (of x_1 - x_n);	Sorts the values of the variables
sqrt (x);	\sqrt{x}
std (x_1 , ..., x_n);	Standard deviation of x_1, \dots, x_n (n-1 in denominator)
sum (of x);	$\sum_i x_i$
trigamma (x);	Derivative of the DIGAMMA(x) function
uss (of x_1 - x_n);	Uncorrected sum of squares

Here are examples of some commonly used transformations:

- logit

```
mu = beta0 + beta1 * z1;
call logistic(mu);
```

- log

```
w = beta0 + beta1 * z1;
mu = exp(w);
```

- probit

```
w = beta0 + beta1 * z1;
mu = cdf('normal', w, 0, 1);
```

- cloglog

```
w = beta0 + beta1 * z1;
mu = 1 - exp(-exp(w));
```

Matrix Functions in PROC MCMC

The MCMC procedure provides you with a number of CALL routines for performing simple matrix operations on declared arrays. With the exception of FILLMATRIX, IDENTITY, and ZEROMATRIX, the CALL routines listed in Table 55.43 do not support matrices or arrays that contain missing values.

Table 55.43 Matrix Functions in PROC MCMC

CALL Routine	Description
ADDMATRIX	Performs an element-wise addition of two matrices or of a matrix and a scalar.
CHOL	Calculates the Cholesky decomposition for a particular symmetric matrix.
DET	Calculates the determinant of a specified matrix, which must be square.
ELEMMULT	Performs an element-wise multiplication of two matrices.
FILLMATRIX	Replaces all of the element values of the input matrix with the specified value. You can use this routine with multidimensional numeric arrays.
IDENTITY	Converts the input matrix to an identity matrix. Diagonal element values of the matrix are set to 1, and the rest of the values are set to 0.
INV	Calculates a matrix that is the inverse of the input matrix. The input matrix must be a square, nonsingular matrix.
MULT	Calculates the matrix product of two input matrices.
SUBTRACTMATRIX	Performs an element-wise subtraction of two matrices or of a matrix and a scalar.
TRANSPOSE	Returns the transpose of a matrix.
ZEROMATRIX	Replaces all of the element values of the numeric input matrix with 0.

ADDMATRIX CALL Routine

The ADDMATRIX CALL routine performs an element-wise addition of two matrices or of a matrix and a scalar.

The syntax of the ADDMATRIX CALL routine is

```
CALL ADDMATRIX (X, Y, Z);
```

where

X specifies a scalar or an input matrix with dimensions $m \times n$ (that is, $X[m, n]$)

Y specifies a scalar or an input matrix with dimensions $m \times n$ (that is, $Y[m, n]$)

Z specifies an output matrix with dimensions $m \times n$ (that is, $Z[m, n]$)

such that

$$Z = X + Y$$

CHOL CALL Routine

The CHOL CALL routine calculates the Cholesky decomposition for a particular symmetric matrix.

The syntax of the CHOL CALL routine is

CALL CHOL (*X*, *Y* <, *validate*>) ;

where

X specifies a symmetric positive-definite input matrix with dimensions $m \times m$ (that is, $X[m, m]$)

Y is a variable that contains the Cholesky decomposition and specifies an output matrix with dimensions $m \times m$ (that is, $Y[m, m]$)

validate specifies an optional argument that can increase the processing speed by avoiding error checking:

If *validate* = 0 or is not specified, then the matrix *X* is checked for symmetry.

If *validate* = 1, then the matrix *X* is assumed to be symmetric.

such that

$$X = YY^*$$

where *Y* is a lower triangular matrix with strictly positive diagonal entries and Y^* denotes the conjugate transpose of *Y*.

Both input and output matrices must be square and have the same dimensions. If *X* is symmetric positive-definite, *Y* is a lower triangle matrix. If *X* is not symmetric positive-definite, *Y* is filled with missing values.

DET CALL Routine

The determinant, the product of the eigenvalues, is a single numeric value. If the determinant of a matrix is zero, then that matrix is singular (that is, it does not have an inverse). The routine performs an LU decomposition and collects the product of the diagonals.

The syntax of the DET CALL routine is

CALL DET (*X*, *a*) ;

where

X specifies an input matrix with dimensions $m \times m$ (that is, $X[m, m]$)

a specifies the returned determinate value

such that

$$a = |X|$$

ELEMMULT CALL Routine

The ELEMMULT CALL routine performs an element-wise multiplication of two matrices.

The syntax of the ELEMMULT CALL routine is

CALL ELEMMULT (X, Y, Z) ;

where

X specifies an input matrix with dimensions $m \times n$ (that is, $X[m, n]$)

Y specifies an input matrix with dimensions $m \times n$ (that is, $Y[m, n]$)

Z specifies an output matrix with dimensions $m \times n$ (that is, $Z[m, n]$)

FILLMATRIX CALL Routine

The FILLMATRIX CALL routine replaces all of the element values of the input matrix with the specified value. You can use the FILLMATRIX CALL routine with multidimensional numeric arrays.

The syntax of the FILLMATRIX CALL routine is

CALL FILLMATRIX (X, Y) ;

where

X specifies an input numeric matrix

Y specifies the numeric value that is used to fill the matrix

IDENTITY CALL Routine

The IDENTITY CALL routine converts the input matrix to an identity matrix. Diagonal element values of the matrix are set to 1, and the rest of the values are set to 0.

The syntax of the IDENTITY CALL routine is

CALL IDENTITY (X) ;

where

X specifies an input matrix with dimensions $m \times m$ (that is, $X[m, m]$)

INV CALL Routine

The INV CALL routine calculates a matrix that is the inverse of the input matrix. The input matrix must be a square, nonsingular matrix.

The syntax of the INV CALL routine is

CALL INV (X, Y) ;

where

X specifies an input matrix with dimensions $m \times m$ (that is, $X[m, m]$)

Y specifies an output matrix with dimensions $m \times m$ (that is, $Y[m, m]$)

MULT CALL Routine

The MULT CALL routine calculates the matrix product of two input matrices.

The syntax of the MULT CALL routine is

CALL MULT (X, Y, Z) ;

where

X specifies an input matrix with dimensions $m \times n$ (that is, $X[m, n]$)

Y specifies an input matrix with dimensions $n \times p$ (that is, $Y[n, p]$)

Z specifies an output matrix with dimensions $m \times p$ (that is, $Z[m, p]$)

The number of columns for the first input matrix must be the same as the number of rows for the second matrix. The calculated matrix is the last argument.

SUBTRACTMATRIX CALL Routine

The SUBTRACTMATRIX CALL routine performs an element-wide subtraction of two matrices or of a matrix and a scalar.

The syntax of the SUBTRACTMATRIX CALL routine is

CALL SUBTRACTMATRIX (X, Y, Z) ;

where

X specifies a scalar or an input matrix with dimensions $m \times n$ (that is, $X[m, n]$)

Y specifies a scalar or an input matrix with dimensions $m \times n$ (that is, $Y[m, n]$)

Z specifies an output matrix with dimensions $m \times n$ (that is, $Z[m, n]$)

such that

$$Z = X - Y$$

TRANSPOSE CALL Routine

The TRANSPOSE CALL routine returns the transpose of a matrix.

The syntax of the TRANSPOSE CALL routine is

CALL TRANSPOSE (X, Y) ;

where

X specifies an input matrix with dimensions $m \times n$ (that is, $X[m, n]$)

Y specifies an output matrix with dimensions $n \times m$ (that is, $Y[n, m]$)

ZEROMATRIX CALL Routine

The ZEROMATRIX CALL routine replaces all of the element values of the numeric input matrix with 0. You can use the ZEROMATRIX CALL routine with multidimensional numeric arrays.

The syntax of the ZEROMATRIX CALL routine is

```
CALL ZEROMATRIX (X) ;
```

where

X specifies a numeric input matrix.

Create Design Matrix

PROC MCMC does not support a CLASS statement; therefore you need to construct the right design matrix (with dummy or indicator variables) prior to calling PROC MCMC. The best tool to use is the TRANSREG procedure (see Chapter 97, “[The TRANSREG Procedure](#)”). This procedure offers both indicator and effects coding methods. You can specify any categorical variables in the CLASS expansion, and use the ZERO= option to select a reference category. You can also specify any other data set variables (predictors, the responses, and so on) to the output data set in the ID statement.

For example, the following statements create a data set that contains two categorical variables (City and G), and two continuous variables (x and resp):

```
title 'Create Design Matrix';
data categorical;
  input City$ G$ x resp @@;
  datalines;
Chicago F 69.0 112.5  Chicago F 56.5  84.0
Chicago M 65.3  98.0  Chicago M 59.8  84.5
NewYork M 62.8 102.5  NewYork M 63.5 102.5
NewYork F 57.3  83.0  NewYork M 57.5  85.0
;
```

Suppose you are interested in creating a design matrix that uses dummy variable coding for the categorical variables City, G and their interaction City * G. You can use the following PROC TRANSREG statements:

```
proc transreg data=categorical design;
  model class(city g city*g / zero=last);
  id x resp;
  output out=input_mcmc(drop=_: Int:);
run;
```

The DESIGN option specifies that the primary goal is to code the design matrix. The MODEL statement indicates the variable of interest. The CLASS option in the MODEL statement expands the variables of interest to a list of “dummy” variables. The ZERO=LAST option sets the reference level. The ID statement includes x and resp in the OUT= data set. And the OUTPUT statement creates a new data set Input_MCMC that stores the design matrix and original variables from the original data set.

A quick call of the PRINT procedure shows the output from the PROC TRANSREG call:

```
proc print data=input_mcmc;
run;
```

Figure 55.15 prints the design matrix that is generated by PROC TRANSREG. The Input_mcmc data set contains all the variables from the original Categorical data set, in addition to corresponding dummy variables (CityChicago, GF, and CityChicagoGF) for the categorical variables.

Figure 55.15 Design Matrix Generated by PROC TRANSREG

Create Design Matrix							
Obs	City Chicago	GF	City Chicago GF	City	G	x	resp
1	1	1	1	Chicago	F	69.0	112.5
2	1	1	1	Chicago	F	56.5	84.0
3	1	0	0	Chicago	M	65.3	98.0
4	1	0	0	Chicago	M	59.8	84.5
5	0	0	0	NewYork	M	62.8	102.5
6	0	0	0	NewYork	M	63.5	102.5
7	0	1	0	NewYork	F	57.3	83.0
8	0	0	0	NewYork	M	57.5	85.0

You can now proceed to call PROC MCMC using this input data set Input_mcmc and the corresponding dummy variables.

PROC TRANSREG automatically creates a macro variable, &_TRGIND, which contains a list of variable names that it creates. The %put &_trgind; statement prints the following:

```
CityChicago GF CityChicagoGF
```

The macro variable &_TRGIND can come handy if you want to build a regression model; you can refer to &_TRGIND in the following way:

```
proc mcmc data=input_mcmc;
  array data[5] 1 &_trgind x;
  array beta[5] beta0-beta4;
  ...;
  call mult(beta, data, mu);
  ...;
```

The first ARRAY statement defines a one-dimensional array of length 5, and it takes on five values: a constant 1 and variables CityChicago, GF, CityChicagoGF, and x. The second ARRAY statement defines an array of beta, which are the model parameters. Later in the program, you can use the CALL MULT function to calculate the regression mean and store the value in the symbol mu.

Modeling Joint Likelihood

PROC MCMC assumes that the input observations are independent and that the joint log likelihood is the sum of individual log-likelihood functions. You specify the log likelihood of one observation in the **MODEL** statement. PROC MCMC evaluates that function for each observation in the data set and cumulatively sums them up. If observations are not independent of each other, this summation produces the incorrect log likelihood.

There are two ways to model dependent data. You can either use the DATA step LAG function or use the PROC option **JOINTMODEL**. The LAG function returns values of a variable from a queue. As PROC MCMC steps through the data set, the LAG function queues each data set variable, and you have access to the current value as well as to all previous values of any variable. If the log likelihood for observation x_i depends only on observations 1 to i in the data set, you can use this SAS function to construct the log-likelihood function for each observation. Note that the LAG function enables you to access observations from different rows, but the log-likelihood function in the **MODEL** statement must be generic enough that it applies to all observations. See “[Example 55.14: Time Independent Cox Model](#)” on page 4617 and “[Example 55.15: Time Dependent Cox Model](#)” on page 4625 for how to use this LAG function.

A second option is to create arrays, store all relevant variables in the arrays, and construct the joint log likelihood for the entire data set instead of for each observation. Following is a simple example that illustrates the usage of this option. For a more realistic example that models dependent data, see “[Example 55.14: Time Independent Cox Model](#)” on page 4617 and “[Example 55.15: Time Dependent Cox Model](#)” on page 4625.

```
/* allocate the sample size. */
data exi;
  call streaminit(17);
  do ind = 1 to 100;
    y = rand("normal", 2.3, 1);
    output;
  end;
run;
```

The log-likelihood function for each observation is as follows:

$$\log(f(y_i|\mu, \sigma)) = \log(\phi(y_i; \mu, \text{var} = \sigma^2))$$

The joint log-likelihood function is as follows:

$$\log(f(\mathbf{y}|\mu, \sigma)) = \sum_i \log(\phi(y_i; \mu, \text{var} = \sigma^2))$$

The following statements fit a simple model with an unknown mean (μ) in PROC MCMC, with the variance in the likelihood assumed known. The **MODEL** statement indicates a normal likelihood for each observation y .

```
proc mcmc data=exi seed=7 outpost=p1;
  parm mu;
  prior mu ~ normal(0, sd=10);
  model y ~ normal(mu, sd=1);
run;
```

The following statements show how you can specify the log-likelihood function for the entire data set:

```
data a;
run;

proc mcmc data=a seed=7 outpost=p2 jointmodel;
  array data[1] / nosymbols;
  begincnst;
    rc = read_array("exi", data, "y");
    n = dim(data, 1);
  endcnst;

  parm mu;
  prior mu ~ normal(0, sd=10);
  ll = 0;
  do i = 1 to n;
    ll = ll + lpdfnorm(data[i], mu, 1);
  end;
  model general(ll);
run;
```

The **JOINTMODEL** option indicates that the function used in the **MODEL** statement calculates the log likelihood for the entire data set, rather than just for one observation. Given this option, PROC MCMC no longer steps through the input data during the simulation. Consequently, you can no longer use any data set variables to construct the log-likelihood function. Instead, you store the data set in arrays and use arrays instead of data set variables to calculate the log likelihood.

The **ARRAY** statement allocates a temporary array (data). The **READ_ARRAY** function selects the y variable from the **exi** data set and stores it in the data array. See the section “**READ_ARRAY Function**” on page 4442. In the programming statements, you use a DO loop to construct the joint log likelihood. The expression **ll** in the **GENERAL** function now takes the value of the joint log likelihood for all data.

You can run the following statements to see that two PROC MCMC runs produce identical results.

```
proc compare data=p1 compare=p2;
  var mu;
run;
```

Regenerating Diagnostics Plots

By default, PROC MCMC generates three plots: the trace plot, the autocorrelation plot, and the kernel density plot. Unless ODS Graphics is enabled before calling the procedure, it is hard to generate the same graph afterwards. Directly using the **Stat.MCMC.Graphics.TraceAutocorrDensity** template is not feasible. The easiest way to regenerate the same graph is with the **%TADPlot** autocall macro. The **%TADPlot** macro requires you to specify an input data set (which usually is the output data set from a previous PROC MCMC call) and a list of variables that you want to plot.

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

A simple regression example, with three parameters, is used here for illustrational purposes. For an explanation of the regression model and the data involved, see the section “[Simple Linear Regression](#)” on page 4408. The following statements generate a SAS data set and fit a regression model:

```

title 'Regenerating Diagnostics Plots';

data Class;
  input Name $ Height Weight @@;
  datalines;
Alfred  69.0 112.5   Alice  56.5  84.0   Barbara 65.3  98.0
Carol   62.8 102.5   Henry  63.5 102.5   James   57.3  83.0
Jane    59.8  84.5   Janet  62.5 112.5   Jeffrey 62.5  84.0
John    59.0  99.5   Joyce  51.3  50.5   Judy    64.3  90.0
Louise  56.3  77.0   Mary   66.5 112.0   Philip  72.0 150.0
Robert  64.8 128.0   Ronald 67.0 133.0   Thomas  57.5  85.0
William 66.5 112.0
;

ods select none;
proc mcmc data=class nmc=50000 thin=5 outpost=classout seed=246810;
  parms beta0 0 beta1 0;
  parms sigma2 1;
  prior beta0 beta1 ~ normal(0, var = 1e6);
  prior sigma2 ~ igamma(3/10, scale = 10/3);
  mu = beta0 + beta1*height;
  model weight ~ normal(mu, var = sigma2);
run;
ods select all;

```

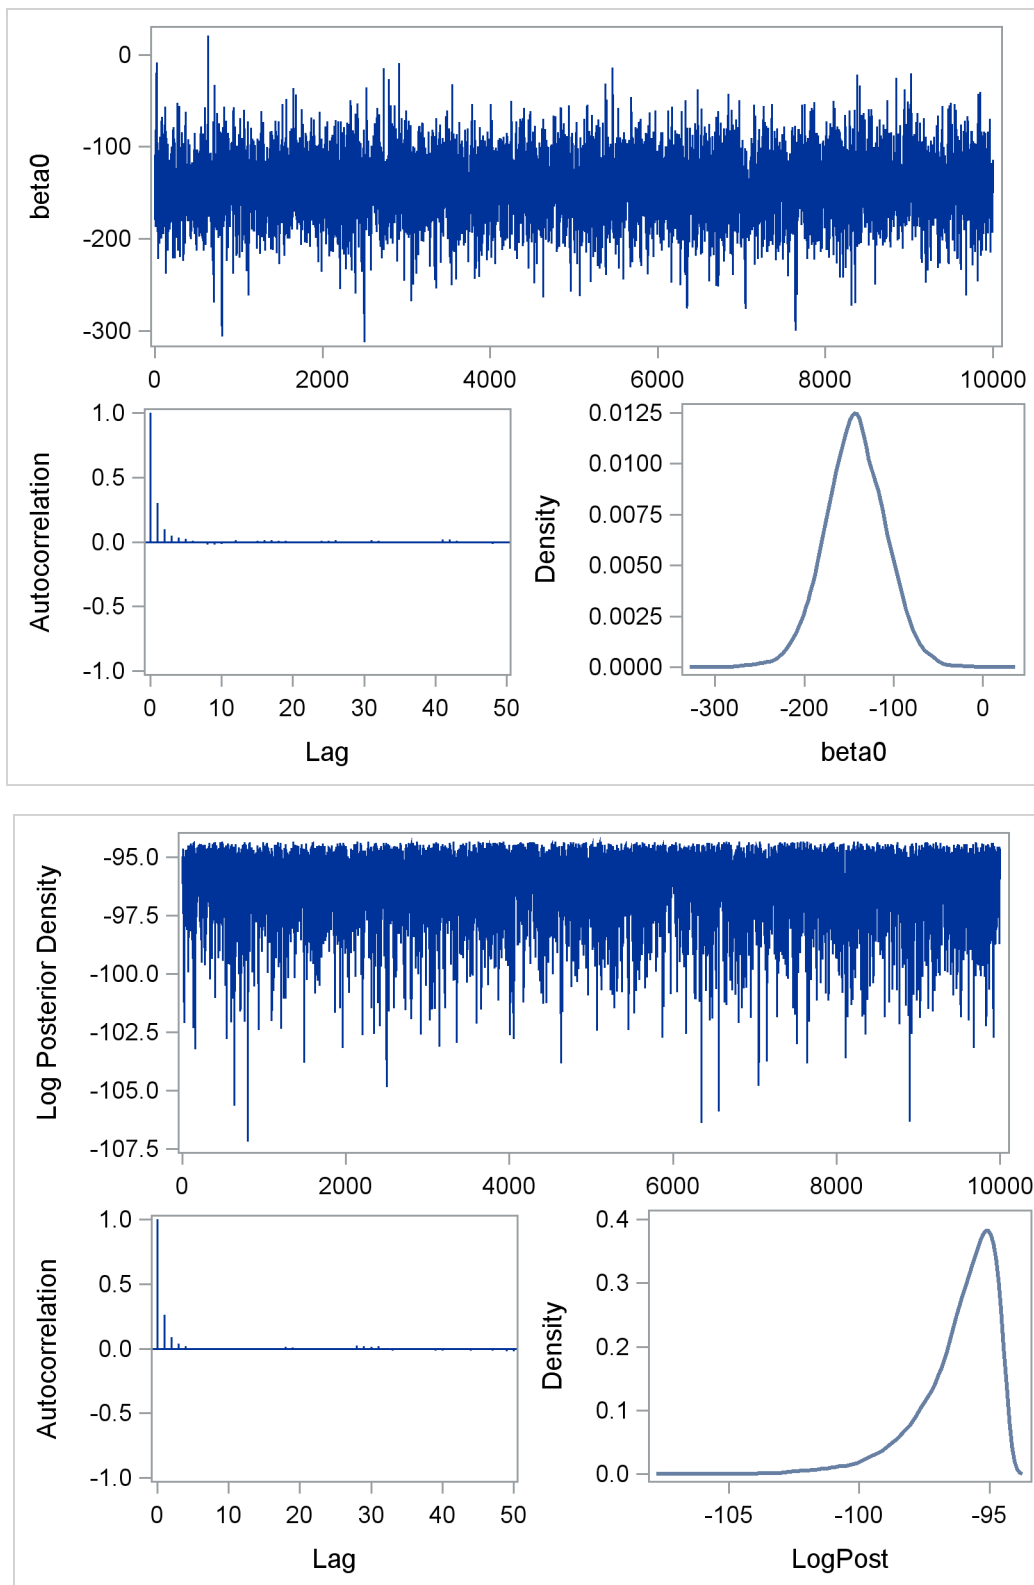

The output data set Classout contains posterior draws for beta0, beta1, and sigma2. It also stores the log of the prior density (LogPrior), log of the likelihood (LogLike), and the log of the posterior density (LogPost). If you want to examine the beta0 and LogPost variable, you can use the following statements to generate the graphs:

```

ods graphics on;
%tadplot(data=classout, var=beta0 logpost);
ods graphics off;

```

[Figure 55.16](#) displays the regenerated diagnostics plots for variables beta0 and Logpost from the data set Classout.

Figure 55.16 Regenerated Diagnostics Plots for beta0 and Logpost

Caterpillar Plot

The caterpillar plot is a side-by-side bar plot of 95% intervals for multiple parameters. Typically, it is used to visualize and compare random-effects parameters, which can come in large numbers in certain models. You can use the %CATER autocall macro to create a caterpillar plot. The %CATER macro requires you specify an input data set and a list of variables that you want to plot.

A random-effects model that has 21 random-effects parameters is used here for illustrational purpose. For an explanation of the random-effects model and the data involved, see “[Example 55.7: Logistic Regression Random-Effects Model](#)” on page 4579. The following statements generate a SAS data set and fit the model:

```

title 'Create a Caterpillar Plot';

data seeds;
  input r n seed extract @@;
  ind = _N_;
  datalines;
10 39 0 0      23 62 0 0      23 81 0 0      26 51 0 0
17 39 0 0      5  6 0 1      53 74 0 1      55 72 0 1
32 51 0 1      46 79 0 1      10 13 0 1      8  16 1 0
10 30 1 0      8  28 1 0      23 45 1 0      0  4  1 0
3  12 1 1      22 41 1 1      15 30 1 1      32 51 1 1
3  7  1 1
;

ods select none;
proc mcmc data=seeds outpost=postout seed=332786 nmc=20000;
  parms beta0 0 beta1 0 beta2 0 beta3 0 s2 1;
  prior s2 ~ igamma(0.01, s=0.01);
  prior beta: ~ general(0);
  w = beta0 + beta1*seed + beta2*extract + beta3*seed*extract;
  random delta ~ normal(w, var=s2) subject=ind;
  pi = logistic(delta);
  model r ~ binomial(n = n, p = pi);
run;
ods select all;

```

The output data set Postout contains posterior draws for all 21 random-effects parameters, delta_1 ... delta_21. You can use the following statements to generate a caterpillar plot for the 21 parameters:

```

ods graphics on;
%CATER(data=postout, var=delta:);
ods graphics off;

```

Figure 55.17 is a caterpillar plot of the random-effects parameters delta_1–delta_21.

Figure 55.17 Caterpillar Plot of the Random-Effects Parameters

If you want to change the display of the caterpillar plot, such as using a different line pattern, color, or size of the markers, you need to first modify the `Stat.MCMC.Graphics.Caterpillar` template and then call the `%CATER` macro again.

You can use the following statements to view the source of the `Stat.MCMC.Graphics.Caterpillar` template:

```
proc template;
  path sashelp.tmplmst;
  source Stat.MCMC.Graphics.Caterpillar;
run;
```

Figure 55.18 lists the source statements of the template that is used to generate the template for the caterpillar plot.

Figure 55.18 Source Statements for Stat.MCMC.Graphics.Caterpillar Template

```

define statgraph Stat.MCMC.Graphics.Caterpillar;
  dynamic _OverallMean _VarName _VarMean _XLower _XUpper _byline_ _bytitle_
    _byfootnote_;
  beginngraph;
    entrytitle "Caterpillar Plot";
    layout overlay / yaxisopts=(offsetmin=0.05 offsetmax=0.05 display=(line
      ticks tickvalues)) xaxisopts=(display=(line ticks tickvalues));
    referenceline x=_OVERALLMEAN / lineattrs=(color=
      GraphReference:ContrastColor);
    HighLowPlot y=_VARNAME high=_XUPPER low=_XLOWER / lineattrs=
      GRAPHCONFIDENCE;
    scatterplot y=_VARNAME x=_VARMEAN / markerattrs=(size=5 symbol=
      circlefilled);
  endlayout;
  if (_BYTITLE_)
    entrytitle _BYLINE_ / textattrs=GRAPHVALUETEXT;
  else
    if (_BYFOOTNOTE_)
      entryfootnote halign=left _BYLINE_;
    endif;
  endif;
  endngraph;
end;

```

You can use the `TEMPLATE` procedure (see Chapter 21, “Statistical Graphics Using ODS”) to run any modified SAS/GRAPH graph template definition and then call the `%CATER` macro again. The `%CATER` macro picks up the change you made to the Caterpillar template and displays the new graph accordingly.

Autocall Macros for Postprocessing

Although PROC MCMC provides a number of convergence diagnostic tests and posterior summary statistics, PROC MCMC performs the calculations only if you specify the options in advance. If you wish to analyze the posterior draws of unmonitored parameters or functions of the parameters that are calculated in later DATA step calls, you can use the autocall macros in Table 55.44.

Table 55.44 Postprocessing Autocall Macros

Macro	Description
%ESS	Effective sample sizes
%GEWEKE ⁴	Geweke diagnostic
%HEIDEL ⁴	Heidelberger-Welch diagnostic
%MCSE	Monte Carlo standard errors
%RAFTERY	Raftery diagnostic
%POSTACF	Autocorrelation
%POSTCOR	Correlation matrix

⁴The `%GEWEKE` and `%HEIDEL` macros use a different optimization routine than that used in PROC MCMC. As a result, there might be numerical differences in some cases, especially when the sample size is small.

Table 55.44 (continued)

Macro	Description
%POSTCOV	Covariance matrix
%POSTINT	Equal-tail and HPD intervals
%POSTSUM	Summary statistics

Table 55.45 lists options that are shared by all postprocessing autocall macros. See Table 55.46 for macro-specific options.

Table 55.45 Shared Options

Option	Description
DATA=SAS-data-set	Input data set that contains posterior samples
VAR=variable-list	Specifies the variables on which you want to carry out the calculation.
PRINT=YES NO	Displays the results. The default is YES.
OUT=SAS-data-set	Specifies a name for the output SAS data set to contain the results.

Suppose that the data set that contains posterior samples is called `post` and that the variables of interest are defined in the macro variable `&PARMS`. The following statements call the `%ESS` macro and calculates the effective sample sizes for each variable:

```
%let parms = alpha beta u_1-u_17;
%ESS(data=post, var=&parms);
```

By default, the ESS estimates are displayed. You can choose not to display the result and save the output to a data set with the following statement:

```
%ESS(data=post, var=&parms, print=NO, out=eout);
```

Some of the macros can take additional options, which are listed in Table 55.46.

Table 55.46 Macro-Specific Options

Macro	Option	Description
%ESS	AUTOCORLAG=numeric	Specifies the maximum number of autocorrelation lags used in computing the ESS estimates. By default, AUTOCORLAG=MIN(500, NOBS/4), where NOBS is the sample size of the input data set.
	HIST=YES NO	Displays a histogram of all ESS estimates. The default is NO.
%HEIDEL	SALPHA=numeric	Specifies the α level for the stationarity test. By default, SALPHA=0.05.
	HALPHA=numeric	Specifies the α level for the halfwidth test. By default, HALPHA=0.05.
	EPS=numeric	Specifies a small positive number ϵ such that if the halfwidth is less than ϵ times the sample mean of the remaining iterations, the halfwidth test is passed. By default, EPS=0.1.

Table 55.46 (continued)

Option	Description	
%GEWEKE	FRAC1= <i>numeric</i>	Specifies the earlier portion of the Markov chain used in the test. By default, FRAC1=0.1.
	FRAC2= <i>numeric</i>	Specifies the latter portion of the Markov chain used in the test. By default, FRAC2=0.5.
%MCSE	AUTOCORLAG= <i>numeric</i>	Specifies the maximum number of autocorrelation lags used in computing the Monte Carlo standard error estimates. By default, AUTOCORLAG=MIN(500, NOBS/4), where NOBS is the sample size of the input data set.
%RAFTERY	Q= <i>numeric</i>	Specifies the order of the quantile of interest. By default, Q=0.025.
	R= <i>numeric</i>	Specifies the margin of error for measuring the accuracy of estimation of the quantile. By default, R=0.005.
	S= <i>numeric</i>	Specifies the probability of attaining the accuracy of the estimation of the quantile. By default, S=0.95.
	EPS= <i>numeric</i>	Specifies the tolerance level for the stationary test. By default, EPS=0.001.
%POSTACF	LAGS=%str(<i>numeric-list</i>)	Specifies autocorrelation lags calculated. The default values are 1, 5, 10, and 50.
%POSTINT	ALPHA= <i>value</i>	Specifies the α level ($0 < \alpha < 1$) for the interval estimates. By default, ALPHA=0.05.

For example, the following statement calculates and displays autocorrelation at lags 1, 6, 11, 50, and 100. Note that the lags in the *numeric-list* need to be separated by commas “,”.

```
%PostACF(data=post, var=&parms, lags=%str(1 to 15 by 5, 50, 100));
```

Gamma and Inverse-Gamma Distributions

The gamma and inverse gamma distributions are widely used in Bayesian analysis. With their respective scale and inverse scale parameterizations, they are a frequent source of confusion in the field. This section aims to clarify their parameterizations and common usages.

The gamma distribution is often used as the conjugate prior for the precision parameter ($\tau = 1/\sigma^2$) in a normal distribution. See Table 55.19 in the section “Standard Distributions” on page 4476 for the density definitions. You can specify the distribution in two ways:

- `gamma(shape=, scale=)` which has mean $\text{shape} \cdot \text{scale}$ and variance $\text{shape} \cdot \text{scale}^2$
- `gamma(shape=, iscale=)` which has mean $\frac{\text{shape}}{\text{iscale}}$ and variance $\frac{\text{shape}}{\text{iscale}^2}$

The parameterization of the gamma distribution that is preferred by most Bayesian analysts is to have the same number in both hyperparameter positions, which results in a prior distribution that has mean 1. To do this, you should use the `iscale=` parameterization. In addition, if you choose a small value (for example,

0.01), the prior distribution takes on a large variance (100 in this example). To specify this prior in PROC MCMC, use `gamma(shape=0.01, iscale=0.01)`⁵, *not* `gamma(shape=0.01, scale=0.01)`.

If you specify the `scale=` parameterization, as in `gamma(shape=0.01, scale=0.01)`, you would get a prior distribution that has mean 0.0001 and variance 0.000001. This would lead to a completely different posterior inference: the prior would push the precision parameter estimate close to 0, or the variance estimate to a large value.

The inverse-gamma distribution is often used as the conjugate prior of the variance parameter (σ^2) in a normal distribution. See Table 55.22 in the section “Standard Distributions” on page 4476 for the density definitions. Similar to the gamma distribution, you can specify the inverse-gamma distribution in two ways:

- `igamma(shape=, scale=)`
- `igamma(shape=, iscale=)`

The inverse gamma distribution does not have a mean when the shape parameter is less than or equal to 1 and does not have a variance when the shape parameter is less than or equal to 2.

A gamma prior distribution on the precision is the equivalent to an inverse gamma prior distribution on the variance. The equivalency is the following:

$$\tau \sim \text{gamma}(\text{shape}=0.01, \text{iscale}=0.01) \Leftrightarrow \sigma^2 \sim \text{igamma}(\text{shape}=0.01, \text{scale}=0.01)$$

NOTE: This mnemonic might help you remember the parameterization scheme of the distributions. If you prefer to have identical hyperparameter values in the distribution, you should specify one and only one “i.” When the “i” appears in the `igamma` distribution name for the variance parameter, choose the `scale=` parameterization; when the “i” appears in the `iscale=` parameterization, choose the `gamma` distribution for the precision parameter.

If you are not sure about the choices of other hyperparameter values and what type of prior distributions they induce, you can write a simple PROC MCMC program and see the distributions as in the following example:

```
data a;
run;

ods graphics on;
ods select DensityPanel;
proc mcmc data=a stats=none diag=none nmc=10000 outpost=gout
  plots=density seed=1;
  parms gamma_3_is2 gamma_001_sc4 igamma_12_sc001 igamma_2_is01;
  prior gamma_3_is2 ~ gamma(shape=3, iscale=2);
  prior gamma_001_sc4 ~ gamma(shape=0.01, scale=4);
  prior igamma_12_sc001 ~ igamma(shape=12, scale=0.01);
  prior igamma_2_is01 ~ igamma(shape=2, iscale=0.1);
  model general(0);
run;
ods graphics off;
```

⁵Specifying the same number at both positions and choosing a small value has been popularized by the WinBUGS software program. The WinBUGS's distribution specification of `dgamma(0.01, 0.01)` is equivalent to specifying `gamma(shape=0.01, iscale=0.01)` in PROC MCMC.

The preceding statements specify four different gamma and inverse gamma distributions with various scale and inverse scale parameter values. The output of kernel density plots of these four prior distributions is shown in Figure 55.19. Note how the X axis scales vary across different distributions.

Figure 55.19 Density Plots of Different Gamma and Inverse Gamma Distributions

Posterior Predictive Distribution

The posterior predictive distribution

$$p(\mathbf{y}_{\text{pred}}|\mathbf{y}) = \int p(\mathbf{y}_{\text{pred}}|\theta) p(\theta|\mathbf{y}) d\theta$$

can often be used to check whether the model is consistent with data. For more information about using predictive distribution as a model checking tool, see Gelman et al. 2004, Chapter 6 and the bibliography in that chapter. The idea is to generate replicate data from $p(\mathbf{y}_{\text{pred}}|\mathbf{y})$ —call them $\mathbf{y}_{\text{pred}}^i$, for $i = 1, \dots, M$, where M is the total number of replicates—and compare them to the observed data to see whether there are any large and systematic differences. Large discrepancies suggest a possible model misfit. One way to compare the replicate data to the observed data is to first summarize the data to some test quantities, such as the mean, standard deviation, order statistics, and so on. Then compute the tail-area probabilities of the test statistics (based on the observed data) with respect to the estimated posterior predictive distribution that uses the M replicate \mathbf{y}_{pred} samples.

Let $T(\cdot)$ denote the function of the test quantity, $T(\mathbf{y})$ the test quantity that uses the observed data, and $T(\mathbf{y}_{\text{pred}}^i)$ the test quantity that uses the i th replicate data from the posterior predictive distribution. You

calculate the tail-area probability by using the following formula:

$$\Pr(T(\mathbf{y}_{\text{pred}}) > T(\mathbf{y})|\theta)$$

The following example shows how you can use PROC MCMC to estimate this probability.

An Example for the Posterior Predictive Distribution

This example uses a normal mixed model to analyze the effects of coaching programs for the scholastic aptitude test (SAT) in eight high schools. For the original analysis of the data, see Rubin (1981). The presentation here follows the analysis and posterior predictive check presented in Gelman et al. (2004). The data are as follows:

```
title 'An Example for the Posterior Predictive Distribution';

data SAT;
  input effect se @@;
  ind=_n_;
  datalines;
28.39 14.9 7.94 10.2 -2.75 16.3
6.82 11.0 -0.64 9.4 0.63 11.4
18.01 10.4 12.16 17.6
;
```

The variable `effect` is the reported test score difference between coached and uncoached students in eight schools. The variable `se` is the corresponding estimated standard error for each school. In a normal mixed effect model, the variable `effect` is assumed to be normally distributed:

$$\text{effect}_i \sim \text{normal}(\mu_i, \text{se}^2) \quad \text{for } i = 1, \dots, 8$$

The parameter μ_i has a normal prior with hyperparameters (m, v) :

$$\mu_i \sim \text{normal}(m, \text{var} = v)$$

The hyperprior distribution on m is a uniform prior on the real axis, and the hyperprior distribution on v is a uniform prior from 0 to infinity.

The following statements fit a normal mixed model and use the **PREDDIST** statement to generate draws from the posterior predictive distribution.

```
ods listing close;
proc mcmc data=SAT outpost=out nmc=40000 seed=12;
  parms m 0;
  parms v 1 /slice;
  prior m ~ general(0);
  prior v ~ general(1, lower=0);
  random mu ~ normal(m, var=v) subject=ind monitor=(mu);
  model effect ~ normal(mu, sd=se);
  predpdist outpred=pout nsim=5000;
run;
ods listing;
```

The ODS LISTING CLOSE statement disables the listing output because you are primarily interested in the samples of the predictive distribution. The **HYPER**, **PRIOR**, and **MODEL** statements specify the Bayesian model of interest. The **PREDDIST** statement generates samples from the posterior predictive distribution and stores the samples in the Pout data set. The predictive variables are named `effect_1`, ..., `effect_8`. When no **COVARIATES** option is specified, the covariates in the original input data set SAT are used in the prediction. The **NSIM=** option specifies the number of predictive simulation iterations.

The following statements use the Pout data set to calculate the four test quantities of interest: the average (mean), the sample standard deviation (sd), the maximum effect (max), and the minimum effect (min). The output is stored in the Pred data set.

```
data pred;
  set pout;
  mean = mean(of effect:);
  sd = std(of effect:);
  max = max(of effect:);
  min = min(of effect:);
run;
```

The following statements compute the corresponding test statistics, the mean, standard deviation, and the minimum and maximum statistics on the real data and store them in macro variables. You then calculate the tail-area probabilities by counting the number of samples in the data set Pred that are greater than the observed test statistics based on the real data.

```
proc means data=SAT noprint;
  var effect;
  output out=stat mean=mean max=max min=min stddev=sd;
run;

data _null_;
  set stat;
  call symputx('mean',mean);
  call symputx('sd',sd);
  call symputx('min',min);
  call symputx('max',max);
run;

data _null_;
  set pred end=eof nobs=nobs;
  ctmean + (mean>&mean);
  ctmin + (min>&min);
  ctmax + (max>&max);
  ctsd + (sd>&sd);
  if eof then do;
    pmean = ctmean/nobs; call symputx('pmean',pmean);
    pmin = ctmin/nobs; call symputx('pmin',pmin);
    pmax = ctmax/nobs; call symputx('pmax',pmax);
    psd = ctsd/nobs; call symputx('psd',psd);
  end;
run;
```

You can plot histograms of each test quantity to visualize the posterior predictive distributions. In addition, you can see where the estimated *p*-values fall on these densities. [Figure 55.20](#) shows the histograms. To

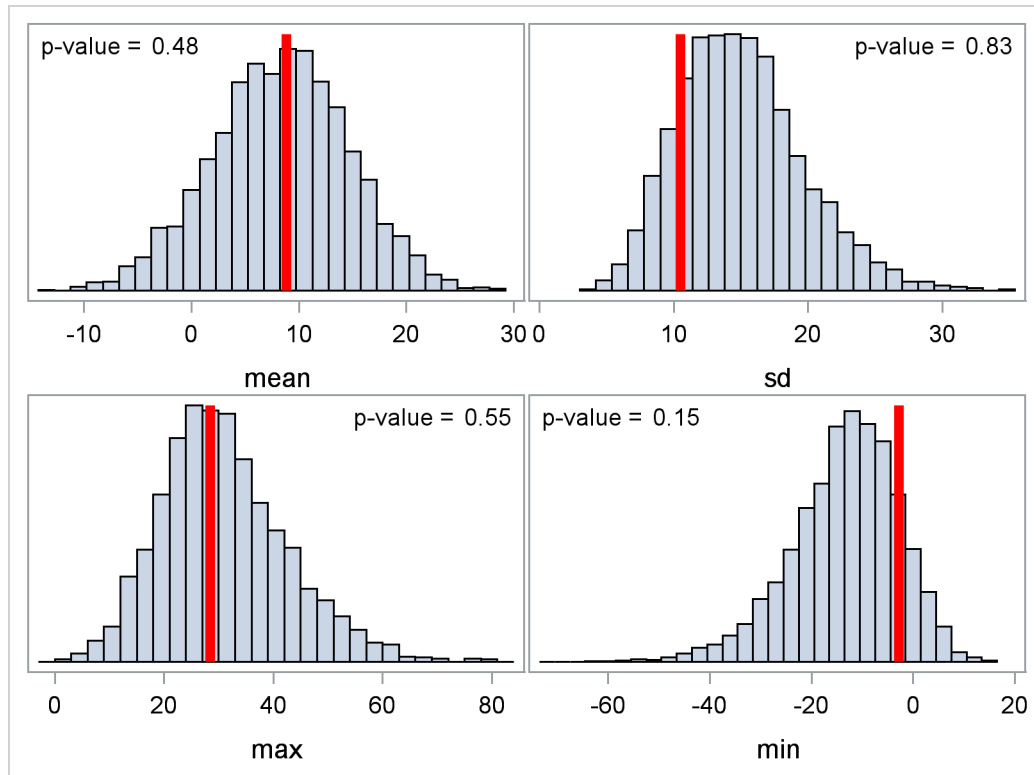

put all four histograms on the same panel, you need to use PROC TEMPLATE to define a new graph template. (See Chapter 21, “[Statistical Graphics Using ODS](#).”) The following statements define the template `twobytwo`:

```
proc template;
  define statgraph twobytwo;
    begingraph;
      layout lattice / rows=2 columns=2;
        layout overlay / yaxisopts=(display=none)
          xaxisopts=(label="mean");
        layout gridded / columns=2 border=false
          autoalign=(topleft topright);
        entry halign=right "p-value =";
        entry halign=left eval(strip(put(&pmean, 12.2)));
      endlayout;
      histogram mean / binaxis=false;
      lineparm x=&mean y=0 slope=. /
        lineattrs=(color=red thickness=5);
    endlayout;
    layout overlay / yaxisopts=(display=none)
      xaxisopts=(label="sd");
    layout gridded / columns=2 border=false
      autoalign=(topleft topright);
    entry halign=right "p-value =";
    entry halign=left eval(strip(put(&psd, 12.2)));
    endlayout;
    histogram sd / binaxis=false;
    lineparm x=&sd y=0 slope=. /
      lineattrs=(color=red thickness=5);
    endlayout;
    layout overlay / yaxisopts=(display=none)
      xaxisopts=(label="max");
    layout gridded / columns=2 border=false
      autoalign=(topleft topright);
    entry halign=right "p-value =";
    entry halign=left eval(strip(put(&pmax, 12.2)));
    endlayout;
    histogram max / binaxis=false;
    lineparm x=&max y=0 slope=. /
      lineattrs=(color=red thickness=5);
    endlayout;
    layout overlay / yaxisopts=(display=none)
      xaxisopts=(label="min");
    layout gridded / columns=2 border=false
      autoalign=(topleft topright);
    entry halign=right "p-value =";
    entry halign=left eval(strip(put(&pmin, 12.2)));
    endlayout;
    histogram min / binaxis=false;
    lineparm x=&min y=0 slope=. /
      lineattrs=(color=red thickness=5);
    endlayout;
  endlayout;
endgraph;
end;
run;
```

You call PROC SGRENDER to create the graph, which is shown in Figure 55.20. (See the SGRENDER procedure in the *SAS/GRAPH: Statistical Graphics Procedures Guide*.) There are no extreme p -values observed; this supports the notion that the predicted results are similar to the actual observations and that the model fits the data.

```
proc sgrender data=pred template=twobytwo;
run;
```

Figure 55.20 Posterior Predictive Distribution Check for the SAT example

Note that the posterior predictive distribution is not the same as the prior predictive distribution. The prior predictive distribution is $p(y)$, which is also known as the marginal distribution of the data. The prior predictive distribution is an integral of the likelihood function with respect to the prior distribution

$$p(y_{\text{pred}}) = \int p(y_{\text{pred}}|\theta)p(\theta)d\theta$$

and the distribution is not conditional on observed data.

Handling of Missing Data

PROC MCMC automatically augments missing values⁶ via the use of the **MODEL** statement. PROC MCMC treats missing values as unknown parameters, assigns distributions to the variables, and incorporates the sampling of the missing data as part of Markov chain.

⁶A missing value is usually, although not necessarily, represented by a single period (.) in the input data set.

(In SAS/STAT 9.3 and earlier releases, by default, PROC MCMC discarded all observations that had missing or partial missing values. PROC MCMC could not model missing values.)

You can use the `MISSING=` option in the PROC MCMC statement to specify how you want PROC MCMC to handle the missing values. If you specify `MISSING=CC` (CC stands for complete cases), PROC MCMC discards all observations that have missing or partial missing values before carrying out the simulation. If you specify `MISSING=AC` (AC stands for all cases), PROC MCMC neither discards any missing values nor augments them.

Generally speaking, there are three types of missing data models, as discussed by Rubin (1976). Also see Little and Rubin (2002) for a comprehensive treatment of missing data analysis. The rest of this section provides an overview of these three types of missing data models and explains how to use PROC MCMC to fit them.

Missing Completely at Random (MCAR)

Data are said to be MCAR if the probability of a missing value (or the failure of observing a value) does not depend on any other observations in the data set, regardless of whether they are observed or missing. That is, the observed and unobserved values are independent of each other: if y_i is missing, it is MCAR if the probability of observing y_i is independent of other y_j (and other covariates x_i) in the data set. Under this assumption, both the observed and unobserved data are random samples of all the data; hence, fitting a model based only on the observed data does not introduce any biases. This type of analysis is called a complete-case analysis. To carry out a complete-case analysis, you must specify `MISSING=CC` in the PROC MCMC statement. (In SAS/STAT 9.3 and earlier, PROC MCMC performed a complete-case analysis when the data contained missing values.)

Missing at Random (MAR)

Data are said to be MAR if the probability of a missing value can depend on some observed quantities but does not depend on any unobserved data. For example, suppose that x_i are completely observed for all observations and some y_i are missing. MAR states that the probability of observing y_i is independent of other missing y_j (values that could have been observed) and that it depends only on x_i (and, potentially, observed y_i).

The MAR assumption states that the missing y_i are no longer random samples and that they need to be modeled (via the likelihood specification of the missing values). At the same time, the independence assumption of the missing values on the unobserved quantities states that the missing mechanism (usually a binary indicator variable such that $r_i = 1$ if y_i is missing and $r_i = 0$ otherwise) can be ignored and does not need to be taken into account. Hence, MAR is sometimes referred to as *ignorably missing*. It is not the missing values that can be ignored, it is the missing mechanism that can be ignored.

By default, PROC MCMC treats the missing data as MAR (this assumes that you do not input a binary indicator variable r_i and model it specifically): each missing value becomes an extra parameter and PROC MCMC updates it in every iteration. PROC MCMC assumes that both the missing values and observed values arise from the same distribution (which is specified in the `MODEL` statement),

$$\mathbf{y} = \{\mathbf{y}_{\text{obs}}, \mathbf{y}_{\text{mis}}\} \sim f(\mathbf{y}|\theta)$$

where \mathbf{y} consists of observed (\mathbf{y}_{obs}) and missing (\mathbf{y}_{mis}) values, and $f(\mathbf{y}|\theta)$ is the likelihood function with parameters θ .

You can use the **MODEL** statement to model missing covariates. Using multiple **MODEL** statements enables you to specify, for example, a marginal distribution for missing values in covariate x and a conditional distribution for the response variable y given x as follows:

```
model x ~ normal(alpha, var=s2_x);
model y ~ normal(beta * x, var=s2_y);
```

In each iteration, PROC MCMC draws samples for every missing value in variable x , then every missing value in variable y , conditional on the drawn values of the x variable.

Missing Not at Random (MNAR)

Data are said to be MNAR if the probability of a missing value depends on unobserved data (or data that could have been observed): the probability that y_i is missing depends on the missing values of other y_i . This is a very general scenario that assumes that the missing mechanism is no longer ignorable (it is sometimes referred to as *nonignorably missing*) and that a model for the missing mechanism is required in order to make correct inferences about the model parameters.

Let $\mathbf{R} = (r_1, \dots, r_n)$ be the missing value indicator for $\mathbf{Y} = (y_1, \dots, y_n)$, where $r_i = 1$ if y_i is missing and $r_i = 0$ otherwise. This \mathbf{R} is usually part of an input data set where you preprocess the response variable and create this missing value indicator variable. Modeling MNAR data implies that you must specify a joint likelihood function over \mathbf{R} and \mathbf{Y} : $f(\mathbf{R}, \mathbf{Y}|\mathbf{X}, \boldsymbol{\theta})$, where \mathbf{X} represents the covariates and $\boldsymbol{\theta}$ represents the model parameters. This joint distribution can be factored in two ways: a pattern-mixture model and a selection model.

The *selection model* factors the joint distribution \mathbf{R} and \mathbf{Y} into a marginal distribution for \mathbf{Y} and a conditional distribution for \mathbf{R} ,

$$f(\mathbf{R}, \mathbf{Y}|\mathbf{X}, \boldsymbol{\theta}) \propto f(\mathbf{Y}|\mathbf{X}, \boldsymbol{\alpha}) \cdot f(\mathbf{R}|\mathbf{Y}, \mathbf{X}, \boldsymbol{\beta})$$

where $\boldsymbol{\theta} = (\boldsymbol{\alpha}, \boldsymbol{\beta})$, $f(\mathbf{R}|\mathbf{Y}, \mathbf{X}, \boldsymbol{\alpha})$ is usually a binary model with a logit or probit link that involves regression parameters $\boldsymbol{\alpha}$, and $f(\mathbf{Y}|\mathbf{X}, \boldsymbol{\beta})$ is the sampling distribution that generates y_i with model parameters $\boldsymbol{\beta}$.

The *pattern-mixture model* factors the opposite way, a marginal distribution for \mathbf{R} and a conditional distribution for \mathbf{Y} ,

$$f(\mathbf{R}, \mathbf{Y}|\mathbf{X}, \boldsymbol{\theta}) \propto f(\mathbf{R}|\mathbf{X}, \boldsymbol{\gamma}) \cdot f(\mathbf{Y}|\mathbf{R}, \mathbf{X}, \boldsymbol{\delta})$$

where $\boldsymbol{\theta} = (\boldsymbol{\gamma}, \boldsymbol{\delta})$.

You can use PROC MCMC to fit either model by specifying multiple **MODEL** statements: one for the marginal distribution and one for the conditional distribution. Suppose that the variable r is the missing data indicator, which is modeled using a logit model, and that the response variable y is a Poisson regression that includes the missing variable indicator as one of its covariates. The following statements are a PROC MCMC program that fits a pattern-mixture model:

```
pi = logistic(alpha * x1);
model r ~ binary(pi);
mu = beta0 + beta1 * x2 + beta3 * r;
model y ~ poisson(exp(mu));
```

The first **MODEL** statement uses a binary model with logit link to model the missing mechanism, and the second **MODEL** statement models the response variable with a Poisson regression that includes the missing

value indicator as one of its covariates. Each of the two sets of regression has its covariates and regression coefficients. If this hypothetical data set contained missing values in covariates `x1` and `x2`, you could add two more **MODEL** statements to handle each variable as follows:

```
model x1 ~ normal(mu1, var=s2_x1);
pi = logistic(alpha * x1);
model r ~ binary(pi);
model x2 ~ normal(mu2, var=s2_x2);
mu = beta0 + beta1 * x2 + beta3 * r;
model y ~ poisson(exp(mu));
```

Functions of Random-Effects Parameters

When you specify a **RANDOM** statement in a program, PROC MCMC internally creates a random-effects parameter for every unique value in the **SUBJECT=** variable. You can calculate any transformations of these random-effects parameters by applying SAS functions to the effect, and you can use the transformed variable in the subsequent statements. For example, the following statements perform a logit transformation of an effect:

```
random u ~ normal(mu, var=s2) subject=students;
p = logistic(u);
...
```

The value of the variable `p` changes with `u` as the procedure steps through the input data set: for different unique values of the `students` variable, `u` takes on a different parameter value, and `p` changes accordingly.

To save all the transformed values in `p` to the **OUTPOST=** data set, you cannot just specify the **MONITOR=(p)** option in the PROC MCMC statement. With such a specification, PROC MCMC can save only one value of `p` (usually the value associated with the last observation in the data set); it cannot save all values. To output all transformed values, you must create an array to store every transformation and use the **MONITOR=** option to save the entire array to the **OUTPOST=** data set. The difficult part of the programming involves the creation of the correct array index to use in different types of the **SUBJECT=** variables. The rest of this section describes how to monitor functions of random-effects parameters in different situations.

Indexing Subject Variable

This subsection describes how to monitor transformation of an effect `u` when the `students` variable is an indexing subject variable. An indexing subject variable is an integer variable that takes value from one to the total number of unique subjects in a variable. In other words, the variable can be used as an index in a SAS array. The indexing subject variable does not need to be sorted for the example code in this section to work. An example of an indexing variable takes the values of (1 2 3 4 5 1 2 3 4 5), where the total number of observation is $n=10$ and the number of unique values is $m=5$.

The following statements create an indexing variable `students` in the data set `a`:

```
data a;
  input students @@;
  datalines;
  1 1 2 2 3 3 4 4 5 5 6 6 7 7 8 8 9 9 10 10
;
```

The following statements run a random-effects model without any response variables. There are only random-effects parameters in the model; the program calculates the logit transformation of each effect, saves the results to the **OUTPOST=** data set, and produces [Figure 55.21](#):

```
proc mcmc data=a monitor=(p) diag=none stats=none outpost=a1
  plots=none seed=1;
  array p[10];
  random u ~ n(0, sd=1) subject=students;
  p[students] = logistic(u);
  model general(0);
run;

proc print data=a1(obs=3);
run;
```

The **ARRAY** statement creates an array **p** of size 10, which is the number of unique values in **students**. The **p** array stores all the transformed values. The **RANDOM** statement declares **u** to be an effect with the subject variable **students**. The **P[STUDENTS]** assignment statement calculates the logit transformations of **u** and saves them in appropriate array elements—this is why the **students** variable must be an indexing variable. Because the **students** variable used in the **p[]** array is also the subject variable in the **RANDOM** statement, PROC MCMC can match each random-effects parameter with the corresponding element in array **p**. The **MONITOR=** option monitors all elements in **p** and saves the output to the **a1** data set. The **a1** data set contains variables **p1–p10**. [Figure 55.21](#) shows the first three observations of the **OUTPOST=** data set.

Figure 55.21 Monitor Functions of Random Effect **u**

Obs	Iteration	p1	p2	p3	p4	p5	p6	p7
1	1	0.5050	0.7334	0.5375	0.5871	0.6862	0.4944	0.5740

3	0.1092	0.7361	-1.1641	-0.8772	-0.4112	-12.3984	0	-12.3984

The variable **p1** is the logit transformation of the variable **u_1**, **p2** is the logit transformation of the variable **u_2**, and so on.

The same idea works for a **students** variable that is unsorted. The following statements create an unsorted indexing variable **students** with repeated measures in each subject, fit the same model, and produce [Figure 55.22](#):

```

data a;
  input students @@;
  datalines;
  1 1 1 3 5 3 4 5 3 1 5 5 4 4 2 2 2 2 4 3
;
proc mcmc data=a monitor=(p) diag=none stats=none outpost=a1
  plots=none seed=1;
  array p[5];
  random u ~ n(0, sd=1) subject=students;
  p[students] = logistic(u);
  model general(0);
run;

proc print data=a1(obs=3);
run;

```

Figure 55.22 Monitor Functions of Random Effect u When the students Variable is Unsorted

Obs	Iteration	p1	p2	p3	p4	p5	u_1
1	1	0.5050	0.6862	0.7334	0.5871	0.5375	0.0198
2	2	0.4944	0.8678	0.5740	0.6812	0.5991	-0.0225
3	3	0.5563	0.4593	0.4254	0.5280	0.7260	0.2261
Obs	u_3	u_5	u_4	u_2	LogReff	LogLike	LogPost
1	1.0120	0.1504	0.3521	0.7826	-5.4865	0	-5.4865
2	0.2983	0.4019	0.7595	1.8819	-6.7793	0	-6.7793
3	-0.3006	0.9742	0.1120	-0.1630	-5.1595	0	-5.1595

There are five random-effects parameters in this example, and the array p also has five elements. The values p1–p5 are the transformations of u_1–u_5, respectively. The u variables are not sorted from u_1 to u_5 because PROC MCMC creates the names according to the order by which the subject variable appears in the input data set. Nevertheless, because students is an indexing variable, the first element p[1] stores the transformation that corresponds to **students=1** (which is u_1), the second element p[2] stores the transformation that corresponds to **students=2**, and so on.

Non-Indexing Subject Variable

A non-indexing subject variable can take values of character literals (for example, names) or numerals (for example, ZIP code or a person's weight). This section illustrates how to monitor functions of random-effects parameters in these situations.

Suppose you have unsorted character literals as the subject variable:

```

data a;
  input students$ @@;
  datalines;
  smith john john mary kay smith lizzy ben ben dylan
  ben toby abby mary kay kay lizzy ben dylan mary
;

```

A statement such as following does not work anymore because a character variable cannot be used as an array index:

```
p[students] = logistic(u);
```

In this situation, you usually need to do two things: (1) find out the number of unique values in the subject variable, and (2) create a numeric index variable that replaces the students array index. You can use the following statements to do the first task:

```

proc sql noprint;
  select count(distinct(students)) into :nuniq from a;
quit;
%put &nuniq;

```

The PROC SQL call counts the distinct values in the students variable and saves the count to the macro variable &nuniq. The macro variable is used later to specify the element size of the p array. In this example, the a data set contains 20 observations and 9 unique elements (the value of &nuniq).

The following statements create an Index variable in the a data set that is in the order by which the students names appear in the data set:

```

proc freq data=a order=data noprint;
  tables students / out=_f(keep=students);
run;

proc print data=_f;
run;

data a(drop=n);
  set a;
  do i = 1 to nobs until(students=n);
    set _f(keep=students rename=(students=n)) point=i nobs=nobs;
    Index = i;
  end;
run;

proc print data=a;
run;

```

The PROC FREQ call identifies the unique students names and saves them to the _f data set, which is displayed in [Figure 55.23](#).

Figure 55.23 Unique Names in the Variable Students

Obs	students
1	smith
2	john
3	mary
4	kay
5	lizzy
6	ben
7	dylan
8	toby
9	abby

The DATA step steps through the a data set and creates an Index variable to match the order in which the students names appear in the data set. The new a data set⁷ is displayed in [Figure 55.24](#).

Figure 55.24 New Index Variable in the a Data Set

Obs	students	Index
1	smith	1
2	john	2
3	john	2
4	mary	3
5	kay	4
6	smith	1
7	lizzy	5
8	ben	6
9	ben	6
10	dylan	7
11	ben	6
12	toby	8
13	abby	9
14	mary	3
15	kay	4
16	kay	4
17	lizzy	5
18	ben	6
19	dylan	7
20	mary	3

Student smith is the first subject, and his Index value is one. The same student appears again in the sixth observation, which is given the same Index value. Now, this Index variable can be used to index the p array, in a similar fashion as demonstrated in previous programs:

⁷The programming code that creates and adds the Index variable to the data set a keeps all variables from the original data set and does not discard them.

```

data _f;
  set _f;
  subj = compress('p_'||students);
run;
proc sql noprint;
  select subj into :pnames separated by ' ' from _f;
quit;
%put &pnames;

proc mcmc data=a monitor=(p) diag=none stats=none outpost=a1
  plots=none seed=1;
  array p[&nuniq] &pnames;
  random u ~ n(0, sd=1) subject=students;
  p[index] = logistic(u);
  model general(0);
run;

proc print data=a1(obs=3);
run;

```

The first part of the DATA step and the PROC SQL call create array names for the *p* array that match the subject names in the *students* variable. It is not necessary to include these steps for the PROC MCMC program to work, but it makes the output more readable. The first DATA step steps through the *_f* data set and creates a *subj* variable that concatenates the prefix characters *p_* with the names of the students. The PROC SQL calls put all the *subj* values to a macro called *&pnames*, which looks like the following:

```
p_smith p_john p_mary p_kay p_lizzy p_ben p_dylan p_toby p_abby
```

In the PROC MCMC program, the **ARRAY** statement defines an *p* array with size *&nuniq* (9), and use the macro variable *&pnames* to name the array elements. The *P[INDEX]* assignment statement uses the *Index* variable to find the correct array element to store the transformation. Figure 55.25 displays the first few observations of the **OUTPOST=a1** data set.

Figure 55.25 First Few Observations of the Outpost Data Set

There are nine random-effects parameters (u_{smith} , u_{john} , and so on). There are nine elements of the p array (p_{smith} , p_{john} , and so on); each is the logit transformation of corresponding u elements.

You can use the same statements for subject variables that are numeric non-indexing variables. The following statements create a `students` variable that take large numbers that cannot be used as indices to an array. The rest of the program monitors functions of the effect u . The output is not displayed here.

```
data a;
  call streaminit(1);
  do i = 1 to 20;
    students = rand("poisson", 20);
    output;
  end;
  drop i;
run;

proc sql noprint;
  select count(distinct(students)) into :nuniq from a;
quit;
%put &nuniq;

proc freq data=a order=data noprint;
  tables students / out=_f(keep=students);
run;

data a(drop=n);
  set a;
  do i = 1 to nobs until(students=n);
    set _f(keep=students rename=(students=n)) point=i nobs=nobs;
    Index = i;
  end;
run;

data _f;
  set _f;
  subj = compress('p_'||students);
proc sql noprint;
  select subj into :pnames separated by ' ' from _f;
quit;
%put &pnames;

proc mcmc data=a monitor=(p) diag=none stats=none outpost=a1
  plots=none seed=1;
  array p[&nuniq] &pnames;
  random u ~ n(0, sd=1) subject=students;
  p[index] = logistic(u);
  model general(0);
run;

proc print data=a1(obs=3);
run;
```

Floating Point Errors and Overflows

When performing a Markov chain Monte Carlo simulation, you must calculate a proposed jump and an objective function (usually a posterior density). These calculations might lead to arithmetic exceptions and overflows. A typical cause of these problems is parameters with widely varying scales. If the posterior variances of your parameters vary by more than a few orders of magnitude, the numerical stability of the optimization problem can be severely reduced and can result in computational difficulties. A simple remedy is to rescale all the parameters so that their posterior variances are all approximately equal. Changing the `SCALE=` option might help if the scale of your parameters is much different than one. Another source of numerical instability is highly correlated parameters. Often a model can be reparameterized to reduce the posterior correlations between parameters.

If parameter rescaling does not help, consider the following actions:

- provide different initial values or try a different seed value
- use boundary constraints to avoid the region where overflows might happen
- change the algorithm (specified in programming statements) that computes the objective function

Problems Evaluating Code for Objective Function

The initial values must define a point for which the programming statements can be evaluated. However, during simulation, the algorithm might iterate to a point where the objective function cannot be evaluated. If you program your own likelihood, priors, and hyperpriors by using SAS statements and the `GENERAL` function in the `MODEL`, `PRIOR`, AND `HYPERPRIOR` statements, you can specify that an expression cannot be evaluated by setting the value you pass back through the `GENERAL` function to missing. This tells the PROC MCMC that the proposed set of parameters is invalid, and the proposal will not be accepted. If you use the shorthand notation that the `MODEL`, `PRIOR`, AND `HYPERPRIOR` statements provide, this error checking is done for you automatically.

Long Run Times

PROC MCMC can take a long time to run for problems with complex models, many parameters, or large input data sets. Although the techniques used by PROC MCMC are some of the best available, they are not guaranteed to converge or proceed quickly for all problems. Ill-posed or misspecified models can cause the algorithms to use more extensive calculations designed to achieve convergence, and this can result in longer run times. You should make sure that your model is specified correctly, that your parameters are scaled to the same order of magnitude, and that your data reasonably match the model that you are specifying.

To speed general computations, you should check over your programming statements to minimize the number of unnecessary operations. For example, you can use the proportional kernel in the priors or the likelihood and not add constants in the densities. You can also use the `BEGINCNST` and `ENDCNST` to reduce unnecessary computations on constants, and the `BEGINNODATA` and `ENDNODATA` statements to reduce observation-level calculations.

Reducing the number of blocks (the number of the `PARMS` statements) can speed up the sampling process. A single-block program is approximately three times faster than a three-block program for the same number

of iterations. On the other hand, you do not want to put too many parameters in a single block, because blocks with large size tend not to produce well-mixed Markov chains.

If some parameters satisfy the conditional independence assumption, such as in the random-effects models or latent variable models, consider using the **RANDOM** statement to model these parameters. This statement takes advantage of the conditional independence assumption and can sample a larger number of parameters at a more efficient pace.

Slow or No Convergence

If the simulator is slow or fails to converge, you can try changing the model as follows:

- Change the number of Monte Carlo iterations (**NMC=**), or the number of burn-in iterations (**NBI=**), or both. Perhaps the chain just needs to run a little longer. Note that after the simulation, you can always use the **DATA** step or the **FIRSTOBS** data set option to throw away initial observations where the algorithm has not yet burned in, so it is not always necessary to set **NBI=** to a large value.
- Increase the number of tuning. The proposal tuning can often work better in large models (models that have more parameters) with larger values of **NTU=**. The idea of tuning is to find a proposal distribution that is a good approximation to the posterior distribution. Sometimes 500 iterations per tuning phase (the default) is not sufficient to find a good approximating covariance.
- Change the initial values to more feasible starting values. Sometimes the proposal tuning starts badly if the initial values are too far away from the main mass of the posterior density, and it might not be able to recover.
- Use the **PROPCOV=** option to start the Markov chain at better starting values. With the **PROPCOV=QUANEW** option, PROC MCMC optimizes the object function and uses the posterior mode as the starting value of the Markov chain. In addition, a quadrature approximation to the posterior mode is used as the proposal covariance matrix. This option works well in many cases and can improve the mixing of the chain and shorten the tuning and burn-in time.
- Parameterize your model to include conjugacy, such as using the gamma prior on the precision parameter in a normal distribution or using an inverse gamma on the variance parameter. For a list of conjugate sampling methods that PROC MCMC supports, see the section “**Conjugate Sampling**” on page 4472.
- Change the blocking by using the **PARMS** statements. Sometimes poor mixing and slow convergence can be attributed to highly correlated parameters being in different parameter blocks.
- Modify the target acceptance rate. A target acceptance rate of about 25% works well for many multi-parameter problems, but if the mixing is slow, a lower target acceptance rate might be better.
- Change the initial scaling or the **TUNEWT=** option to possibly help the proposal tuning.
- Consider using a different proposal distribution. If from a trace plot you see that a chain traverses to the tail area and sometimes takes quite a few simulations before it comes back, you can consider using a *t* proposal distribution. You can do this by either using the PROC option **PROPDIST=T** or using a **PARMS** statement option **T**.

- Transform parameters and sample on a different scale. For example, if a parameter has a gamma distribution, sample on the logarithm scale instead. A parameter a that has a gamma distribution is equivalent to $\log(a)$ that has an egamma distribution, with the same distribution specification. For example, the following two formulations are equivalent:

```
parm a;
prior a ~ gamma(shape = 0.001, scale = 0.001);
```

and

```
parm la;
prior la ~ egamma(shape = 0.001, scale = 0.001);
a = exp(la);
```

See “[Example 55.6: Nonlinear Poisson Regression Models](#)” on page 4570 and “[Example 55.20: Using a Transformation to Improve Mixing](#)” on page 4654. You can also use the logit transformation on parameters that have $\text{uniform}(0, 1)$ priors. This prior is often used on probability parameters. The logit transformation is as follows: $q = \log(\frac{p}{1-p})$. The distribution on q is the Jacobian of the transformation: $\exp(-q)(1 + \exp(-q))^{-2}$. Again, the following two formulations are equivalent:

```
parm p;
prior p ~ uniform(0, 1);
```

and

```
parm q;
lp = -q - 2 * log(1 + exp(-q));
prior q ~ general(lp);
p = 1/(1+exp(-q));
```

Precision of Solution

In some applications, PROC MCMC might produce parameter values that are not precise enough. Usually, this means that there were not enough iterations in the simulation. At best, the precision of MCMC estimates increases with the square of the simulation sample size. Autocorrelation in the parameter values deflate the precision of the estimates. For more information about autocorrelations in Markov chains, see the section “[Autocorrelations](#)” on page 152.

Handling Error Messages

PROC MCMC does not have a debugger. This section covers a few ways to debug and resolve error messages.

Using the PUT Statement

Adding the PUT statement often helps to find errors in a program. The following statements produce an error:

```
data a;
run;

proc mcmc data=a seed=1;
  parms sigma lt w;

  beginnodata;
  prior sigma ~ unif(0.001,100);
  s2 = sigma*sigma;
  prior lt ~ gamma(shape=1, iscale=0.001);
  t = exp(lt);
  c = t/s2;
  d = 1/(s2);
  prior w ~ gamma(shape=c, iscale=d);
  endnodata;

  model general(0);
run;
```

```
ERROR: PROC MCMC is unable to generate an initial value for the
       parameter w. The first parameter in the prior distribution is
       missing.
```

To find out why the shape parameter *c* is missing, you can add the put statement and examine all the calculations that lead up to the assignment of *c*:

```
proc mcmc data=a seed=1;
  parms sigma lt w;

  beginnodata;
  prior sigma ~ unif(0.001,100);
  s2 = sigma*sigma;
  prior lt ~ gamma(shape=1, iscale=0.001);
  t = exp(lt);
  c = t/s2;
  d = 1/(s2);
  put c= t= s2= lt=; /* display the values of these symbols. */
  prior w ~ gamma(shape=c, iscale=d);
  endnodata;

  model general(0);
run;
```

In the log file, you see the following:

```
c=. t=. s2=. lt=.
c=. t=. s2=2500.0500003 lt=1000
c=. t=. s2=2500.0500003 lt=1000
```

```
ERROR: PROC MCMC is unable to generate an initial value for the parameter w.
       The first parameter in the prior distribution is missing.
```

You can ignore the first few lines. They are the results of initial set up by PROC MCMC. The last line is important. The variable `c` is missing because `t` is the exponential of a very large number, 1000, in `lt`. The value 1000 is assigned to `lt` by PROC MCMC because none was given. The gamma prior with shape of 1 and inverse scale of 0.001 has mode 0 (see “[Standard Distributions](#)” on page 4476 for more details). PROC MCMC avoids starting the Markov chain at the boundary of the support of the distribution, and it uses the mean value here instead. The mean of the gamma prior is 1000, hence the problem. You can change how the initial value is generated by using the PROC statement `INIT=RANDOM`. Remember to take out the `put` statement once you identify the problem. Otherwise, you will see a voluminous output in the log file.

Using the HYPER Statement

You can use the `HYPER` statement to narrow down possible errors in the prior distribution specification. With multiple `PRIOR` statements in a program, you might see the following error message if one of the prior distributions is not specified correctly:

```
ERROR: The initial prior parameter specifications must yield log
       of positive prior density values.
```

This message is displayed when PROC MCMC detects an error in the prior distribution calculation but cannot pinpoint the specific parameter at fault. It is frequently, although not necessarily, associated with parameters that have `GENERAL` or `DGENERAL` distributions. If you have a complicated model with many `PRIOR` statements, finding the parameter at fault can be time consuming. One way is to change a subset of the `PRIOR` statements to `HYPER` statements. The two statements are treated the same in PROC MCMC and the simulation is not affected, but you get a different message if the hyperprior distributions are calculated incorrectly:

```
ERROR: The initial hyperprior parameter specifications must yield
       log of positive hyperprior density values.
```

This message can help you identify more easily which distributions are producing the error, and you can then use the `PUT` statement to further investigate.

Computational Resources

It is impossible to estimate how long it will take for a general Markov chain to converge to its stationary distribution. It takes a skilled and thoughtful analysis of the chain to decide whether it has converged to the target distribution and whether the chain is mixing rapidly enough. In some cases, you might be able to estimate how long a particular simulation might take. The running time of a program that does not have `RANDOM` statements is approximately linear to the following factors: the number of samples in the input data set, the number of simulations, the number of blocks in the program, and the speed of your computer. For an analysis that uses a data set of size `nsamples`, a simulation length of `nsim`, and a block design of

nblocks, PROC MCMC evaluates the log-likelihood function the following number of times, excluding the tuning phase:

$$\text{nsamples} \times \text{nsim} \times \text{nblocks}$$

The faster your computer evaluates a single log-likelihood function, the faster this program runs. Suppose you have nsamples equal to 200, nsim equal to 55,000, and nblocks equal to 3. PROC MCMC evaluates the log-likelihood function approximately 3.3×10^7 times. If your computer can evaluate the log likelihood for one observation 10^6 times per second, this program takes approximately a half a minute to run. If you want to increase the number of simulations five-fold, the run time increases approximately five-fold.

Each **RANDOM** statement adds one pass through the input data at each iteration. If the Metropolis algorithm is used to sample the random-effects parameter, the conditional density (objective function) is calculated twice per pass through the data, which requires a computational resource that is approximately equivalent to adding two blocks of parameters.

Of course, larger problems take longer than shorter ones, and if your model is amenable to frequentist treatment, then one of the other SAS procedures might be more suitable. With “regular” likelihoods and a lot of data, the results of standard frequentist analysis are often asymptotically equivalent to a Bayesian approach. If PROC MCMC requires too much CPU time, then perhaps another SAS/STAT tool would be suitable.

Displayed Output

This section describes the output that PROC MCMC displays. For a quick reference of all ODS table names, see the section “[ODS Table Names](#)” on page 4537. ODS tables are arranged under four groups, which are listed in the following sections: “[Model and Data Related ODS Tables](#)” on page 4533, “[Sampling Related ODS Tables](#)” on page 4534, “[Posterior Statistics Related ODS Tables](#)” on page 4535, “[Convergence Diagnostics Related ODS Tables](#)” on page 4535, and “[Optimization Related ODS Tables](#)” on page 4536.

Model and Data Related ODS Tables

Missing Data Information Table

The “Missing Data Information” table (ODS table name MISSDATAINFO) displays the name of the response variable that contains missing values, the number of missing observations, the corresponding observation indices in the input data set, and the sampling method used in the simulation for the missing values.

Number of Observation Table

The “NObs” table (ODS table name NOBS) shows the number of observations that is in the data set and the number of observations that is used in the analysis. By default, observations with missing values are not used (see the section “[Handling of Missing Data](#)” on page 4518 for more details). This table is displayed by default.

Parameters

The “Parameters” table (ODS table name Parameters) shows the name of each parameter, the block number of each parameter, the sampling method used for the block, the initial values, and the prior or hyperprior distributions. This table is displayed by default.

REObsInfo

The “Random Effect Observation Information” table (ODS table name REObsInfo) lists the name of the random effect, each subject value, the number of observations in each subject, and their corresponding observation indices in the input data set. You can request this table by specifying the [REOBSINFO](#) option.

REParameters

The “REParameters” table (ODS table name REParameters) lists the name of the random effect, sampling algorithm, the subject variable, the number of subjects, unique values of the subject variable, and the prior distribution. This table is displayed by default if a [RANDOM](#) statement is used in the program.

Sampling Related ODS Tables**Burn-In History**

The “Burn-In History” table (ODS table name BurnInHistory) shows the scales and acceptance rates for each parameter block in the burn-in phase. The table is not displayed by default and can be requested by specifying the option [MCHISTORY=BRIEF | DETAILED](#).

Parameters Initial Value Table

The “Parameters Initial” table (ODS table name ParametersInit) shows the value of each parameter after the tuning phase. This table is not displayed by default and can be requested by specifying the option [INIT=PINIT](#).

Posterior Samples

The “Posterior Samples” table (ODS table name PosteriorSample) stores posterior draws of all parameters. It is not printed by PROC MCMC. You can create an ODS output data set of the chain by specifying the following:

```
ODS OUTPUT PosteriorSample = SAS-data-set;
```

Sampling History

The “Sampling History” table (ODS table name SamplingHistory) shows the scales and acceptance rates for each parameter block in the main sampling phase. The table is not displayed by default and can be requested by specifying the option [MCHISTORY=BRIEF | DETAILED](#).

Tuning Covariance

The “Tuning Covariance” table (ODS table name TuneCov) shows the proposal covariance matrices for each parameter block after the tuning phase. The table is not displayed by default and can be requested by specifying the option [INIT=PINIT](#). For more details about proposal tuning, see the section “[Tuning the Proposal Distribution](#)” on page 4469.

Tuning History

The “Tuning History” table (ODS table name TuningHistory) shows the number of tuning phases used in establishing the proposal distribution. The table also displays the scales and acceptance rates for each parameter block at each of the tuning phases. For more information about the self-adapting proposal tuning algorithm used by PROC MCMC, see the section “[Tuning the Proposal Distribution](#)” on page 4469. The table is not displayed by default and can be requested by specifying the option [MCHISTORY=BRIEF | DETAILED](#).

Tuning Probability Vector

The “Tuning Probability” table (ODS table name TuneP) shows the proposal probability vector for each discrete parameter block (when the option DISCRETE=GEO is specified and the geometric proposal distribution is used for discrete parameters) after the tuning phase. The table is not displayed by default and can be requested by specifying the option `INIT=PINIT`. For more information about proposal tuning, see the section “[Tuning the Proposal Distribution](#)” on page 4469.

Posterior Statistics Related ODS Tables

PROC MCMC calculates some essential posterior statistics and outputs them to a number of ODS tables that you can request and save individually. For details of the calculations, see the section “[Summary Statistics](#)” on page 153.

Summary Statistics

The “Posterior Summaries” table (ODS table name PostSummaries) contains basic statistics for each parameter. The table lists the number of posterior samples, the posterior mean and standard deviation estimates, and the percentile estimates. This table is displayed by default.

Correlation Matrix

The “Posterior Correlation Matrix” table (ODS table name Corr) contains the posterior correlation of model parameters. The table is not displayed by default and can be requested by specifying the option `STATS=CORR`.

Covariance Matrix

The “Posterior Covariance Matrix” table (ODS table name Cov) contains the posterior covariance of model parameters. The table is not displayed by default and can be requested by specifying the option `STATISTICS=COV`.

Deviance Information Criterion

The “Deviance Information Criterion” table (ODS table name DIC) contains the DIC of the model. The table is not displayed by default and can be requested by specifying the option `DIC`. For details of the calculations, see the section “[Deviance Information Criterion \(DIC\)](#)” on page 155.

Interval Statistics

The “Posterior Intervals” table (ODS table name PostIntervals) contains the equal-tail and highest posterior density (HPD) interval estimates for each parameter. The default α value is 0.05, and you can change it to other levels by using the `STATISTICS=` option. This table is displayed by default.

Convergence Diagnostics Related ODS Tables

PROC MCMC has convergence diagnostic tests that check for Markov chain convergence. PROC MCMC produces a number of ODS tables that you can request and save individually. For details in calculation, see the section “[Statistical Diagnostic Tests](#)” on page 144.

Autocorrelation

The “Autocorrelations” table (ODS table name AUTOCORR) contains the first order autocorrelations of the posterior samples for each parameter. The “Parameter” column states the name of the parameter. By default,

PROC MCMC displays lag 1, 5, 10, and 50 estimates of the autocorrelations. You can request different autocorrelations by using the **DIAGNOSTICS = AUTOCORR(LAGS=)** option. This table is displayed by default.

Effective Sample Size

The “Effective Sample Sizes” table (ODS table name ESS) calculates the effective sample size of each parameter. See the section “[Effective Sample Size](#)” on page 152 for more details. The table is displayed by default.

Monte Carlo Standard Errors

The “Monte Carlo Standard Errors” table (ODS table name MCSE) calculates the standard errors of the posterior mean estimate. See the section “[Standard Error of the Mean Estimate](#)” on page 153 for more details. The table is displayed by default.

Geweke Diagnostics

The “Geweke Diagnostics” table (ODS table name Geweke) lists the result of the Geweke diagnostic test. See the section “[Geweke Diagnostics](#)” on page 146 for more details. The table is displayed by default.

Heidelberger-Welch Diagnostics

The “Heidelberger-Welch Diagnostics” table (ODS table name Heidelberger) lists the result of the Heidelberger-Welch diagnostic test. The test is consisted of two parts: a stationary test and a half-width test. See the section “[Heidelberger and Welch Diagnostics](#)” on page 148 for more details. The table is not displayed by default and can be requested by specifying **DIAGNOSTICS = HEIDEL**.

Raftery-Lewis Diagnostics

The “Raftery-Lewis Diagnostics” table (ODS table name Raftery) lists the result of the Raftery-Lewis diagnostic test. See the section “[Raftery and Lewis Diagnostics](#)” on page 149 for more details. The table is not displayed by default and can be requested by specifying **DIAGNOSTICS = RAFTERY**.

Summary Statistics for Prediction

The “Posterior Summaries for Prediction” table (ODS table name PredSummaries) contains basic statistics for each prediction. The table lists the number of posterior samples, the posterior mean and standard deviation estimates, and the percentile estimates. This table is displayed by default if any **PREDDIST** statement is used in the program.

Interval Statistics for Prediction

The “Posterior Intervals for Prediction” table (ODS table name PredIntervals) contains the equal-tail and highest posterior density (HPD) interval estimates for each prediction. The default α value is 0.05, and you can change it to other levels by using the **STATISTICS** option in a **PREDDIST** statement, or the **STATISTICS=** option in the PROC MCMC statement if the option is not specified in a statement. This table is displayed by default if any **PREDDIST** statement is used in the program.

Optimization Related ODS Tables

PROC MCMC can perform optimization on the joint posterior distribution. This is requested by the **PROPCOV=** option. The most commonly used optimization method is the quasi-Newton method: **PROPCOV=QUANEW(ITPRINT)**. The **ITPRINT** option displays the ODS tables, listed as follows:

Input Options

The “Input Options” table (ODS table name InputOptions) lists optimization options used in the procedure.

Optimization Start

The “Optimization Start” table (ODS table name ProblemDescription) shows the initial state of the optimization.

Iteration History

The “Iteration History” table (ODS table name IterHist) shows iteration history of the optimization.

Optimization Results

The “Optimization Results” table (ODS table name IterStop) shows the results of the optimization, includes information about the number of function calls, and the optimized objective function, which is the joint log posterior density.

Convergence Status

The “Convergence Status” table (ODS table name ConvergenceStatus) shows whether the convergence criterion is satisfied.

Parameters Value After Optimization Table

The “Parameter Values After Optimization” table (ODS table name OptiEstimates) lists the parameter values that maximize the joint log posterior. These are the maximum a posteriori point estimates, and they are used to start the Markov chain.

Covariance Matrix After Optimization Table

The “Proposal Covariance” table (ODS table name OptiCov) lists covariance matrices for each block parameter by using quadrature approximation at the posterior mode. These covariance matrices are used in the proposal distribution.

ODS Table Names

PROC MCMC assigns a name to each table it creates. You can use these names to refer to the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 55.47](#). For more information about ODS, see Chapter 21, “[Statistical Graphics Using ODS](#).”

Table 55.47 ODS Tables Produced in PROC MCMC

ODS Table Name	Description	Statement or Option
AutoCorr	Autocorrelation statistics for each parameter	Default
BurnInHistory	History of burn-in phase sampling	MCHISTORY=BRIEF DETAILED
ConvergenceStatus	Optimization convergence status	PROPCOV=method(ITPRINT)
Corr	Correlation matrix of the posterior samples	STATS=CORR

Table 55.47 (continued)

ODS Table Name	Description	Statement or Option
Cov	Covariance matrix of the posterior samples	STATS=COV
DIC	Deviance information criterion	DIC
ESS	Effective sample size for each parameter	Default
MCSE	Monte Carlo standard error for each parameter	Default
Geweke	Geweke diagnostics for each parameter	Default
Heidelberger	Heidelberger-Welch diagnostics for each parameter	DIAGNOSTICS=HEIDEL
InputOptions	Optimization input table	PROPCOV=method(ITPRINT)
IterHist	Optimization iteration history	PROPCOV=method(ITPRINT)
IterStop	Optimization results table	PROPCOV=method(ITPRINT)
MissDataInfo	Response variable, number of missing observations, missing observation indices, and sampling algorithm	Default with sampling of missing values
NObs	Number of observations	Default
OptiEstimates	Parameter values after either optimization	PROPCOV=method(ITPRINT)
OptiCov	Covariance used in proposal distribution after optimization	PROPCOV=method(ITPRINT)
Parameters	Summary of the PARMS, BLOCKING, PRIOR, sampling method, and initial value specification	Default
ParametersInit	Parameter values after the tuning phase	INIT=PINIT
PosteriorSample	Posterior samples for each parameter	(For ODS output data set only)
PostIntervals	Equal-tail and HPD intervals for each parameter	Default
PostSummaries	Basic posterior statistics for each parameter, including sample size, mean, standard deviation, and percentiles	Default
PredIntervals	Equal-tail and HPD intervals for each prediction	Default with any PREDDIST statement
PredSummaries	Basic posterior statistics for each prediction	Default with any PREDDIST statement
ProblemDescription	Optimization table	PROPCOV=method(ITPRINT)
REObsInfo	Random effect, subject values, number of observations in each unique subject value, and corresponding observation indices	REOBSINFO

Table 55.47 (continued)

ODS Table Name	Description	Statement or Option
REParameters	Random effect, sampling method, subject variable, number of subjects, unique values of the subject variable, and prior distribution of the random effect	Default with any RANDOM statement
Raftery	Raftery-Lewis diagnostics for each parameter	DIAGNOSTICS=RAFTERY
SamplingHistory TuneCov	History of main phase sampling Proposal covariance matrix (for continuous parameters) after the tuning phase	MCHISTORY=BRIEF DETAILED INIT=PINIT
TuneP	Proposal probability vector (for discrete parameters) after the tuning phase	INIT=PINIT and DISCRETE=GEO
TuningHistory	History of proposal distribution tuning	MCHISTORY=BRIEF DETAILED

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS.](#)”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC MCMC generates are listed in [Table 55.48](#).

Table 55.48 Graphs Produced by PROC MCMC

ODS Graph Name	Plot Description	Statement & Option
ADPanel	Autocorrelation function and density panel	PLOTS=(AUTOCORR DENSITY)
AutocorrPanel	Autocorrelation function panel	PLOTS=AUTOCORR
AutocorrPlot	Autocorrelation function plot	PLOTS(UNPACK)=AUTOCORR
DensityPanel	Density panel	PLOTS=DENSITY
DensityPlot	Density plot	PLOTS(UNPACK)=DENSITY

Examples: MCMC Procedure

Example 55.1: Simulating Samples From a Known Density

This example illustrates how you can obtain random samples from a known function. The target distributions are the normal distribution (a standard distribution) and a mixture of the normal distributions (a nonstandard distribution). For more information, see the sections “[Standard Distributions](#)” on page 4476 and “[Specifying a New Distribution](#)” on page 4490). This example also shows how you can use PROC MCMC to estimate an integral (area under a curve). Monte Carlo simulation is data-independent; hence, you do not need an input data set from which to draw random samples from the desired distribution.

Sampling from a Normal Density

When you run a simulation without an input data set, the posterior distribution is the same as the prior distribution. Hence, if you want to generate samples from a distribution, you declare the distribution in the **PRIOR** statement and set the likelihood function to a constant. Although there is no contribution from any data set variable to the likelihood calculation, you still must specify a data set and the **MODEL** statement needs a distribution. You can input an empty data set and use the **GENERAL** function to provide a flat likelihood. The following statements generate 10,000 samples from a standard normal distribution:

```

title 'Simulating Samples from a Normal Density';
data x;
run;

ods graphics on;
proc mcmc data=x outpost=simout seed=23 nmc=10000
    statistics=(summary interval) diagnostics=none;
    ods exclude nob;
    parm alpha 0;
    prior alpha ~ normal(0, sd=1);
    model general(0);
run;
```

The ODS GRAPHICS ON statement enables ODS Graphics. The PROC MCMC statement specifies the input and output data sets, a random number seed, and the size of the simulation sample. The **STATISTICS=** option displays only the summary and interval statistics. The ODS EXCLUDE statement excludes the display of the NObs table. PROC MCMC draws independent samples from the normal distribution directly (see [Output 55.1.1](#)). Therefore, the simulation does not require any tuning, and PROC MCMC omits the default burn-in phrase.

Output 55.1.1 Parameters Information

Simulating Samples from a Normal Density				
The MCMC Procedure				
Parameters				
Block	Parameter	Sampling Method	Initial Value	Prior Distribution
1	alpha	Direct	0	normal(0, sd=1)

The summary statistics ([Output 55.1.2](#)) are what you would expect from a standard normal distribution.

Output 55.1.2 MCMC Summary and Interval Statistics from a Normal Target Distribution

Simulating Samples from a Normal Density						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
alpha	10000	0.00195	0.9949	-0.6544	0.00965	0.6709
Posterior Intervals						
Parameter	Alpha	Equal-Tail Interval		HPD Interval		
alpha	0.050	-1.9485	1.9507	-1.9664	1.9302	

The trace plot ([Output 55.1.3](#)) shows perfect mixing with no autocorrelation in the lag plot. This is expected because these are independent draws.

Output 55.1.3 Diagnostics Plots for α 

You can overlay the estimated kernel density with the true density to visually compare the densities, as displayed in [Output 55.1.4](#). To create the kernel comparison plot, you first call PROC KDE (see Chapter 48, “[The KDE Procedure](#)”) to obtain a kernel density estimate of the posterior density on α . Then you evaluate a grid of α values on a normal density. The following statements evaluate kernel density and compute the corresponding normal density:

```
proc kde data=simout;
  ods exclude inputs controls;
  univar alpha /out=sample;
run;

data den;
  set sample;
  alpha = value;
  true = pdf('normal', alpha, 0, 1);
  keep alpha density true;
run;
```

Next you plot the two curves on top of each other by using PROC SGPLOT (see Chapter 21, “[Statistical Graphics Using ODS](#)”) as follows:

```
proc sgplot data=den;
  yaxis label="Density";
  series y=density x=alpha / legendlabel = "MCMC Kernel";
  series y=true x=alpha / legendlabel = "True Density";
  discretelegend;
run;
```

[Output 55.1.4](#) shows the result. You can see that the kernel estimate and the true density are very similar to each other.

Output 55.1.4 Estimated Density versus the True Density

Density Visualization Macro

In programs that do not involve any data set variables, PROC MCMC samples directly from the (joint) prior distributions of the parameters. The modification makes the sampling from a known distribution more efficient and more precise. For example, you can write simple programs, such as the following macro, to understand different aspects of a prior distribution of interest, such as its moments, intervals, shape, spread, and so on:

```

%macro density(dist=, seed=0);
  %let savenote = %sysfunc(getoption(notes));
  options nonotes;
  title "&dist distribution.";
  data _a;
  run;

  ods select densitypanel postsummaries postintervals;
  proc mcmc data=_a nmc=10000 diag=none nologdist
    plots=density seed=&seed;
    parms alpha;
    prior alpha ~ &dist;
    model general(0);
  run;

  proc datasets nolist;
    delete _a;
  run;
  options &savenote;
%mend;

%density(dist=beta(4, 12), seed=1);

```

The macro %density creates an empty data set, invokes PROC MCMC, draws 10,000 samples from a beta(4, 12) distribution, displays summary and interval statistics, and generates a kernel density plot. Summary and interval statistics from the beta distribution are displayed in [Output 55.1.5](#).

Output 55.1.5 Beta Distribution Statistics

beta(4, 12) distribution.						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
alpha	10000	0.2494	0.1039	0.1731	0.2397	0.3148
Posterior Intervals						
Parameter	Alpha	Equal-Tail Interval		HPD Interval		
alpha	0.050	0.0775	0.4800	0.0657	0.4590	

The distribution is displayed in [Output 55.1.6](#).

Output 55.1.6 Density Plot

Calculation of Integrals

One advantage of MCMC methods is to estimate any integral under the curve of a target distribution. This can be done fairly easily using the MCMC procedure. Suppose you are interested in estimating the following cumulative probability:

$$\int_{\alpha=0}^{1.3} \phi(\alpha|0, 1) d\alpha$$

To estimate this integral, PROC MCMC draws samples from the distribution and counts the portion of the simulated values that fall within the desired range of [0, 1.3]. This becomes a Monte Carlo estimate of the integral. The following statements simulate samples from a standard normal distribution and estimate the integral:

```
proc mcmc data=x outpost=simout seed=23 nmc=10000 nologdist
  monitor=(int) statistics=(summary) diagnostics=none;
  ods select postsummaries;
  parm alpha 0;
  prior alpha ~ normal(0, sd=1);
  int = (0 <= alpha <= 1.3);
  model general(0);
run;
```

The ODS SELECT statement displays the posterior summary statistics table. The **MONITOR=** option outputs analysis on the variable int (the integral estimate). The **STATISTICS=** option computes the summary

statistics. The **NOLOGDIST** option omits the calculation of the log of the prior distribution at each iteration, shortening the simulation time⁸. The **INT** assignment statement sets **int** to be 1 if the simulated **alpha** value falls between 0 and 1.3, and 0 otherwise. PROC MCMC supports the usage of the IF-ELSE logical control if you need to account for more complex conditions. [Output 55.1.7](#) displays the estimated integral value:

Output 55.1.7 Monte Carlo Integral from a Normal Distribution

beta(4, 12) distribution.						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	25%	50%	75%
int	10000	0.4079	0.4915	0	0	1.0000

In this simulation, 4079 samples fall between 0 and 1.3, making the expected probability 0.4079. In this example, you can verify the actual cumulative probability by calling the CDF function in the DATA step:

```
data _null_;
  int = cdf("normal", 1.3, 0, 1) - cdf("normal", 0, 0, 1);
  put int=;
run;
```

The value is 0.4032.

Sampling from a Mixture of Normal Densities

Suppose you are interested in generating samples from a three-component mixture of normal distributions, with the density specified as follows:

$$p(\alpha) = 0.3 \cdot \phi(-3, \sigma = 2) + 0.4 \cdot \phi(2, \sigma = 1) + 0.3 \cdot \phi(10, \sigma = 4)$$

The distribution is not one of the standard distributions that PROC MCMC supports. Hence you need to construct the density function and supply it to the procedure. The following statements generate random samples from this mixture density:

```
title 'Simulating Samples from a Mixture of Normal Densities';
data x;
run;

proc mcmc data=x outpost=simout seed=1234 nmc=30000;
  ods select TADpanel;
  parm alpha 0.3;
  lp = logpdf('normalmix', alpha, 3, 0.3, 0.4, 0.3, -3, 2, 10, 2, 1, 4);
  prior alpha ~ general(lp);
  model general(0);
run;
```

⁸In this example, the **NOLOGDIST** option saves only a fraction of the time. But in more complex simulation schemes that involve a larger number of distributions and parameters, the time reduction could be significant.

The ODS SELECT statement displays the diagnostic plots. All other tables, such as the **NObs** tables, are excluded. The PROC MCMC statement uses the input data set X, saves output to the Simout data set, sets a random number seed, and draws 30,000 samples.

The LP assignment statement evaluates the log density of alpha at the mixture density, using the SAS function LOGPDF. The number 3 after alpha in the LOGPDF function indicates that the density is a three-component normal mixture. The following three numbers, 0.3, 0.4, and 0.3, are the weights in the mixture; -3, 2, and 10 are the means; 2, 1, and 4 are the standard deviations. The **PRIOR** statement assigns this log density function to alpha as its prior. Note that the **GENERAL** function interprets the density on the log scale, and not the original scale—you must use the LOGPDF function, not the PDF function. **Output 55.1.8** displays the results. The kernel density clearly shows three modes.

Output 55.1.8 Plots of Posterior Samples from a Mixture Normal Distribution

Using the following set of statements similar to the previous example, you can overlay the estimated kernel density with the true density. The comparison is shown in **Output 55.1.9**.

```
proc kde data=simout;
  ods exclude inputs controls;
  univar alpha /out=sample;
run;

data den;
  set sample;
  alpha = value;
  true = pdf('normalmix', alpha, 3, 0.3, 0.4, 0.3, -3, 2, 10, 2, 1, 4);
  keep alpha density true;
run;
```

```

proc sgplot data=den;
  yaxis label="Density";
  series y=density x=alpha / legendlabel = "MCMC Kernel";
  series y=true x=alpha / legendlabel = "True Density";
  discretelegend;
run;

```

Output 55.1.9 Estimated Density versus the True Density

Example 55.2: Box-Cox Transformation

Box-Cox transformations (Box and Cox 1964) are often used to find a power transformation of a dependent variable to ensure the normality assumption in a linear regression model. This example illustrates how you can use PROC MCMC to estimate a Box-Cox transformation for a linear regression model. Two different priors on the transformation parameter λ are considered: a continuous prior and a discrete prior. You can estimate the probability of λ being 0 with a discrete prior but not with a continuous prior. The IF-ELSE statements are demonstrated in the example.

Using a Continuous Prior on λ

The following statements create a SAS data set with measurements of y (the response variable) and x (a single dependent variable):

```

title 'Box-Cox Transformation, with a Continuous Prior on Lambda';
data boxcox;
  input y x @@;
  datalines;
10.0  3.0  72.6  8.3  59.7  8.1  20.1  4.8  90.1  9.8  1.1  0.9
78.2  8.5  87.4  9.0  9.5  3.4  0.1  1.4  0.1  1.1  42.5  5.1
57.0  7.5  9.9  1.9  0.5  1.0 121.1  9.9  37.5  5.9  49.5  6.7

... more lines ...

2.6  1.8  58.6  7.9  81.2  8.1  37.2  6.9
;

```

The Box-Cox transformation of y takes on the form of:

$$y(\lambda) = \begin{cases} \frac{y^\lambda - 1}{\lambda} & \text{if } \lambda \neq 0; \\ \log(y) & \text{if } \lambda = 0. \end{cases}$$

The transformed response $y(\lambda)$ is assumed to be normally distributed:

$$y_i(\lambda) \sim \text{normal}(\beta_0 + \beta_1 x_i, \sigma^2)$$

The likelihood with respect to the original response y_i is as follows:

$$p(y_i | \lambda, \beta, \sigma^2, x_i) \propto \phi(y_i | \beta_0 + \beta_1 x_i, \sigma^2) \cdot J(\lambda, y_i)$$

where $J(\lambda, y_i)$ is the Jacobian:

$$J(\lambda, y) = \begin{cases} y_i^{\lambda-1} & \text{if } \lambda \neq 0; \\ 1/y_i & \text{if } \lambda = 0. \end{cases}$$

And on the log-scale, the Jacobian becomes:

$$\log(J(\lambda, y)) = \begin{cases} (\lambda - 1) \cdot \log(y_i) & \text{if } \lambda \neq 0; \\ -\log(y_i) & \text{if } \lambda = 0. \end{cases}$$

There are four model parameters: λ , $\boldsymbol{\beta} = \{\beta_0, \beta_1\}$, and σ^2 . You can consider using a flat prior on $\boldsymbol{\beta}$ and a gamma prior on σ^2 .

To consider only power transformations ($\lambda \neq 0$), you can use a continuous prior (for example, a uniform prior from -2 to 2) on λ . One issue with using a continuous prior is that you cannot estimate the probability of $\lambda = 0$. To do so, you need to consider a discrete prior that places positive probability mass on the point 0. See “[Modeling \$\lambda = 0\$](#) ” on page 4553.

The following statements fit a Box-Cox transformation model:

```

ods graphics on;
proc mcmc data=boxcox nmc=50000 thin=10 propcov=quanew seed=12567
    monitor=(lda);
    ods select PostSummaries PostIntervals TADpanel;

    parms beta0 0  beta1 0  lda 1 s2 1;

    beginnodata;
    prior beta: ~ general(0);
    prior s2 ~ gamma(shape=3, scale=2);
    prior lda ~ unif(-2,2);
    sd = sqrt(s2);
    endnodata;

    ys = (y**lda-1)/lda;
    mu = beta0+beta1*x;
    ll = (lda-1)*log(y)+lpdfnorm(ys, mu, sd);
    model general(ll);
run;

```

The **PROPCOV=** option initializes the Markov chain at the posterior mode and uses the estimated inverse Hessian matrix as the initial proposal covariance matrix. The **MONITOR=** option selects λ as the variable to report. The ODS SELECT statement displays the summary statistics table, the interval statistics table, and the diagnostic plots.

The **PARMS** statement puts all four parameters, β_0 , β_1 , λ , and σ^2 , in a single block and assigns initial values to each of them. Three **PRIOR** statements specify previously stated prior distributions for these parameters. The assignment to **sd** transforms a variance to a standard deviation. It is better to place the transformation inside the **BEGINNODATA** and **ENDNODATA** statements to save computational time.

The assignment to the symbol **ys** evaluates the Box-Cox transformation of y , where μ is the regression mean and ll is the log likelihood of the transformed variable ys . Note that the log of the Jacobian term is included in the calculation of ll .

Summary statistics and interval statistics for λ are listed in [Output 55.2.1](#).

Output 55.2.1 Box-Cox Transformation

Box-Cox Transformation, with a Continuous Prior on Lambda						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles 25%	50%	75%
lda	5000	0.4702	0.0284	0.4515	0.4703	0.4884

Output 55.2.1 *continued*

Parameter	Posterior Intervals			
	Alpha	Equal-Tail Interval		HPD Interval
lda	0.050	0.4162	0.5269	0.4197 0.5298

The posterior mean of λ is 0.47, with a 95% equal-tail interval of [0.42, 0.53] and a similar HPD interval. The preferred power transformation would be 0.5 (rounding λ up to the square root transformation).

Output 55.2.2 shows diagnostics plots for lda. The chain appears to converge, and you can proceed to make inferences. The density plot shows that the posterior density is relatively symmetric around its mean estimate.

Output 55.2.2 Diagnostic Plots for λ 

To verify the results, you can use PROC TRANSREG (see Chapter 97, “[The TRANSREG Procedure](#)”) to find the estimate of λ .

```
proc transreg data=boxcox details pbo;
  ods output boxcox = bc;
  model boxcox(y / convenient lambda=-2 to 2 by 0.01) = identity(x);
  output out=trans;
run;
```

Output from PROC TRANSREG is shown in [Output 55.2.5](#) and [Output 55.2.4](#). PROC TRANSREG produces a similar point estimate of $\lambda = 0.46$, and the 95% confidence interval is shown in [Output 55.2.5](#).

Output 55.2.3 Box-Cox Transformation Using PROC TRANSREG

Output 55.2.4 Estimates Reported by PROC TRANSREG

Box-Cox Transformation, with a Continuous Prior on Lambda				
The TRANSREG Procedure				
Model Statement Specification Details				
Type	DF	Variable	Description	Value
Dep	1	BoxCox(y)	Lambda Used	0.5
			Lambda	0.46
			Log Likelihood	-167.0
			Conv. Lambda	0.5
			Conv. Lambda LL	-168.3
			CI Limit	-169.0
			Alpha	0.05
			Options	Convenient Lambda Used
Ind	1	Identity(x)	DF	1

The ODS data set Bc contains the 95% confidence interval estimates produced by PROC TRANSREG. This ODS table is rather large, and you want to see only the relevant portion. The following statements generate the part of the table that is important and display [Output 55.2.5](#):

```
proc print noobs label data=bc(drop=rmse);
  title2 'Confidence Interval';
  where ci ne ' ' or abs(lambda - round(lambda, 0.5)) < 1e-6;
  label convenient = '00'x ci = '00'x;
run;
```

The estimated 90% confidence interval is [0.41, 0.51], which is very close to the reported Bayesian credible intervals. The resemblance of the intervals is probably due to the noninformative prior that you used in this analysis.

Output 55.2.5 Estimated Confidence Interval on λ

Box-Cox Transformation, with a Continuous Prior on Lambda				
Confidence Interval

BoxCox(y)	0.49	0.95	-167.79	*
BoxCox(y)	0.50	+	-168.28	*
BoxCox(y)	0.51	0.95	-168.89	*
BoxCox(y)	1.00	0.89	-253.09	
BoxCox(y)	1.50	0.79	-345.35	
BoxCox(y)	2.00	0.70	-435.01	

Modeling $\lambda = 0$

With a continuous prior on λ , you can get only a continuous posterior distribution, and this makes the probability of $\Pr(\lambda = 0|\text{data})$ equal to 0 by definition. To consider $\lambda = 0$ as a viable solution to the Box-Cox transformation, you need to use a discrete prior that places some probability mass on the point 0 and allows for a meaningful posterior estimate of $\Pr(\lambda = 0|\text{data})$.

This example uses a simulation study where the data are generated from an exponential likelihood. The simulation implies that the correct transformation should be the logarithm and λ should be 0. Consider the

following exponential model:

$$y = \exp(x + \epsilon),$$

where $\epsilon \sim \text{normal}(0, 1)$. The transformed data can be fitted with a linear model:

$$\log(y) = x + \epsilon$$

The following statements generate a SAS data set with a gridded x and corresponding y :

```
title 'Box-Cox Transformation, Modeling Lambda = 0';
data boxcox;
  do x = 1 to 8 by 0.025;
    ly = x + normal(7);
    y = exp(ly);
    output;
  end;
run;
```

The log-likelihood function, after taking the Jacobian into consideration, is as follows:

$$\log p(y_i | \lambda, x_i) = \begin{cases} (\lambda - 1) \log(y_i) - \frac{1}{2} \left(\log \sigma^2 + \frac{((y_i^\lambda - 1)/\lambda - x_i)^2}{\sigma^2} \right) + C_1 & \text{if } \lambda \neq 0; \\ -\log(y_i) - \frac{1}{2} \left(\log \sigma^2 + \frac{(\log(y_i) - x_i)^2}{\sigma^2} \right) + C_2 & \text{if } \lambda = 0. \end{cases}$$

where C_1 and C_2 are two constants.

You can use the function [DGENERAL](#) to place a discrete prior on λ . The function is similar to the function [GENERAL](#), except that it indicates a discrete distribution. For example, you can specify a discrete uniform prior from -2 to 2 using

```
prior lda ~ dgeneral(1, lower=-2, upper=2);
```

This places equal probability mass on five points, -2 , -1 , 0 , 1 , and 2 . This prior might not work well here because the grid is too coarse. To consider smaller values of λ , you can sample a parameter that takes a wider range of integer values and transform it back to the λ space. For example, set α as your model parameter and give it a discrete uniform prior from -200 to 200 . Then define λ as $\alpha/100$ so λ can take values between -2 and 2 but on a finer grid.

The following statements fit a Box-Cox transformation by using a discrete prior on λ :

```
proc mcmc data=boxcox outpost=simout nmc=50000 thin=10 seed=12567
  monitor=(lda);

ods select PostSummaries PostIntervals;
parms s2 1 alpha 10;

beginnodata;
prior s2 ~ gamma(shape=3, scale=2);
if alpha=0 then lp = log(2);
  else lp = log(1);
prior alpha ~ dgeneral(lp, lower=-200, upper=200);
lda = alpha * 0.01;
sd = sqrt(s2);
endnodata;
```

```

if alpha=0 then
  ll = -ly+lpdfnorm(ly, x, sd);
else do;
  ys = (y**lda - 1)/lda;
  ll = (lda-1)*ly+lpdfnorm(ys, x, sd);
end;
model general(ll);
run;

```

There are two parameters, `s2` and `alpha`, in the model. They are placed in a single **PARMS** statement so that they are sampled in the same block.

The parameter `s2` takes a gamma distribution, and `alpha` takes a discrete prior. The IF-ELSE statements state that `alpha` takes twice as much prior density when it is 0 than otherwise. Note that on the original scale, $\Pr(\alpha = 0) = 2 \cdot \Pr(\alpha \neq 0)$. Translating that to the log scale, the densities become $\log(2)$ and $\log(1)$, respectively. The LDA assignment statement transforms `alpha` to the parameter of interest: `lda` takes values between -2 and 2 . You can model `lda` on an even smaller scale by dividing `alpha` by a larger constant. However, an increment of 0.01 in the Box-Cox transformation is usually sufficient. The SD assignment statement calculates the square root of the variance term.

The log-likelihood function uses another set of IF-ELSE statements, separating the case of $\lambda = 0$ from the others. The formulas are stated previously. The output of the program is shown in [Output 55.2.6](#).

Output 55.2.6 Box-Cox Transformation

Box-Cox Transformation, Modeling Lambda = 0						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
lda	5000	-0.00002	0.00201	0	0	0
Posterior Intervals						
Parameter	Alpha	Equal-Tail Interval		HPD Interval		
lda	0.050	0	0	0	0	0

From the summary statistics table, you see that the point estimate for λ is 0 and both of the 95% equal-tail and HPD credible intervals are 0. This strongly suggests that $\lambda = 0$ is the best estimate for this problem. In addition, you can also count the frequency of λ among posterior samples to get a more precise estimate on the posterior probability of λ being 0.

The following statements use PROC FREQ to produce [Output 55.2.7](#) and [Output 55.2.8](#):

```
proc freq data=simout;
  ods select onewayfreqs freqplot;
  tables lda /nocum plot=freqplot(scale=percent);
run;
ods graphics off;
```

Output 55.2.7 shows the frequency count table. An estimate of $\Pr(\lambda = 0|\text{data})$ is 96%. The conclusion is that the log transformation should be the appropriate transformation used here, which agrees with the simulation setup. Output 55.2.8 shows the histogram of λ .

Output 55.2.7 Frequency Counts of λ

Box-Cox Transformation, Modeling Lambda = 0		
The FREQ Procedure		
lda	Frequency	Percent
-0.0100	106	2.12
0	4798	95.96
0.0100	96	1.92

Output 55.2.8 Histogram of λ

Example 55.3: Logistic Regression Model with a Diffuse Prior

This example illustrates how to fit a logistic regression model with a diffuse prior in PROC MCMC. You can also use the BAYES statement in PROC GENMOD. See Chapter 40, “[The GENMOD Procedure](#).”

The following statements create a SAS data set with measurements of the number of deaths, y , among n beetles that have been exposed to an environmental contaminant x :

```

title 'Logistic Regression Model with a Diffuse Prior';
data beetles;
  input n y x @@;
  datalines;

```

You can model the data points y_i with a binomial distribution,

$$y_i | p_i \sim \text{binomial}(n_i, p_i)$$

where p_i is the success probability and links to the regression covariate x_i through a logit transformation:

$$\text{logit}(p_i) = \log\left(\frac{p_i}{1 - p_i}\right) = \alpha + \beta x_i$$

The priors on α and β are both diffuse normal:

$$\begin{aligned} \alpha &\sim \text{normal}(0, \text{var} = 10000) \\ \beta &\sim \text{normal}(0, \text{var} = 10000) \end{aligned}$$

These statements fit a logistic regression with PROC MCMC:

```

ods graphics on;
proc mcmc data=beetles ntu=1000 nmc=20000 nthin=2 propcov=quanew
  diag=(mcse ess) outpost=beetleout seed=246810;
  ods select PostSummaries PostIntervals mcse ess TADpanel;
  parms (alpha beta) 0;
  prior alpha beta ~ normal(0, var = 10000);
  p = logistic(alpha + beta*x);
  model y ~ binomial(n,p);
run;

```

The key statement in the program is the assignment to p that calculates the probability of death. The SAS function LOGISTIC does the proper transformation. The **MODEL** statement specifies that the response variable, y , is binomially distributed with parameters n (from the input data set) and p . The summary statistics table, interval statistics table, the Monte Carlo standard error table, and the effective sample sizes table are shown in [Output 55.3.1](#).

Output 55.3.1 MCMC Results

Logistic Regression Model with a Diffuse Prior						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	25%	Percentiles 50%	75%
alpha	10000	-11.7707	2.0997	-13.1243	-11.6683	-10.3003
beta	10000	0.2920	0.0542	0.2537	0.2889	0.3268
Posterior Intervals						
Parameter	Alpha	Equal-Tail Interval		HPD Interval		
alpha	0.050	-16.3332	-7.9675	-15.8822	-7.6673	
beta	0.050	0.1951	0.4087	0.1901	0.4027	
Logistic Regression Model with a Diffuse Prior						
The MCMC Procedure						
Monte Carlo Standard Errors						
Parameter	MCSE	Standard Deviation		MCSE/SD		
alpha	0.0422	2.0997		0.0201		
beta	0.00110	0.0542		0.0203		
Effective Sample Sizes						
Parameter	ESS	Autocorrelation Time		Efficiency		
alpha	2470.1	4.0484		0.2470		
beta	2435.4	4.1060		0.2435		

The summary statistics table shows that the sample mean of the output chain for the parameter alpha is -11.7707. This is an estimate of the mean of the marginal posterior distribution for the intercept parameter alpha. The estimated posterior standard deviation for alpha is 2.0997. The two 95% credible intervals for alpha are both negative, which indicates with very high probability that the intercept term is negative. On the other hand, you observe a positive effect on the regression coefficient beta. Exposure to the environment contaminant increases the probability of death.

The Monte Carlo standard errors of each parameter are significantly small relative to the posterior standard deviations. A small MCSE/SD ratio indicates that the Markov chain has stabilized and the mean estimates do not vary much over time. Note that the precision in the parameter estimates increases with the square of the MCMC sample size, so if you want to double the precision, you must quadruple the MCMC sample size.

MCMC chains do not produce independent samples. Each sample point depends on the point before it. In this case, the correlation time estimate, read from the effective sample sizes table, is roughly 4. This means that it takes four observations from the MCMC output to make inferences about α with the same precision that you would get from using an independent sample. The effective sample size of 2470 reflects this loss of efficiency. The coefficient β has similar efficiency. You can often observe that some parameters have significantly better mixing (better efficiency) than others, even in a single Markov chain run.

Output 55.3.2 Plots for Parameters in the Logistic Regression Example

Output 55.3.2 continued

Trace plots and autocorrelation plots of the posterior samples are shown in [Output 55.3.2](#). Convergence looks good in both parameters; there is good mixing in the trace plot and quick drop-off in the ACF plot.

One advantage of Bayesian methods is the ability to directly answer scientific questions. In this example, you might want to find out the posterior probability that the environmental contaminant increases the probability of death—that is, $\Pr(\beta > 0|y)$. This can be estimated using the following steps:

```
proc format;
  value betafmt low=0 = 'beta <= 0' 0<-high = 'beta > 0';
run;

proc freq data=beetleout;
  tables beta /nocum;
  format beta betafmt.;
run;
```

Output 55.3.3 Frequency Counts

Logistic Regression Model with a Diffuse Prior		
The FREQ Procedure		
beta	Frequency	Percent

beta > 0	10000	100.00

All of the simulated values for β are greater than zero, so the sample estimate of the posterior probability that $\beta > 0$ is 100%. The evidence overwhelmingly supports the hypothesis that increased levels of the environmental contaminant increase the probability of death.

If you are interested in making inference based on any quantities that are transformations of the random variables, you can either do it directly in PROC MCMC or by using the DATA step after you run the simulation. Transformations sometimes can make parameter inference quite formidable using direct analytical methods, but with simulated chains, it is easy to compute chains for any set of parameters. Suppose you are interested in the lethal dose and want to estimate the level of the covariate x that corresponds to a probability of death, p . Abbreviate this quantity as ldp . In other words, you want to solve the logit transformation with a fixed value p . The lethal dose is as follows:

$$ldp = \frac{\log\left(\frac{p}{1-p}\right) - \alpha}{\beta}$$

You can obtain an estimate of any ldp by using the posterior mean estimates for α and β . For example, $lp95$, which corresponds to $p = 0.95$, is calculated as follows:

$$lp95 = \frac{\log\left(\frac{0.95}{1-0.95}\right) + 11.77}{0.29} = 50.79$$

where -11.77 and 0.29 are the posterior mean estimates of α and β , respectively, and 50.79 is the estimated lethal dose that leads to a 95% death rate.

While it is easy to obtain the point estimates, it is harder to estimate other posterior quantities, such as the standard deviation directly. However, with PROC MCMC, you can trivially get estimates of any posterior quantities of $lp95$. Consider the following program in PROC MCMC:

```
proc mcmc data=beetles ntu=1000 nmc=20000 nthin=2 propcov=quanew
    outpost=beetleout seed=246810 plot=density
    monitor=(pi30 ld05 ld50 ld95);
    ods select PostSummaries PostIntervals densitypanel;
    parms (alpha beta) 0;
    begincnst;
        c1 = log(0.05 / 0.95);
        c2 = -c1;
    endcnst;

    beginnodata;
    prior alpha beta ~ normal(0, var = 10000);
    pi30 = logistic(alpha + beta*30);
    ld05 = (c1 - alpha) / beta;
    ld50 = - alpha / beta;
    ld95 = (c2 - alpha) / beta;
    endnodata;
    pi = logistic(alpha + beta*x);
    model y ~ binomial(n,pi);
run;
ods graphics off;
```

The program estimates four additional posterior quantities. The three lpd quantities, ld05, ld50, and ld95, are the three levels of the covariate that kills 5%, 50%, and 95% of the population, respectively. The predicted probability when the covariate x takes the value of 30 is π_{30} . The **MONITOR=** option selects the quantities of interest. The **PLOTS=** option selects kernel density plots as the only ODS graphical output, excluding the trace plot and autocorrelation plot.

Programming statements between the **BEGINCNST** and **ENDCNST** statements define two constants. These statements are executed once at the beginning of the simulation. The programming statements between the **BEGINNODATA** and **ENDNODATA** statements evaluate the quantities of interest. The symbols, π_{30} , ld05, ld50, and ld95, are functions of the parameters alpha and beta only. Hence, they should not be processed at the observation level and should be included in the **BEGINNODATA** and **ENDNODATA** statements. [Output 55.3.4](#) lists the posterior summary and [Output 55.3.5](#) shows the density plots of these posterior quantities.

Output 55.3.4 PROC MCMC Results

Logistic Regression Model with a Diffuse Prior						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
π_{30}	10000	0.0524	0.0253	0.0340	0.0477	0.0662
ld05	10000	29.9281	1.8814	28.8430	30.1727	31.2563
ld50	10000	40.3745	0.9377	39.7271	40.3165	40.9612
ld95	10000	50.8210	2.5353	49.0372	50.5157	52.3100
Posterior Intervals						
Parameter	Alpha	Equal-Tail Interval		HPD Interval		
π_{30}	0.050	0.0161	0.1133	0.0109	0.1008	
ld05	0.050	25.6409	32.9660	26.2193	33.2774	
ld50	0.050	38.6706	42.3718	38.6194	42.2811	
ld95	0.050	46.7180	56.7667	46.3221	55.8774	

The posterior mean estimate of π_{95} is 50.82, which is close to the estimate of 50.79 by using the posterior mean estimates of the parameters. With PROC MCMC, in addition to the mean estimate, you can get the standard deviation, quantiles, and interval estimates at any level of significance.

From the density plots, you can see, for example, that the sample distribution for π_{30} is skewed to the right, and almost all of your posterior belief concerning π_{30} is concentrated in the region between zero and 0.15.

Output 55.3.5 Density Plots of Quantities of Interest in the Logistic Regression Example

It is easy to use the DATA step to calculate these quantities of interest. The following DATA step uses the simulated values of α and β to create simulated values from the posterior distributions of ld_{05} , ld_{50} , ld_{95} , and π_{30} :

```
data transout;
  set beetleout;
  pi30 = logistic(alpha + beta*30);
  ld05 = (log(0.05 / 0.95) - alpha) / beta;
  ld50 = (log(0.50 / 0.50) - alpha) / beta;
  ld95 = (log(0.95 / 0.05) - alpha) / beta;
run;
```

Subsequently, you can use SAS/INSIGHT, or the UNIVARIATE, CAPABILITY, or KDE procedures to analyze the posterior sample. If you want to regenerate the default ODS graphs from PROC MCMC, see “Regenerating Diagnostics Plots” on page 4505.

Example 55.4: Logistic Regression Model with Jeffreys' Prior

A controlled experiment was run to study the effect of the rate and volume of air inspired on a transient reflex vasoconstriction in the skin of the fingers. Thirty-nine tests under various combinations of rate and volume of air inspired were obtained (Finney 1947). The result of each test is whether or not vasoconstriction occurred. Pregibon (1981) uses this set of data to illustrate the diagnostic measures he proposes for detecting influential observations and to quantify their effects on various aspects of the maximum likelihood fit. The following statements create the data set Vaso:

```

title 'Logistic Regression Model with Jeffreys Prior';
data vaso;
  input vol rate resp @@;
  lvol = log(vol);
  lrate = log(rate);
  ind = _n_;
  cnst = 1;
  datalines;

0.95 1.9 0 0.75 1.9 0 1.3 1.625 1
;

```

The variable `resp` represents the outcome of a test. The variable `lvol` represents the log of the volume of air intake, and the variable `lrate` represents the log of the rate of air intake. You can model the data by using logistic regression. You can model the response with a binary likelihood:

$$\text{resp}_i \sim \text{binary}(p_i)$$

with

$$p_i = \frac{1}{1 + \exp(-(\beta_0 + \beta_1 \text{lvol}_i + \beta_2 \text{lrate}_i))}$$

Let \mathbf{X} be the design matrix in the regression. Jeffreys' prior for this model is

$$p(\boldsymbol{\beta}) \propto |\mathbf{X}'\mathbf{M}\mathbf{X}|^{1/2}$$

where \mathbf{M} is a 39 by 39 matrix with off-diagonal elements being 0 and diagonal elements being $p_i(1 - p_i)$. For details on Jeffreys' prior, see “[Jeffreys' Prior](#)” on page 129. You can use a number of matrix functions, such as the determinant function, in PROC MCMC to construct Jeffreys' prior. The following statements illustrate how to fit a logistic regression with Jeffreys' prior:

```

%let n = 39;
proc mcmc data=vaso nmc=10000 outpost=mcmcout seed=17;
  ods select PostSummaries PostIntervals;

  array beta[3] beta0 beta1 beta2;
  array m[&n, &n];
  array x[1] / nosymbols;
  array xt[3, &n];
  array xtm[3, &n];
  array xmx[3, 3];
  array p[&n];

  parms beta0 1 beta1 1 beta2 1;

```

```

begincnst;
  if (ind eq 1) then do;
    rc = read_array("vaso", x, "cnst", "lvol", "lrate");
    call transpose(x, xt);
    call zeromatrix(m);
  end;
endcnst;

beginnodata;
call mult(x, beta, p);          /* p = x * beta */
do i = 1 to &n;
  p[i] = 1 / (1 + exp(-p[i])); /* p[i] = 1/(1+exp(-x*beta)) */
  m[i,i] = p[i] * (1-p[i]);
end;
call mult (xt, m, xtm);          /* xtm = xt * m */
call mult (xtm, x, xmx);         /* xmx = xtm * x */
call det (xmx, lp);              /* lp = det(xmx) */
lp = 0.5 * log(lp);              /* lp = -0.5 * log(lp) */
prior beta: ~ general(lp);
endnodata;

model resp ~ bern(p[ind]);
run;

```

The first **ARRAY** statement defines an array `beta` with three elements: `beta0`, `beta1`, and `beta2`. The subsequent statements define arrays that are used in the construction of Jeffreys' prior. These include `m` (the **M** matrix), `x` (the design matrix), `xt` (the transpose of `x`), and some additional work spaces.

The explanatory variables `lvol` and `lrate` are saved in the array `x` in the **BEGINCNST** and **ENDCNST** statements. See “**BEGINCNST/ENDCNST Statement**” on page 4441 for details. After all the variables are read into `x`, you transpose the `x` matrix and store it to `xt`. The **ZEROMATRIX** function call assigns all elements in matrix `m` the value zero. To avoid redundant calculation, it is best to perform these calculations as the last observation of the data set is processed—that is, when `ind` is 39.

You calculate Jeffreys' prior in the **BEGINNODATA** and **ENDNODATA** statements. The probability vector `p` is the product of the design matrix `x` and parameter vector `beta`. The diagonal elements in the matrix `m` are $p_i(1 - p_i)$. The expression `lp` is the logarithm of Jeffreys' prior. The **PRIOR** statement assigns `lp` as the prior for the β regression coefficients. The **MODEL** statement assigns a binary likelihood to `resp`, with probability `p[ind]`. The `p` array is calculated earlier using the matrix function **MULT**. You use the `ind` variable to pick out the right probability value for each `resp`.

Posterior summary statistics are displayed in [Output 55.4.1](#).

Output 55.4.1 PROC MCMC Results, Jeffreys' prior

Logistic Regression Model with Jeffreys Prior						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	25%	Percentiles 50%	75%
beta0	10000	-2.9587	1.3258	-3.8117	-2.7938	-2.0007
beta1	10000	5.2905	1.8193	3.9861	5.1155	6.4145
beta2	10000	4.6889	1.8189	3.3570	4.4914	5.8547
Posterior Intervals						
Parameter	Alpha	Equal-Tail Interval		HPD Interval		
beta0	0.050	-5.8247	-0.7435	-5.5936	-0.6027	
beta1	0.050	2.3001	9.3789	1.8590	8.7222	
beta2	0.050	1.6788	8.6643	1.3611	8.2490	

You can also use PROC GENMOD to fit the same model by using the following statements:

```
proc genmod data=vaso descending;
  ods select PostSummaries PostIntervals;
  model resp = lvol lrate / d=bin link=logit;
  bayes seed=17 coeffprior=jeffreys nmc=20000 thin=2;
run;
```

The MODEL statement indicates that resp is the response variable and lvol and lrate are the covariates. The options in the MODEL statement specify a binary likelihood and a logit link function. The BAYES statement requests Bayesian capability. The SEED=, NMC=, and THIN= arguments work in the same way as in PROC MCMC. The COEFFPRIOR=JEFFREYS option requests Jeffreys' prior in this analysis.

The PROC GENMOD statements produce [Output 55.4.2](#), with estimates very similar to those reported in [Output 55.4.1](#). Note that you should not expect to see identical output from PROC GENMOD and PROC MCMC, even with the simulation setup and identical random number seed. The two procedures use different sampling algorithms. PROC GENMOD uses the adaptive rejection metropolis algorithm (ARMS) (Gilks and Wild 1992; Gilks 2003) while PROC MCMC uses a random walk Metropolis algorithm. The asymptotic answers, which means that you let both procedures run an very long time, would be the same as they both generate samples from the same posterior distribution.

Output 55.4.2 PROC GENMOD Results

Logistic Regression Model with Jeffreys Prior

lrate	0.050	1.5906	8.5272	1.3351	8.1152	

Example 55.5: Poisson Regression

You can use the Poisson distribution to model the distribution of cell counts in a multiway contingency table. Aitkin et al. (1989) have used this method to model insurance claims data. Suppose the following hypothetical insurance claims data are classified by two factors: age group (with two levels) and car type (with three levels). The following statements create the data set:

```

title 'Poisson Regression';
data insure;
  input n c car $ age;
  ln = log(n);
  datalines;
500  42  small  0
1200 37  medium 0
100   1  large  0
400 101  small  1
500  73  medium 1
300  14  large  1
;

proc transreg data=insure design;
  model class(car / zero=last);
  id n c age ln;
  output out=input_insure(drop=_: Int:);
run;

```

The variable *n* represents the number of insurance policy holders and the variable *c* represents the number of insurance claims. The variable *car* is the type of car involved (classified into three groups), and it is coded into two levels. The variable *age* is the age group of a policy holder (classified into two groups).

Assume that the number of claims *c* has a Poisson probability distribution and that its mean, μ_i , is related to the factors *car* and *age* for observation *i* by

$$\begin{aligned}\log(\mu_i) &= \log(n_i) + \mathbf{x}'\boldsymbol{\beta} \\ &= \log(n_i) + \beta_0 + \\ &\quad \text{car}_i(1)\beta_1 + \text{car}_i(2)\beta_2 + \text{car}_i(3)\beta_3 + \\ &\quad \text{age}_i(1)\beta_4 + \text{age}_i(2)\beta_5\end{aligned}$$

The indicator variables $\text{car}_i(j)$ is associated with the *j*th level of the variable *car* for observation *i* in the following way:

$$\text{car}_i(j) = \begin{cases} 1 & \text{if } \text{car} = j \\ 0 & \text{if } \text{car} \neq j \end{cases}$$

A similar coding applies to *age*. The $\boldsymbol{\beta}$'s are parameters. The logarithm of the variable *n* is used as an offset—that is, a regression variable with a constant coefficient of 1 for each observation. Having the offset constant in the model is equivalent to fitting an expanded data set with 3000 observations, each with response variable *y* observed on an individual level. The log link relates the mean and the factors *car* and *age*.

The following statements run PROC MCMC:

```
proc mcmc data=input_insure outpost=insureout nmc=5000 propcov=quanew
    maxtune=0 seed=7;
    ods select PostSummaries PostIntervals;
    array data[4] 1 &_trgind age;
    array beta[4] alpha beta_car1 beta_car2 beta_age;
    parms alpha beta;
    prior alpha beta: ~ normal(0, prec = 1e-6);
    call mult(data, beta, mu);
    model c ~ poisson(exp(mu+ln));
run;
```

The analysis uses a relatively flat prior on all the regression coefficients, with mean at 0 and precision at 10^{-6} . The option **MAXTUNE=0** skips the tuning phase because the optimization routine (**PROPCOV=QUANEW**) provides good initial values and proposal covariance matrix.

There are four parameters in the model: *alpha* is the intercept; *beta_car1* and *beta_car2* are coefficients for the class variable *car*, which has three levels; and *beta_age* is the coefficient for *age*. The symbol *mu* connects the regression model and the Poisson mean by using the log link. The **MODEL** statement specifies a Poisson likelihood for the response variable *c*.

Posterior summary and interval statistics are shown in [Output 55.5.1](#).

Output 55.5.1 MCMC Results

Poisson Regression						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	25%	50%	75%

carlarge	5000	-1.8040	0.2764	-1.9859	-1.7929	-1.6101
carmedium	5000	-0.6908	0.1311	-0.7797	-0.6898	-0.6044
age1	5000	1.3207	0.1384	1.2264	1.3209	1.4140

Posterior Intervals					
Parameter	Alpha	Equal-Tail Interval		HPD Interval	
Intercept	0.050	-2.9154	-2.3893	-2.8997	-2.3850
carlarge	0.050	-2.3668	-1.2891	-2.2992	-1.2378
carmedium	0.050	-0.9437	-0.4231	-0.9434	-0.4230
age1	0.050	1.0455	1.5871	1.0266	1.5629

Note that the descending option in the CLASS statement reverses the sort order of the class variable `age` so that the results agree with PROC MCMC. If this option is not used, the estimate for `age` has a reversed sign as compared to [Output 55.5.2](#).

Example 55.6: Nonlinear Poisson Regression Models

This example illustrates how to fit a nonlinear Poisson regression with PROC MCMC. In addition, it shows how you can improve the mixing of the Markov chain by selecting a different proposal distribution or by sampling on the transformed scale of a parameter. This example shows how to analyze count data for calls to a technical support help line in the weeks immediately following a product release. This information could be used to decide upon the allocation of technical support resources for new products. You can model the number of daily calls as a Poisson random variable, with the average number of calls modeled as a nonlinear function of the number of weeks that have elapsed since the product's release. The data are input into a SAS data set as follows:

```

title 'Nonlinear Poisson Regression';
data calls;
  input weeks calls @@;
  datalines;
1   0   1   2   2   2   1   3   1   3   3
4   5   4   8   5   5   5   9   6  17   6   9
7  24   7  16   8  23   8  27
;

```

During the first several weeks after a new product is released, the number of questions that technical support receives concerning the product increases in a sigmoidal fashion. The expression for the mean value in the classic Poisson regression involves the log link. There is some theoretical justification for this link, but with MCMC methodologies, you are not constrained to exploring only models that are computationally convenient. The number of calls to technical support tapers off after the initial release, so in this example you can use a logistic-type function to model the mean number of calls received weekly for the time period immediately following the initial release. The mean function $\lambda(t)$ is modeled as follows:

$$\lambda_i = \frac{\gamma}{1 + \exp[-(\alpha + \beta t_i)]}$$

The likelihood for every observation calls_i is

$$\text{calls}_i \sim \text{Poisson}(\lambda_i)$$

Past experience with technical support data for similar products suggests the following prior distributions:

$$\begin{aligned}\gamma &\sim \text{gamma}(\text{shape} = 3.5, \text{scale} = 12) \\ \alpha &\sim \text{normal}(-5, \text{sd} = 0.5) \\ \beta &\sim \text{normal}(0.75, \text{sd} = 0.5)\end{aligned}$$

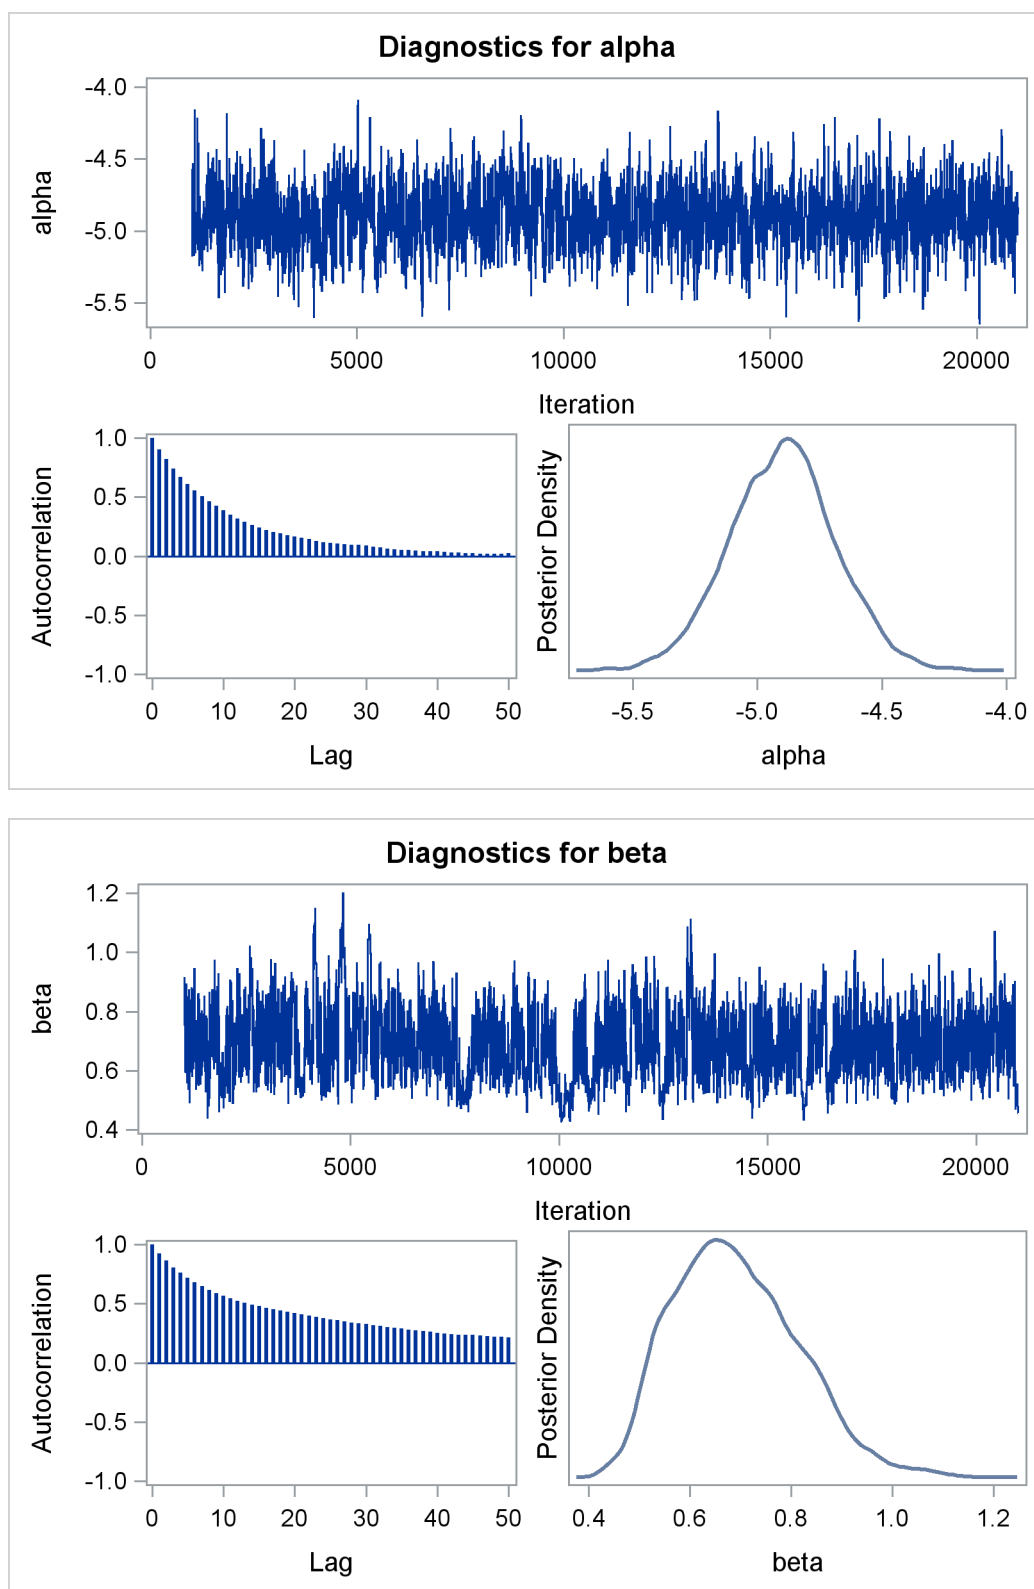

The following PROC MCMC statements fit this model:

```
ods graphics on;
proc mcmc data=calls outpost=callout seed=53197 ntu=1000 nmc=20000
    propcov=quanew stats=none diag=ess;
    ods select TADpanel ess;
    parms alpha -4 beta 1 gamma 2;
    prior gamma ~ gamma(3.5, scale=12);
    prior alpha ~ normal(-5, sd=0.25);
    prior beta ~ normal(0.75, sd=0.5);
    lambda = gamma*logistic(alpha+beta*weeks);
    model calls ~ poisson(lambda);
run;
```

The one **PARMS** statement defines a block of all parameters and sets their initial values individually. The **PRIOR** statements specify the informative prior distributions for the three parameters. The assignment statement defines λ , the mean number of calls. Instead of using the SAS function LOGISTIC, you can use the following statement to calculate λ and get the same result:

```
lambda = gamma / (1 + exp(-(alpha+beta*weeks)));
```

Mixing is not particularly good with this run of PROC MCMC. The ODS SELECT statement displays the diagnostic graphs and effective sample sizes (ESS) calculation while excluding all other output. The graphical output is shown in [Output 55.6.1](#), and the ESS of each parameters are all relatively low ([Output 55.6.2](#)).

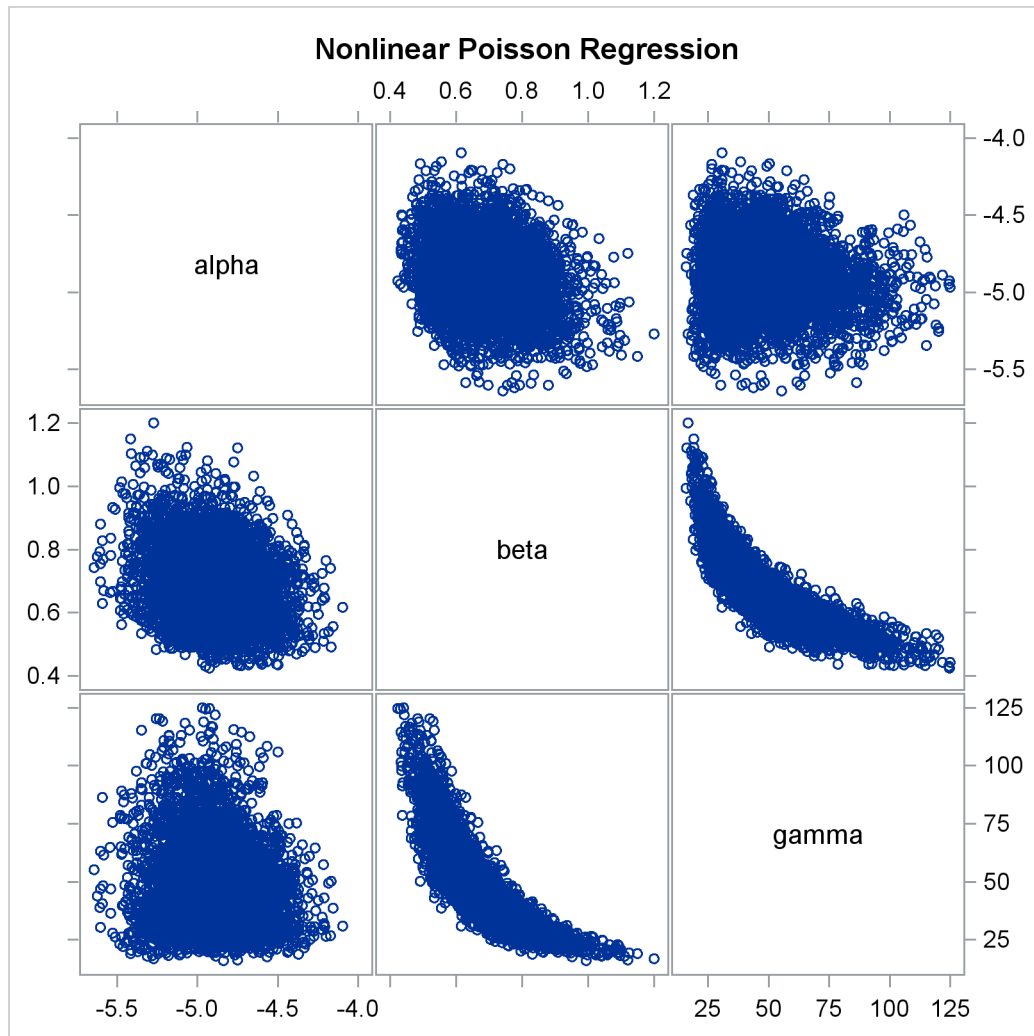

Output 55.6.1 Plots for Parameters

Output 55.6.1 *continued***Output 55.6.2** Effective Sample Sizes

Nonlinear Poisson Regression			
The MCMC Procedure			
Effective Sample Sizes			
Parameter	ESS	Autocorrelation Time	Efficiency
alpha	897.4	22.2870	0.0449
beta	231.6	86.3540	0.0116
gamma	162.9	122.8	0.0081

Often a simple scatter plot of the posterior samples can reveal a potential cause of the bad mixing. You can use PROC SGSCATTER to generate pairwise scatter plots of the three model parameters. The following statements generate [Output 55.6.3](#):

```
proc sgscatter data=callout;
  matrix alpha beta gamma;
run;
```

Output 55.6.3 Pairwise Scatter Plots of the Parameters

The nonlinearity in parameters β and γ stands out immediately. This explains why a random walk Metropolis with normal proposal has a difficult time exploring the joint distribution efficiently—the algorithm works best when the target distribution is unimodal and symmetric (normal-like). When there is nonlinearity in the parameters, it is impossible to find a single proposal scale parameter that optimally adapts to different regions of the joint parameter space. As a result, the Markov chain can be inefficient in traversing some parts of the distribution. This is evident in examining the trace plot of the γ parameter. You see that the Markov chain sometimes gets stuck in the far-right tail and does not travel back to the high-density area quickly. This effect can be seen around the simulations 8,000 and 18,000 in [Output 55.6.1](#).

Reparameterization can often improve the mixing of the Markov chain. Note that the parameter γ has a positive support and that the posterior distribution is right-skewed. This suggests that the chain might mix more rapidly if you sample on the logarithm of the parameter γ .

Let $\delta = \log(\gamma)$, and reparameterize the mean function as follows:

$$\lambda_i = \frac{\exp(\delta)}{1 + \exp[-(\alpha + \beta t_i)]}$$

To obtain the same inference, you use an induced prior on δ based on the gamma prior on the gamma parameter. This involves a transformation of variables, and you can obtain the following equivalency, where $|\exp(\delta)|$ is the Jacobian:

$$\begin{aligned}\pi(\gamma) &= \text{gamma}(\gamma; a, \text{scale} = b) = \frac{1}{b^a \Gamma(a)} \gamma^{a-1} \exp(-\gamma/b) \\ \Leftrightarrow \pi(\delta) &= \text{gamma}(\gamma = \exp(\delta); a, \text{scale} = b) \cdot |\exp(\delta)|\end{aligned}$$

The distribution on δ simplifies to the following:

$$\pi(\delta) = \frac{1}{b^a \Gamma(a)} \exp(a\delta) \exp(-\exp(\delta)/b)$$

PROC MCMC supports such a distribution on the logarithm transformation of a gamma random variable. It is called the [ExpGamma](#) distribution.

In the original model, you specify a prior on gamma:

```
prior gamma ~ gamma(3.5, scale=12);
```

You can obtain the same inference by specifying an [ExpGamma](#) prior on δ and take an exponential transformation to get back to gamma:

```
prior delta ~ egamma(3.5, scale=12);
gamma = exp(delta);
```

The following statements produce [Output 55.6.6](#) and [Output 55.6.4](#):

```
proc mcmc data=calls outpost=tcallout seed=53197 ntu=1000 nmc=20000
  propcov=quanew diag=ess plots=(trace) monitor=(alpha beta gamma);
  ods select PostSummaries PostIntervals ESS TRACEpanel;
  parms alpha -4 beta 1 delta 2;
  prior alpha ~ normal(-5, sd=0.25);
  prior beta ~ normal(0.75, sd=0.5);
  prior delta ~ egamma(3.5, scale=12);
  gamma = exp(delta);
  lambda = gamma*logistic(alpha+beta*weeks);
  model calls ~ poisson(lambda);
run;
```

The [PARMS](#) statement declares δ , instead of gamma, as a model parameter. The prior distribution of δ is [egamma](#), as opposed to the [gamma](#) distribution. The [GAMMA](#) assignment statement transforms δ to gamma. The [LAMBDA](#) assignment statement calculates the mean for the Poisson by using the gamma parameter. The [MODEL](#) statement specifies a Poisson likelihood for the calls response.

The trace plots in [Output 55.6.4](#) show better mixing of the parameters, and the effective sample sizes in [Output 55.6.5](#) show substantial improvements over the original formulation of the model. The improvements are especially obvious in beta and gamma, where the increase is fivefold to tenfold.

Output 55.6.4 Plots for Parameters, Sampling on the Log Scale of Gamma**Output 55.6.5** Effective Sample Sizes, Sampling on the Log Scale of Gamma

gamma	0.050	23.2996	96.7209	19.6588	86.2425	

Note that the delta parameter has a more symmetric density than the skewed gamma parameter. A pairwise scatter plot (Output 55.6.7) shows a more linear relationship between beta and delta. The Metropolis algorithm always works better if the target distribution is approximately normal.

```
proc sgscatter data=tcallout;
  matrix alpha beta delta;
run;
```

Output 55.6.7 Pairwise Scatter Plots of the Transformed Parameters

If you are still unsatisfied with the slight nonlinearity in the parameters β and δ , you can try another transformation on β . Normally you would not want to do a logarithm transformation on a parameter that has support on the real axis, because you would risk taking the logarithm of negative values. However, because all the β samples are positive and the marginal posterior distribution is away from 0, you can try a such a transformation.

Let $\kappa = \log(\beta)$. The prior distribution on κ is the following:

$$\pi(\kappa) = \text{normal}(\beta = \exp(\kappa); \mu, \sigma^2) \cdot |\exp(\kappa)|$$

You can specify the prior distribution in PROC MCMC by using a **GENERAL** function:

```
parms kappa;
lprior = logpdf("normal", exp(kappa), 0.75, 0.5) + kappa;
prior kappa ~ general(lp);
beta = exp(kappa);
```

The **PARMS** statement declares the transformed parameter kappa, which will be sampled. The **LPRIOR** assignment statement defines the logarithm of the prior distribution on kappa. The **LOGPDF** function is used here to simplify the specification of the distribution. The **PRIOR** statement specifies the nonstandard distribution as the prior on kappa. Finally, the **BETA** assignment statement transforms kappa back to the beta parameter.

Applying logarithm transformations on both beta and gamma yields the best mixing. (The results are not shown here, but you can find the code in the file *mcmcex6.sas* in the SAS Sample Library.) The transformed parameters kappa and delta have much clearer linear correlation. However, the improvement over the case where gamma alone is transformed is only marginally significant (50% increase in ESS).

This example illustrates that PROC MCMC can fit Bayesian nonlinear models just as easily as Bayesian linear models. More importantly, transformations can sometimes improve the efficiency of the Markov chain, and that is something to always keep in mind. Also see “[Example 55.20: Using a Transformation to Improve Mixing](#)” on page 4654 for another example of how transformations can improve mixing of the Markov chains.

Example 55.7: Logistic Regression Random-Effects Model

This example illustrates how you can use PROC MCMC to fit random-effects models. In the example “[Random-Effects Model](#)” on page 4419 in “[Getting Started: MCMC Procedure](#)” on page 4408, you already saw PROC MCMC fit a linear random-effects model. This example shows how to fit a logistic random-effects model in PROC MCMC. Although you can use PROC MCMC to analyze random-effects models, you might want to first consider some other SAS procedures. For example, you can use PROC MIXED (see Chapter 59, “[The MIXED Procedure](#)”) to analyze linear mixed effects models, PROC NL MIXED (see Chapter 64, “[The NL MIXED Procedure](#)”) for nonlinear mixed effects models, and PROC GLIMMIX (see Chapter 41, “[The GLIMMIX Procedure](#)”) for generalized linear mixed effects models. In addition, a sampling-based Bayesian analysis is available in the MIXED procedure through the **PRIOR** statement (see “[PRIOR Statement](#)” on page 4935).

The data are taken from Crowder (1978). The *Seeds* data set is a 2×2 factorial layout, with two types of seeds, *O. aegyptiaca* 75 and *O. aegyptiaca* 73, and two root extracts, *bean* and *cucumber*. You observe *r*, which is the number of germinated seeds, and *n*, which is the total number of seeds. The independent variables are *seed* and *extract*.

The following statements create the data set:

```

title 'Logistic Regression Random-Effects Model';
data seeds;
    input r n seed extract @@;
    ind = _N_;
    datalines;
10 39 0 0      23 62 0 0      23 81 0 0      26 51 0 0
17 39 0 0      5  6 0 1      53 74 0 1      55 72 0 1
32 51 0 1      46 79 0 1      10 13 0 1      8  16 1 0
10 30 1 0      8  28 1 0      23 45 1 0      0  4  1 0
3  12 1 1      22 41 1 1      15 30 1 1      32 51 1 1
3  7  1 1
;

```

You can model each observation r_i as having its own probability of success p_i , and the likelihood is as follows:

$$r_i \sim \text{binomial}(n_i, p_i)$$

You can use the logit link function to link the covariates of each observation, `seed` and `extract`, to the probability of success,

$$\begin{aligned}\mu_i &= \beta_0 + \beta_1 \cdot \text{seed}_i + \beta_2 \cdot \text{extract}_i + \beta_3 \cdot \text{seed}_i \cdot \text{extract}_i \\ p_i &= \text{logistic}(\mu_i + \delta_i)\end{aligned}$$

where δ_i is assumed to be an iid random effect with a normal prior:

$$\delta_i \sim \text{normal}(0, \text{var} = \sigma^2)$$

The four β regression coefficients and the standard deviation σ^2 in the random effects are model parameters; they are given noninformative priors as follows:

$$\begin{aligned}\pi(\beta_0, \beta_1, \beta_2, \beta_3) &\propto 1 \\ \sigma^2 &\sim \text{igamma}(\text{shape} = 0.01, \text{scale} = 0.01)\end{aligned}$$

Another way of expressing the same model is as

$$p_i = \text{logistic}(\delta_i)$$

where

$$\delta_i \sim \text{normal}(\beta_0 + \beta_1 \cdot \text{seed}_i + \beta_2 \cdot \text{extract}_i + \beta_3 \cdot \text{seed}_i \cdot \text{extract}_i, \sigma^2)$$

The two models are equivalent. In the first model, the random effects δ_i centers at 0 in the normal distribution, and in the second model, δ_i centers at the regression mean. This hierarchical centering can sometimes improve mixing.

The following statements fit the second model and generate [Output 55.7.1](#):

```
proc mcmc data=seeds outpost=postout seed=332786 nmc=20000;
  ods select PostSummaries PostIntervals;
  parms beta0 0 beta1 0 beta2 0 beta3 0 s2 1;
  prior s2 ~ igamma(0.01, s=0.01);
  prior beta: ~ general(0);
  w = beta0 + beta1*seed + beta2*extract + beta3*seed*extract;
  random delta ~ normal(w, var=s2) subject=ind;
  pi = logistic(delta);
  model r ~ binomial(n = n, p = pi);
run;
```

The PROC MCMC statement specifies the input and output data sets, sets a seed for the random number generator, and requests a large simulation size. The ODS SELECT statement displays the summary statistics and interval statistics tables. The [PARMS](#) statement declares the model parameters, and the [PRIOR](#) statements specify the prior distributions for β and σ^2 .

The symbol w calculates the regression mean, and the **RANDOM** statement specifies the random effect, with a normal prior distribution, centered at w with variance σ^2 . Note that the variable w is a function of the input data set variables. You can use data set variable in constructing the hyperparameters of the random-effects parameters, as long as the hyperparameters remain constant within each subject group. The **SUBJECT=** option indicates the group index for the random-effects parameters.

The symbol π is the logit transformation. The **MODEL** specifies the response variable r as a binomial distribution with parameters n and π .

Output 55.7.1 lists the posterior mean and interval estimates of the regression parameters.

Example 55.8: Nonlinear Poisson Regression Multilevel Random-Effects Model

This example uses the pump failure data of Gaver and O'Muircheartaigh (1987) to illustrate how to fit a multilevel random-effects model with PROC MCMC. The number of failures and the time of operation are recorded for 10 pumps. Each of the pumps is classified into one of two groups that correspond to either continuous or intermittent operation. The following statements generate the data set:

```

title 'Nonlinear Poisson Regression Random-Effects Model';
data pump;
  input y t group @@;
  pump = _n_;
  logtstd = log(t) - 2.4564900;
  datalines;
5   94.320 1    1   15.720 2    5   62.880 1
14  125.760 1    3    5.240 2   19   31.440 1
1    1.048 2    1    1.048 2    4    2.096 2
22   10.480 2
;

```

Each row denotes data for a single pump, and the variable `logtstd` contains the centered operation times. Letting y_{ij} denote the number of failures for the j th pump in the i th group, Draper (1996) considers the following hierarchical model for these data, where the data set variable `logtstd` is $\log t_{ij} - \overline{\log t}$:

$$\begin{aligned}
 y_{ij} | \lambda_{ij} &\sim \text{Poisson}(\lambda_{ij}) \\
 \log \lambda_{ij} &= \alpha_i + \beta_i (\log t_{ij} - \overline{\log t}) + e_{ij}
 \end{aligned}$$

This model specifies different intercepts and slopes for each group ($i = 1, 2$), and the random effect e_{ij} is a mechanism for accounting for overdispersion. You can use noninformative priors on the parameters α_i , β_i , and σ^2 , and a normal prior on e_{ij} ,

$$\begin{aligned}
 u_i &= \begin{pmatrix} \alpha_i \\ \beta_i \end{pmatrix} \sim \text{mvn} \left(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1e6 & 0 \\ 0 & 1e6 \end{pmatrix} \right) \text{ for } i = 1, 2 \\
 \sigma^2 &\sim \text{igamma}(\text{shape} = 0.01, \text{scale} = 0.01) \\
 e_{ij} | \sigma^2 &\sim \text{normal}(0, \sigma^2)
 \end{aligned}$$

where u_i is a multidimensional random effect. The following statements fit such a random-effects model:

```

ods graphics on;
proc mcmc data=pump outpost=postout seed=248601 nmc=10000
  plots=trace stats=none diag=none;
  ods select tracepanel;
  array u[2] alpha beta;
  array mu[2] (0 0);
  parms s2;
  prior s2 ~ igamma(0.01, scale=0.01);
  random u ~ mvn(mu, sd=1e6, rho=0) subject=group monitor=(u);
  random e ~ normal(0, var=s2) subject=pump monitor=(random(1));
  w = alpha + beta * logtstd;
  lambda = exp(w+e);
  model y ~ poisson(lambda);
run;

```

The PROC MCMC statement specifies the input data set (Pump), the output data set (Postout), a seed for the random number generator, and a simulation sample size of 10,000. The program requests that only trace plots be produced, disabling all posterior calculations and convergence diagnostics tests. The ODS SELECT statement displays the trace plots, which are the primary focus.

The first **ARRAY** statement declares an array `u` of size 2 and names the elements `alpha` and `beta`. The array `u` stores the random-effects parameters `alpha` and `beta`. The next **ARRAY** statement defines the mean of the multivariate normal prior on `u`.

The **PARMS** statement declares the only model parameter here, the variance `s2` in the prior distribution for the random effect e_{ij} . The **PRIOR** statement specifies an inverse-gamma prior on the variance. The first **RANDOM** statement specifies a multivariate normal prior on `u`. The `mvn` distribution is a multivariate normal distribution with a first-order autoregressive covariance. When the argument `rho` is set to 0, this distribution simplifies to a multivariate normal distribution with a shared variance. The **RANDOM** statement also indicates the group variable as its subject index and monitors all elements `u`. The second **RANDOM** statement specifies a normal prior on the effect `e`, where the subject index variable is `pump`. The **MONITOR=** option requests that PROC MCMC randomly choose one of the 10 `e` random-effects parameters to monitor.

Next, programming statements construct the mean of the Poisson likelihood, and the **MODEL** statement specifies the likelihood function for each observation.

Output 55.8.1 shows trace plots for σ^2 , α_1 , α_2 , β_1 , β_2 , and e_8 . You can see that the chains are mixing poorly.

Output 55.8.1 Trace Plots of σ^2 , α , β , and e_8 without Hierarchical Centering

Output 55.8.1 continued

To improve mixing, you can repeat the same analysis by using a hierarchical centering technique, where instead of using a normal prior centered at 0 on e_{ij} , you center the random effects on the group means:

$$y_{ij} | \lambda_{ij} \sim \text{Poisson}(\lambda_{ij})$$

$$\log \lambda_{ij} \sim \text{normal}(\alpha_i + \beta_i (\log t_{ij} - \overline{\log t}), \text{var} = \sigma^2)$$

The following statements illustrate how to fit a multilevel hierarchical centering random-effects model:

```
proc mcmc data=pump outpost=postout_c seed=248601 nmc=10000
  plots=trace diag=none;
  ods select tracepanel postsummaries postintervals;
  array u[2] alpha beta;
  array mu[2] (0 0);
  parms s2 1;
  prior s2 ~ igamma(0.01, scale=0.01);
  random u ~ mvn(mu, sd=1e6, rho=0) subject=group monitor=(u);
  w = alpha + beta * logtstd;
  random llambda ~ normal(w, var = s2) subject=pump monitor=(random(1));
  lambda = exp(llambda);
  model y ~ poisson(lambda);
run;
```

The difference between these statements and the previous statements on page 4582 is that these statements have the variable w as the prior mean of the random effect λ_{ij} (lambdaij). The symbol λ_{ij} is the exponential of the corresponding $\log \lambda_{ij}$ (lambdaij), and the **MODEL** statement assigns the response variable y a Poisson likelihood with a mean parameter λ_{ij} , the same way it did in the previous statements.

The trace plots of the monitored parameters are shown in [Output 55.8.2](#). The mixing is significantly improved over the previous model. The posterior summary and interval statistics tables are shown in [Output 55.8.3](#).

Output 55.8.2 Trace Plots of σ^2 , α , and β with Hierarchical Centering

Output 55.8.2 continued

You can generate a caterpillar plot (Output 55.8.4) of the random-effects parameters by calling the %CATER macro:

```
%CATER(data=postout_c, var=llambda:);
ods graphics off;
```

Varying llambda indicates nonconstant dispersion in the Poisson model.

Output 55.8.4 Caterpillar Plots of the Random-Effects Parameters

Example 55.9: Multivariate Normal Random-Effects Model

Gelfand et al. (1990) use a multivariate normal hierarchical model to estimate growth regression coefficients for the growth of 30 young rats in a control group over a period of 5 weeks. The following statements create a SAS data set with measurements of Weight, Age (in days), and Subject.

```

title 'Multivariate Normal Random-Effects Model';
data rats;
  array days[5] (8 15 22 29 36);
  input weight @@;
  subject = ceil(_n_/5);

;

```

The model assumes normal measurement errors,

$$\text{Weight}_{ij} \sim \text{normal}(\alpha_i + \beta_i \text{Age}_{ij}, \sigma^2), \quad i = 1 \cdots 30; j = 1 \cdots 5$$

where i indexes rat (Subject variable), j indexes the time period, Weight_{ij} and Age_{ij} denote the weight and age of the i th rat in week j , and σ^2 is the variance in the normal likelihood. The individual intercept and slope coefficients are modeled as the following:

$$\theta_i = \begin{pmatrix} \alpha_i \\ \beta_i \end{pmatrix} \sim \text{MVN} \left(\theta_c = \begin{pmatrix} \alpha_c \\ \beta_c \end{pmatrix}, \Sigma_c \right), \quad i = 1, \dots, 30$$

You can use the following independent prior distributions on θ_c , Σ_c , and σ^2 :

$$\begin{aligned} \theta_c &\sim \text{MVN} \left(\mu_0 = \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \Sigma_0 = \begin{pmatrix} 1000 & 0 \\ 0 & 1000 \end{pmatrix} \right) \\ \Sigma_c &\sim \text{iwishart} \left(\rho = 2, S = \rho \cdot \begin{pmatrix} 0.01 & 0 \\ 0 & 10 \end{pmatrix} \right) \\ \sigma^2 &\sim \text{igamma}(\text{shape} = 0.01, \text{scale} = 0.01) \end{aligned}$$

The following statements fit this multivariate normal random-effects model:

```
proc mcmc data=rats nmc=10000 outpost=postout
  seed=17 init=random;
  ods select Parameters REParameters PostSummaries;
  array theta[2] alpha beta;
  array theta_c[2];
  array Sig_c[2,2];
  array mu0[2] (0 0);
  array Sig0[2,2] (1000 0 0 1000);
  array S[2,2] (0.02 0 0 20);

  parms theta_c Sig_c {121 0 0 0.26} var_y;
  prior theta_c ~ mvn(mu0, Sig0);
  prior Sig_c ~ iwish(2, S);
  prior var_y ~ igamma(0.01, scale=0.01);

  random theta ~ mvn(theta_c, Sig_c) subject=subject
    monitor=(alpha_9 beta_9 alpha_25 beta_25);
  mu = alpha + beta * age;
  model weight ~ normal(mu, var=var_y);
run;
```

The ODS SELECT statement displays information about model parameters, random-effects parameters, and the posterior summary statistics. The ARRAY statements allocate memory space for the multivariate parameters and hyperparameters in the model. The parameters are θ (theta where the variable name of each element is alpha or beta), θ_c (theta_c), and Σ_c (Sig_c). The hyperparameters are μ_0 (mu0), Σ_0 (Sig0), and S (S). The multivariate hyperparameters are assigned with constant values using parentheses ().

The PARMS statement declares model parameters and assigns initial values to Sig_c using braces { }. The PRIOR statements specify the prior distributions. The RANDOM statement defines an array random effect theta and specifies a multivariate normal prior distribution. The SUBJECT= option indicates cluster membership for each of the random-effects parameter. The MONITOR= option monitors the individual intercept and slope coefficients of subjects 9 and 25.

You can use the following syntax in the RANDOM statement to monitor all parameters in an array random effect:

```
monitor=(theta)
```

This would produce posterior summary statistics on $\alpha_1 \cdots \alpha_{30}$ and $\beta_1 \cdots \beta_{30}$.

The following syntax monitors all α_i parameters:

```
monitor=(alpha)
```

If you did not name elements of theta to be alpha and beta, the SAS System creates variable names automatically in a consecutive fashion, as in theta1 and theta2.

Output 55.9.1 Parameter and Random-Effects Parameter Information Table

Multivariate Normal Random-Effects Model					
The MCMC Procedure					
Parameters					
Block	Parameter	Array Index	Sampling Method	Initial Value	Prior Distribution

Sig_c3	10000	-1.4267	2.3320	-2.7324	-1.2288	0.0789
Sig_c4	10000	1.0591	0.2979	0.8472	1.0104	1.2145
var_y	10000	37.6855	5.9591	33.4151	36.9994	41.2448
alpha_9	10000	119.4	5.6756	115.6	119.2	123.2
alpha_25	10000	86.5673	6.3694	82.4621	86.7183	90.7307
beta_9	10000	7.4670	0.2382	7.3109	7.4730	7.6260
beta_25	10000	6.7804	0.2612	6.6144	6.7756	6.9526

Output 55.9.2 displays posterior summary statistics for model parameters and the random-effects parameters for subjects 9 and 25. You can see that there is a substantial difference in the intercepts and growth rates between the two rats.

A seemingly confusing message might occur if a symbol name matches an internally generated variable name for elements of an array. For example, if, instead of using the symbol `var_y` in the SAS program for the model variance σ^2 , you used `s2`, the SAS System produces the following error message:

```
ERROR: The initial value 0 for the parameter S2 is outside of the prior
distribution support set.
```

This is confusing because the program does not assign an initial value for the parameter `s2` in the **PARMS** statement, and you might expect that PROC MCMC would not generate an invalid initial value. The confusion is caused by the **ARRAY** statement that defines the array variable `S`:

```
array S[2,2] (0.02 0 0 20);
```

Elements of `S` are automatically given names `s1`–`s4`. PROC MCMC interprets `s2` as an element in `S` that was given a value of 0, hence producing this error message.

Example 55.10: Missing at Random Analysis

This example illustrates how PROC MCMC treats missing at random (MAR) data. For a short overview of missing data problems, see the section “[Handling of Missing Data](#)” on page 4518.

Researchers studied the effects of air pollution on respiratory disease in children. The response variable (`y`) represented whether a child exhibited wheezing symptoms; it was recorded as 1 for symptoms exhibited and

0 for no symptoms exhibited. City of residency (x1) and maternal smoking status (x2) were the explanatory variables. The variable x1 was coded as 1 if the child lived in the more polluted city, Steel City, and 0 if the child lived in Green Hills. The variable x2 was the number of cigarettes the mother reported that she smoked per day. Both the covariates contain missing values: 17 for x1 and 30 for x2, respectively. The total number of observations in the data set is 390. The following statements generate the data set air:

```

title 'Missing at Random Analysis';
data air;
  input y x1 x2 @@;
  datalines;
0 0 0 0 0 0 0 1 0 0 0 0 0 0 11 0 1 7

;

```

Suppose you want to fit a logistic regression model for whether the subject develops wheezing symptoms with density for the $i = 1, \dots, 390$ subjects as follows:

$$\begin{aligned}
 y_i &\sim \text{binary}(p_i) \\
 \text{logit}(p_i) &= \beta_0 + \beta_1 \cdot x1_i + \beta_2 \cdot x2_i \\
 \pi(\beta_0), \pi(\beta_1), \pi(\beta_2) &= \text{normal}(0, \sigma^2 = 10)
 \end{aligned}$$

Suppose you specify a joint distribution of x1 and x2 in terms of the product of a conditional and marginal distribution; that is,

$$p(x1, x2 | \alpha) = p(x1 | x2, \alpha_{10}, \alpha_{11}) p(x2 | \alpha_{20})$$

where $p(x1_i | x2_i, \alpha_{10}, \alpha_{11})$ could be a logistic model and $p(x2_i | \alpha_{20})$ could be a Poisson distribution that models the following counts:

$$\begin{aligned}
 p(x1_i | x2_i, \alpha_{10}, \alpha_{11}) &= \text{binary}(p_{c,i}) \\
 \text{logit}(p_{c,i}) &= \alpha_{10} + \alpha_{11} \cdot x2_i \\
 \pi(\alpha_{10}), \pi(\alpha_{11}) &= \text{normal}(0, \sigma^2 = 10) \\
 p(x2_i | \alpha_{20}) &= \text{Poisson}(e^{\alpha_{20}}) \\
 \pi(\alpha_{20}) &= \text{normal}(0, \sigma^2 = 2)
 \end{aligned}$$

The researchers are interested in interpreting how the odds of developing a wheeze changes for a child living in the more polluted city. The odds ratio can be written as the follows:

$$OR_{x1} = \exp(\beta_1)$$

Similarly, the odds ratio for the maternal smoking effect can be written as follows:

$$OR_{x2} = \exp(\beta_2)$$

The following statements fit a Bayesian logistic regression with missing covariates:

```
proc mcmc data=air seed=1181 nmc=10000 monitor=(_parms_ orx1 orx2)
  stats=(summary interval) diag=none plots=none;
  parms beta0 -1 beta1 0.1 beta2 .01;
  parms alpha10 0 alpha11 0 alpha20 0;

  prior beta: alpha1: ~ normal(0,var=10);
  prior alpha20 ~ normal(0,var=2);

  beginnodata;
  pm = exp(alpha20);
  orx1 = exp(beta1);
  orx2 = exp(beta2);
  endnodata;
  model x2 ~ poisson(pm) monitor=(1 3 10);
  p1 = logistic(alpha10 + alpha11 * x2);
  model x1 ~ binary(p1) monitor=(random(3));
  p = logistic(beta0 + beta1*x1 + beta2*x2);
  model y ~ binary(p);
run;
```

The **PARMS** statements specify the parameters in the model and assign initial values to each of them. The **PRIOR** statements specify priors for all the model parameters. The notations **beta:** and **alpha:** in the **PRIOR** statements are shorthand for all variables that start with “beta,” and “alpha,” respectively. The shorthand notation is not necessary, but it keeps your code succinct.

The **BEGINNODATA** and **ENDNODATA** statements enclose three programming statements that calculate the Poisson mean (pm) and the two odds ratios (ORX1 and ORX2). These enclosed statements are independent of any data set variables, and they are run only once per iteration to reduce unnecessary observation-level computations.

The first **MODEL** statement assigns a Poisson likelihood with mean pm to x2. The statement models missing values in x2 automatically, creating one variable for each of the missing values, and augments them accordingly. By default, PROC MCMC does not output analyses of the posterior samples of the missing values. You can use the **MONITOR=** option to choose the missing values that you want to monitor. In the example, the first, third, and tenth missing values are monitored.

The P1 assignment statement calculates $p_{c,i}$. The second **MODEL** statement assigns a binary likelihood with probability p1 and requests a random choice of three missing data variables of x1 to monitor.

The P assignment statement calculates p_i in the logistic model. The third **MODEL** statement specifies the complete data likelihood function for Y.

Output 55.10.1 displays the number of observations read from the DATA= data set, the number of observations used in the analysis, and the “Missing Data Information” table. No observations were omitted from the data set in the analysis.

The “Missing Data Information” table lists the variables that contain missing values, which are x1 and x2, the number of missing observations in each variable, the observation indices of these missing values, and the sampling algorithms used. By default, the first 20 observation indices of each variable are printed in the table.

Output 55.10.1 Observation Information and Missing Data Information

Missing at Random Analysis											
The MCMC Procedure											
Number of Observations Read										390	
Number of Observations Used										390	
Missing Data Information Table											
Variable	Number of Missing Obs	Observation Indices									Sampling Method
x2	30	14	41	50	55	59	66	71	83	N-Metropolis	
		88	90	118	158	174	175				
		178	183	196	203	210	212				
		...									
x1	17	50	92	93	167	194	231	273	Inverse CDF		
		296	303	304	308	330	349				
		373	385	388	390						

There are 30 missing values in the variable x2, and 17 in x1. Internally, PROC MCMC creates 30 and 17 variables for the missing values in x2 and x1, respectively. The default naming convention for these missing values is to concatenate the response variable and the observation number. For example, the first missing value in x2 is the fourteenth observation, and the corresponding variable is x2_14.

Output 55.10.2 displays the summary and interval statistics for each parameter, the odds ratios, and the monitored missing values.

Output 55.10.2 Posterior Summary and Interval Statistics

x1_304	0.050	0	1.0000	0	1.0000
x1_373	0.050	0	1.0000	0	1.0000

The odds ratio for x1 is the multiplicative change in the odds of a child wheezing in Steel City compared to the odds of the child wheezing in Green Hills. The estimated odds ratio (ORX1) value is 1.6736 with a corresponding 95% equal-tail credible interval of (1.0248, 2.5939). City of residency is a significant factor in a child's wheezing status. The estimated odds ratio for x2 is the multiplicative change in the odds of developing a wheeze for each additional reported cigarette smoked per day. The odds ratio of ORX2 indicates that the odds of a child developing a wheeze is 1.0150 times higher for each reported cigarette a mother smokes. The corresponding 95% equal-tail credible interval is (0.9695, 1.0619). Since this interval contains the value 1, maternal smoking is not considered to be an influential effect.

Example 55.11: Nonignorably Missing Data (MNAR) Analysis

This example illustrates how to fit a nonignorably missing data model (MNAR) with PROC MCMC. For a short overview of missing data problems, see the section “[Handling of Missing Data](#)” on page 4518.

This data set comes from an environmental study that involve workers in a cotton factory. A similar data set was analyzed from Ibrahim, Chen, and Lipsitz (2001). There are 912 workers in the data set, and the response variable of interest is whether they develop dyspnea (difficult or labored respiration). The data are collected over three time points, and there are six covariates. The following statements create the data set:

```

title 'Nonignorably Missing Data Analysis';
data dyspnea;
  input smoke1 smoke2 smoke3 y1 y2 y3 yrswrk1 yrswrk2 yrswrk3
        age expd sex hgt;
  datalines;
0 0 0 0 0 0 28.1 33.1 39.1 48 1 1 165.0
0 0 0 0 . 0 5.1 10.1 16.1 45 1 0 147.0
0 0 0 0 . 0 26.0 31.0 37.0 46 1 0 156.0

... more lines ...

1 1 1 0 . . 6.0 11.0 17.0 25 0 1 180.0
0 0 0 0 . . 20.0 25.0 31.0 42 0 0 159.0
;

```

The following variables are included in the data set:

- y1, y2, and y3: dichotomous outcome at the three time periods, which takes the value 1 if the worker has dyspnea, 0 if not (there are missing values in y2 and y3)
- smoke1, smoke2, smoke3: smoking status (0=no, and 1=yes)
- yrswrk1, yrswrk2, yrswrk3: years worked at the cotton factory
- age: age of the worker
- expd: cotton dust exposure (0=no, 1=yes)
- sex: gender (0=female, 1=male)
- hgt: height of the worker

Prior to the analysis, three missing data indicator variables (r1, r2, and r3, one for each of the response variables) are created, and they are set to 1 if the response variable is missing, and 0 otherwise. The covariates age, hgt, yrswrk1, yrswrk2, and yrswrk3 are standardized:

```

data dyspnea;
  array y[3] y1-y3;
  array r[3];
  set dyspnea;
  do i = 1 to 3;
    if y[i] = . then r[i] = 1;
    else r[i] = 0;
  end;
  output;
run;

proc standard data=dyspnea out=dyspnea mean=0 std=1;
  var age hgt yrswrk;
run;

```

There are no missing values in response variable y_1 , 128 missing values in y_2 , and 131 in y_3 . Ibrahim, Chen, and Lipsitz (2001) used a logistic regression for each of the response variables, where δ_i is a scalar random effect on the observational level:

$$\begin{aligned}
 y_{ki} &\sim \text{binary}(p_{ki}) \quad k = 1, 2, 3; \quad i = 1, \dots, 912 \\
 p_{ki} &= \text{logistic}(\mu_{ki} + \delta_i) \\
 \mu_{ki} &= \beta_1 + \beta_2 \cdot \text{expd}_i + \beta_3 \cdot \text{sex}_i + \beta_4 \cdot \text{hgt}_i + \beta_5 \cdot \text{age}_i + \beta_6 \cdot \text{yrswrk}_{ki} + \beta_7 \cdot \text{smoke}_{ki} \\
 \delta_i &\sim n(0, \sigma^2)
 \end{aligned}$$

Ibrahim, Chen, and Lipsitz (2001) noted that taking δ_i to be higher dimensional (3) would make the model either not identifiable or nearly not identifiable because of the multiple missing values for some subjects.

The first response variable y_1 does not contain any missing values, making it meaningless to model the corresponding r_1 because every value is 1. Hence, only r_2 and r_3 are considered in the missing mechanism part of the model. Ibrahim, Chen, and Lipsitz (2001) suggest the following logistic regression for r_2 and r_3 , where the regression mean for each r depends not only on the current response variable y but also the response from previous time period:

$$\begin{aligned}
 r_{ki} &\sim \text{binary}(q_{ki}) \quad k = 2, 3; \quad i = 1, \dots, 912 \\
 q_{ki} &= \text{logistic}(v_{ki}) \\
 \mu_c &= \phi_1 + \phi_2 \cdot \text{expd}_i + \phi_3 \cdot \text{sex}_i + \phi_4 \cdot \text{hgt}_i + \phi_5 \cdot \text{age}_i + \phi_6 \cdot \text{yrswrk}_{ki} + \phi_7 \cdot \text{smoke}_{ki} \\
 v_{2i} &= \mu_c + \phi_8 \cdot y_{1i} + \phi_9 \cdot y_{2i} \\
 v_{3i} &= \mu_c + \phi_9 \cdot y_{2i} + \phi_{10} \cdot y_{3i}
 \end{aligned}$$

The missing mechanism model introduces an additional 10 parameters to the model. Normal priors with large standard deviations are used here.

The following statements fit a nonignorably missing model to the dyspnea data set:

```

ods select MissDataInfo REParameters PostSummaries PostIntervals;
proc mcmc data=dyspnea seed=17 outpost=dysp2 nmc=20000
    propcov=simplex diag=none monitor=(beta1-beta7);
    array p[3];
    array yrswrk[3];
    array smoke[3];

    parms beta1-beta7 s2;
    parms phi1-phi10;
    prior beta: phi: ~ n(0, var=1e6);
    prior s2 ~ igamma(2, scale=2);
    random d ~ n(0, var=s2) subject=_obs_;
    mu = beta1 + beta2*expd + beta3*sex + beta4*hgt + beta5*age + d;
    do i = 1 to 3;
        p[i] = logistic(mu + beta6*yrswrk[i] + beta7*smoke[i]);
    end;
    model y1 ~ binary(p1);
    model y2 ~ binary(p2);
    model y3 ~ binary(p3);

    nu = phi1 + phi2*expd + phi3*sex + phi4*hgt + phi5*age;
    q2 = logistic(nu + phi6*yrswrk[2] + phi7*smoke[2] +
        phi8*y1 + phi9*y2);
    model r2 ~ binary(q2);
    q3 = logistic(nu + phi6*yrswrk[3] + phi7*smoke[3] +
        phi9*y2 + phi10*y3);
    model r3 ~ binary(q3);
run;

```

The first **ARRAY** statement declares an array `p` of size 3. This array stores three binary probabilities of the response variables. The next two **ARRAY** statements create storage arrays for some of `yrswrk` and `smoke` variables for later programming convenience. The first **PARMS** statement declares eight parameters, $\beta_1 - \beta_7$ and σ^2 . The second **PARMS** statement declares the 10 ϕ parameters for the missing mechanism model. The **PRIOR** statements assign prior distributions to these parameters.

The **RANDOM** statement defines an observational-level random effect `d` that has a normal prior with variance `s2`. The **SUBJECT=_OBS_** option enables the specification of individual random effects without an explicit input data set variable.

The **MU** assignment statement and the following **DO** loop statements calculate the binary probabilities for the three response variables. Note that different `yrswrk` and `smoke` variables are used in the **DO** loop for different years. The three **MODEL** statements assign three binary distributions to the response variables.

The **NU** assignment statement starts the calculation for the regression mean in the logistic model for `r2` and `r3`. The variables `q2` and `q3` are the binary probabilities for the missing mechanisms. Note that their calculations are conditional on the response variables `y` (pattern mixture model). The last two **MODEL** statements for `r2` and `r3` complete the specification of the models.

Missing data information and random-effects parameters information are displayed in [Output 55.11.1](#). You can read the total number of missing observations from each variable and its indices from the table. The missing values are sampled using the inverse CDF method. There are 912 random-effects parameters in the model.

Output 55.11.1 Missing Data and Random-Effects Information

Example 55.12: Change Point Models

Consider the data set from Bacon and Watts (1971), where y_i is the logarithm of the height of the stagnant surface layer and the covariate x_i is the logarithm of the flow rate of water. The following statements create the data set:

```

title 'Change Point Model';
data stagnant;
  input y x @@;
  ind = _n_;
  datalines;
1.12 -1.39 1.12 -1.39 0.99 -1.08 1.03 -1.08
0.92 -0.94 0.90 -0.80 0.81 -0.63 0.83 -0.63
0.65 -0.25 0.67 -0.25 0.60 -0.12 0.59 -0.12
0.51 0.01 0.44 0.11 0.43 0.11 0.43 0.11
0.33 0.25 0.30 0.25 0.25 0.34 0.24 0.34
0.13 0.44 -0.01 0.59 -0.13 0.70 -0.14 0.70
-0.30 0.85 -0.33 0.85 -0.46 0.99 -0.43 0.99
-0.65 1.19
;

```

A scatter plot (Output 55.12.1) shows the presence of a nonconstant slope in the data. This suggests a change point regression model (Carlin, Gelfand, and Smith 1992). The following statements generate the scatter plot in Output 55.12.1:

```

ods graphics on;
proc sgplot data=stagnant;
  scatter x=x y=y;
run;

```

Output 55.12.1 Scatter Plot of the Stagnant Data Set

Let the change point be cp . Following formulation by Spiegelhalter et al. (1996b), the regression model is as follows:

$$y_i \sim \begin{cases} \text{normal}(\alpha + \beta_1(x_i - cp), \sigma^2) & \text{if } x_i < cp \\ \text{normal}(\alpha + \beta_2(x_i - cp), \sigma^2) & \text{if } x_i \geq cp \end{cases}$$

You might consider the following diffuse prior distributions:

$$\begin{aligned} cp &\sim \text{uniform}(-1.3, 1.1) \\ \alpha, \beta_1, \beta_2 &\sim \text{normal}(0, \text{var} = 1e6) \\ \sigma^2 &\sim \text{uniform}(0, 5) \end{aligned}$$

The following statements generate [Output 55.12.2](#):

```
proc mcmc data=stagnant outpost=postout seed=24860 ntu=1000
      nmc=20000;
      ods select PostSummaries;
      ods output PostSummaries=ds;

      array beta[2];
      parms alpha cp beta1 beta2;
      parms s2;

      prior cp ~ unif(-1.3, 1.1);
      prior s2 ~ uniform(0, 5);
```

```

prior alpha beta: ~ normal(0, v = 1e6);

j = 1 + (x >= cp);
mu = alpha + beta[j] * (x - cp);
model y ~ normal(mu, var=s2);
run;

```

The PROC MCMC statement specifies the input data set (Stagnant), the output data set (Postout), a random number seed, a tuning sample of 1000, and an MCMC sample of 20000. The ODS SELECT statement displays only the summary statistics table. The ODS OUTPUT statement saves the summary statistics table to the data set Ds.

The **ARRAY** statement allocates an array of size 2 for the beta parameters. You can use beta1 and beta2 as parameter names without allocating an array, but having the array makes it easier to construct the likelihood function. The two **PARMS** statements put the five model parameters in two blocks. The three **PRIOR** statements specify the prior distributions for these parameters.

The symbol j indicates the segment component of the regression. When x is less than the change point, (x < cp) returns 0 and j is assigned the value 1; if x is greater than or equal to the change point, (x >= cp) returns 1 and j is 2. The symbol mu is the mean for the jth segment, and beta[j] changes between the two regression coefficients depending on the segment component. The **MODEL** statement assigns the normal model to the response variable y.

Posterior summary statistics are shown in [Output 55.12.2](#).

Output 55.12.2 MCMC Estimates of the Change Point Regression Model

Change Point Model						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
alpha	20000	0.5349	0.0249	0.5188	0.5341	0.5509
cp	20000	0.0283	0.0314	0.00728	0.0303	0.0493
beta1	20000	-0.4200	0.0146	-0.4293	-0.4198	-0.4111
beta2	20000	-1.0136	0.0167	-1.0248	-1.0136	-1.0023
s2	20000	0.000451	0.000145	0.000348	0.000425	0.000522

You can use PROC SGPLOT to visualize the model fit. [Output 55.12.3](#) shows the fitted regression lines over the original data. In addition, on the bottom of the plot is the kernel density of the posterior marginal distribution of cp, the change point. The kernel density plot shows the relative variability of the posterior distribution on the data plot. You can use the following statements to create the plot:

```

data _null_;
  set ds;
  call symputx(parameter, mean);
run;

data b;
  missing A;
  input x1 @@;
  if x1 eq .A then x1 = &cp;
  if _n_ <= 2 then y1 = &alpha + &beta1 * (x1 - &cp);
  else y1 = &alpha + &beta2 * (x1 - &cp);
  datalines;
-1.5 A 1.2
;

proc kde data=postout;
  univar cp / out=m1 (drop=count);
run;

data m1;
  set m1;
  density = (density / 25) - 0.653;
run;

data all;
  set stagnant b m1;
run;

proc sgplot data=all noautolegend;
  scatter x=x y=y;
  series x=x1 y=y1 / lineattrs = graphdata2;
  series x=value y=density / lineattrs = graphdata1;
run;
ods graphics off;

```

The macro variables &alpha, &beta1, &beta2, and &cp store the posterior mean estimates from the data set Ds. The data set b contains three predicted values, at the minimum and maximum values of x and the estimated change point &cp. These input values give you fitted values from the regression model. Data set M1 contains the kernel density estimates of the parameter cp. The density is scaled down so the curve would fit in the plot. Finally, you use PROC SGPLOT to overlay the scatter plot, regression line and kernel density plots in the same graph.

Output 55.12.3 Estimated Fit to the Stagnant Data Set

Example 55.13: Exponential and Weibull Survival Analysis

This example covers two commonly used survival analysis models: the exponential model and the Weibull model. The deviance information criterion (DIC) is used to do model selections, and you can also find programs that visualize posterior quantities. Exponential and Weibull models are widely used for survival analysis. This example shows you how to use PROC MCMC to analyze the treatment effect for the E1684 melanoma clinical trial data. These data were collected to assess the effectiveness of using interferon alpha-2b in chemotherapeutic treatment of melanoma. The following statements create the data set:

```

data e1684;
  input t t_cen treatment @@;
  if t = . then do;
    t = t_cen;
    v = 0;
  end;
  else
    v = 1;
  ifn = treatment - 1;
  et = exp(t);
  lt = log(t);
  drop t_cen;
  datalines;
1.57808 0.00000 2 1.48219 0.00000 2 . 7.33425 1
2.23288 0.00000 1 . 9.38356 2 3.27671 0.00000 1
. 9.64384 1 1.66575 0.00000 2 0.94247 0.00000 1
1.68767 0.00000 2 2.34247 0.00000 2 0.89863 0.00000 1

... more lines ...

3.39178 0.00000 1 . 4.36164 2 . 4.81918 2
;

```

The data set E1684 contains the following variables: t is the failure time that equals the censoring time whether the observation was censored, v indicates whether the observation is an actual failure time or a censoring time, $treatment$ indicates two levels of treatments, and ifn indicates the use of interferon as a treatment. The variables et and lt are the exponential and logarithm transformation of the time t . The published data contains other potential covariates that are not listed here. This example concentrates on the effectiveness of the interferon treatment.

Exponential Survival Model

The density function for exponentially distributed survival times is as follows:

$$p(t_i | \lambda_i) = \lambda_i \exp(-\lambda_i t_i)$$

Note that this formulation of the exponential distribution is different from what is used in the SAS probability function PDF. The definition used in PDF for the exponential distributions is as follows:

$$p(t_i | v_i) = \frac{1}{v_i} \exp\left(-\frac{t_i}{v_i}\right)$$

The relationship between λ and v is as follows:

$$\lambda_i = \frac{1}{v_i}$$

The corresponding survival function, using the λ_i formulation, is as follows:

$$S(t_i | \lambda_i) = \exp(-\lambda_i t_i)$$

If you have a sample $\{t_i\}$ of n independent exponential survival times, each with mean λ_i , then the likelihood function in terms of λ is as follows:

$$\begin{aligned} L(\lambda|t) &= \prod_{i=1}^n p(t_i|\lambda_i)^{v_i} S(t_i|\lambda_i)^{1-v_i} \\ &= \prod_{i=1}^n (\lambda_i \exp(-\lambda_i t_i))^{v_i} (\exp(-\lambda_i t_i))^{1-v_i} \\ &= \prod_{i=1}^n \lambda_i^{v_i} \exp(-\lambda_i t_i) \end{aligned}$$

If you link the covariates to λ with $\lambda_i = \exp \mathbf{x}_i' \boldsymbol{\beta}$, where \mathbf{x}_i is the vector of covariates corresponding to the i th observation and $\boldsymbol{\beta}$ is a vector of regression coefficients, then the log-likelihood function is as follows:

$$l(\boldsymbol{\beta}|t, \mathbf{x}) = \sum_{i=1}^n v_i \mathbf{x}_i' \boldsymbol{\beta} - t_i \exp(\mathbf{x}_i' \boldsymbol{\beta})$$

In the absence of prior information about the parameters in this model, you can choose diffuse normal priors for the $\boldsymbol{\beta}$:

$$\boldsymbol{\beta} \sim \text{normal}(0, \text{sd}=10000)$$

There are two ways to program the log-likelihood function in PROC MCMC. You can use the SAS functions LOGPDF and LOGSDF. Alternatively, you can use the simplified log-likelihood function, which is more computationally efficient. You get identical results by using either approaches.

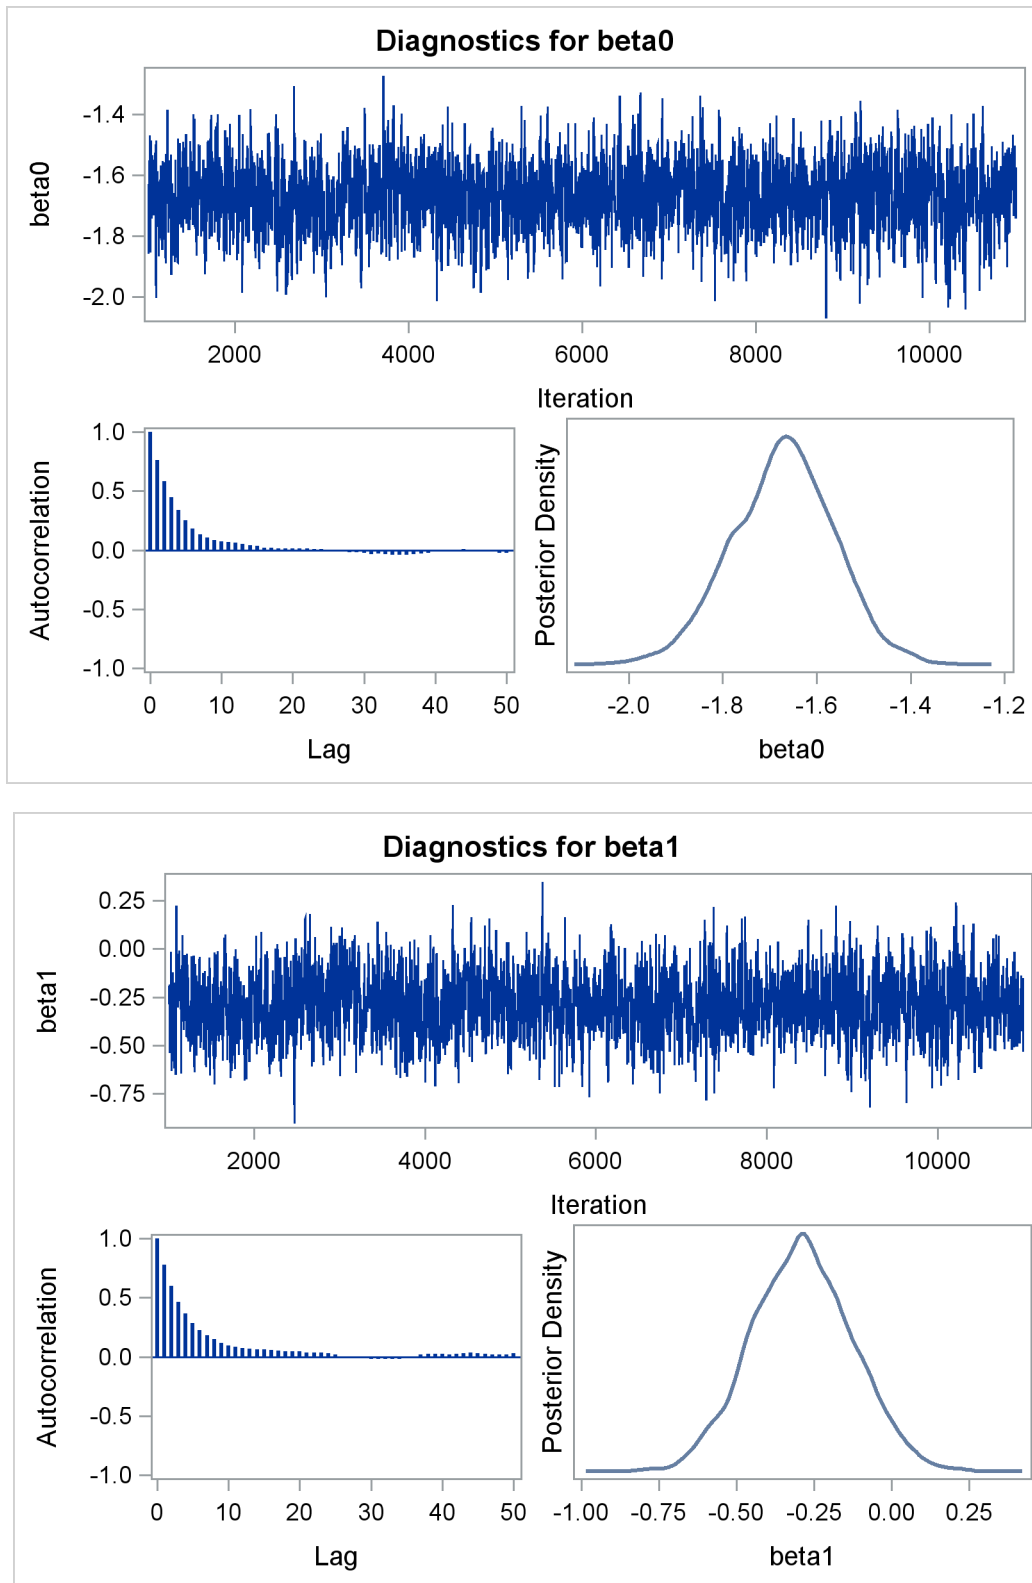

The following PROC MCMC statements fit an exponential model with simplified log-likelihood function:

```
title 'Exponential Survival Model';
ods graphics on;
proc mcmc data=e1684 outpost=expsurvout nmc=10000 seed=4861;
  ods select PostSummaries PostIntervals TADpanel
             ess mcse;
  parms (beta0 beta1) 0;
  prior beta: ~ normal(0, sd = 10000);
  /* *****
  /* (1) the logpdf and logsdf functions are not used */
  /* *****
  /*      nu = 1/exp(beta0 + beta1*ifn);
  /*      llike = v*logpdf("exponential", t, nu) +
  /*              (1-v)*logsdf("exponential", t, nu);
  /*
  /* *****
  /* (2) the simplified likelihood formula is used */
  /* *****
  l_h = beta0 + beta1*ifn;
  llike = v*(l_h) - t*exp(l_h);
  model general(llike);
run;
```

The two assignment statements that are commented out calculate the log-likelihood function by using the SAS functions LOGPDF and LOGSDF for the exponential distribution. The next two assignment statements calculate the log likelihood by using the simplified formula. The first approach is slower because of the redundant calculation involved in calling both LOGPDF and LOGSDF.

An examination of the trace plots for β_0 and β_1 (see [Output 55.13.1](#)) reveals that the sampling has gone well with no particular concerns about the convergence or mixing of the chains.

Output 55.13.1 Posterior Plots for β_0 and β_1 in the Exponential Survival Analysis

The MCMC results are shown in [Output 55.13.2](#).

Output 55.13.2 Posterior Summary and Interval Statistics

Exponential Survival Model						
The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
beta0	10000	-1.6715	0.1091	-1.7426	-1.6684	-1.5964
beta1	10000	-0.2879	0.1615	-0.4001	-0.2892	-0.1803
Posterior Intervals						
Parameter	Alpha	Equal-Tail Interval		HPD Interval		
beta0	0.050	-1.8907	-1.4639	-1.8930	-1.4673	
beta1	0.050	-0.5985	0.0300	-0.6104	0.0169	

The Monte Carlo standard errors and effective sample sizes are shown in [Output 55.13.3](#). The posterior means for β_0 and β_1 are estimated with high precision, with small standard errors with respect to the standard deviation. This indicates that the mean estimates have stabilized and do not vary greatly in the course of the simulation. The effective sample sizes are roughly the same for both parameters.

Output 55.13.3 MCSE and ESS

Exponential Survival Model			
The MCMC Procedure			
Monte Carlo Standard Errors			
Parameter	MCSE	Standard Deviation	MCSE/SD
beta0	0.00302	0.1091	0.0277
beta1	0.00485	0.1615	0.0301
Effective Sample Sizes			
Parameter	ESS	Autocorrelation Time	Efficiency
beta0	1304.1	7.6682	0.1304
beta1	1107.2	9.0319	0.1107

The next part of this example shows fitting a Weibull regression to the data and then comparing the two models with DIC to see which one provides a better fit to the data.

Weibull Survival Model

The density function for Weibull distributed survival times is as follows:

$$p(t_i | \alpha, \lambda_i) = \alpha t_i^{\alpha-1} \exp(\lambda_i - \exp(\lambda_i) t_i^\alpha)$$

Note that this formulation of the Weibull distribution is different from what is used in the SAS probability function PDF. The definition used in PDF is as follows:

$$p(t_i | \alpha, \gamma_i) = \exp\left(-\left(\frac{t_i}{\gamma_i}\right)^\alpha\right) \frac{\alpha}{\gamma_i} \left(\frac{t_i}{\gamma_i}\right)^{\alpha-1}$$

The relationship between λ and γ in these two parameterizations is as follows:

$$\lambda_i = -\alpha \log \gamma_i$$

The corresponding survival function, using the λ_i formulation, is as follows:

$$S(t_i | \alpha, \lambda_i) = \exp(-\exp(\lambda_i) t_i^\alpha)$$

If you have a sample $\{t_i\}$ of n independent Weibull survival times, with parameters α , and λ_i , then the likelihood function in terms of α and λ is as follows:

$$\begin{aligned} L(\alpha, \lambda | t) &= \prod_{i=1}^n p(t_i | \alpha, \lambda_i)^{v_i} S(t_i | \alpha, \lambda_i)^{1-v_i} \\ &= \prod_{i=1}^n (\alpha t_i^{\alpha-1} \exp(\lambda_i - \exp(\lambda_i) t_i^\alpha))^{v_i} (\exp(-\exp(\lambda_i) t_i^\alpha))^{1-v_i} \\ &= \prod_{i=1}^n (\alpha t_i^{\alpha-1} \exp(\lambda_i))^{v_i} (\exp(-\exp(\lambda_i) t_i^\alpha)) \end{aligned}$$

If you link the covariates to λ with $\lambda_i = \mathbf{x}_i' \boldsymbol{\beta}$, where \mathbf{x}_i is the vector of covariates corresponding to the i th observation and $\boldsymbol{\beta}$ is a vector of regression coefficients, the log-likelihood function becomes this:

$$l(\alpha, \boldsymbol{\beta} | t, \mathbf{x}) = \sum_{i=1}^n v_i (\log(\alpha) + (\alpha - 1) \log(t_i) + \mathbf{x}_i' \boldsymbol{\beta}) - \exp(\mathbf{x}_i' \boldsymbol{\beta}) t_i^\alpha$$

As with the exponential model, in the absence of prior information about the parameters in this model, you can use diffuse normal priors on $\boldsymbol{\beta}$. You might want to choose a diffuse gamma distribution for α . Note that when $\alpha = 1$, the Weibull survival likelihood reduces to the exponential survival likelihood. Equivalently, by looking at the posterior distribution of α , you can conclude whether fitting an exponential survival model would be more appropriate than the Weibull model.

PROC MCMC also enables you to make inference on any functions of the parameters. Quantities of interest in survival analysis include the value of the survival function at specific times for specific treatments and the relationship between the survival curves for different treatments. With PROC MCMC, you can compute a sample from the posterior distribution of the interested survival functions at any number of points. The data in this example range from about 0 to 10 years, and the treatment of interest is the use of interferon.

Like in the previous exponential model example, there are two ways to fit this model: using the SAS functions LOGPDF and LOGSDF, or using the simplified log likelihood functions. The example uses the latter method. The following statements run PROC MCMC and produce [Output 55.13.4](#):

```

title 'Weibull Survival Model';
proc mcmc data=e1684 outpost=weisurvout nmc=10000 seed=1234
    monitor=(_parms_ surv_ifn surv_noifn);
    ods select PostSummaries;
    ods output PostSummaries=ds PostIntervals=is;
    array surv_ifn[10];
    array surv_noifn[10];
    parms alpha 1 (beta0 beta1) 0;
    prior beta: ~ normal(0, var=10000);
    prior alpha ~ gamma(0.001,is=0.001);

    beginnodata;
        do t1 = 1 to 10;
            surv_ifn[t1] = exp(-exp(beta0+beta1)*t1**alpha);
            surv_noifn[t1] = exp(-exp(beta0)*t1**alpha);
        end;
    endnodata;

    lambda = beta0 + beta1*ifn;
    /******
    /* (1) the logpdf and logsdf functions are not used */
    /******
    /*      gamma = exp(-lambda /alpha);
    /*      llike = v*logpdf('weibull', t, alpha, gamma) +
    /*              (1-v)*logsdf('weibull', t, alpha, gamma);
    /*
    /******
    /* (2) the simplified likelihood formula is used */
    /******
    llike = v*(log(alpha) + (alpha-1)*log(t) + lambda) -
            exp(lambda)*(t**alpha);
    model general(llike);
run;

```

The **MONITOR=** option indicates the parameters and quantities of interest that PROC MCMC tracks. The symbol **_PARMS_** specifies all model parameters. The array **surv_ifn** stores the expected survival probabilities for patients who received interferon over a period of 10 years. Similarly, **surv_noifn** stores the expected survival probabilities for patients who did not received interferon.

The **BEGINNODATA** and **ENDNODATA** statements enclose the calculations for the survival probabilities. The assignment statements proceeding the **MODEL** statement calculate the log likelihood for the Weibull survival model. The **MODEL** statement specifies the log likelihood that you programmed.

An examination of the trace plots for α , β_0 , and β_1 (not displayed here) reveals that the sampling has gone well, with no particular concerns about the convergence or mixing of the chains.

Output 55.13.4 displays the posterior summary statistics.

Output 55.13.4 Posterior Summary Statistics

Weibull Survival Model						
The MCMC Procedure						
Posterior Summaries

surv_noifn6	10000	0.3475	0.0411	0.3195	0.3459	0.3745
surv_noifn7	10000	0.3034	0.0411	0.2758	0.3012	0.3299
surv_noifn8	10000	0.2661	0.0406	0.2384	0.2630	0.2921
surv_noifn9	10000	0.2342	0.0399	0.2069	0.2311	0.2592
surv_noifn10	10000	0.2069	0.0389	0.1803	0.2035	0.2312

An examination of the α parameter reveals that the exponential model might not be inappropriate here. The estimated posterior mean of α is 0.7856 with a posterior standard deviation of 0.0533. As noted previously, if $\alpha = 1$, then the Weibull survival distribution is the exponential survival distribution. With these data, you can see that the evidence is in favor of $\alpha < 1$. The value 1 is almost 4 posterior standard deviations away from the posterior mean. The following statements compute the posterior probability of the hypothesis that $\alpha < 1$:

```
proc format;
  value alphafmt low-<1 = 'alpha < 1' 1-high = 'alpha >= 1';
run;

proc freq data=weisurvout;
  tables alpha /nocum;
  format alpha alphafmt.;
run;
```

The PROC FREQ results are shown in [Output 55.13.5](#).

Output 55.13.5 Frequency Analysis of α

Weibull Survival Model		
The FREQ Procedure		
alpha	Frequency	Percent
alpha < 1	9998	99.98
alpha >= 1	2	0.02

The output from PROC FREQ shows that 100% of the 10000 simulated values for α are less than 1. This is a very strong indication that the exponential model is too restrictive to model these data well.

You can examine the estimated survival probabilities over time individually, either through the posterior summary statistics or by looking at the kernel density plots. Alternatively, you might find it more informative to examine these quantities in relation with each other. For example, you can use a side-by-side box plot to display these posterior distributions by using PROC SGPLOT (“[Statistical Graphics Using ODS](#)” on page 579). First you need to take the posterior output data set `Weisurvout` and stack variables that you want to plot. For example, to plot all the survival times for patients who received interferon, you want to stack `surv_inf1–surv_inf10`. The macro `%Stackdata` takes an input data set `dataset`, stacks the wanted variables `vars`, and outputs them into the output data set.

The following statements define the macro `stackdata`:

```
/* define macro stackdata */
%macro StackData(dataset,output,vars);
  data &output;
    length var $ 32;
    if 0 then set &dataset nobs=nnn;
    array l11[*] &vars;
    do jjj=1 to dim(l11);
      do iii=1 to nnn;
        set &dataset point=iii;
        value = l11[jjj];
        call vname(l11[jjj],var);
        output;
      end;
    end;
  stop;
  keep var value;
run;
%mend;

/* stack the surv_ifn variables and saved them to survifn. */
%StackData(weisurvout, survifn, surv_ifn1–surv_ifn10);
```

Once you stack the data, use PROC SGPLOT to create the side-by-side box plots. The following statements generate [Output 55.13.6](#):

```
proc sgplot data=survifn;
  yaxis label='Survival Probability' values=(0 to 1 by 0.2);
  xaxis label='Time' discreteorder=data;
  vbox value / category=var;
run;
```

Output 55.13.6 Side-by-Side Box Plots of Estimated Survival Probabilities

There is a clear decreasing trend over time of the survival probabilities for patients who receive the treatment. You might ask how does this group compare to those who did not receive the treatment? In this case, you want to overlay the two predicted curves for the two groups of patients and add the corresponding credible interval. See [Output 55.13.7](#). To generate the graph, you first take the posterior mean estimates from the ODS output table ds and the lower and upper HPD interval estimates is, store them in the data set Surv, and draw the figure by using PROC SGPLOT.

The following statements generate data set Surv:

```
data surv;
  set ds;
  if _n_ >= 4 then do;
    set is point=_n_;
    group = 'with interferon';
    time = _n_ - 3;
    if time > 10 then do;
      time = time - 10;
      group = 'without interferon';
    end;
  end;
```

```

output;
end;
keep time group mean hpdlower hpdupper;
run;

```

The following SGLOT statements generate [Output 55.13.7](#):

```

proc sgplot data=surv;
  yaxis label="Survival Probability" values=(0 to 1 by 0.2);
  series x=time y=mean / group = group name='i';
  band x=time lower=hpdlower upper=hpdupper / group = group transparency=0.7;
  keylegend 'i';
run;
ods graphics off;

```

In [Output 55.13.7](#), the solid line is the survival curve for patients who received interferon; the shaded region centers at the solid line is the 95% HPD intervals; the medium-dashed line is the survival curve for patients who did not receive interferon; and the shaded region around the dashed line is the corresponding 95% HPD intervals.

Output 55.13.7 Predicted Survival Probability Curves with 95% HPD Intervals

The plot suggests that there is an effect of using interferon because patients who received interferon have sustained better survival probabilities than those who did not. However, the effect might not be very significant, as the 95% credible intervals of the two groups do overlap. For more on these interferon studies, see Ibrahim, Chen, and Lipsitz (2001).

Weibull or Exponential?

Although the evidence from the Weibull model fit shows that the posterior distribution of α has a significant amount of density mass less than 1, suggesting that the Weibull model is a better fit to the data than the exponential model, you might still be interested in comparing the two models more formally. You can use the Bayesian model selection criterion (see the section “[Deviance Information Criterion \(DIC\)](#)” on page 155) to determine which model fits the data better.

The PROC MCMC [DIC](#) option requests the calculation of DIC, and the procedure displays the ODS output table [DIC](#). The table includes the posterior mean of the deviation, $\overline{D(\theta)}$, deviation at the estimate, $D(\hat{\theta})$, effective number of parameters, p_D , and DIC. It is important to remember that the standardizing term, $p(y)$, which is a function of the data alone, is not taken into account in calculating the DIC. This term is irrelevant only if you compare two models that have the *same* likelihood function. If you do not have identical likelihood functions, using DIC for model selection purposes without taking this standardizing term into account can produce incorrect results. In addition, you want to be careful in interpreting the DIC whenever you use the [GENERAL](#) function to construct the log-likelihood, as the case in this example. Using the [GENERAL](#) function, you can obtain identical posterior samples with two log-likelihood functions that differ only by a constant. This difference translates to a difference in the DIC calculation, which could be very misleading.

If $\alpha = 1$, the Weibull likelihood is identical to the exponential likelihood. It is safe in this case to directly compare DICs from these two models. However, if you do not want to work out the mathematical detail or you are uncertain of the equivalence, a better way of comparing the DICs is to run the Weibull model twice: once with α being a parameter and once with $\alpha = 1$. This ensures that the likelihood functions are the same, and the DIC comparison is meaningful.

The following statements fit a Weibull model:

```
title 'Model Comparison between Weibull and Exponential';
proc mcmc data=e1684 outpost=weisurvout nmc=10000 seed=4861 dic;
  ods select dic;
  parms alpha 1 (beta0 betal) 0;
  prior beta: ~ normal(0, var=10000);
  prior alpha ~ gamma(0.001,is=0.001);

  lambda = beta0 + betal*ifn;
  llike = v*(log(alpha) + (alpha-1)*log(t) + lambda) -
          exp(lambda)*(t**alpha);
  model general(llike);
run;
```

The **DIC** option requests the calculation of DIC, and the table is displayed in [Output 55.13.8](#).

Output 55.13.8 DIC Table from the Weibull Model

Model Comparison between Weibull and Exponential	
The MCMC Procedure	
Deviance Information Criterion	
Dbar (posterior mean of deviance)	858.623
Dmean (deviance evaluated at posterior mean)	855.633
pD (effective number of parameters)	2.990
DIC (smaller is better)	861.614
<p>The GENERAL or DGENERAL function is used in this program. To make meaningful comparisons, you must ensure that all GENERAL or DGENERAL functions include appropriate normalizing constants. Otherwise, DIC comparisons can be misleading.</p>	

The note in [Output 55.13.8](#) reminds you of the importance of ensuring identical likelihood functions when you use the **GENERAL** function. The DIC value is 861.6.

Based on the same set of code, the following statements fit an exponential model by setting $\alpha = 1$:

```
proc mcmc data=e1684 outpost=expsurvout nmc=10000 seed=4861 dic;
  ods select dic;
  parms beta0 beta1 0;
  prior beta: ~ normal(0, var=10000);
  begincnst;
    alpha = 1;
  endcnst;

  lambda = beta0 + beta1*ifn;
  llike = v*(log(alpha) + (alpha-1)*log(t) + lambda) -
    exp(lambda)*(t**alpha);
  model general(llike);
run;
```

[Output 55.13.9](#) displays the DIC table.

Output 55.13.9 DIC Table from the Exponential Model

Model Comparison between Weibull and Exponential	
The MCMC Procedure	
Deviance Information Criterion	
Dbar (posterior mean of deviance)	870.133
Dmean (deviance evaluated at posterior mean)	868.190
pD (effective number of parameters)	1.943
DIC (smaller is better)	872.075
The GENERAL or DGENERAL function is used in this program. To make meaningful comparisons, you must ensure that all GENERAL or DGENERAL functions include appropriate normalizing constants. Otherwise, DIC comparisons can be misleading.	

The DIC value of 872.075 is greater than 861. A smaller DIC indicates a better fit to the data; hence, you can conclude that the Weibull model is more appropriate for this data set. You can see the equivalencing of the exponential model you fitted in “[Exponential Survival Model](#)” on page 4605 by running the following comparison.

The following statements are taken from the section “[Exponential Survival Model](#)” on page 4605, and they fit the same exponential model:

```
proc mcmc data=e1684 outpost=expsurvout1 nmc=10000 seed=4861 dic;
  ods select none;
  parms (beta0 beta1) 0;
  prior beta: ~ normal(0, sd = 10000);
  l_h = beta0 + beta1*ifn;
  llike = v*(l_h) - t*exp(l_h);
  model general(llike);
run;

proc compare data=expsurvout compare=expsurvout1;
  var beta0 beta1;
run;
```

The posterior samples of beta0 and beta1 in the data set Expsurvout1 are identical to those in the data set Expsurvout. The comparison results are not shown here.

Example 55.14: Time Independent Cox Model

This example has two purposes. One is to illustrate how to use PROC MCMC to fit a Cox proportional hazard model. Specifically, the time independent model. See “[Example 55.15: Time Dependent Cox Model](#)” on page 4625 for an example on fitting time dependent Cox model. Note that it is much easier to fit a Bayesian Cox model by specifying the BAYES statement in PROC PHREG (see Chapter 67, “[The PHREG Procedure](#)”). If you are interested only in fitting a Cox regression survival model, you should use PROC PHREG.

The second objective of this example is to demonstrate how to model data that are not independent. That is the case where the likelihood for observation i depends on other observations in the data set. In other words, if you work with a likelihood function that cannot be broken down simply as $L(\mathbf{y}) = \prod_i^n L(y_i)$, you can use this example for illustrative purposes. By default, PROC MCMC assumes that the programming statements and model specification is intended for a single row of observations in the data set. The Cox model is chosen because the complexity in the data structure requires more elaborate coding.

The Cox proportional hazard model is widely used in the analysis of survival time, failure time, or other duration data to explain the effect of exogenous explanatory variables. The data set used in this example is taken from Krall, Uthoff, and Harley (1975), who analyzed data from a study on myeloma in which researchers treated 65 patients with alkylating agents. Of those patients, 48 died during the study and 17 survived. The following statements generate the data set that is used in this example:

```
data Myeloma;
  input Time Vstatus LogBUN HGB Platelet Age LogWBC Frac
        LogPBM Protein SCalc;
  label Time='survival time'
        VStatus='0=alive 1=dead';
  datalines;
1.25 1 2.2175 9.4 1 67 3.6628 1 1.9542 12 10
1.25 1 1.9395 12.0 1 38 3.9868 1 1.9542 20 18
2.00 1 1.5185 9.8 1 81 3.8751 1 2.0000 2 15
2.00 1 1.7482 11.3 0 75 3.8062 1 1.2553 0 12

... more lines ...

77.00 0 1.0792 14.0 1 60 3.6812 0 0.9542 0 12
;

proc sort data = Myeloma;
  by descending time;
run;

data _null_;
  set Myeloma nobs=_n;
  call symputx('N', _n);
  stop;
run;
```

The variable Time represents the survival time in months from diagnosis. The variable VStatus consists of two values, 0 and 1, indicating whether the patient was alive or dead, respectively, at the end of the study. If the value of VStatus is 0, the corresponding value of Time is censored. The variables thought to be related to survival are LogBUN (log(BUN) at diagnosis), HGB (hemoglobin at diagnosis), Platelet (platelets at diagnosis: 0=abnormal, 1=normal), Age (age at diagnosis in years), LogWBC (log(WBC) at diagnosis), Frac (fractures at diagnosis: 0=none, 1=present), LogPBM (log percentage of plasma cells in bone marrow), Protein (proteinuria at diagnosis), and SCalc (serum calcium at diagnosis). Interest lies in identifying important prognostic factors from these explanatory variables. In addition, there are 65 (&n) observations in the data set Myeloma. The likelihood used in these examples is the Breslow likelihood:

$$L(\boldsymbol{\beta}) = \prod_{i=1}^n \left[\prod_{j=1}^{d_i} \frac{\exp(\boldsymbol{\beta}' \mathbf{Z}_j(t_i))}{\sum_{l \in \mathcal{R}_i} \exp(\boldsymbol{\beta}' \mathbf{Z}_l(t_i))} \right]^{v_i}$$

where

- β is the vector parameters
- n is the total number of observations in the data set
- t_i is the i th time, which can be either event time or censored time
- $\mathbf{Z}_l(t)$ is the vector explanatory variables for the l th individual at time t
- d_i is the multiplicity of failures at t_i . If there are no ties in time, d_i is 1 for all i .
- \mathcal{R}_i is the risk set for the i th time t_i , which includes all observations that have survival time greater than or equal to t_i
- v_i indicates whether the patient is censored. The value 0 corresponds to censoring. Note that the censored time t_i enters the likelihood function only through the formation of the risk set \mathcal{R}_i .

Priors on the coefficients are independent normal priors with very large variance (1e6). Throughout this example, the symbol \mathbf{bZ} represents the regression term $\beta' \mathbf{Z}_j(t_i)$ in the likelihood, and the symbol \mathbf{S} represents the term $\sum_{l \in \mathcal{R}_i} \exp(\beta' \mathbf{Z}_l(t_i))$.

The regression model considered in this example uses the following formula:

$$\begin{aligned} \beta' \mathbf{Z}_j = & \beta_1 \text{logbun} + \beta_2 \text{hgb} + \beta_3 \text{platelet} + \beta_4 \text{age} + \\ & \beta_5 \text{logwbc} + \beta_6 \text{frac} + \beta_7 \text{logpbm} + \beta_8 \text{protein} + \beta_9 \text{scal} \end{aligned}$$

The hard part of coding this in PROC MCMC is the construction of the risk set \mathcal{R}_i . \mathcal{R}_i contains all observations that have survival time greater than or equal to t_i . First suppose that there are no ties in time. Sorting the data set by the variable time into descending order gives you \mathcal{R}_i that is in the right order. Observation i 's risk set consists of all data points j such that $j \leq i$ in the data set. You can cumulatively increment \mathbf{S} in the SAS statements.

With potential ties in time, at observation i , you need to know whether any subsequent observations, $i + 1$ and so on, have the same survival time as t_i . Suppose that the i th, the $i + 1$, and the $i + 2$ observations all have the same survival time; all three of them need to be included in the risk set calculation. This means that to calculate the likelihood for some observations, you need to access both the previous and subsequent observations in the data set. There are two ways to do this. One is to use the LAG function; the other is to use the option [JOINTMODEL](#).

The LAG function returns values from a queue (see *SAS Language Reference: Dictionary*). So for the i th observation, you can use LAG1 to access variables from the previous row in the data set. You want to compare the lag1 value of time with the current time value. Depending on whether the two time values are equal, you can add correction terms in the calculation for the risk set \mathbf{S} .

The following statements sort the data set by time into descending order, with the largest survival time on top:

```

title 'Cox Model with Time Independent Covariates';
proc freq data=myeloma;
    ods select none;
    tables time / out=freqs;
run;

proc sort data = freqs;
    by descending time;
run;

data myelomaM;
    set myeloma;
    ind = _N_;
run;
ods select all;

```

The following statements run PROC MCMC and produce [Output 55.14.1](#):

```

proc mcmc data=myelomaM outpost=outi nmc=50000 ntu=3000 seed=1;
    ods select PostSummaries PostIntervals;
    array beta[9];
    parms beta: 0;
    prior beta: ~ normal(0, var=1e6);

    bZ = beta1 * LogBUN + beta2 * HGB + beta3 * Platelet
        + beta4 * Age + beta5 * LogWBC + beta6 * Frac +
        beta7 * LogPBM + beta8 * Protein + beta9 * SCalc;

    if ind = 1 then do;                /* first observation          */
        S = exp(bZ);
        l = vstatus * bZ;
        v = vstatus;
    end;
    else if (1 < ind < &N) then do;
        if (lag1(time) ne time) then do;
            l = vstatus * bZ;
            l = l - v * log(S); /* correct the loglike value */
            v = vstatus;        /* reset v count value   */
            S = S + exp(bZ);
        end;
        else do;                /* still a tie           */
            l = vstatus * bZ;
            S = S + exp(bZ);
            v = v + vstatus;    /* add # of nonsensored values */
        end;
    end;
    else do;                /* last observation      */
        if (lag1(time) ne time) then do;
            l = - v * log(S); /* correct the loglike value */
            S = S + exp(bZ);
            l = l + vstatus * (bZ - log(S));
        end;
        else do;

```

```

      S = S + exp(bZ) ;
      l = vstatus * bZ - (v + vstatus) * log(S) ;
    end;
  end;
  model general(l) ;
run;

```

The symbol `bZ` is the regression term, which is independent of the time variable. The symbol `ind` indexes observation numbers in the data set. The symbol `S` keeps track of the risk set term for every observation. The symbol `l` calculates the log likelihood for each observation. Note that the value of `l` for observation `ind` is not necessarily the correct log likelihood value for that observation, especially in cases where the observation `ind` is in the tied times. Correction terms are added to subsequent values of `l` when the time variable becomes different in order to make up the difference. The total sum of `l` calculated over the entire data set is correct. The symbol `v` keeps track of the sum of `vstatus`, as censored data do not enter the likelihood and need to be taken out.

You use the function `LAG1` to detect if two adjacent time values are different. If they are, you know that the current observation is in a different risk set than the last one. You then need to add a correction term to the log likelihood value of `l`. The IF-ELSE statements break the observations into three parts: the first observation, the last observation and everything in the middle.

Output 55.14.1 Summary Statistics on Cox Model with Time Independent Explanatory Variables and Ties in the Survival Time, Using PROC MCMC

An alternative to using the LAG function is to use the PROC option [JOINTMODEL](#). With this option, the log-likelihood function you specify applies not to a single observation but to the entire data set. See “[Modeling Joint Likelihood](#)” on page 4504 for details on how to properly use this option. The basic idea is that you store all necessary data set variables in arrays and use only the arrays to construct the log likelihood of the entire data set. This approach works here because for every observation i , you can use index to access different values of arrays to construct the risk set S . To use the [JOINTMODEL](#) option, you need to do some additional data manipulation. You want to create a stop variable for each observation, which indicates the observation number that should be included in S for that observation. For example, if observations 4, 5, 6 all have the same survival time, the stop value for all of them is 6.

The following statements generate a new data set MyelomaM that contains the stop variable:

```
data myelomaM;
  merge myelomaM freqs(drop=percent);
  by descending time;
  retain stop;
  if first.time then do;
    stop = _n_ + count - 1;
  end;
run;
```

The following SAS program fits the same Cox model by using the [JOINTMODEL](#) option:

```
data a;
run;

proc mcmc data=a outpost=outa nmc=50000 ntu=3000 seed=1 jointmodel;
  ods select none;
  array beta[9];
  array data[1] / nosymbols;
  array timeA[1] / nosymbols;
  array vstatusA[1] / nosymbols;
  array stopA[1] / nosymbols;
  array bZ[&n];
  array S[&n];

  beginncnst;
```

```

rc = read_array("myelomam", data, "logbun", "hgb", "platelet",
               "age", "logwbc", "frac", "logpbm", "protein", "scalp");
rc = read_array("myelomam", timeA, "time");
rc = read_array("myelomam", vstatusA, "vstatus");
rc = read_array("myelomam", stopA, "stop");
endcnst;

parms (beta:) 0;
prior beta: ~ normal(0, var=1e6);

jl = 0;
/* calculate each bZ and cumulatively adding S as if there are no ties.*/
call mult(data, beta, bZ);
S[1] = exp(bZ[1]);
do i = 2 to &n;
    S[i] = S[i-1] + exp(bZ[i]);
end;

do i = 1 to &n;
    /* correct the S[i] term, when needed. */
    if(stopA[i] > i) then do;
        do j = (i+1) to stopA[i];
            S[i] = S[i] + exp(bZ[j]);
        end;
    end;
    jl = jl + vstatusA[i] * (bZ[i] - log(S[i]));
end;
model general(jl);
run;
ods select all;

```

No output tables were produced because this PROC MCMC run produces identical posterior samples as does the previous example.

Because the [JOINTMODEL](#) option is specified here, you do not need to specify myelomaM as the input data set. An empty data set a is used to speed up the procedure run.

Multiple [ARRAY](#) statements allocate array symbols that are used to store the parameters (beta), the response and the covariates (data, timeA, vstatusA, and stopA), and the work space (bZ and S). The data, timeA, vstatusA, and stopA arrays are declared with the [/NOSYMBOLS](#) option. This option enables PROC MCMC to dynamically resize these arrays to match the dimensions of the input data set. See the section [“READ_ARRAY Function”](#) on page 4442. The bZ and S arrays store the regression term and the risk set term for every observation.

The [BEGINCNST](#) and [ENDCNST](#) statements enclose programming statements that read the data set variables into these arrays. The rest of the programming statements construct the log likelihood for the entire data set.

The CALL MULT function calculates the regression term in the model and stores the result in the array bZ. In the first DO loop, you sum the risk set term S as if there are no ties in time. This underevaluates some of the S elements. For observations that have a tied time, you make the necessary correction to the corresponding S values. The correction takes place in the second DO loop. Any observation that has a tied time also has a stopA[i] that is different from i. You add the right terms to S and sum up the joint log likelihood jl. The [MODEL](#) statement specifies that the log likelihood takes on the value of jl.

To see that you get identical results from these two approaches, use PROC COMPARE to compare the posterior samples from two runs:

```
proc compare data=outi compare=outa;
  ods select comparesummary;
  var beta1-beta9;
run;
```

The output is not shown here.

Generally, the **JOINTMODEL** option can be slightly faster than using the default setup. The savings come from avoiding the overhead cost of accessing the data set repeatedly at every iteration. However, the speed gain is not guaranteed because it largely depends on the efficiency of your programs.

PROC PHREG fits the same model, and you get very similar results to PROC MCMC. The following statements fit the model using PROC PHREG and produce [Output 55.14.2](#):

```
proc phreg data=Myeloma;
  ods select PostSummaries PostIntervals;
  model Time*VStatus(0)=LogBUN HGB Platelet Age LogWBC
    Frac LogPBM Protein ScalC;
  bayes seed=1 nmc=10000 outpost=phout;
run;
```

Example 55.15: Time Dependent Cox Model

This example uses the same Myeloma data set as in “[Example 55.14: Time Independent Cox Model](#)” on page 4617, and illustrates the fitting of a time dependent Cox model. The following statements generate the data set once again:

```
data Myeloma;
  input Time Vstatus LogBUN HGB Platelet Age LogWBC Frac
        LogPBM Protein SCalc;
  label Time='survival time'
        VStatus='0=alive 1=dead';

... more lines ...

77.00 0 1.0792 14.0 1 60 3.6812 0 0.9542 0 12
;
```

To model $\mathbf{Z}_i(t_i)$ as a function of the survival time, you can relate time t_i to covariates by using this formula:

$$\boldsymbol{\beta}'\mathbf{Z}_j(t_i) = (\beta_1 + \beta_2 t_i)\text{logbun} + (\beta_3 + \beta_4 t_i)\text{hgb} + (\beta_5 + \beta_6 t_i)\text{platelet}$$

For illustrational purposes, only three explanatory variables, LOGBUN, HGB, and PLATELET, are used in this example.

Since $\mathbf{Z}_j(t_i)$ depends on t_i , every term in the summation of $\sum_{l \in \mathcal{R}_i} \exp(\boldsymbol{\beta}'\mathbf{Z}_l(t_i))$ is a product of the current time t_i and all observations that are in the risk set. You can use the **JOINTMODEL** option, as in the last example, or you can modify the input data set such that every row contains not only the current observation but also all observations that are in the corresponding risk set. When you construct the log likelihood for each observation, you have all the relevant data at your disposal.

The following statements illustrate how you can create a new data set with different risk sets at different rows:

```

title 'Cox Model with Time Dependent Covariates';
proc sort data = Myeloma;
    by descending time;
run;

data _null_;
    set Myeloma nobs=_n;
    call symputx('N', _n);
    stop;
run;

ods select none;
proc freq data=myeloma;
    tables time / out=freqs;
run;
ods select all;

proc sort data = freqs;
    by descending time;
run;

data myelomaM;
    set myeloma;
    ind = _N_;
run;

data myelomaM;
    merge myelomaM freqs(drop=percent); by descending time;
    retain stop;
    if first.time then do;
        stop = _n_ + count - 1;
    end;
run;

%macro array(list);
    %global mcmccarray;
    %let mcmccarray = ;
    %do i = 1 %to 32000;
        %let v = %scan(&list, &i, %str( ));
        %if %nrbquote(&v) ne %then %do;
            array _&v[&n];
            %let mcmccarray = &mcmccarray array _&v[&n] _&v.1 - _&v.&n%str(;);
            do i = 1 to stop;
                set myelomaM(keep=&v) point=i;
                _&v[i] = &v;
            end;
        %end;
    %else %let i = 32001;
    %end;
%mend;

```

```

data z;
  set myelomaM;
  %array(logbun hgb platelet);
  drop vstatus logbun hgb platelet count stop;
run;

data myelomaM;
  merge myelomaM z; by descending time;
run;

```

The data set MyelomaM contains 65 observations and 209 variables. For each observation, you see added variables stop, _logbun1 through _logbun65, _hgb1 through _hgb65, and _platelet1 through _platelet65. The variable stop indicates the number of observations that are in the risk set of the current observation. The rest are transposed values of model covariates of the entire data set. The data set contains a number of missing values. This is due to the fact that only the relevant observations are kept, such as _logbun1 to _logbunstop. The rest of the cells are filled in with missing values. For example, the first observation has a unique survival time of 92 and stop is 1, making it a risk set of itself. You see nonmissing values only in _logbun1, _hgb1, and _platelet1.

The following statements fit the Cox model by using PROC MCMC:

```

proc mcmc data=myelomaM outpost=outi nmc=50000 ntu=3000 seed=17
  missing=ac;
  ods select PostSummaries PostIntervals;
  array beta[6];
  &mcmcarray
  parms (beta:) 0;
  prior beta: ~ normal(0, prec=1e-6);

  b = (beta1 + beta2 * time) * logbun +
      (beta3 + beta4 * time) * hgb +
      (beta5 + beta6 * time) * platelet;
  S = 0;
  do i = 1 to stop;
    S = S + exp( (beta1 + beta2 * time) * _logbun[i] +
                (beta3 + beta4 * time) * _hgb[i] +
                (beta5 + beta6 * time) * _platelet[i]);
  end;
  loglike = vstatus * (b - log(S));

  model general(loglike);
run;

```

Note that the option **MISSING=** is set to AC. This is due to missing cells in the input data set. You must use this option so that PROC MCMC retains observations that contain missing values.

The macro variable &mcmcarray is defined in the earlier part in this example. You can use a **%put** statement to print its value:

```
%put &mcmcarray;
```

This statement prints the following:

```
array _logbun[65] _logbun1 - _logbun65; array _hgb[65] _hgb1 - _hgb65; array
```

```
_platelet[65] _platelet1 - _platelet65;
```

The macro uses the [ARRAY](#) statement to allocate three arrays, each of which links their corresponding data set variables. This makes it easier to reference these data set variables in the program. The [PARMS](#) statement puts all the parameters in the same block. The [PRIOR](#) statement gives them normal priors with large variance. The symbol *b* is the regression term, and *S* is cumulatively added from 1 to stop for each observation in the DO loop. The symbol *loglike* completes the construction of log likelihood for each observation and the [MODEL](#) statement completes the model specification.

Posterior summary and interval statistics are shown in [Output 55.15.1](#).

Output 55.15.1 Summary Statistics on Cox Model with Time Dependent Explanatory Variables and Ties in the Survival Time, Using PROC MCMC

Cox Model with Time Dependent Covariates

beta6	0.050	-0.1107	0.0295	-0.1122	0.0269	

You can also use the option [JOINTMODEL](#) to get the same inference and avoid transposing the data for every observation:

```
proc mcmc data=myelomaM outpost=outa nmc=50000 ntu=3000 seed=17 jointmodel;
ods select none;
array beta[6];          array timeA[&n];          array vstatusA[&n];
array logbunA[&n];      array hgbA[&n];          array plateletA[&n];
array stopA[&n];        array bZ[&n];            array S[&n];

beginncnst;
timeA[ind]=time;          vstatusA[ind]=vstatus;
```

```

        logbunA[ind]=logbun;      hgbA[ind]=hgb;
        plateletA[ind]=platelet;  stopA[ind]=stop;
    endcnst;

    parms (beta:) 0;
    prior beta: ~ normal(0, prec=1e-6);

    j1 = 0;
    do i = 1 to &n;
        v1 = beta1 + beta2 * timeA[i];
        v2 = beta3 + beta4 * timeA[i];
        v3 = beta5 + beta6 * timeA[i];
        bZ[i] = v1 * logbunA[i] + v2 * hgbA[i] + v3 * plateletA[i];

        /* sum over risk set without considering ties in time. */
        S[i] = exp(bZ[i]);
        if (i > 1) then do;
            do j = 1 to (i-1);
                b1 = v1 * logbunA[j] + v2 * hgbA[j] + v3 * plateletA[j];
                S[i] = S[i] + exp(b1);
            end;
        end;
    end;

    /* make correction to the risk set due to ties in time. */
    do i = 1 to &n;
        if(stopA[i] > i) then do;
            v1 = beta1 + beta2 * timeA[i];
            v2 = beta3 + beta4 * timeA[i];
            v3 = beta5 + beta6 * timeA[i];
            do j = (i+1) to stopA[i];
                b1 = v1 * logbunA[j] + v2 * hgbA[j] + v3 * plateletA[j];
                S[i] = S[i] + exp(b1);
            end;
        end;
        j1 = j1 + vstatusA[i] * (bZ[i] - log(S[i]));
    end;
    model general(j1);
run;

```

The multiple **ARRAY** statements allocate array symbols that are used to store the parameters (beta), the response (timeA), the covariates (vstatusA, logbunA, hgbA, plateletA, and stopA), and work space (bZ and S). The bZ and S arrays store the regression term and the risk set term for every observation. Programming statements in the **BEGINCNST** and **ENDCNST** statements input the response and covariates from the data set to the arrays.

Using the same technique shown in the example “[Example 55.14: Time Independent Cox Model](#)” on page 4617, the next DO loop calculates the regression term and corresponding S for every observation, pretending that there are no ties in time. This means that the risk set for observation *i* involves only observation 1 to *i*. The correction terms are added to the corresponding S[i] in the second DO loop, conditional on whether the stop variable is greater than the observation count itself. The symbol j1 cumulatively adds the log likelihood for the entire data set, and the **MODEL** statement specifies the joint log-likelihood function.

The following statements run PROC COMPARE and show that the output data set outa contains identical posterior samples as outi:

```
proc compare data=outi compare=outa;
  ods select comparesummary;
  var beta1-beta6;
run;
```

The results are not shown here.

The following statements use PROC PHREG to fit the same time dependent Cox model:

```
proc phreg data=Myeloma;
  ods select PostSummaries PostIntervals;
  model Time*VStatus(0)=LogBUN z2 hgb z3 platelet z4;
  z2 = Time*logbun;
  z3 = Time*hgb;
  z4 = Time*platelet;
  bayes seed=1 nmc=10000 outpost=phout;
run;
```

Coding is simpler than PROC MCMC. See [Output 55.15.2](#) for posterior summary and interval statistics:

Example 55.16: Piecewise Exponential Frailty Model

This example illustrates how to fit a piecewise exponential frailty model using PROC MCMC. Part of the notation and presentation in this example follows Clayton (1991) and the Luek example in Spiegelhalter et al. (1996a).

Generally speaking, the proportional hazards model assumes the hazard function,

$$\lambda_i(t|\mathbf{z}_i) = \lambda_0(t) \exp\{\boldsymbol{\beta}'\mathbf{z}_i\}$$

where $i = 1 \cdots n$ indexes subject, $\lambda_0(t)$ is the baseline hazard function, and \mathbf{z}_i are the covariates for subject i . If you define $N_i(t)$ to be the number of observed failures of the i th subject up to time t , then the hazard function for the i th subject can be seen as a special case of a *multiplicative intensity model* (Clayton 1991). The intensity process for $N_i(t)$ becomes

$$I_i(t) = Y_i(t)\lambda_0(t) \exp(\boldsymbol{\beta}'\mathbf{z}_i)$$

where $Y_i(t)$ indicates observation of the subject at time t (taking the value of 1 if the subject is observed and 0 otherwise). Under *noninformative censoring*, the corresponding likelihood is proportional to

$$\prod_{i=1}^n \left[\prod_{t \geq 0} I_i(t) \right]^{dN_i(t)} \exp \left[- \int_{t \geq 0} I_i(t) dt \right]$$

where $dN_i(t)$ is the increment of $N_i(t)$ over the small time interval $[t, t + dt)$: it takes a value of 1 if the subject i fails in the time interval, 0 otherwise. This is a Poisson kernel with the random variable being the increments of dN_i and the means $I_i(t)dt$

$$dN_i(t) \sim \text{Poisson}(I_i(t)dt)$$

where

$$I_i(t)dt = Y_i(t) \exp(\boldsymbol{\beta}'\mathbf{z}_i) d\Lambda_0(t)$$

and

$$\Lambda_0(t) = \int_0^t \lambda_0(u) du.$$

The integral is the increment in the integrated baseline hazard function that occurs during the time interval $[t, t + dt)$.

This formulation provides an alternative way to fit a piecewise exponential model. You partition the time axis to a few intervals, where each interval has its own hazard rate, $\Lambda_0(t)$. You count the $Y_i(t)$ and $dN_i(t)$ in each interval, and fit a Poisson model to each count.

The following DATA step creates the data set Blind (Lin 1994) that represents 197 diabetic patients who have a high risk of experiencing blindness in both eyes as defined by DRS criteria:

```

title 'Piecewise Exponential Model';
data Blind;
    input ID Time Status DiabeticType Treatment @@;
    datalines;

        ... more lines ...

      1705  8.00 0 0 1 1705  8.00 0 0 0 1717 51.60 0 1 1 1717 42.33 1 1 0
      1727 49.97 0 1 1 1727  2.90 1 1 0 1746 45.90 0 0 1 1746  1.43 1 0 0
      1749 41.93 0 1 1 1749 41.93 0 1 0
    ;

```

One eye of each patient is treated with laser photocoagulation. The hypothesis of interest is whether the laser treatment delays the occurrence of blindness. The following variables are included in `Blind`:

- ID, patient's identification
- Time, failure time
- Status, event indicator (0=censored and 1=uncensored)
- Treatment, treatment received (1=laser photocoagulation and 0=otherwise)
- DiabeticType, type of diabetes (0=juvenile onset with age of onset at 20 or under, and 1= adult onset with age of onset over 20)

For illustrational purposes, a piecewise exponential model that ignores the patient-level frailties is first fit to the entire data set. The formulation of the Poisson counting process makes it straightforward to add the frailty terms, as it is demonstrated later.

The following statements create a partition (of length 8) along the time axis, with $s_0 < s_1 < s_2 < \dots < s_J$, with $s_0 = 0.1 < y_i$ and $s_J = 80 > y_i$ for all i . The time intervals are stored in the `Partition` data set:

```

data partition;
    input int_1-int_9;
    datalines;
        0.1  6.545  13.95  26.47  38.8  45.88  54.35  62 80
    ;

```

To obtain reasonable estimates, placing an equal number of observations in each interval is recommended. You can find the partition points by calculating the percentile statistics of the time variable (for example, by using the `UNIVARIATE` procedure).

The following regression model and prior distributions are used in the analysis:

$$\begin{aligned}\beta'z_i &= \beta_1\text{treatment} + \beta_2\text{diabetictype} + \beta_3\text{treatment} * \text{diabetictype} \\ \beta_1, \beta_2, \beta_3 &\sim \text{normal}(0, \text{var} = 1e6) \\ \lambda_j &\sim \text{gamma}(\text{shape} = 0.01, \text{iscale} = 0.01) \quad \text{for } j = 1 \dots 8\end{aligned}$$

The following statements calculate $Y_i(t)$ for each observation i , at every time point t in the Partition data set. The statements also find the observed failure time interval, $dN_i(t)$, for each observation:

```
%let n = 8;
data _a;
  set blind;
  if _n_ eq 1 then set partition;
  array int[*] int_;
  array Y[&n];
  array dN[&n];
  do k = 1 to (dim(int)-1);
    Y[k] = (time - int[k] + 0.001 >= 0);
    dN[k] = Y[k] * (int[k+1] - time - 0.001 >= 0) * status;
  end;
  output;
  drop int_: k;
run;
```

The DATA step reads in the Blind data set. At the first observation, it also reads in the Partition data set. The first **ARRAY** statement creates the int array and name the elements int_. Because the names match the variable names in the Partition data set, all values of the int_ variables (there is only one observation) in the Partition data set are therefore stored in the int array. The next two **ARRAY** statements create arrays Y and dN, each with length 8. They store values of $Y_i(t)$ and $dN_i(t)$, resulting from each failure time in the Blind data set.

The following statements print the first 10 observations of the constructed data set _a and display them in [Output 55.16.1](#):

```
proc print data=_a(obs=10);
run;
```

Output 55.16.1 First 10 Observations of the Data Set _a

Piecewise Exponential Model

7	25	20.60	0	0	1	1	1	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
8	25	20.60	0	0	0	1	1	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
9	29	38.77	0	0	1	1	1	1	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0
10	29	0.30	1	0	0	1	0	0	0	0	0	0	0	1	0	0	0	0	0	0	0	0	0

The first subject in _a experienced blindness in the left eye at time 46.23, and the time falls in the sixth interval as defined in the Partition data set. Therefore, Y1 through Y6 all take a value of 1, and Y7 and Y8 are 0. The variable dN# takes on a value of 1 if the subject is observed to go blind in that interval. Since the first observation is censored (status == 1), the actual failure time is unknown. Hence all dN# are 0. The first observed failure time occurs in observation number 4 (the right eye of the second subject), where the time variable takes a value of 31.30, Y1 through Y4 are 1, and dN4 is 1.

Note that each observation in the _a data set has 8 Y and 8 dN, meaning that you would need eight **MODEL** statements in a PROC MCMC call, each for a Poisson likelihood. Alternatively, you can expand _a, put one Y and one dN in every observation, and fit the data using a single **MODEL** statement in PROC MCMC. The following statements expand the data set _a and save the results in the data set _b:

```
data _b;
  set _a;
  array y[*] y;;
  array dn[*] dn;;
  do i = 1 to (dim(y));
    y_val      = y[i];
    dn_val     = dn[i];
    int_index  = i;
    output;
  end;
  keep y_ dn_ diabetictype treatment int_index id;
run;
```

```
data _b;
  set _b;
  rename y_val=Y dn_val=dN;
run;
```

You can use the following PROC PRINT statements to see the first few observations in `_b`:

```
proc print data=_b(obs=10);
run;
```

Output 55.16.2 First 20 Observations of the Data Set `_b`

Obs	ID	Diabetic Type	Treatment	Y	dN	int_ index
1	5	1	1	1	0	1
2	5	1	1	1	0	2
3	5	1	1	1	0	3
4	5	1	1	1	0	4
5	5	1	1	1	0	5
6	5	1	1	1	0	6
7	5	1	1	0	0	7
8	5	1	1	0	0	8
9	5	1	0	1	0	1
10	5	1	0	1	0	2

The data set `_b` now contains 3,152 observations (see [Output 55.16.2](#) for the first few observations). The Time and Status variables are no longer needed; hence they are discarded from the data set. The `int_index` variable is an index variable that indicates interval membership of each observation.

Because the variable `Y` does not contribute to the likelihood calculation when it takes a value of 0 (it amounts to a Poisson likelihood that has a mean and response variable that are both 0), you can remove these observations. This speeds up the calculation in PROC MCMC:

```
data inputdata;
  set _b;
  if Y > 0;
run;
```

The data set `Inputdata` has 1,775 observations, as opposed to 3,152 observations in `_b`. The following statements fit a piecewise exponential model in PROC MCMC:

```
proc mcmc data=inputdata nmc=10000 outpost=postout seed=12351
  maxtune=5 stats=summary diag=none;
ods select PostSummaries;
parms beta1-beta3 0;
prior beta: ~ normal(0, var = 1e6);
random lambda ~ gamma(0.01, iscale = 0.01) subject=int_index;
bZ = beta1*treatment + beta2*diabetictype + beta3*treatment*diabetictype;
idt = exp(bZ) * lambda;
model dN ~ poisson(idt);
run;
```

The **PARMS** statement declares three regression parameters, beta1–beta3. The **PRIOR** statement specifies a noninformative normal prior on the regression coefficients. The **RANDOM** statement specifies the random effect, lambda, its prior distribution, and interval membership which is indexed by the data set variable int_index.

The symbol bZ calculates the regression mean, and the symbol idt is the mean of the Poisson likelihood. It corresponds to the equation

$$I_i(t)dt = Y_i(t) \exp(\beta'z) d\Lambda_0(t)$$

Note that the $Y_i(t)$ term is omitted in the assignment statement because Y takes only the value of 1 in the input data set.

Output 55.16.3 displays posterior estimates of the three regression parameters.

Output 55.16.3 Posterior Summary Statistics

The MCMC Procedure						
Posterior Summaries						
Parameter	N	Mean	Standard Deviation	Percentiles		
				25%	50%	75%
beta1	10000	−0.4174	0.2129	−0.5612	−0.4282	−0.2770
beta2	10000	0.3138	0.1956	0.1881	0.3121	0.4387
beta3	10000	−0.7899	0.3308	−0.9999	−0.7935	−0.5741

To understand the results, you can create a 2×2 table (Table 55.49) and plug in the posterior mean estimates to the regression model. A −0.41 estimate for subjects who received laser treatment and had juvenile diabetes suggests that the laser treatment is effective in delaying blindness. And the effect is much more pronounced (−0.80) for adult subjects who have diabetes and received treatment.

Table 55.49 Estimates of Regression Effects in the Survival Model

$\hat{\beta}'z$		Diabetic Type	
		0	1
Treatment	0	0	0.32
	1	−0.41	−0.80

You can also use the macro %CATER (“Caterpillar Plot” on page 4508) to draw a caterpillar plot to visualize the eight hazards in the model:

```
ods graphics on;
%cater(data=postout, var=lambda_);
ods graphics off;
```

Output 55.16.4 Caterpillar Plot of the Hazards in the Piecewise Exponential Model

The fitted hazards show a nonconstant underlying hazard function (read along the y-axis as $\lambda_{\#}$ are hazards along the time-axis) in the model.

Now suppose you want to include patient-level information and fit a frailty model to the blind data set, where the random effect enters the model through the regression term, where the subject is indexed by the variable ID in the data.

$$\begin{aligned}\beta'z_i &= \beta_1 \text{treatment} + \beta_2 \text{diabetictype} + \beta_3 \text{treatment} * \text{diabetictype} + u_{id} \\ u_{id} &\sim \text{normal}(0, \text{var} = \sigma^2) \\ \sigma^2 &\sim \text{igamma}(\text{shape} = 0.01, \text{scale} = 0.01)\end{aligned}$$

where id indexes patient.

The actual coding in PROC MCMC of a piecewise exponential frailty model is rather straightforward:

```
ods select none;
proc mcmc data=inputdata nmc=10000 outpost=postout seed=12351
  stats=summary diag=none;
  parms beta1-beta3 0 s2;
  prior beta: ~ normal(0, var = 1e6);
  prior s2 ~ igamma(0.01, scale=0.01);
  random lambda ~ gamma(0.01, iscale = 0.01) subject=int_index;
  random u ~ normal(0, var=s2) subject=id;
  bZ = beta1*treatment + beta2*diabetictype + beta3*treatment*diabetictype + u;
  idt = exp(bZ) * lambda;
  model dN ~ poisson(idt);
run;
```

A second **RANDOM** statement defines a subject-level random effect u , and the random-effects parameters enter the model in the term for the regression mean, bZ . An additional model parameter, $s2$, the variance of the random-effects parameters, is needed for the model. The results are not shown here.

Example 55.17: Normal Regression with Interval Censoring

You can use PROC MCMC to fit failure time data that can be right, left, or interval censored. To illustrate, a normal regression model is used in this example.

Assume that you have the following simple regression model with no covariates:

$$y = \mu + \sigma\epsilon$$

where y is a vector of response values (the failure times), μ is the grand mean, σ is an unknown scale parameter, and ϵ are errors from the standard normal distribution. Instead of observing y_i directly, you only observe a truncated value t_i . If the true y_i occurs after the censored time t_i , it is called *right censoring*. If y_i occurs before the censored time, it is called *left censoring*. A failure time y_i can be censored at both ends, and this is called *interval censoring*. The likelihood for y_i is as follows:

$$p(y_i|\mu) = \begin{cases} \phi(y_i|\mu, \sigma) & \text{if } y_i \text{ is uncensored} \\ S(t_{l,i}|\mu) & \text{if } y_i \text{ is right censored by } t_{l,i} \\ 1 - S(t_{r,i}|\mu) & \text{if } y_i \text{ is left censored by } t_{r,i} \\ S(t_{l,i}|\mu) - S(t_{r,i}|\mu) & \text{if } y_i \text{ is interval censored by } t_{l,i} \text{ and } t_{r,i} \end{cases}$$

where $S(\cdot)$ is the survival function, $S(t) = \Pr(T > t)$.

Gentleman and Geyer (1994) uses the following data on cosmetic deterioration for early breast cancer patients treated with radiotherapy:

```

title 'Normal Regression with Interval Censoring';
data cosmetic;
  label tl = 'Time to Event (Months)';
  input tl tr @@;
  datalines;
45 . 6 10 . 7 46 . 46 . 7 16 17 . 7 14
37 44 . 8 4 11 15 . 11 15 22 . 46 . 46 .
25 37 46 . 26 40 46 . 27 34 36 44 46 . 36 48
37 . 40 . 17 25 46 . 11 18 38 . 5 12 37 .
. 5 18 . 24 . 36 . 5 11 19 35 17 25 24 .
32 . 33 . 19 26 37 . 34 . 36 .
;

```

The data consist of time interval endpoints (in months). Nonmissing equal endpoints ($tl = tr$) indicates noncensoring; a nonmissing lower endpoint ($tl \neq .$) and a missing upper endpoint ($tr = .$) indicates right censoring; a missing lower endpoint ($tl = .$) and a nonmissing upper endpoint ($tr \neq .$) indicates left censoring; and nonmissing unequal endpoints ($tl \neq tr$) indicates interval censoring.

With this data set, you can consider using proper but diffuse priors on both μ and σ , for example:

$$\begin{aligned} \mu &\sim \text{normal}(0, \text{sd} = 1000) \\ \sigma &\sim \text{gamma}(0.001, \text{iscale} = 0.001) \end{aligned}$$

The following SAS statements fit an interval censoring model and generate [Output 55.17.1](#):

```
proc mcmc data=cosmetic outpost=postout seed=1 nmc=20000 missing=AC;
  ods select PostSummaries PostIntervals;
  parms mu 60 sigma 50;

  prior mu ~ normal(0, sd=1000);
  prior sigma ~ gamma(shape=0.001, iscale=0.001);

  if (tl^=. and tr^=. and tl=tr) then
    llike = logpdf('normal',tr,mu,sigma);
  else if (tl^=. and tr=.) then
    llike = logsdf('normal',tl,mu,sigma);
  else if (tl=. and tr^=.) then
    llike = logcdf('normal',tr,mu,sigma);
  else
    llike = log(sdf('normal',tl,mu,sigma) -
      sdf('normal',tr,mu,sigma));

  model general(llike);
run;
```

Because there are missing cells in the input data, you want to use the **MISSING=AC** option so that PROC MCMC does not delete any observations that contain missing values. The IF-ELSE statements distinguish different censoring cases for y_i , according to the likelihood. The SAS functions LOGCDF, LOGSDF, LOGPDF, and SDF are useful here. The **MODEL** statement assigns `llike` as the log likelihood to the response. The Markov chain appears to have converged in this example (evidence not shown here), and the posterior estimates are shown in [Output 55.17.1](#).

Example 55.18: Constrained Analysis

Conjoint analysis uses regression techniques to model consumer preferences and to estimate consumer utility functions. A problem with conventional conjoint analysis is that sometimes your estimated utilities do not make sense. Your results might suggest, for example, that the consumers would prefer to spend more on a product than to spend less. With PROC MCMC, you can specify constraints on the part-worth utilities (parameter estimates). Suppose that the consumer product being analyzed is an off-road motorcycle. The relevant attributes are how large each motorcycle is (less than 300cc, 301–550cc, and more than 551cc), how much it costs (less than \$5000, \$5001–\$6000, \$6001–\$7000, and more than \$7000), whether or not it has an electric starter, whether or not the engine is counter-balanced, and whether the bike is from Japan or Europe. The preference variable is a ranking of the bikes. You could perform an ordinary conjoint analysis with PROC TRANSREG (see Chapter 97, “[The TRANSREG Procedure](#)”) as follows:

```
options validvarname=any;
proc format;
  value sizef 1 = '< 300cc' 2 = '300-550cc' 3 = '> 551cc';
  value pricef 1 = '< $5000' 2 = '$5000 - $6000'
               3 = '$6001 - $7000' 4 = '> $7000';
  value startf 1 = 'Electric Start' 2 = 'Kick Start';
  value balf 1 = 'Counter Balanced' 2 = 'Unbalanced';
  value orif 1 = 'Japanese' 2 = 'European';
run;

data bikes;
  input Size Price Start Balance Origin Rank @@;
  format size sizef. price pricef. start startf.
         balance balf. origin orif.;
  datalines;

3 3 1 1 2 1 1 3 2 1 1 5 3 4 2 2 2 12
2 3 2 2 1 9 1 1 1 2 1 8 2 2 1 2 2 10
2 4 1 1 1 4 3 1 1 2 1 11 3 2 2 1 1 2
;

title 'Ordinary Conjoint Analysis by PROC TRANSREG';
proc transreg data=bikes utilities cprefix=0 lprefix=0;
  ods select Utilities;
  model identity(rank / reflect) =
    class(size price start balance origin / zero=sum);
  output out=coded(drop=intercept) replace;
run;
```

The DATA step reads the experimental design and dependent variable Rank and assigns formats to label the factor levels. PROC TRANSREG is run specifying UTILITIES, which requests a conjoint analysis. The rank variable is reflected around its mean ($1 \rightarrow 12$, $2 \rightarrow 11$, ..., $12 \rightarrow 1$) so that in the analysis, larger part-worth utilities correspond to higher preference. The OUT=CODED data set contains the reflected ranks and a binary coding of the factors that can be used in other analyses. See Kuhfeld (2004) for more information about conjoint analysis and coding with PROC TRANSREG.

The Utilities table from the conjoint analysis is shown in [Output 55.18.1](#). Notice the part-worth utilities for price. The part-worth utility for < \$5000 is 0.25. As price increases to the \$5000–\$6000 range, utility

decreases to -0.5 . Then as price increases to the \$6001–\$7000 range, part-worth utility *increases* to 0.5. Finally, for the most expensive bikes, utility decreases again to -0.25 . In cases like this, you might want to impose constraints on the solution so that the part-worth utility for price never increases as prices go up.

Output 55.18.1 Ordinary Conjoint Analysis by PROC TRANSREG

You could run PROC TRANSREG again, specifying monotonicity constraints on the part-worth utilities for price:

```

title 'Constrained Conjoint Analysis by PROC TRANSREG';
proc transreg data=bikes utilities cprefix=0 lprefix=0;
  ods select ConservUtilities;
  model identity(rank / reflect) =
    monotone(price / tstandard=center)
    class(size start balance origin / zero=sum);
run;

```

The output from this PROC TRANSREG step is shown in [Output 55.18.2](#).

Output 55.18.2 Constrained Conjoint Analysis by PROC TRANSREG

This monotonicity constraint is one of the few constraints on the part-worth utilities that you can specify in PROC TRANSREG. In contrast, PROC MCMC enables you to specify any constraint that can be written in the DATA step language. You can perform the restricted conjoint analysis with PROC MCMC by using the coded factors that were output from PROC TRANSREG. The data set is Coded.

The likelihood is a simple regression model:

$$\text{rank}_i \sim \text{normal}(\mathbf{x}_i' \boldsymbol{\beta}, \sigma)$$

where rank is the response, the covariates are '< 300cc'n, '300-500cc'n, '< \$5000'n, '\$5000 - \$6000'n, '\$6001 - \$7000'n, 'Electric Start'n, 'Counter Balanced'n, and Japanese. Note that OPTIONS VALIDVAR-NAME=ANY enables PROC TRANSREG to create names for the coded variables with blanks and special characters. That is why the name-literal notation ('*variable-name*'n) is used for the input data set variables.

Suppose that there are two constraints you want to put on some of the parameters: one is that the parameters for '< \$5000'n, '\$5000 - \$6000'n, and '\$6001 - \$7000'n decrease in order, and the other is that the parameter for 'Counter Balanced'n is strictly positive. You can consider a truncated multivariate normal prior as follows:

$$(\beta_{< \$5000'n}, \beta_{\$5000 - \$6000'n}, \beta_{\$6001 - \$7000'n}, \beta_{\text{Counter Balanced'n}}) \sim \text{MVN}(0, \sigma \mathbf{I})$$

with the following set of constraints:

$$\begin{aligned}\beta_{<\$5000'n} &> \beta_{\$5000 - \$6000'n} > \beta_{\$6001 - \$7000'n} > 0 \\ \beta_{\text{Counter Balanced}'n} &> 0\end{aligned}$$

The condition that $\beta_{\$6001 - \$7000'n} > 0$ reflects an implied constraint that, by definition, 0 is the utility for the highest price range, $> \$7000$, which is the reference level for the binary coded price variable. The following statements fit the desired model:

```

title 'Bayesian Constrained Conjoint Analysis by PROC MCMC';

  endnodata;

  mean = intercept +
    pw300cc          * '< 300cc'n          +
    pw300_550cc      * '300-550cc'n          +
    pw5000           * '< $5000'n          +
    pw5000_6000      * '$5000 - $6000'n      +
    pw6001_7000      * '$6001 - $7000'n      +
    pwElectricStart  * 'Electric Start'n      +
    pwCounterBalanced * 'Counter Balanced'n +
    pwJapanese       * Japanese;
  model rank ~ normal(mean, prec=tau);
run;

```

The two [ARRAY](#) statements allocate a 4×4 dimensional array for the prior covariance and an array of size 4 for the prior means. In the [BEGINCNST](#) and [ENDCNST](#) statements, the [CALL IDENTITY](#) function sets sigma to be an identity matrix; the [CALL MULT](#) function sets sigma's diagonal elements to be 100 (the diagonal variance terms); and the [CALL ZEROMATRIX](#) function sets mu to be a vector of zeros (the prior

means). For matrix functions in PROC MCMC, see the section “[Matrix Functions in PROC MCMC](#)” on page 4498.

There are two [PARMS](#) statements, with each of them naming a block of parameters. The first [PARMS](#) statement blocks the following: the intercept, the two size parameters, the one start-type parameter, the one origin parameter, and the precision. The second [PARMS](#) statement blocks the three price parameters and the one balance parameter, parameters that have the constraint multivariate normal prior. The second [PARMS](#) statement also specifies initial values for the parameter estimates. The initial values reflect the constraints on these parameters. The initial part-worth utilities all decrease from 0.3 to 0.2 to 0.1 to 0.0 (for the implicit reference level) as the prices increase. Also, the initial part-worth utility for the counter-balanced engine is set to a positive value, 1.

In the [PRIOR](#) statements, regression coefficients without constraints are given an independent normal prior with mean at 0 and variance of 100. The next IF-ELSE construction imposes the constraints. When these constraints are met, pw5000, pw5000_6000, pw6001_7000, pwCounterBalanced are jointly distributed as a multivariate normal prior with mean mu and covariance sigma. Otherwise, the prior is not defined and lp is assigned a missing value. The parameter tau is given a gamma prior, which is a conjugate prior for that parameter.

The model specification is linear. The mean is comprised of an intercept and the sum of terms like pw300cc * '< 300cc'n, which is a parameter times an input data set variable. The [MODEL](#) statement specifies that the linear model for rank is normally distributed with mean mean and precision tau.

The MCMC results are shown in [Output 55.18.3](#).

The estimates of the part-worth utility for the price categories are ordered as expected. This agrees with the intuition that there is a higher preference for a less expensive motor bike when all other things are equal, and that is what you see when you look at the estimated posterior means for the price part-worths. The estimated standard deviations of the price part-worths in this model are of approximately the same order of magnitude as the posterior means. This indicates that the part-worth utilities for this subject are

not significantly far from each other, and that this subject's ranking of the options was not significantly influenced by the difference in price.

One advantage of Bayesian analysis is that you can incorporate prior information in the data analysis. Constraints on the parameter space are one possible source of information that you might have before you examine the data. This example shows that it can be accomplished in PROC MCMC.

Example 55.19: Implement a New Sampling Algorithm

This example illustrates using the `UDS` statement to implement a new Markov chain sampler. The algorithm demonstrated here is proposed by Holmes and Held (2006), hereafter referred to as HH. They presented a Gibbs sampling algorithm for generating draws from the posterior distribution of the parameters in a probit regression model. The notation follows closely to HH.

The data used here is the remission data set from a PROC LOGISTIC example:

```
title 'Implement a New Sampling Algorithm';
data inputdata;
  input remiss cell smear infil li blast temp;
  ind = _n_;
  cnst = 1;
  label remiss='Complete Remission';
  datalines;
1  0.8  0.83  0.66  1.9  1.1    0.996

... more lines ...

0  1    0.73  0.73  0.7  0.398  0.986
;
```

The variable `remiss` is the cancer remission indicator variable with a value of 1 for remission and a value of 0 for nonremission. There are six explanatory variables: `cell`, `smear`, `infil`, `li`, `blast`, and `temp`. These variables are the risk factors thought to be related to cancer remission. The binary regression model is as follows:

$$\text{remiss}_i \sim \text{binary}(p_i)$$

where the covariates are linked to p_i through a probit transformation:

$$\text{probit}(p_i) = \mathbf{x}'\boldsymbol{\beta}$$

$\boldsymbol{\beta}$ are the regression coefficients and \mathbf{x}' the explanatory variables. Suppose you want to use independent normal priors on the regression coefficients:

$$\beta_i \sim \text{normal}(0, \text{var} = 25)$$

Fitting a probit model with PROC MCMC is straightforward. You can use the following statements:

```
proc mcmc data=inputdata nmc=100000 propcov=quanew seed=17
  outpost=mcmcout;
  ods select PostSummaries ess;
  parms beta0-beta6;
```

```

prior beta: ~ normal(0,var=25);
mu = beta0 + beta1*cell + beta2*smear +
      beta3*infil + beta4*li + beta5*blast + beta6*temp;
p = cdf('normal', mu, 0, 1);
model remiss ~ bern(p);
run;

```

The expression `mu` is the regression mean, and the CDF function links `mu` to the probability of remission `p` in the binary likelihood.

The summary statistics and effective sample sizes tables are shown in [Output 55.19.1](#). There are high autocorrelations among the posterior samples, and efficiency is relatively low. The correlation time is reduced only after a large amount of thinning.

As an alternative to the random walk Metropolis, you can use the Gibbs algorithm to sample from the posterior distribution. The Gibbs algorithm is described in the section “[Gibbs Sampler](#)” on page 135. While the Gibbs algorithm generally applies to a wide range of statistical models, the actual implementation can be problem-specific. In this example, performing a Gibbs sampler involves introducing a class of auxil-

iary variables (also known as latent variables). You first reformulate the model by adding a z_i for each observation in the data set:

$$\begin{aligned} y_i &= \begin{cases} 1 & \text{if } z_i > 0 \\ 0 & \text{otherwise} \end{cases} \\ z_i &= \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i \\ \epsilon &\sim \text{normal}(0, 1) \\ \boldsymbol{\beta} &\sim \pi(\boldsymbol{\beta}) \end{aligned}$$

If $\boldsymbol{\beta}$ has a normal prior, such as $\pi(\boldsymbol{\beta}) = N(\mathbf{b}, \mathbf{v})$, you can work out a closed form solution to the full conditional distribution of $\boldsymbol{\beta}$ given the data and the latent variables z_i . The full conditional distribution is also a multivariate normal, due to the conjugacy of the problem. See the section “Conjugate Priors” on page 129. The formula is shown here:

$$\begin{aligned} \boldsymbol{\beta} | \mathbf{z}, \mathbf{x} &\sim \text{normal}(\mathbf{B}, \mathbf{V}) \\ \mathbf{B} &= \mathbf{V}((\mathbf{v})^{-1} \mathbf{b} + \mathbf{x}' \mathbf{z}) \\ \mathbf{V} &= (\mathbf{v}^{-1} + \mathbf{x}' \mathbf{x})^{-1} \end{aligned}$$

The advantage of creating the latent variables is that the full conditional distribution of \mathbf{z} is also easy to work with. The distribution is a truncated normal distribution:

$$z_i | \boldsymbol{\beta}, \mathbf{x}_i, y_i \sim \begin{cases} \text{normal}(\mathbf{x}_i \boldsymbol{\beta}, 1) I(z_i > 0) & \text{if } y_i = 1 \\ \text{normal}(\mathbf{x}_i \boldsymbol{\beta}, 1) I(z_i \leq 0) & \text{otherwise} \end{cases}$$

You can sample $\boldsymbol{\beta}$ and \mathbf{z} iteratively, by drawing $\boldsymbol{\beta}$ given \mathbf{z} and vice versa. HH point out that a high degree of correlation could exist between $\boldsymbol{\beta}$ and \mathbf{z} , and it makes this iterative way of sampling inefficient. As an improvement, HH proposed an algorithm that samples $\boldsymbol{\beta}$ and \mathbf{z} jointly. At each iteration, you sample z_i from the posterior marginal distribution (this is the distribution that is conditional only on the data and not on any parameters) and then sample $\boldsymbol{\beta}$ from the same posterior full conditional distribution as described previously:

1. Sample z_i from its posterior marginal distribution:

$$\begin{aligned} z_i | \mathbf{z}_{-i}, y_i &\sim \begin{cases} \text{normal}(m_i, v_i) I(z_i > 0) & \text{if } y_i = 1 \\ \text{normal}(m_i, v_i) I(z_i \leq 0) & \text{otherwise} \end{cases} \\ m_i &= \mathbf{x}_i \mathbf{B} - w_i (z_i - \mathbf{x}_i \mathbf{B}) \\ v_i &= 1 + w_i \\ w_i &= h_i / (1 - h_i) \\ h_i &= (\mathbf{H})_{ii}, \mathbf{H} = \mathbf{x} \mathbf{V} \mathbf{x}' \end{aligned}$$

2. Sample $\boldsymbol{\beta}$ from the same posterior full conditional distribution described previously.

For a detailed description of each of the conditional terms, refer to the original paper.

PROC MCMC cannot sample from the probit model by using this sampling scheme but you can implement the algorithm by using the `UDS` statement. To sample z_i from its marginal, you need a function that draws random variables from a truncated normal distribution. The functions, `RLTNORM` and `RRTNORM`, generate left- and right-truncated normal variates, respectively. The algorithm is taken from Robert (1995).

The functions are written in PROC FCMP (see the FCMP Procedure in the *Base SAS Procedures Guide*):

```
proc fcmp outlib=sasuser.funcs.uds;
  /*****
  /* Generate left-truncated normal variate */
  *****/
  function rltnorm(mu,sig,lwr);
  if lwr<mu then do;
    ans = lwr-1;
    do while(ans<lwr);
      ans = rand('normal',mu,sig);
    end;
  end;
  else do;
    mul = (lwr-mu)/sig;
    alpha = (mul + sqrt(mul**2 + 4))/2;
    accept=0;
    do while(accept=0);
      z = mul + rand('exponential')/alpha;
      lrho = -(z-alpha)**2/2;
      u = rand('uniform');
      lu = log(u);
      if lu <= lrho then accept=1;
    end;
    ans = sig*z + mu;
  end;
  return(ans);
endsub;

  /*****
  /* Generate right-truncated normal variate */
  *****/
  function rrtnorm(mu,sig,uppr);
  ans = 2*mu - rltnorm(mu,sig, 2*mu-uppr);
  return(ans);
endsub;
run;
```

The function call to RLTNORM(mu,sig,lwr) generates a random number from the left-truncated normal distribution:

$$\theta \sim \text{normal}(\mu, \text{sd} = \text{sig}) I(\theta > \text{lwr})$$

Similarly, the function call to RRTNORM(mu,sig,uppr) generates a random number from the right-truncated normal distribution:

$$\theta \sim \text{normal}(\mu, \text{sd} = \text{sig}) I(\theta < \text{uppr})$$

These functions are used to generate the latent variables z_i .

Using the algorithm A1 from the HH paper as an example, [Output 55.50](#) lists a line-by-line implementation with the PROC MCMC coding style. The table is broken into three portions: set up the constants, initialize the parameters, and sample one draw from the posterior distribution. The left column of the table is identical to the A1 algorithm stated in the appendix of HH. The right column of the table lists SAS statements.

Table 55.50 Holmes and Held (2006), algorithm A1. Side-by-Side Comparison to SAS

Define Constants	In the BEGINCNST/ENDCNST Statements

$Z \sim \text{normal}(0, I_n) \text{Ind}(Y, Z)$	<pre> do j=1 to &n; if(y[j]=1) then Z[j] = rltnorm(0,1,0); else Z[j] = rrtnorm(0,1,0); end; </pre>
$B \leftarrow SZ$	<pre>call mult(S,Z,B);</pre>

Draw One Sample	Subroutine HH
<pre> FOR j = 1 to n $z_{old} \leftarrow Z[j]$ $m \leftarrow X[j,]B$ $m \leftarrow m - W[j](Z[j] - m)$ $Z[j] \sim \text{normal}(m, Q[j])\text{Ind}(Y[j], Z[j])$ $B \leftarrow B + (Z[j] - z_{old})S[,j]$ END $T \sim \text{normal}(0, I_p)$ $\beta[,i] \leftarrow B + LT$ </pre>	<pre> do j=1 to &n; zold = Z[j]; m = 0; do k= 1 to &p; m = m + X[j,k] * B[k]; end; m = m - W[j]*(Z[j]-m); if (y[j]=1) then Z[j] = rltnorm(m,sQ[j],0); else Z[j] = rrtnorm(m,sQ[j],0); diff = Z[j] - zold; do k= 1 to &p; B[k] = B[k] + diff * S[k,j]; end; end; do j = 1 to &p; T[j] = rand('normal'); end; call mult(L,T,T); call addmatrix(B,T,beta); </pre>

The following statements define the subroutine HH (algorithm A1) in PROC FCMP and store it in library `sasuser.funcs.uds`:

```

/* define the HH algorithm in PROC FCMP. */
%let n = 27;
%let p = 7;
options cmplib=sasuser.funcs;
proc fcmp outlib=sasuser.funcs.uds;
  subroutine HH(beta[*],Z[*],B[*],x[*,*],y[*],W[*],sQ[*],S[*,*],L[*,*]);
    outargs beta, Z, B;
    array T[&p] / nosym;
    do j=1 to &n;
      zold = Z[j];
      m = 0;
      do k = 1 to &p;
        m = m + X[j,k] * B[k];
      end;
      m = m - W[j]*(Z[j]-m);
      if (y[j]=1) then
        Z[j] = rltnorm(m,sQ[j],0);
      else
        Z[j] = rrtnorm(m,sQ[j],0);
      diff = Z[j] - zold;
      do k = 1 to &p;
        B[k] = B[k] + diff * S[k,j];
      end;
    end;
  endsubr;
endproc;

```

```

end;
do j=1 to &p;
    T[j] = rand('normal');
end;
call mult(L,T,T);
call addmatrix(B,T,beta);
endsub;
run;

```

Note that one-dimensional array arguments take the form of *name*[*] and two-dimensional array arguments take the form of *name*[*,*]. Three variables, *beta*, *Z*, and *B*, are OUTARGS variables, making them the only arguments that can be modified in the subroutine. For the **UDS** statement to work, all OUTARGS variables have to be model parameters. Technically, only *beta* and *Z* are model parameters, and *B* is not. The reason that *B* is declared as an OUTARGS is because the array must be updated throughout the simulation, and this is the only way to modify its values. The input array *x* contains all of the explanatory variables, and the array *y* stores the response. The rest of the input arrays, *W*, *sQ*, *S*, and *L*, store constants as detailed in the algorithm. The following statements illustrate how to fit a Bayesian probit model by using the HH algorithm:

```

options cmplib=sasuser.funcs;

proc mcmc data=inputdata nmc=5000 monitor=(beta) outpost=hhout;
    ods select PostSummaries ess;
    array xtx[&p,&p];          /* work space */
    array xt[&p,&n];           /* work space */
    array v[&p,&p];            /* work space */
    array HatMat[&n,&n];       /* work space */
    array S[&p,&n];            /* V * Xt */
    array W[&n];
    array y[1]/ nosymbols; /* y stores the response variable */
    array x[1]/ nosymbols; /* x stores the explanatory variables */
    array sQ[&n];             /* sqrt of the diagonal elements of Q */
    array B[&p];              /* conditional mean of beta */
    array L[&p,&p];            /* Cholesky decomp of conditional cov */
    array Z[&n];              /* latent variables Z */
    array beta[&p] beta0-beta6; /* regression coefficients */

    beginncnst;
        call streaminit(83101);
        if ind=1 then do;
            rc = read_array("inputdata", x, "cnst", "cell", "smear", "infil",
                           "li", "blast", "temp");
            rc = read_array("inputdata", y, "remiss");
            call identity(v);
            call mult(v, 25, v);
            call transpose(x,xt);
            call mult(xt,x,xtx);
            call inv(v,v);
            call addmatrix(xtx,v,xtx);
            call inv(xtx,v);
            call chol(v,L);
            call mult(v,xt,S);
            call mult(x,S,HatMat);

```

```

do j=1 to &n;
    H = HatMat[j,j];
    W[j] = H/(1-H);
    sQ[j] = sqrt(W[j] + 1);
end;

do j=1 to &n;
    if(y[j]=1) then
        Z[j] = rltnorm(0,1,0);
    else
        Z[j] = rrtnorm(0,1,0);
    end;
    call mult(S,Z,B);
end;
endcnst;

uds HH(beta,Z,B,x,y,W,sQ,S,L);
parms z: beta: 0 B1-B7 / uds;
prior z: beta: B1-B7 ~ general(0);

model general(0);
run;

```

The **OPTIONS** statement names the catalog of FCMP subroutines to use. The **cmplib** library stores the subroutine **HH**. You do not need to set a random number seed in the **PROC MCMC** statement because all random numbers are generated from the **HH** subroutine. The initialization of the **rand** function is controlled by the **streaminit** function, which is called in the program with a seed value of 83101.

A number of arrays are allocated. Some of them, such as **xtx**, **xt**, **v**, and **HatMat**, allocate work space for constant arrays. Other arrays are used in the subroutine sampling. Explanations of the arrays are shown in comments in the statements.

In the **BEGINCNST** and **ENDCNST** statement block, you read data set variables in the arrays **x** and **y**, calculate all the constant terms, and assign initial values to **Z** and **B**. For the **READ_ARRAY** function, see the section “**READ_ARRAY Function**” on page 4442. For listings of all array functions and their definitions, see the section “**Matrix Functions in PROC MCMC**” on page 4498.

The **UDS** statement declares that the subroutine **HH** is used to sample the parameters **beta**, **Z**, and **B**. You also specify the **UDS** option in the **PARMS** statement. Because all parameters are updated through the **UDS** interface, it is not necessary to declare the actual form of the prior for any of the parameters. Each parameter is declared to have a prior of **general(0)**. Similarly, it is not necessary to declare the actual form of the likelihood. The **MODEL** statement also takes a flat likelihood of the form **general(0)**.

Summary statistics and effective sample sizes are shown in [Output 55.19.2](#). The posterior estimates are very close to what was shown in [Output 55.19.1](#). The **HH** algorithm produces samples that are much less correlated.

Output 55.19.2 Holms and Held

It is interesting to compare the two approaches of fitting a generalized linear model. The random walk Metropolis on a seven-dimensional parameter space produces autocorrelations that are substantially higher than the HH algorithm. A much longer chain is needed to produce roughly equivalent effective sample sizes. On the other hand, the Metropolis algorithm is faster to run. The running time of these two examples is roughly the same, with the random walk Metropolis with 100000 samples, a 20-fold increase over that in the HH algorithm example. The speed difference can be attributed to a number of factors, ranging from the implementation of the software and the overhead cost of calling PROC FCMP subroutine and functions. In addition, the HH algorithm requires more parameters by creating an equal number of latent variables as the sample size. Sampling more parameters takes time. A larger number of parameters also increases the challenge in convergence diagnostics, because it is imperative to have convergence in all parameters before you make valid posterior inferences. Finally, you might feel that coding in PROC MCMC is easier. However, this really is not a fair comparison to make here. Writing a Metropolis algorithm from scratch would have probably taken just as much, if not more, effort than the HH algorithm.

Example 55.20: Using a Transformation to Improve Mixing

Proper transformations of parameters can often improve the mixing in PROC MCMC. You already saw this in “[Example 55.6: Nonlinear Poisson Regression Models](#)” on page 4570, which sampled using the log scale of parameters that are strictly positive, such as the gamma priors. This example shows another useful transformation: the logit transformation on parameters that take a uniform prior on $[0, 1]$.

The data set is taken from Sharples (1990). It is used in Chaloner and Brant (1988) and Chaloner (1994) to identify outliers in the data set in a two-level hierarchical model. Congdon (2003) also uses this data set to demonstrate the same technique. This example uses the data set to illustrate how mixing can be improved using transformation and does not address the question of outlier detection as in those papers. The following statements create the data set:

```
data inputdata;
  input nobs grp y @@;
  ind = _n_;
  datalines;
1 1 24.80 2 1 26.90 3 1 26.65
4 1 30.93 5 1 33.77 6 1 63.31
1 2 23.96 2 2 28.92 3 2 28.19
4 2 26.16 5 2 21.34 6 2 29.46
1 3 18.30 2 3 23.67 3 3 14.47
4 3 24.45 5 3 24.89 6 3 28.95
1 4 51.42 2 4 27.97 3 4 24.76
4 4 26.67 5 4 17.58 6 4 24.29
1 5 34.12 2 5 46.87 3 5 58.59
4 5 38.11 5 5 47.59 6 5 44.67
;
```

There are five groups (grp , $j = 1, \dots, 5$) with six observations (nobs , $i = 1, \dots, 6$) in each. The two-level hierarchical model is specified as follows:

$$\begin{aligned} y_{ij} &\sim \text{normal}(\theta_j, \text{prec} = \tau_w) \\ \theta_j &\sim \text{normal}(\mu, \text{prec} = \tau_b) \\ \mu &\sim \text{normal}(0, \text{prec} = 1e - 6) \\ \tau &\sim \text{gamma}(0.001, \text{iscale} = 0.001) \\ p &\sim \text{uniform}(0, 1) \end{aligned}$$

with the precision parameters related to each other in the following way:

$$\begin{aligned} \tau_b &= \tau / p \\ \tau_w &= \tau_b - \tau \end{aligned}$$

The total number of parameters in this model is eight: $\theta_1, \dots, \theta_5, \mu, \tau$, and p .

The following statements fit the model:

```
ods graphics on;
proc mcmc data=inputdata nmc=50000 thin=10 outpost=m1 seed=17
    plot=trace;
    ods select ess tracepanel;
    parms p;
    parms tau;
    parms mu;

    prior p ~ uniform(0,1);
    prior tau ~ gamma(shape=0.001, iscale=0.001);
    prior mu ~ normal(0, prec=0.00000001);
    beginnodata;
    taub = tau/p;
    tauw = taub-tau;
    endnodata;

    random theta ~ normal(mu, prec=taub) subject=grp monitor=(theta);
    model y ~ normal(theta, prec=tauw);
run;
```

The ODS SELECT statement displays the effective sample size table and the trace plots. The ODS GRAPHICS ON statement enables ODS Graphics. The PROC MCMC statement specifies the usual options for the procedure run and produces trace plots (**PLOTS=TRACE**). The three **PARMS** statements put three model parameters, p , τ , and μ , in three different blocks. The **PRIOR** statements specify the prior distributions, and the programming statements enclosed with the **BEGINNODATA** and **ENDNODATA** statements calculate the transformation to τ_{aub} and τ_{uw} . The **RANDOM** statement specifies the random effect, its prior distribution, and the subject variable. The resulting trace plots are shown in [Output 55.20.1](#), and the effective sample size table is shown in [Output 55.20.2](#).

Output 55.20.1 Trace Plots

Output 55.20.1 *continued*

Output 55.20.2 Bad Effective Sample Sizes

Implement a New Sampling Algorithm			
The MCMC Procedure			
Effective Sample Sizes			
Parameter	ESS	Autocorrelation Time	Efficiency
p	81.3	61.5342	0.0163
tau	61.2	81.7440	0.0122
mu	5000.0	1.0000	1.0000
theta_1	4839.9	1.0331	0.9680
theta_2	2739.7	1.8250	0.5479
theta_3	1346.6	3.7130	0.2693
theta_4	4897.5	1.0209	0.9795
theta_5	338.1	14.7866	0.0676

The trace plots show that most parameters have relatively good mixing. Two exceptions appear to be p and τ . The trace plot of p shows a slow periodic movement. The τ parameter does not have good mixing either. When the values are close to zero, the chain stays there for periods of time. An inspection of the effective sample sizes table reveals the same conclusion: p and τ have much smaller ESSs than the rest of the parameters.

A scatter plot of the posterior samples of p and τ reveals why mixing is bad in these two dimensions. The following statements generate the scatter plot in [Output 55.20.3](#):

```
title 'Scatter Plot of Parameters on Original Scales';

proc sgplot data=m1;
  yaxis label = 'p';
  xaxis label = 'tau' values=(0 to 0.4 by 0.1);
  scatter x = tau y = p;
run;
```

Output 55.20.3 Scatter Plot of τ versus p

The two parameters clearly have a nonlinear relationship. It is not surprising that the Metropolis algorithm does not work well here. The algorithm is designed for cases where the parameters are linearly related with each other.

To improve on mixing, you can sample on the log of τ , instead of sampling on τ . The formulation is:

$$\begin{aligned}\tau &\sim \text{gamma}(\text{shape} = 0.001, \text{iscale} = 0.001) \\ \log(\tau) &\sim \text{egamma}(\text{shape} = 0.001, \text{iscale} = 0.001)\end{aligned}$$

See the section “[Standard Distributions](#)” on page 4476 for the definitions of the [gamma](#) and [egamma](#) distributions. In addition, you can sample on the logit of p . Note that

$$p \sim \text{uniform}(0, 1)$$

is equivalent to

$$\text{lgp} = \text{logit}(p) \sim \text{logistic}(0, 1)$$

The following statements fit the same model by using transformed parameters:

```
proc mcmc data=inputdata nmc=50000 thin=10 outpost=m2 seed=17
    monitor=(p tau mu) plot=trace;
    ods select ess tracepanel;
    parms ltau lgp mu ;

    prior ltau ~ egamma(shape=0.001,iscale=0.001);
    prior lgp ~ logistic(0,1);
    prior mu ~ normal(0,prec=0.00000001);

    beginnodata;
    tau = exp(ltau);
    p = logistic(lgp);
    taub = tau/p;
    tauw = taub-tau;
    endnodata;

    random theta ~ normal(mu, prec=taub) subject=grp monitor=(theta);
    model y ~ normal(theta,prec=tauw);
run;
```

The variable `lgp` is the logit transformation of p , and `ltau` is the log transformation of τ . The prior for `ltau` is [egamma](#), and the prior for `lgp` is [logistic](#). The TAU and P assignment statements transform the parameters back to their original scales. The rest of the programs remain unchanged. Trace plots ([Output 55.20.4](#)) and effective sample size ([Output 55.20.5](#)) both show significant improvements in the mixing for both p and τ .

Output 55.20.4 Trace Plots after Transformation

Output 55.20.4 continued

Output 55.20.5 Effective Sample Sizes after Transformation

The MCMC Procedure			
Effective Sample Sizes			
Parameter	ESS	Autocorrelation Time	Efficiency
p	3119.4	1.6029	0.6239
tau	2588.0	1.9320	0.5176
mu	5000.0	1.0000	1.0000
theta_1	4866.0	1.0275	0.9732
theta_2	5244.5	0.9534	1.0489
theta_3	5000.0	1.0000	1.0000
theta_4	5000.0	1.0000	1.0000
theta_5	4054.8	1.2331	0.8110

The following statements generate [Output 55.20.6](#) and [Output 55.20.7](#):

```

title 'Scatter Plot of Parameters on Transformed Scales';

proc sgplot data=m2;
  yaxis label = 'logit(p)';
  xaxis label = 'log(tau)';
  scatter x = ltau y = lgp;
run;

title 'Scatter Plot of Parameters on Original Scales';

proc sgplot data=m2;
  yaxis label = 'p';
  xaxis label = 'tau' values=(0 to 5.0 by 1);
  scatter x = tau y = p;
run;
ods graphics off;

```

Output 55.20.6 Scatter Plot of $\log(\tau)$ versus $\logit(p)$, After Transformation

Output 55.20.7 Scatter Plot of τ versus p , After Transformation

The scatter plot of $\log(\tau)$ versus $\text{logit}(p)$ shows a linear relationship between the two transformed parameters, and this explains the improvement in mixing. In addition, the transformations also help the Markov chain better explore in the original parameter space. [Output 55.20.7](#) shows a scatter plot of τ versus p . The plot is similar to [Output 55.20.3](#). However, note that τ has a far longer tail in [Output 55.20.7](#), extending all the way to 5 as opposed to 0.15 in [Output 55.20.3](#). This means that the second Markov chain can explore this dimension of the parameter more efficiently, and as a result, you are able to draw more precise inference with an equal number of simulations.

Example 55.21: Gelman-Rubin Diagnostics

PROC MCMC does not have the Gelman-Rubin test (see the section “[Gelman and Rubin Diagnostics](#)” on page 145) as a part of its diagnostics. The Gelman-Rubin diagnostics rely on parallel chains to test whether they all converge to the same posterior distribution. This example demonstrates how you can carry out this convergence test. The regression model from the section “[Simple Linear Regression](#)” on page 4408 is used. The model has three parameters: β_0 and β_1 are the regression coefficients, and σ^2 is the variance of the error distribution.

The following statements generate the data set:

```

title 'Simple Linear Regression, Gelman-Rubin Diagnostics';

data Class;
  input Name $ Height Weight @@;
  datalines;
Alfred 69.0 112.5   Alice 56.5 84.0   Barbara 65.3 98.0
Carol 62.8 102.5   Henry 63.5 102.5   James 57.3 83.0
Jane 59.8 84.5    Janet 62.5 112.5   Jeffrey 62.5 84.0
John 59.0 99.5    Joyce 51.3 50.5    Judy 64.3 90.0
Louise 56.3 77.0   Mary 66.5 112.0    Philip 72.0 150.0
Robert 64.8 128.0  Ronald 67.0 133.0  Thomas 57.5 85.0
William 66.5 112.0
  ;

```

To run a Gelman-Rubin diagnostic test, you want to start Markov chains at different places in the parameter space. Suppose you want to start β_0 at 10, -15, and 0; β_1 at -5, 10, and 0; and σ^2 at 1, 20, and 50. You can put these starting values in the following Init SAS data set:

```

data init;
  input Chain beta0 beta1 sigma2;
  datalines;
1 10 -5 1
2 -15 10 20
3 0 0 50
  ;

```

The following statements run PROC MCMC three times, each with starting values specified in the data set Init:

```

/* define constants */
%let nchain = 3;
%let nparm = 3;
%let nsim = 50000;
%let var = beta0 beta1 sigma2;

%macro gmcmmc;
  %do i=1 %to &nchain;
    data _null_;
      set init;
      if Chain=&i;
        %do j = 1 %to &nparm;
          call symputx("init&j", %scan(&var, &j));
        %end;
      stop;
    run;

    proc mcmc data=class outpost=out&i init=reinit nbi=0 nmc=&nsim
      stats=none seed=7;
      parms beta0 &init1 beta1 &init2;
      parms sigma2 &init3 / n;
      prior beta0 beta1 ~ normal(0, var = 1e6);
      prior sigma2 ~ igamma(3/10, scale = 10/3);

```

```

        mu = beta0 + beta1*height;
        model weight ~ normal(mu, var = sigma2);
    run;
%end;
%mend;

ods listing close;
%gmcmc;
ods listing;

```

The macro variables `nchain`, `nparm`, `nsim`, and `var` define the number of chains, the number of parameters, the number of Markov chain simulations, and the parameter names, respectively. The macro `GMCMC` gets initial values from the data set `Init`, assigns them to the macro variables `init1`, `init2` and `init3`, starts the Markov chain at these initial values, and stores the posterior draws to three output data sets: `Out1`, `Out2`, and `Out3`.

In the `PROC MCMC` statement, the `INIT=REINIT` option restarts the Markov chain after tuning at the assigned initial values. No burn-in is requested.

You can use the autocall macro `GELMAN` to calculate the Gelman-Rubin statistics by using the three chains. The `GELMAN` macro has the following arguments:

```
%macro gelman(dset, nparm, var, nsim, nc=3, alpha=0.05);
```

The argument `dset` is the name of the data set that stores the posterior samples from all the runs, `nparm` is the number of parameters, `var` is the name of the parameters, `nsim` is the number of simulations, `nc` is the number of chains with a default value of 3, and `alpha` is the α significant level in the test with a default value of 0.05. This macro creates two data sets: `_Gelman_Ests` stores the diagnostic estimates and `_Gelman_Parms` stores the names of the parameters.

The following statements calculate the Gelman-Rubin diagnostics:

```

data all;
    set out1(in=in1) out2(in=in2) out3(in=in3);
    if in1 then Chain=1;
    if in2 then Chain=2;
    if in3 then Chain=3;
run;

%gelman(all, &nparm, &var, &nsim);

data GelmanRubin(label='Gelman-Rubin Diagnostics');
    merge _Gelman_Parms _Gelman_Ests;
run;

proc print data=GelmanRubin;
run;

```

The Gelman-Rubin statistics are shown in [Output 55.21.1](#).

Output 55.21.1 Gelman-Rubin Diagnostics of the Regression Example

Simple Linear Regression, Gelman-Rubin Diagnostics					
Obs	Parameter	Between- chain	Within- chain	Estimate	Upper Bound
1	beta0	5384.76	1168.64	1.0002	1.0001
2	beta1	1.20	0.30	1.0002	1.0002
3	sigma2	8034.41	2890.00	1.0010	1.0011

The Gelman-Rubin statistics do not reveal any concerns about the convergence or the mixing of the multiple chains. To get a better visual picture of the multiple chains, you can draw overlapping trace plots of these parameters from the three Markov chains runs.

The following statements create [Output 55.21.2](#):

```
/* plot the trace plots of three Markov chains. */
%macro trace;
  %do i = 1 %to &nparm;
    proc sgplot data=all cycleattrs;
      series x=Iteration y=%scan(&var, &i) / group=Chain;
    run;
  %end;
%mend;
%trace;
```

Output 55.21.2 Trace Plots of Three Chains for Each of the Parameters

Output 55.21.2 *continued*

The trace plots show that three chains all eventually converge to the same regions even though they started at very different locations. In addition to the trace plots, you can also plot the potential scale reduction factor (PSRF). See the section “[Gelman and Rubin Diagnostics](#)” on page 145 for definition and details.

The following statements calculate PSRF for each parameter. They use the GELMAN macro repeatedly and can take a while to run:

```

/* define sliding window size */
%let nwin = 200;
data PSRF;
run;

%macro PSRF(nsim);
  %do k = 1 %to %sysevalf(&nsim/&nwin, floor);
    %gelman(all, &nparm, &var, nsim=%sysevalf(&k*&nwin));
    data GelmanRubin;
      merge _Gelman_Parms _Gelman_Ests;
    run;

    data PSRF;
      set PSRF GelmanRubin;

```

Output 55.21.3 PSRF Plot for Each Parameter

Output 55.21.3 continued

PSRF is the square root of the ratio of the between-chain variance and the within-chain variance. A large PSRF indicates that the between-chain variance is substantially greater than the within-chain variance, so that longer simulation is needed. You want the PSRF to converge to 1 eventually, as it appears to be the case in this simulation study.

Overview: MDS Procedure

Multidimensional scaling (MDS) refers to a class of methods. These methods estimate coordinates for a set of objects in a space of specified dimensionality. The input data are measurements of distances between pairs of objects. A variety of models can be used that include different ways of computing distances and various functions relating the distances to the actual data. The MDS procedure fits two- and three-way, metric and nonmetric multidimensional scaling models.

The data for the MDS procedure consist of one or more square symmetric or asymmetric matrices of similarities or dissimilarities between *objects* or *stimuli* (Kruskal and Wish 1978, pp. 7–11). Such data are also called *proximity* data. In psychometric applications, each matrix typically corresponds to a *subject*, and models that fit different parameters for each subject are called *individual difference* models.

Missing values are permitted. In particular, if the data are all missing except within some off-diagonal rectangle, the analysis is called *unfolding*. There are, however, many difficulties intrinsic to unfolding models (Heiser 1981). PROC MDS does not perform external unfolding; for analyses requiring external unfolding, use the TRANSREG procedure instead.

The MDS procedure estimates the following parameters by nonlinear least squares:

configuration	the coordinates of each object in a Euclidean (Kruskal and Wish 1978, pp. 17–19) or weighted Euclidean space (Kruskal and Wish 1978, pp. 61–63) of one or more dimensions
dimension coefficients	for each data matrix, the coefficients that multiply each coordinate of the <i>common</i> or <i>group</i> weighted Euclidean space to yield the <i>individual</i> unweighted Euclidean space. These coefficients are the square roots of the <i>subject weights</i> (Kruskal and Wish 1978, pp. 61–63). A plot of the dimension coefficients is directly interpretable in that it shows how a unit square in the group space is transformed to a rectangle in each individual space. A plot of subject weights has no such simple interpretation. The weighted Euclidean model is related to the INDSCAL model (Carroll and Chang 1970).
transformation parameters	intercept, slope, or exponent in a linear, affine, or power transformation relating the distances to the data (Kruskal and Wish 1978, pp. 19–22). For a nonmetric analysis, monotone transformations involving no explicit parameters are used (Kruskal and Wish 1978, pp. 22–25). For a discussion of metric versus nonmetric transformations, see Kruskal and Wish (1978, pp. 76–78).

Depending on the LEVEL= option, PROC MDS fits either a regression model of the form

$$fit(datum) = fit(trans(distance)) + error$$

or a measurement model of the form

$$fit(trans(datum)) = fit(distance) + error$$

where

<i>fit</i>	is a predetermined power or logarithmic transformation specified by the FIT= option.
<i>trans</i>	is an estimated (“optimal”) linear, affine, power, or monotone transformation specified by the LEVEL= option.
<i>datum</i>	is a measure of the similarity or dissimilarity of two objects or stimuli.
<i>distance</i>	is a distance computed from the estimated coordinates of the two objects and estimated dimension coefficients in a space of one or more dimensions. If there are no dimension coefficients (COEF=IDENTITY), this is an unweighted Euclidean distance. If dimension coefficients are used (COEF=DIAGONAL), this is a weighted Euclidean distance where the weights are the squares of the dimension coefficients; alternatively, you can multiply each dimension by its coefficient and compute an unweighted Euclidean distance.
<i>error</i>	is an error term assumed to have an approximately normal distribution and to be independently and identically distributed for all data. Under these assumptions, least-squares estimation is statistically appropriate.

For an introduction to multidimensional scaling, see Kruskal and Wish (1978) and Arabie, Carroll, and DeSarbo (1987). A more advanced treatment is given by Young (1987). Many practical issues of data collection and analysis are discussed in Schiffman, Reynolds, and Young (1981). The fundamentals of psychological measurement, including both unidimensional and multidimensional scaling, are expounded by Torgerson (1958). Nonlinear least-squares estimation of PROC MDS models is discussed in Null and Sarle (1982).

Getting Started: MDS Procedure

The simplest application of PROC MDS is to reconstruct a map from a table of distances between points on the map (Kruskal and Wish 1978, pp. 7–9). A data set containing a table of flying mileages between 10 U.S. cities is available in the Sashelp library.

Since the flying mileages are very good approximations to Euclidean distance, no transformation is needed to convert distances from the model to data. The analysis can therefore be done at the absolute level of measurement, as displayed in the following PROC MDS step (LEVEL=ABSOLUTE). The following statements produce [Figure 56.1](#) and [Figure 56.2](#):

```
title 'Analysis of Flying Mileages between Ten U.S. Cities';

ods graphics on;

proc mds data=sashelp.mileages level=absolute;
  id city;
run;
```

PROC MDS first displays the iteration history. In this example, only one iteration is required. The badness-of-fit criterion 0.001689 indicates that the data fit the model extremely well. You can also see that the fit is excellent in the fit plot in [Figure 56.2](#).

Figure 56.1 Iteration History from PROC MDS

Analysis of Flying Mileages between Ten U.S. Cities				
Multidimensional Scaling: Data=SASHELP.MILEAGES.DATA				
Shape=TRIANGLE Condition=MATRIX Level=ABSOLUTE				
Coef=IDENTITY Dimension=2 Formula=1 Fit=1				
Gconverge=0.01 Maxiter=100 Over=1 Ridge=0.0001				
Iteration	Type	Badness- of-Fit Criterion	Change in Criterion	Convergence Measure
0	Initial	0.003273	.	0.8562
1	Lev-Mar	0.001689	0.001584	0.005128
Convergence criterion is satisfied.				

While PROC MDS can recover the relative positions of the cities, it cannot determine absolute location or orientation. In this case, north is toward the bottom of the plot. (See the first plot in [Figure 56.2](#).)

Figure 56.2 Plot of Estimated Configuration and Fit

Figure 56.2 continued

Syntax: MDS Procedure

The following statements are available in the MDS procedure:

```

PROC MDS < options > ;
  VAR variables ;
  INVAR variables ;
  ID | OBJECT variable ;
  MATRIX | SUBJECT variable ;
  WEIGHT variables ;
  BY variables ;

```

The PROC MDS statement is required. All other statements are optional.

PROC MDS Statement

PROC MDS < options > ;

The PROC MDS statement invokes the MDS procedure. PROC MDS produces an iteration history by default. Graphical displays are produced when ODS Graphics is enabled. Additional displayed output is controlled by the interaction of the PCONFIG, PCOEF, PTRANS, PFIT, and PFITROW options with the PININ, PINIT, PITER, and PFINAL options. The PCONFIG, PCOEF, PTRANS, PFIT, and PFITROW options specify *which* estimates and fit statistics are to be displayed. The PININ, PINIT, PITER, and PFINAL options specify *when* the estimates and fit statistics are to be displayed. If you specify at least one of the PCONFIG, PCOEF, PTRANS, PFIT, and PFITROW options but none of the PININ, PINIT, PITER, and PFINAL options, the final results (PFINAL) are displayed. If you specify at least one of the PININ, PINIT, PITER, and PFINAL options but none of the PCONFIG, PCOEF, PTRANS, PFIT, and PFITROW options, all estimates (PCONFIG, PCOEF, PTRANS) and the fit statistics for each matrix and for the entire sample (PFIT) are displayed. If you do not specify any of these nine options, no estimates or fit statistics are displayed (except the badness-of-fit criterion in the iteration history).

The types of estimates written to the OUT= data set are determined by the OCONFIG, OCOEF, OTRANS, and OCRIT options. If you do not specify any of these four options, the estimates of all the parameters of the PROC MDS model and the value of the badness-of-fit criterion appear in the OUT= data set. If you specify one or more of these options, only the information requested by the specified options appears in the OUT= data set. Also, the OITER option causes these statistics to be written to the OUT= data set after initialization and on each iteration, as well as after the iterations have terminated.

Table 56.2 summarizes the options available in the PROC MDS statement.

Table 56.2 Summary of PROC MDS Statement Options

Option	Description
Data Set Options	
DATA=	Specifies the input SAS data set
INITIAL=	Specifies the input SAS data set containing initial values
OUT=	Specifies the output data set
OUTFIT=	Specifies the output fit data set
OUTRES=	Specifies the output residual data set
Input Control	
CUTOFF=	Replaces data values with missing values
SHAPE=	Specifies the shape of the input data matrices
SIMILAR=	Specifies that the data are similarity measurements
Model	
COEF=	Specifies the type of matrix for the coefficients
CONDITION=	Specifies the conditionality of the data
DIMENSION=	Specifies the number of dimensions
LEVEL=	Specifies the measurement level
NEGATIVE	Permits slopes or powers to be negative
UNTIE	Permits tied data to be untied

Table 56.2 *continued*

Option	Description
Initialization	
INAV=	Affects the computation of initial coordinates
NOULB	Specifies the missing data initialization
RANDOM=	Specifies initial random coordinates
Estimation	
ALTERNATE=	Specifies the alternating-least-squares algorithm
CONVERGE=	Specifies the convergence criterion
EPSILON=	Specifies the amount added to squared distances
FIT=	Specifies a predetermined transformation
FORMULA=	Specifies the badness-of-fit formula
GCONVERGE=	Specifies the gradient convergence criterion
MAXITER=	Specifies the maximum number of iterations
MCONVERGE=	Specifies the monotone convergence criterion
MINCRIT=	Specifies the minimum badness-of-fit criterion
NONORM	Suppresses normalization of the initial and final estimates
OVER=	Specifies the maximum overrelaxation factor
RIDGE=	Specifies the initial ridge value
SINGULAR=	Specifies the singularity criterion
Control Output Data Set Contents	
OCOEF	Writes the dimension coefficients to the OUT= data set
OCONFIG	Writes the coordinates of the objects to the OUT= data set
OCRIT	Writes the badness-of-fit criterion to the OUT= data set
OITER	Writes current values after initialization and on every iteration
OTRANS	Writes the transformation parameter estimates to the OUT= data set
Control Displayed Output	
DECIMALS=	Specifies how many decimal places to use
NOPHIST	Suppresses the iteration history
PCOEF	Displays the estimated dimension coefficients
PCONFIG	Displays the estimated coordinates
PDATA	Displays each data matrix
PFINAL	Displays final estimates
PFIT	Displays the badness-of-fit criterion
PFITROW	Displays the badness-of-fit criterion for each row
PINAVDATA	Displays INAV= data set information
PINEIGVAL	Displays the initial eigenvalues
PINEIGVEC	Displays the initial eigenvectors
PININ	Displays values read from the INITIAL= data set
PINIT	Displays initial values
PITER	Displays estimates on each iteration
PLOTS=	Controls the graphical displays
PTRANS	Displays the estimated transformation parameters

ALTERNATE | ALT=NONE | NO | N

ALTERNATE | ALT=MATRIX | MAT | M | SUBJECT | SUB | S

ALTERNATE | ALT=ROW | R <=n>

determines what form of alternating-least-squares algorithm is used. The default depends on the amount of memory available. The following ALTERNATE= options are listed in order of decreasing memory requirements:

ALT=NONE	causes all parameters to be adjusted simultaneously on each iteration. This option is usually best for a small number of subjects and objects.
ALT=MATRIX	adjusts all the parameters for the first subject, then all the parameters for the second subject, and so on, and finally adjusts all parameters that do not correspond to a subject, such as coordinates and unconditional transformations. This option usually works best for a large number of subjects with a small number of objects.
ALT=ROW	treats subject parameters the same way as the ALTERNATE=MATRIX option but also includes separate stages for unconditional parameters and for subsets of the objects. The ALT=ROW option usually works best for a large number of objects. Specifying ALT=ROW= n divides the objects into subsets of n objects each, except possibly for one subset when n does not divide the number of objects evenly. If you omit $=n$, the number of objects in the subsets is determined from the amount of memory available. The smaller the value of n , the less memory is required.

When you specify the LEVEL=ORDINAL option, the monotone transformation is always computed in a separate stage and is listed as a separate iteration in the iteration history. In this case, estimation is done by iteratively reweighted least squares. The weights are recomputed according to the FORMULA= option on each monotone iteration; hence, it is possible for the badness-of-fit criterion to increase after a monotone iteration.

COEF=IDENTITY | IDEN | I

COEF=DIAGONAL | DIAG | D

specifies the type of matrix for the dimension coefficients.

COEF=IDENTITY	is the default, which yields Euclidean distances.
COEF=DIAGONAL	produces weighted Euclidean distances, in which each subject can have different weights for the dimensions. The dimension coefficients that PROC MDS outputs are related to the square roots of what are called subject weights in PROC ALSCAL; the normalization in PROC MDS also differs from that in PROC ALSCAL. The weighted Euclidean model is related to the INDSCAL model (Carroll and Chang 1970).

CONDITION | COND=UN | U**CONDITION | COND=MATRIX | MAT | M | SUBJECT | SUB | S****CONDITION | COND=ROW | R**

specifies the conditionality of the data (Young 1987, pp. 60–63). The data are divided into disjoint subsets called *partitions*. Within each partition, a separate transformation is applied, as specified by the LEVEL= option. The three types of conditionality are as follows:

COND=UN	(unconditional) puts all the data into a single partition.
COND=MATRIX	(matrix conditional) makes each data matrix a partition.
COND=ROW	(row conditional) makes each row of each data matrix a partition.

The default is CONDITION=MATRIX. The CONDITION= option also determines the default value for the SHAPE= option. If you specify the CONDITION=ROW option and omit the SHAPE= option, each data matrix is stored as a square and possibly asymmetric matrix. If you specify the CONDITION=UN or CONDITION=MATRIX option and omit the SHAPE= option, only one triangle is stored. See the [SHAPE=](#) option for details.

CONVERGE | CONV= p

sets both the gradient convergence criterion and the monotone convergence criterion to p , where $0 \leq p \leq 1$. The default is CONVERGE=0.01; smaller values might greatly increase the number of iterations required. Values less than 0.0001 might be impossible to satisfy because of the limits of machine precision. (See the [GCONVERGE=](#) and [MCONVERGE=](#) options.)

CUTOFF= n

replaces data values less than n with missing values. The default is CUTOFF=0.

DATA=SAS-data-set

specifies the SAS data set containing one or more square matrices to be analyzed. In typical psychometric data, each matrix contains judgments from one subject, so there is a one-to-one correspondence between data matrices and subjects.

The data matrices contain similarity or dissimilarity measurements to be modeled and, optionally, weights for these data. The data are generally assumed to be dissimilarities unless you use the SIMILAR option. However, if there are nonmissing diagonal values and these values are predominantly larger than the off-diagonal values, the data are assumed to be similarities and are treated as if the SIMILAR option is specified. The diagonal elements are not otherwise used in fitting the model.

Each matrix must have exactly the same number of observations as the number of variables specified by the VAR statement or determined by defaults. This number is the number of objects or stimuli.

The first observation and variable are assumed to contain data for the first object, the second observation and variable are assumed to contain data for the second object, and so on.

When there are two or more matrices, the observations in each matrix must correspond to the same objects in the same order as in the first matrix.

The matrices can be symmetric or asymmetric, as specified by the SHAPE= option.

DECIMALS | DEC=*n*

specifies how many decimal places to use when displaying the parameter estimates and fit statistics. The default is DECIMALS=2, which is generally reasonable except in conjunction with the LEVEL=ABSOLUTE option and very large or very small data.

DIMENSION | DIMENS | DIM=*n* < TO *m* < BY=*i* > >

specifies the number of dimensions to use in the MDS model, where $1 \leq n, m < \text{number of objects}$. The parameter *i* can be either positive or negative but not zero. If you specify different values for *n* and *m*, a separate model is fitted for each requested dimension. If you specify only DIMENSION=*n*, then only *n* dimensions are fitted. The default is DIMENSION=2 if there are three or more objects; otherwise, DIMENSION=1 is the only valid specification. The analyses for each number of dimensions are done independently. For information about choosing the dimensionality, see Kruskal and Wish (1978, pp. 48–60).

EPSILON | EPS=*n*

specifies a number *n*, $0 < n < 1$, that determines the amount added to squared distances computed from the model to avoid numerical problems such as division by 0. This amount is computed as ϵ equal to *n* times the mean squared distance in the initial configuration. The distance in the MDS model is thus computed as

$$\text{distance} = \sqrt{\text{sqdist} + \epsilon}$$

where *sqdist* is the squared Euclidean distance or the weighted squared Euclidean distance.

The default is EPSILON=1E-12, which is small enough to have no practical effect on the estimates unless the FIT= value is nonpositive and there are dissimilarities that are very close to 0. Hence, when the FIT= value is nonpositive, dissimilarities less than *n* times 100 times the maximum dissimilarity are not permitted.

FIT=DISTANCE | DIS | D**FIT=SQUARED | SQU | S****FIT=LOG | L****FIT=*n***

specifies a predetermined (not estimated) transformation to apply to both sides of the MDS model before the error term is added.

The default is FIT=DISTANCE or, equivalently, FIT=1, which fits data to distances.

The option FIT=SQUARED or FIT=2 fits squared data to squared distances. This gives greater importance to large data and distances and lesser importance to small data and distances in fitting the model.

The FIT=LOG or FIT=0 option fits log data to log distances. This gives lesser importance to large data and distances and greater importance to small data and distances in fitting the model.

In general, the FIT=*n* option fits *n*th-power data to *n*th-power distances. Values of *n* that are large in absolute value can cause floating-point overflows.

If the FIT= value is 0 or negative, the data must be strictly positive (see the EPSILON= option). Negative data might produce strange results with any value other than FIT=1.

FORMULA | FOR=0 | OLS | O**FORMULA | FOR=1 | USS | U****FORMULA | FOR=2 | CSS | C**

determines how the badness-of-fit criterion is standardized in correspondence with stress formulas 1 and 2 (Kruskal and Wish 1978, pp. 24–26). The default is FORMULA=1 unless you specify FIT=LOG, in which case the default is FORMULA=2. Data partitions are defined by the CONDITION= option.

FORMULA=0 fits a regression model by ordinary least squares (Null and Sarle 1982) without standardizing the partitions; this option cannot be used with the LEVEL=ORDINAL option. The badness-of-fit criterion is the square root of the error sum of squares.

FORMULA=1 standardizes each partition by the uncorrected sum of squares of the (possibly transformed) data; this option should not be used with the FIT=LOG option. With the FIT=DISTANCE and LEVEL=ORDINAL options, this is equivalent to Kruskal's stress formula 1 or an obvious generalization thereof. With the FIT=SQUARED and LEVEL=ORDINAL options, this is equivalent to Young's s-stress formula 1 or an obvious generalization thereof. The badness-of-fit criterion is analogous to $\sqrt{1 - R^2}$, where R is a multiple correlation about the origin.

FORMULA=2 standardizes each partition by the corrected sum of squares of the (possibly transformed) data; this option is the recommended method for unfolding. With the FIT=DISTANCE and LEVEL=ORDINAL options, this is equivalent to Kruskal's stress formula 2 or an obvious generalization thereof. With the FIT=SQUARED and LEVEL=ORDINAL options, this is equivalent to Young's s-stress formula 2 or an obvious generalization thereof. The badness-of-fit criterion is analogous to $\sqrt{1 - R^2}$, where R is a multiple correlation computed with a denominator corrected for the mean.

GCONVERGE | GCONV=p

sets the gradient convergence criterion to p , where $0 \leq p \leq 1$. The default is GCONVERGE=0.01; smaller values might greatly increase the number of iterations required. Values less than 0.0001 might be impossible to satisfy because of the limits of machine precision.

The gradient convergence measure is the multiple correlation of the Jacobian matrix with the residual vector, uncorrected for the mean. (See the **CONVERGE=** and **MCONVERGE=** options.)

INAV=DATA | D**INAV=SSCP | S**

affects the computation of initial coordinates. The default is INAV=DATA.

INAV=DATA computes a weighted average of the data matrices. Its value is estimated only if an element is missing from every data matrix. The weighted average of the data matrices with missing values filled in is then converted to a scalar products matrix (or what would be a scalar products matrix if the fit were perfect), from which the initial coordinates are computed.

INAV=SSCP estimates missing values in each data matrix and converts each data matrix to a scalar products matrix. The initial coordinates are computed from the unweighted average of the scalar products matrices.

INITIAL | IN=SAS-data-set

specifies a SAS data set containing initial values for some or all of the parameters of the MDS model. If the INITIAL= option is omitted, the initial values are computed from the data.

LEVEL=ABSOLUTE | ABS | A**LEVEL=RATIO | RAT | R****LEVEL=INTERVAL | INT | I****LEVEL=LOGINTERVAL | LOG | L****LEVEL=ORDINAL | ORD | O**

specifies the measurement level of the data and hence the type of estimated (optimal) transformations applied to the data or distances (Young 1987, pp. 57–60; Krantz et al. 1971, pp. 9–12) within each partition as specified by the CONDITION= option. LEVEL=ORDINAL specifies a nonmetric analysis, while all other LEVEL= options specify metric analyses. The default is LEVEL=ORDINAL.

LEVEL=ABSOLUTE	permits no optimal transformations. Hence, the distinction between regression and measurement models is irrelevant.
LEVEL=RATIO	fits a regression model in which the distances are multiplied by a slope parameter in each partition (a linear transformation). In this case, the regression model is equivalent to the measurement model with the slope parameter reciprocated.
LEVEL=INTERVAL	fits a regression model in which the distances are multiplied by a slope parameter and added to an intercept parameter in each partition (an affine transformation). In this case, the regression and measurement models differ if there is more than one partition.
LEVEL=LOGINTERVAL	fits a regression model in which the distances are raised to a power and multiplied by a slope parameter in each partition (a power transformation).
LEVEL=ORDINAL	fits a measurement model in which a least-squares monotone increasing transformation is applied to the data in each partition. At the ordinal measurement level, the regression and measurement models differ.

MAXITER | ITER=*n*

specifies the maximum number of iterations, where $n \geq 0$. The default is MAXITER=100.

MCONVERGE | MCONV=*p*

sets the monotone convergence criterion to p , where $0 \leq p \leq 1$, for use with the LEVEL=ORDINAL option. The default is MCONVERGE=0.01; if you want greater precision, MCONVERGE=0.001 is usually reasonable, but smaller values might greatly increase the number of iterations required.

The monotone convergence criterion is the Euclidean norm of the change in the optimally scaled data divided by the Euclidean norm of the optimally scaled data, averaged across partitions defined by the CONDITION= option. (See the [CONVERGE=](#) and [GCONVERGE=](#) options.)

MINCRIT | CRITMIN=*n*

causes iteration to terminate when the badness-of-fit criterion is less than or equal to n , where $n \geq 0$. The default is MINCRIT=1E-6.

NEGATIVE

permits slopes or powers to be negative with the LEVEL=RATIO, INTERVAL, or LOGINTERVAL option.

NONORM

suppresses normalization of the initial and final estimates.

NOPHIST | NOPRINT | NOP

suppresses the output of the iteration history.

NOULB

causes missing data to be estimated during initialization by the average nonmissing value, where the average is computed according to the FIT= option. Otherwise, missing data are estimated by interpolating between the Rabinowitz (1976) upper and lower bounds.

OCOEF

writes the dimension coefficients to the OUT= data set. See the OUT= option for interactions with other options.

OCONFIG

writes the coordinates of the objects to the OUT= data set. See the OUT= option for interactions with other options.

OCRIT

writes the badness-of-fit criterion to the OUT= data set. See the OUT= option for interactions with other options.

OITER | OUTITER

writes current values to the output data sets after initialization and on every iteration. Otherwise, only the final values are written to any output data sets. (See the OUT=, OUTFIT=, and OUTRES= options.)

OTRANS

writes the transformation parameter estimates to the OUT= data set if any such estimates are computed. There are no transformation parameters with the LEVEL=ORDINAL option. See the OUT= option for interactions with other options.

OUT=SAS-data-set

creates a SAS data set containing, by default, the estimates of all the parameters of the PROC MDS model and the value of the badness-of-fit criterion. However, if you specify one or more of the OCONFIG, OCOEF, OTRANS, and OCRIT options, only the information requested by the specified options appears in the OUT= data set. (See also the OITER option.)

OUTFIT=SAS-data-set

creates a SAS data set containing goodness-of-fit and badness-of-fit measures for each partition as well as for the entire data set. (See also the OITER option.)

OUTRES=SAS-data-set

creates a SAS data set containing one observation for each nonmissing data value from the DATA= data set. Each observation contains the original data value, the estimated distance computed from the MDS model, transformed data and distances, and the residual. (See also the OITER option.)

OVER=*n*

specifies the maximum overrelaxation factor, where $n \geq 1$. Values between 1 and 2 are generally reasonable. The default is OVER=2 with the LEVEL=ORDINAL, ALTERNATE=MATRIX, or ALTERNATE=ROW option; otherwise, the default is OVER=1. Use this option only if you have convergence problems.

PCOEF

produces the estimated dimension coefficients.

PCONFIG

produces the estimated coordinates of the objects in the configuration.

PDATA

displays each data matrix.

PFINAL

displays final estimates.

PFIT

displays the badness-of-fit criterion and various types of correlations between the data and fitted values for each data matrix, as well as for the entire sample.

PFITROW

displays the badness-of-fit criterion and various types of correlations between the data and fitted values for each row, as well as for each data matrix and for the entire sample. This option works only with the CONDITION=ROW option.

PINAVDATA

displays the sum of the weights and the weighted average of the data matrices computed during initialization with the INAV=DATA option.

PINEIGVAL

displays the eigenvalues computed during initialization.

PINEIGVEC

displays the eigenvectors computed during initialization.

PININ

displays values read from the INITIAL= data set. Since these values might be incomplete, the PFIT and PFITROW options do not apply.

PINIT

displays initial values.

PI TER

displays estimates on each iteration.

PLOTS< (*global-plot-option*) > <= *plot-request* < (*options*) > >

PLOTS< (*global-plot-options*) > <= (*plot-request* < (*options*) > <... *plot-request* < (*options*) > > >

specifies options that control the details of the plots. When you specify only one plot request, you can omit the parentheses around the plot request.

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;

proc mds plots(flip);
run;

ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The global plot option is as follows:

FLIP

flips or interchanges the X-axis and Y-axis dimensions for configuration and coefficient plots.

The plot requests include the following:

COEFFICIENTS(ONE)

combines the INDSCAL coefficients panel of plots into a single plot. By default, the display consists of a panel with two plots. The vectors are displayed in the left plot, and the labels are displayed in the right plot. The right plot provides a magnification of the region of the vector endpoints. In contrast, the single display, requested by COEFFICIENTS(ONE), is more compact, but there is less room for vector labels. It is often easier to identify the vectors in the default display.

NONE

suppresses all plots.

By default, a fit plot is produced. When more than one dimension is requested, plots of the configuration are also plotted. For individual differences models with more than one dimension, the subject weights or coefficients are plotted. When more than one value is specified for the DIMENSION= option, the badness-of-fit plot is produced.

PTRANS

displays the estimated transformation parameters if any are computed. There are no transformation parameters with the LEVEL=ORDINAL option.

RANDOM<=seed>

causes initial coordinate values to be pseudo-random numbers. In one dimension, the pseudo-random numbers are uniformly distributed on an interval. In two or more dimensions, the pseudo-random numbers are uniformly distributed on the circumference of a circle or the surface of a (hyper)sphere.

RIDGE=*n*

specifies the initial ridge value, where $n \geq 0$. The default is RIDGE=1E-4.

If you get a floating-point overflow in the first few iterations, specify a larger value such as RIDGE=0.01, RIDGE=1, or RIDGE=100.

If you know that the initial estimates are very good, using RIDGE=0 might speed convergence.

SHAPE=TRIANGULAR | TRIANGLE | TRI | T**SHAPE=SQUARE | SQU | S**

determines whether the entire data matrix for each subject or only one triangle of the matrix is stored and analyzed. If you specify the CONDITION=ROW option, the default is SHAPE=SQUARE. Otherwise, the default is SHAPE=TRIANGLE.

SHAPE=SQUARE causes the entire matrix to be stored and analyzed. The matrix can be asymmetric.

SHAPE=TRIANGLE causes only one triangle to be stored. However, PROC MDS reads both upper and lower triangles to look for nonmissing values and to symmetrize the data if needed. If corresponding elements in the upper and lower triangles both contain nonmissing values, only the average of the two values is stored and analyzed (Kruskal and Wish 1978, p. 74). Also, if an OUTRES= data set is requested, only the average of the two corresponding elements is output.

SIMILAR | SIM<=*max*>

causes the data to be treated as similarity measurements rather than dissimilarities. If =*max* is not specified, each data value is converted to a dissimilarity by subtracting it from the maximum value in the data set or BY group. If =*max* is specified, each data value is subtracted from the maximum of *max* and the data. The diagonal data are included in computing these maxima.

By default, the data are assumed to be dissimilarities unless there are nonmissing diagonal values and these values are predominantly larger than the off-diagonal values. In this case, the data are assumed to be similarities and are treated as if the SIMILAR option is specified.

SINGULAR=*p*

specifies the singularity criterion p , $0 \leq p \leq 1$. The default is SINGULAR=1E-8.

UNTIE

permits tied data to be assigned different optimally scaled values with the LEVEL=ORDINAL option. Otherwise, tied data are assigned equal optimally scaled values. The UNTIE option has no effect with values of the LEVEL= option other than LEVEL=ORDINAL.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC MDS to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the MDS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

If the INITIAL= data set contains the BY variables, the BY groups must appear in the same order as in the DATA= data set. If the BY variables are not in the INITIAL= data set, the entire data set is used to provide initial values for each BY group in the DATA= data set.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

ID Statement

ID | **OBJECT** | **OBJ** *variable* ;

The ID statement specifies a variable in the DATA= data set that contains descriptive labels for the objects. The labels are used in the output and are copied to the OUT= data set. If there is more than one data matrix, only the ID values from the observations containing the first data matrix are used.

The ID variable is not used to establish any correspondence between observations and variables.

If the ID statement is omitted, the variable labels or names are used as object labels.

INVAR Statement

INVAR *variables* ;

The INVAR statement specifies the numeric variables in the INITIAL= data set that contain initial parameter estimates. The first variable corresponds to the first dimension, the second variable to the second dimension, and so on.

If the INVAR statement is omitted, the variables Dim1, ..., Dim m are used, where m is the maximum number of dimensions.

MATRIX Statement

MATRIX | MAT | SUBJECT | SUB *variable* ;

The MATRIX statement specifies a variable in the DATA= data set that contains descriptive labels for the data matrices or subjects. The labels are used in the output and are copied to the OUT= and OUTRES= data sets. Only the first observation from each data matrix is used to obtain the label for that matrix.

If the MATRIX statement is omitted, the matrices are labeled 1, 2, 3, and so on.

VAR Statement

VAR *variables* ;

The VAR statement specifies the numeric variables in the DATA= data set that contain similarity or dissimilarity measurements on a set of objects or stimuli. Each variable corresponds to one object.

If the VAR statement is omitted, all numeric variables that are not specified in another statement are used.

To analyze a subset of the objects in a data set, you can specify the variable names corresponding to the columns in the subset, but you must also use a DATA step or a WHERE clause to specify the rows in the subset. PROC MDS expects to read one or more square matrices, and you must ensure that the rows in the data set correctly correspond to the columns in number and order.

WEIGHT Statement

WEIGHT *variables* ;

The WEIGHT statement specifies numeric variables in the DATA= data set that contain weights for each similarity or dissimilarity measurement. These weights are used to compute weighted least-squares estimates. The number of WEIGHT variables must be the same as the number of VAR variables, and the variables in the WEIGHT statement must be in the same order as the corresponding variables in the VAR statement.

If the WEIGHT statement is omitted, all data within a partition are assigned equal weights.

Data with zero or negative weights are ignored in fitting the model but are included in the OUTRES= data set and in monotone transformations.

Details: MDS Procedure

Formulas

The following notation is used:

A_p	intercept for partition p
B_p	slope for partition p
C_p	power for partition p
D_{rcs}	distance computed from the model between objects r and c for subject s
F_{rcs}	data weight for objects r and c for subject s obtained from the c th WEIGHT variable, or 1 if there is no WEIGHT statement
f	value of the FIT= option
N	number of objects
O_{rcs}	observed dissimilarity between objects r and c for subject s
P_{rcs}	partition index for objects r and c for subject s
Q_{rcs}	dissimilarity after applying any applicable estimated transformation for objects r and c for subject s
R_{rcs}	residual for objects r and c for subject s
S_p	standardization factor for partition p
$T_p(\cdot)$	estimated transformation for partition p
V_{sd}	coefficient for subject s on dimension d
X_{nd}	coordinate for object n on dimension d

Summations are taken over nonmissing values.

Distances are computed from the model as

$$\begin{aligned}
 D_{rcs} &= \sqrt{\sum_d (X_{rd} - X_{cd})^2} && \text{for COEF=IDENTITY:} \\
 &&& \text{Euclidean distance} \\
 &= \sqrt{\sum_d V_{sd}^2 (X_{rd} - X_{cd})^2} && \text{for COEF=DIAGONAL:} \\
 &&& \text{weighted Euclidean distance}
 \end{aligned}$$

Partition indexes are

$$\begin{aligned}
 P_{rcs} &= 1 && \text{for CONDITION=UN} \\
 &= s && \text{for CONDITION=MATRIX} \\
 &= (s-1)N + r && \text{for CONDITION=ROW}
 \end{aligned}$$

The estimated transformation for each partition is

$$\begin{aligned}
 T_p(d) &= d && \text{for LEVEL=ABSOLUTE} \\
 &= B_p d && \text{for LEVEL=RATIO} \\
 &= A_p + B_p d && \text{for LEVEL=INTERVAL} \\
 &= B_p d^{C_p} && \text{for LEVEL=LOGINTERVAL}
 \end{aligned}$$

For LEVEL=ORDINAL, $T_p(\cdot)$ is computed as a least-squares monotone transformation.

For LEVEL=ABSOLUTE, RATIO, or INTERVAL, the residuals are computed as

$$\begin{aligned}
 Q_{rcs} &= O_{rcs} \\
 R_{rcs} &= Q_{rcs}^f - [T_{P_{rcs}}(D_{rcs})]^f
 \end{aligned}$$

For LEVEL=ORDINAL, the residuals are computed as

$$\begin{aligned}
 Q_{rcs} &= T_{P_{rcs}}(O_{rcs}) \\
 R_{rcs} &= Q_{rcs}^f - D_{rcs}^f
 \end{aligned}$$

If f is 0, then natural logarithms are used in place of the f th powers.

For each partition, let

$$U_p = \frac{\sum_{r,c,s} F_{rcs}}{\sum_{r,c,s|P_{rcs}=p} F_{rcs}}$$

and

$$\bar{Q}_p = \frac{\sum_{r,c,s|P_{rcs}=p} Q_{rcs} F_{rcs}}{\sum_{r,c,s|P_{rcs}=p} F_{rcs}}$$

Then the standardization factor for each partition is

$$\begin{aligned}
 S_p &= 1 && \text{for FORMULA=0} \\
 &= U_p \sum_{r,c,s|P_{rcs}=p} Q_{rcs}^2 F_{rcs} && \text{for FORMULA=1} \\
 &= U_p \sum_{r,c,s|P_{rcs}=p} (Q_{rcs} - \bar{Q}_p)^2 F_{rcs} && \text{for FORMULA=2}
 \end{aligned}$$

The badness-of-fit criterion that the MDS procedure tries to minimize is

$$\sqrt{\sum_{r,c,s} \frac{R_{rcs}^2 F_{rcs}}{S_{P_{rcs}}}}$$

OUT= Data Set

The OUT= data set contains the following variables:

- BY variables, if any
- `_ITER_` (if the OUTITER option is specified), a numeric variable containing the iteration number
- `_DIMENS_`, a numeric variable containing the number of dimensions
- `_MATRIX_` or the variable in the MATRIX statement, identifying the data matrix or subject to which the observation pertains. This variable contains a missing value for observations that pertain to the data set as a whole and not to a particular matrix, such as the coordinates (`_TYPE_='CONFIG'`).
- `_TYPE_`, a character variable of length 10 identifying the type of information in the observation

The values of `_TYPE_` are as follows:

CONFIG	the estimated coordinates of the configuration of objects
DIAGCOEF	the estimated dimension coefficients for COEF=DIAGONAL
INTERCEPT	the estimated intercept parameters
SLOPE	the estimated slope parameters
POWER	the estimated power parameters
CRITERION	the badness-of-fit criterion

- `_LABEL_` or the variable in the ID statement, containing the variable label or value of the ID variable of the object to which the observation pertains. This variable contains a missing value for observations that do not pertain to a particular object or dimension.
- `_NAME_`, a character variable containing the variable name of the object or dimension to which the observation pertains. This variable contains a missing value for observations that do not pertain to a particular object or dimension.
- Dim1, ..., Dim m , where m is the maximum number of dimensions

OUTFIT= Data Set

The OUTFIT= data set contains various measures of goodness and badness of fit. There is one observation for the entire sample plus one observation for each matrix. For the CONDITION=ROW option, there is also one observation for each row.

The OUTFIT= data set contains the following variables:

- BY variables, if any
- `_ITER_` (if the OUTITER option is specified), a numeric variable containing the iteration number

- `_DIMENS_`, a numeric variable containing the number of dimensions
- `_MATRIX_` or the variable in the `MATRIX` statement, identifying the data matrix or subject to which the observation pertains
- `_LABEL_` or the variable in the `ID` statement, containing the variable label or value of the `ID` variable of the object to which the observation pertains when `CONDITION=ROW`
- `_NAME_`, a character variable containing the variable name of the object or dimension to which the observation pertains when `CONDITION=ROW`
- `N`, the number of nonmissing data
- `WEIGHT`, the weight of the partition
- `CRITER`, the badness-of-fit criterion
- `DISCORR`, the correlation between the transformed data and the distances for `LEVEL=ORDINAL` or the correlation between the data and the transformed distances otherwise
- `UDISCORR`, the correlation uncorrected for the mean between the transformed data and the distances for `LEVEL=ORDINAL` or the correlation between the data and the transformed distances otherwise
- `FITCORR`, the correlation between the fit-transformed data and the fit-transformed distances
- `UFITCORR`, the correlation uncorrected for the mean between the fit-transformed data and the fit-transformed distances

OUTRES= Data Set

The OUTRES= data set has one observation for each nonmissing data value. It contains the following variables:

- BY variables, if any
- `_ITER_` (if the `OUTITER` option is specified), a numeric variable containing the iteration number
- `_DIMENS_`, a numeric variable containing the number of dimensions
- `_MATRIX_` or the variable in the `MATRIX` statement, identifying the data matrix or subject to which the observation pertains
- `_ROW_`, containing the variable label or value of the `ID` variable of the row to which the observation pertains
- `_COL_`, containing the variable label or value of the `ID` variable of the column to which the observation pertains
- `DATA`, the original data value
- `TRANDATA`, the optimally transformed data value when `LEVEL=ORDINAL`

- DISTANCE, the distance computed from the PROC MDS model
- TRANSDIST, the optimally transformed distance when the LEVEL= option is not ORDINAL or ABSOLUTE
- FITDATA, the data value further transformed according to the FIT= option
- FITDIST, the distance further transformed according to the FIT= option
- WEIGHT, the combined weight of the data value based on the WEIGHT variable(s), if any, and the standardization specified by the FORMULA= option
- RESIDUAL, FITDATA minus FITDIST

If you assign a nonmissing data value a weight of zero, PROC MDS will ignore it when the model is fit, but the value will still appear in the OUTRES= data set (see the section “[WEIGHT Statement](#)” on page 4693).

INITIAL= Data Set

The INITIAL= data set has the same structure as the OUT= data set but is not required to have all of the variables or observations that appear in the OUT= data set. You can use an OUT= data set previously created by PROC MDS (without the OUTITER option) as an INITIAL= data set in a subsequent invocation of the procedure.

The only variables that are required are Dim1, . . . , Dim m (where m is the maximum number of dimensions) or equivalent variables specified in the INVAR statement. If these are the only variables, then all the observations are assumed to contain coordinates of the configuration; you cannot read dimension coefficients or transformation parameters.

To read initial values for the dimension coefficients or transformation parameters, the INITIAL= data set must contain the _TYPE_ variable and either the variable specified in the ID statement or, if no ID statement is used, the variable _NAME_. In addition, if there is more than one data matrix, either the variable specified in the MATRIX statement or, if no MATRIX statement is used, the variable _MATRIX_ or _MATNUM_ is required.

If the INITIAL= data set contains the variable _DIMENS_, initial values are obtained from observations with the corresponding number of dimensions. If there is no _DIMENS_ variable, the same observations are used for each number of dimensions analyzed.

If you want PROC MDS to read initial values from some but not all of the observations in the INITIAL= data set, use the WHERE= data set option to select the desired observations.

Missing Values

Missing data in the similarity or dissimilarity matrices are ignored in fitting the model and are omitted from the OUTRES= data set. Any matrix that is completely missing is omitted from the analysis.

Missing weights are treated as 0.

Missing values are also permitted in the INITIAL= data set, but a large number of missing values might yield a degenerate initial configuration.

Normalization of the Estimates

In multidimensional scaling models, the parameter estimates are not uniquely determined; the estimates can be transformed in various ways without changing their badness of fit. The initial and final estimates from PROC MDS are, therefore, normalized (unless you specify the NONORM option) to make it easier to compare results from different analyses.

The configuration always has a mean of 0 for each dimension.

With the COEF=IDENTITY option, the configuration is rotated to a principal-axis orientation. Unless you specify the LEVEL=ABSOLUTE option, the entire configuration is scaled so that the root-mean-square element is 1, and the transformations are adjusted to compensate.

With the COEF=DIAGONAL option, each dimension is scaled to a root-mean-square value of 1, and the dimension coefficients are adjusted to compensate. Unless you specify the LEVEL=ABSOLUTE option, the dimension coefficients are normalized as follows. If you specify the CONDITION=UN option, all of the dimension coefficients are scaled to a root-mean-square value of 1. For other values of the CONDITION= option, the dimension coefficients are scaled separately for each subject to a root-mean-square value of 1. In either case, the transformations are adjusted to compensate.

Each dimension is reflected to give a positive rank correlation with the order of the objects in the data set.

For the LEVEL=ORDINAL option, if the intercept, slope, or power parameters are fitted, the transformed data are normalized to eliminate these parameters if possible.

Comparison with Earlier Procedures

PROC MDS shares many of the features of the ALSCAL procedure (Young, Lewycky, and Takane 1986; Young 1982), as well as some features of the MLSCALE procedure (Ramsay 1986). Both PROC ALSCAL and PROC MLSCALE are no longer a part of SAS; however, they are described in the *SUGI Supplemental Library User's Guide, Version 5 Edition*. The MDS procedure generally produces results similar to those from the ALSCAL procedure (Young, Lewycky, and Takane 1986; Young 1982) if you use the following options in PROC MDS:

- FIT=SQUARED
- FORMULA=1 except for unfolding data, which require FORMULA=2
- PFINAL to get output similar to that from PROC ALSCAL

Running the MDS procedure with certain options generally produces results similar to those from using the MLSCALE procedure (Ramsay 1986) with other options. This is illustrated with the following statements:

```
proc mds fit=log level=loginterval ... ;
```

```
proc mlscale stvarnce=constant suvarnce=constant ... ;
```

Alternatively, using the FIT=DISTANCE option in the PROC MDS statement produces results similar to those from specifying the NORMAL option in the PROC MLSCALE statement.

Displayed Output

Unless you specify the NOPHIST option, PROC MDS displays the iteration history containing the following:

- Iteration number
- Type of iteration:

Initial	initial configuration
Monotone	monotone transformation
Gau-New	Gauss-Newton step
Lev-Mar	Levenberg-Marquardt step
- Badness-of-Fit Criterion
- Change in Criterion
- Convergence Measures:

Monotone	the Euclidean norm of the change in the optimally scaled data divided by the Euclidean norm of the optimally scaled data, averaged across partitions
Gradient	the multiple correlation of the Jacobian matrix with the residual vector, uncorrected for the mean

Depending on what options are specified, PROC MDS can also display the following tables:

- Data Matrix and possibly Weight Matrix for each subject
- Eigenvalues from the computation of the initial coordinates
- Sum of Data Weights and Pooled Data Matrix computed during initialization with INAV=DATA
- Configuration, the estimated coordinates of the objects
- Dimension Coefficients
- A table of transformation parameters, including one or more of the following:

Intercept
Slope
Power
- A table of fit statistics for each matrix and possibly each row, including the following:

Number of Nonmissing Data
Weight of the matrix or row, permitting both observation weights and standardization factors
Badness-of-Fit Criterion

Distance Correlation computed between the distances and data with optimal transformation

Uncorrected Distance Correlation not corrected for the mean

Fit Correlation computed after applying the FIT= transformation to both distances and data

Uncorrected Fit Correlation not corrected for the mean

ODS Table Names

PROC MDS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 56.3](#). For more information about ODS, see Chapter 20, “[Using the Output Delivery System.](#)”

Table 56.3 ODS Tables Produced by PROC MDS

ODS Table Name	Description	Option
ConvergenceStatus	Convergence status	default
DimensionCoef	Dimension coefficients	PCOEF with COEF= not IDENTITY
FitMeasures	Measures of fit	PFIT
IterHistory	Iteration history	default
PConfig	Configuration of coordinates	PCONFIG
PData	Data matrices	PDATA
PInAvData	INAV= data set information	PINAVDATA
PInEigval	Initial eigenvalues	PINEIGVAL
PInEigvec	Initial eigenvectors	PINEIGVEC
PInWeight	Initialization weights	PINWEIGHT
Transformations	Transformation parameters	PTRANS with LEVEL=RATIO, INTERVAL, LOGINTERVAL

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS.](#)”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

All graphs are produced by default when they are appropriate. You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC MDS generates are listed in [Table 56.4](#), along with the required options.

Table 56.4 Graphs Produced by PROC MDS

ODS Graph Name	Plot Description	Option
BadnessPlot	Badness of fit	DIMENSION= <i>range</i>
CoefficientsPlot	Individual coefficients	DIMENSION= <i>n</i> , <i>n</i> > 1 COEF=DIAGONAL
ConfigPlot	Configuration	DIMENSION= <i>n</i> , <i>n</i> > 1
FitPlot	Fit	default

Example: MDS Procedure

Example 56.1: Jacobowitz Body Parts Data from Children and Adults

Jacobowitz (1975) collected conditional rank-order data regarding perceived similarity of parts of the body from children of ages 6, 8, and 10 years and from college sophomores. The data set includes data from 15 children (6-year-olds) and 15 sophomores. The method of data collection and some results of an analysis are also described by Young (1987, pp. 4–10). The following statements create the input data set:

```
data body;
  title 'Jacobowitz Body Parts Data from 6-Year-Olds and Adults';

The data are analyzed as row conditional (CONDITION=ROW) at the ordinal level of measurement (LEVEL=ORDINAL) by using the weighted Euclidean model (COEF=DIAGONAL) in three dimensions (DIMENSION=3). The final estimates are displayed (PFINAL). The estimates (OUT=OUT) and fitted values (OUTRES=RES) are saved in output data sets. The following statements produce [Output 56.1.1](#):

Often the output of greatest interest in an MDS analysis is the graphical output. The first plots show two-dimensional view of the three-dimensional configuration. Next, the coefficients are plotted. The last plot is the fit plot.

In the fit plot, the transformed data are plotted on the vertical axis, and the distances from the model are plotted on the horizontal axis. If the model fits perfectly, all points lie on a diagonal line from lower left to upper right. The vertical departure of each point from this diagonal line represents the residual of the corresponding observation.

The configuration has a tripodal shape with **Body** at the apex. The three legs of the tripod can be distinguished in the plot of dimension 2 by dimension 1, which shows three distinct clusters with **Body** in the center. Dimension 1 separates head parts from arm and leg parts. Dimension 2 separates arm parts from leg parts. The plot of dimension 3 by dimension 1 shows the tripod from the side. Dimension 3 distinguishes the more inclusive body parts (at the top) from the less inclusive body parts (at the bottom).

The plots of dimension coefficients show that children differ from adults primarily in the emphasis given to dimension 2. Children give about the same weight (approximately 1) to each dimension. Adults are much more variable than children, but all have coefficients less than 1.0 for dimension 2, with an average of about 0.7. Referring back to the configuration plot, you can see that adults consider arm parts to be more similar to leg parts than children do. Many adults also give a high weight to dimension 1, indicating that they consider head parts to be more dissimilar from arm and leg parts than children do. Dimension 3 shows considerable variability for both children and adults.

Overview: MI Procedure

Missing values are an issue in a substantial number of statistical analyses. Most SAS statistical procedures exclude observations with any missing variable values from the analysis. These observations are called incomplete cases. While using only complete cases is simple, you lose information that is in the incomplete cases. Excluding observations with missing values also ignores the possible systematic difference between the complete cases and incomplete cases, and the resulting inference might not be applicable to the population of all cases, especially with a smaller number of complete cases.

Some SAS procedures use all the available cases in an analysis—that is, cases with useful information. For example, the CORR procedure estimates a variable mean by using all cases with nonmissing values for this variable, ignoring the possible missing values in other variables. The CORR procedure also estimates a correlation by using all cases with nonmissing values for this pair of variables. This estimation might make better use of the available data, but the resulting correlation matrix might not be positive definite.

Another strategy is single imputation, in which you substitute a value for each missing value. Standard statistical procedures for complete data analysis can then be used with the filled-in data set. For example, each missing value can be imputed from the variable mean of the complete cases. This approach treats missing values as if they were known in the complete-data analyses. Single imputation does not reflect the uncertainty about the predictions of the unknown missing values, and the resulting estimated variances of the parameter estimates are biased toward zero (Rubin 1987, p. 13).

Instead of filling in a single value for each missing value, multiple imputation replaces each missing value with a set of plausible values that represent the uncertainty about the right value to impute (Rubin 1976, 1987). The multiply imputed data sets are then analyzed by using standard procedures for complete data and combining the results from these analyses. No matter which complete-data analysis is used, the process of combining results from different data sets is essentially the same.

Multiple imputation does not attempt to estimate each missing value through simulated values, but rather to represent a random sample of the missing values. This process results in valid statistical inferences that properly reflect the uncertainty due to missing values; for example, valid confidence intervals for parameters.

Multiple imputation inference involves three distinct phases:

1. The missing data are filled in m times to generate m complete data sets.
2. The m complete data sets are analyzed by using standard procedures.
3. The results from the m complete data sets are combined for the inference.

The MI procedure is a multiple imputation procedure that creates multiply imputed data sets for incomplete p -dimensional multivariate data. It uses methods that incorporate appropriate variability across the m imputations. The imputation method of choice depends on the patterns of missingness in the data and the type of the imputed variable.

A data set with variables Y_1, Y_2, \dots, Y_p (in that order) is said to have a *monotone missing pattern* when the event that a variable Y_j is missing for a particular individual implies that all subsequent variables Y_k , $k > j$, are missing for that individual.

For data sets with monotone missing patterns, the variables with missing values can be imputed sequentially with covariates constructed from their corresponding sets of preceding variables. To impute missing values

for a continuous variable, you can use a regression method (Rubin 1987, pp. 166–167), a predictive mean matching method (Heitjan and Little 1991; Schenker and Taylor 1996), or a propensity score method (Rubin 1987, pp. 124, 158; Lavori, Dawson, and Shera 1995). To impute missing values for a classification variable, you can use a logistic regression method when the classification variable has a binary or ordinal response, or use a discriminant function method when the classification variable has a binary or nominal response.

For data sets with arbitrary missing patterns, you can use either of the following methods to impute missing values: a Markov chain Monte Carlo (MCMC) method (Schafer 1997) that assumes multivariate normality, or a fully conditional specification (FCS) method (Brand 1999; van Buuren 2007) that assumes the existence of a joint distribution for all variables.

You can use the MCMC method to impute either all the missing values or just enough missing values to make the imputed data sets have monotone missing patterns. With a monotone missing data pattern, you have greater flexibility in your choice of imputation models, such as the monotone regression method that do not use Markov chains. You can also specify a different set of covariates for each imputed variable.

An FCS method does not start with an explicitly specified multivariate distribution for all variables, but rather uses a separate conditional distribution for each imputed variable. For each imputation, the process contains two phases: the preliminary filled-in phase followed by the imputation phase. At the filled-in phase, the missing values for all variables are filled in sequentially over the variables taken one at a time. These filled-in values provide starting values for these missing values at the imputation phase. At the imputation phase, the missing values for each variable are imputed sequentially for a number of burn-in iterations before the imputation.

As in methods for data sets with monotone missing patterns, you can use a regression method or a predictive mean matching method to impute missing values for a continuous variable, a logistic regression method to impute missing values for a classification variable with a binary or ordinal response, and a discriminant function method to impute missing values for a classification variable with a binary or nominal response.

After the m complete data sets are analyzed using standard SAS procedures, the MIANALYZE procedure can be used to generate valid statistical inferences about these parameters by combining results from the m analyses.

Often, as few as three to five imputations are adequate in multiple imputation (Rubin 1996, p. 480). The relative efficiency of the small m imputation estimator is high for cases with little missing information (Rubin 1987, p. 114). (Also see the section “[Multiple Imputation Efficiency](#)” on page 4771.)

Multiple imputation inference assumes that the model (variables) you used to analyze the multiply imputed data (the analyst’s model) is the same as the model used to impute missing values in multiple imputation (the imputer’s model). But in practice, the two models might not be the same. The consequences for different scenarios (Schafer 1997, pp. 139–143) are discussed in the section “[Imputer’s Model Versus Analyst’s Model](#)” on page 4771.

Getting Started: MI Procedure

The Fitness data described in the REG procedure are measurements of 31 individuals in a physical fitness course. See Chapter 79, “[The REG Procedure](#),” for more information.

The Fitness1 data set is constructed from the Fitness data set and contains three variables: Oxygen, RunTime, and RunPulse. Some values have been set to missing, and the resulting data set has an arbitrary pattern of missingness in these three variables.

```

```

Suppose that the data are multivariate normally distributed and the missing data are missing at random (MAR). That is, the probability that an observation is missing can depend on the observed variable values of the individual, but not on the missing variable values of the individual. See the section “[Statistical Assumptions for Multiple Imputation](#)” on page 4745 for a detailed description of the MAR assumption.

The following statements invoke the MI procedure and impute missing values for the Fitness1 data set:

```

proc mi data=Fitness1 seed=501213 mu0=50 10 180 out=outmi;
  mcmc;
  var Oxygen RunTime RunPulse;
run;

```

The “Model Information” table in [Figure 57.1](#) describes the method used in the multiple imputation process. By default, the MCMC statement uses the Markov chain Monte Carlo (MCMC) method with a single chain to create five imputations. The posterior mode, the highest observed-data posterior density, with a noninformative prior, is computed from the expectation-maximization (EM) algorithm and is used as the starting value for the chain.

Figure 57.1 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FITNESS1
Method	MCMC
Multiple Imputation Chain	Single Chain
Initial Estimates for MCMC	EM Posterior Mode
Start	Starting Value
Prior	Jeffreys
Number of Imputations	5
Number of Burn-in Iterations	200
Number of Iterations	100
Seed for random number generator	501213

The MI procedure takes 200 burn-in iterations before the first imputation and 100 iterations between imputations. In a Markov chain, the information in the current iteration influences the state of the next iteration. The burn-in iterations are iterations in the beginning of each chain that are used both to eliminate the series of dependence on the starting value of the chain and to achieve the stationary distribution. The between-imputation iterations in a single chain are used to eliminate the series of dependence between the two imputations.

The “Missing Data Patterns” table in [Figure 57.2](#) lists distinct missing data patterns with their corresponding frequencies and percentages. An “X” means that the variable is observed in the corresponding group, and a “.” means that the variable is missing. The table also displays group-specific variable means. The MI procedure sorts the data into groups based on whether the analysis variables are observed or missing. For a detailed description of missing data patterns, see the section “[Missing Data Patterns](#)” on page 4746.

Figure 57.2 Missing Data Patterns

Missing Data Patterns

2	X	X	.	4	12.90
3	X	.	.	3	9.68
4	.	X	X	1	3.23
5	.	X	.	2	6.45

Missing Data Patterns			
-----Group Means-----			
Group	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

After the completion of m imputations, the “Variance Information” table in [Figure 57.3](#) displays the between-imputation variance, within-imputation variance, and total variance for combining complete-data inferences. It also displays the degrees of freedom for the total variance. The relative increase in variance due to missing values, the fraction of missing information, and the relative efficiency (in units of variance) for each variable are also displayed. A detailed description of these statistics is provided in the section “Combining Inferences from Multiply Imputed Data Sets” on page 4769.

Figure 57.3 Variance Information

Variance Information				
Variable	-----Variance-----			DF
	Between	Within	Total	
Oxygen	0.056930	0.954041	1.022356	25.549
RunTime	0.000811	0.064496	0.065469	27.721
RunPulse	0.922032	3.269089	4.375528	15.753

Variance Information			
Variable	Relative Increase in Variance	Fraction Missing Information	Relative Efficiency
Oxygen	0.071606	0.068898	0.986408
RunTime	0.015084	0.014968	0.997015
RunPulse	0.338455	0.275664	0.947748

The “Parameter Estimates” table in [Figure 57.4](#) displays the estimated mean and standard error of the mean for each variable. The inferences are based on the t distribution. The table also displays a 95% confidence interval for the mean and a t statistic with the associated p -value for the hypothesis that the population mean is equal to the value specified with the MU0= option. A detailed description of these statistics is provided in the section “Combining Inferences from Multiply Imputed Data Sets” on page 4769.

Figure 57.4 Parameter Estimates

Parameter Estimates					
Variable	Mean	Std Error	95% Confidence Limits		DF
Oxygen	47.094040	1.011116	45.0139	49.1742	25.549
RunTime	10.572073	0.255870	10.0477	11.0964	27.721
RunPulse	171.787793	2.091776	167.3478	176.2278	15.753

Parameter Estimates					
Variable	Minimum	Maximum	Mu0	t for H0: Mean=Mu0	Pr > t
Oxygen	46.783898	47.395550	50.000000	-2.87	0.0081
RunTime	10.526392	10.599616	10.000000	2.24	0.0336
RunPulse	170.774818	173.122002	180.000000	-3.93	0.0012

In addition to the output tables, the procedure also creates a data set with imputed values. The imputed data sets are stored in the outmi data set, with the index variable `_Imputation_` indicating the imputation numbers. The data set can now be analyzed using standard statistical procedures with `_Imputation_` as a BY variable.

The following statements list the first 10 observations of data set outmi:

```
proc print data=outmi (obs=10);
    title 'First 10 Observations of the Imputed Data Set';
run;
```

The table in Figure 57.5 shows that the precision of the imputed values differs from the precision of the observed values. You can use the `ROUND=` option to make the imputed values consistent with the observed values.

Figure 57.5 Imputed Data Set

First 10 Observations of the Imputed Data Set				
Obs	_Imputation_	Oxygen	RunTime	Run Pulse
1	1	44.6090	11.3700	178.000
2	1	45.3130	10.0700	185.000
3	1	54.2970	8.6500	156.000
4	1	59.5710	8.0747	155.925
5	1	49.8740	9.2200	176.837
6	1	44.8110	11.6300	176.000
7	1	42.8857	11.9500	176.000
8	1	46.9992	10.8500	173.099
9	1	39.4420	13.0800	174.000
10	1	60.0550	8.6300	170.000

Syntax: MI Procedure

The following statements are available in the MI procedure:

```
PROC MI < options > ;
    BY variables ;
    CLASS variables ;
    EM < options > ;
    FCS < options > ;
    FREQ variable ;
    MCMC < options > ;
    MONOTONE < options > ;
    TRANSFORM transform (variables< / options >) < ... transform (variables< / options >) > ;
    VAR variables ;
```

The `BY` statement specifies groups in which separate multiple imputation analyses are performed.

The `CLASS` statement lists the classification variables in the `VAR` statement. Classification variables can be either character or numeric.

The EM statement uses the EM algorithm to compute the maximum likelihood estimate (MLE) of the data with missing values, assuming a multivariate normal distribution for the data.

The FREQ statement specifies the variable that represents the frequency of occurrence for other values in the observation.

For a data set with a monotone missing pattern, you can use the MONOTONE statement to specify applicable monotone imputation methods; otherwise, you can use either the MCMC statement assuming multivariate normality or the FCS method assuming a joint distribution for variables exists. Note that you can specify no more than one of these statements. When none of these three statements is specified, the MCMC method with its default options is used.

The FCS statement uses a multivariate imputation by chained equations method to impute values for a data set with an arbitrary missing pattern, assuming a joint distribution exists for the data.

The MCMC statement uses a Markov chain Monte Carlo method to impute values for a data set with an arbitrary missing pattern, assuming a multivariate normal distribution for the data.

The MONOTONE statement specifies monotone methods to impute continuous and classification variables for a data set with a monotone missing pattern.

The TRANSFORM statement specifies the variables to be transformed before the imputation process; the imputed values of these transformed variables are reverse-transformed to the original forms before the imputation.

The VAR statement lists the numeric variables to be analyzed. If you omit the VAR statement, all numeric variables not listed in other statements are used.

The PROC MI statement is the only required statement for the MI procedure. The rest of this section provides detailed syntax information for each of these statements, beginning with the PROC MI statement. The remaining statements are presented in alphabetical order.

PROC MI Statement

PROC MI <options> ;

The PROC MI statement invokes the MI procedure. [Table 57.1](#) summarizes the options available in the PROC MI statement.

Table 57.1 Summary of PROC MI Options

Option	Description
Data Sets	
DATA=	Specifies the input data set
OUT=	Specifies the output data set with imputed values
Imputation Details	
NIMPUTE=	Specifies the number of imputations
SEED=	Specifies the seed to begin random number generator
ROUND=	Specifies units to round imputed variable values
MAXIMUM=	Specifies maximum values for imputed variable values
MINIMUM=	Specifies minimum values for imputed variable values

Table 57.1 *continued*

Option	Description
MINMAXITER=	Specifies the maximum number of iterations to impute values in the specified range
SINGULAR=	Specifies the singularity criterion
Statistical Analysis	
ALPHA=	Specifies the level for the confidence interval, $(1 - \alpha)$
MU0=	Specifies means under the null hypothesis
Printed Output	
NOPRINT	Suppresses all displayed output
SIMPLE	Displays univariate statistics and correlations

The following options can be used in the PROC MI statement. They are listed in alphabetical order.

ALPHA= α

specifies that confidence limits be constructed for the mean estimates with confidence level $100(1 - \alpha)\%$, where $0 < \alpha < 1$. The default is ALPHA=0.05.

DATA=SAS-data-set

names the SAS data set to be analyzed by PROC MI. By default, the procedure uses the most recently created SAS data set.

MAXIMUM=numbers

specifies maximum values for imputed variables. When an intended imputed value is greater than the maximum, PROC MI redraws another value for imputation. If only one number is specified, that number is used for all variables. If more than one number is specified, you must use a VAR statement, and the specified numbers must correspond to variables in the VAR statement. The default number is a missing value, which indicates no restriction on the maximum for the corresponding variable

The MAXIMUM= option is related to the MINIMUM= and ROUND= options, which are used to make the imputed values more consistent with the observed variable values. These options are applicable only if you use the MCMC method or the monotone regression method.

When specifying a maximum for the first variable only, you must also specify a missing value after the maximum. Otherwise, the maximum is used for all variables.

For example, the “MAXIMUM= 100 .” option sets a maximum of 100 for the first analysis variable only and no maximum for the remaining variables. The “MAXIMUM= . 100” option sets a maximum of 100 for the second analysis variable only and no maximum for the other variables.

MINIMUM=numbers

specifies the minimum values for imputed variables. When an intended imputed value is less than the minimum, PROC MI redraws another value for imputation. If only one number is specified, that number is used for all variables. If more than one number is specified, you must use a VAR statement, and the specified numbers must correspond to variables in the VAR statement. The default number is a missing value, which indicates no restriction on the minimum for the corresponding variable

MINMAXITER=number

specifies the maximum number of iterations for imputed values to be in the specified range when the option MINIMUM or MAXIMUM is also specified. The default is MINMAXITER=100.

MU0=numbers**THETA0=numbers**

specifies the parameter values μ_0 under the null hypothesis $\mu = \mu_0$ for the population means corresponding to the analysis variables. Each hypothesis is tested with a t test. If only one number is specified, that number is used for all variables. If more than one number is specified, you must use a VAR statement, and the specified numbers must correspond to variables in the VAR statement. The default is MU0=0.

If a variable is transformed as specified in a TRANSFORM statement, then the same transformation for that variable is also applied to its corresponding specified MU0= value in the t test. If the parameter values μ_0 for a transformed variable are not specified, then a value of zero is used for the resulting μ_0 after transformation.

NIMPUTE=number

specifies the number of imputations. The default is NIMPUTE=5. You can specify NIMPUTE=0 to skip the imputation. In this case, only tables of model information, missing data patterns, descriptive statistics (SIMPLE option), and MLE from the EM algorithm (EM statement) are displayed.

NOPRINT

suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, “Using the Output Delivery System,” for more information.

OUT=SAS-data-set

creates an output SAS data set that contains imputation results. The data set includes an index variable, `_Imputation_`, to identify the imputation number. For each imputation, the data set contains all variables in the input data set with missing values being replaced by the imputed values. See the section “Output Data Sets” on page 4767 for a description of this data set.

ROUND=numbers

specifies the units to round variables in the imputation. If only one number is specified, that number is used for all continuous variables. If more than one number is specified, you must use a VAR statement, and the specified numbers must correspond to variables in the VAR statement. When the classification variables are listed in the VAR statement, their corresponding roundoff units are not used. The default number is a missing value, which indicates no rounding for imputed variables.

When specifying a roundoff unit for the first variable only, you must also specify a missing value after the roundoff unit. Otherwise, the roundoff unit is used for all variables. For example, the option “ROUND= 10 .” sets a roundoff unit of 10 for the first analysis variable only and no rounding for the remaining variables. The option “ROUND= . 10” sets a roundoff unit of 10 for the second analysis variable only and no rounding for other variables.

The ROUND= option sets the precision of imputed values. For example, with a roundoff unit of 0.001, each value is rounded to the nearest multiple of 0.001. That is, each value has three significant digits after the decimal point. See [Example 57.3](#) for an illustration of this option.

SEED=number

specifies a positive integer to start the pseudo-random number generator. The default is a value generated from reading the time of day from the computer's clock. However, in order to duplicate the results under identical situations, you must use the same value of the seed explicitly in subsequent runs of the MI procedure.

The seed information is displayed in the "Model Information" table so that the results can be reproduced by specifying this seed with the SEED= option. You need to specify the same seed number in the future to reproduce the results.

SIMPLE

displays simple descriptive univariate statistics and pairwise correlations from available cases. For a detailed description of these statistics, see the section "[Descriptive Statistics](#)" on page 4743.

SINGULAR=p

specifies the criterion for determining the singularity of a covariance matrix based on standardized variables, where $0 < p < 1$. The default is SINGULAR=1E-8.

Suppose that \mathbf{S} is a covariance matrix and v is the number of variables in \mathbf{S} . Based on the spectral decomposition $\mathbf{S} = \mathbf{\Gamma}\mathbf{\Lambda}\mathbf{\Gamma}'$, where $\mathbf{\Lambda}$ is a diagonal matrix of eigenvalues λ_j , $j = 1, \dots, v$, where $\lambda_i \geq \lambda_j$ when $i < j$, and $\mathbf{\Gamma}$ is a matrix with the corresponding orthonormal eigenvectors of \mathbf{S} as columns, \mathbf{S} is considered singular when an eigenvalue λ_j is less than $p\bar{\lambda}$, where the average $\bar{\lambda} = \sum_{k=1}^v \lambda_k / v$.

BY Statement

BY variables ;

You can specify a BY statement with PROC MI to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the MI procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* ;

The CLASS statement specifies the classification variables in the VAR statement. Classification variables can be either character or numeric. The CLASS statement must be used in conjunction with either an FCS or MONOTONE statement.

Classification levels are determined from the formatted values of the classification variables. See “The FORMAT Procedure” in the *Base SAS Procedures Guide* for details.

EM Statement

EM *< options >* ;

The expectation-maximization (EM) algorithm is a technique for maximum likelihood estimation in parametric models for incomplete data. The EM statement uses the EM algorithm to compute the MLE for (μ, Σ) , the means and covariance matrix, of a multivariate normal distribution from the input data set with missing values. Either the means and covariances from complete cases or the means and standard deviations from available cases can be used as the initial estimates for the EM algorithm. You can also specify the correlations for the estimates from available cases.

You can also use the EM statement with the NIMPUTE=0 option in the PROC MI statement to compute the EM estimates without multiple imputation, as shown in [Example 57.1](#).

The following seven options are available with the EM statement (in alphabetical order):

CONVERGE=*p*

XCONV=*p*

sets the convergence criterion. The value must be between 0 and 1. The iterations are considered to have converged when the change in the parameter estimates between iteration steps is less than *p* for each parameter—that is, for each of the means and covariances. For each parameter, the change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change. By default, CONVERGE=1E–4.

INITIAL=CC | AC | AC(R=*r*)

sets the initial estimates for the EM algorithm. The INITIAL=CC option uses the means and covariances from complete cases; the INITIAL=AC option uses the means and standard deviations from available cases, and the correlations are set to zero; and the INITIAL=AC(R= *r*) option uses the means and standard deviations from available cases with correlation *r*, where $-1/(p - 1) < r < 1$ and *p* is the number of variables to be analyzed. The default is INITIAL=AC.

ITPRINT

prints the iteration history in the EM algorithm.

MAXITER=*number*

specifies the maximum number of iterations used in the EM algorithm. The default is MAXITER=200.

OUT=SAS-data-set

creates an output SAS data set that contains results from the EM algorithm. The data set contains all variables in the input data set, with missing values being replaced by the expected values from the EM algorithm. See the section “[Output Data Sets](#)” on page 4767 for a description of this data set.

OUTEM=SAS-data-set

creates an output SAS data set of TYPE=COV that contains the MLE of the parameter vector (μ , Σ). These estimates are computed with the EM algorithm. See the section “[Output Data Sets](#)” on page 4767 for a description of this output data set.

OUTITER < (options) > =SAS-data-set

creates an output SAS data set of TYPE=COV that contains parameters for each iteration. The data set includes a variable named `_iteration_` to identify the iteration number. The parameters in the output data set depend on the options specified. You can specify the MEAN and COV options to output the mean and covariance parameters. When no options are specified, the output data set contains the mean parameters for each iteration. See the section “[Output Data Sets](#)” on page 4767 for a description of this data set.

FCS Statement

FCS < options > ;

The FCS statement specifies a multivariate imputation by fully conditional specification methods. If you specify an FCS statement, you must also specify a VAR statement.

Table 57.2 summarizes the options available for the FCS statement.

Table 57.2 Summary of Options in FCS

Option	Description
Imputation Details	
NBITER=	Specifies the number of burn-in iterations
Data Set	
OUTITER=	Outputs parameter estimates used in iterations
ODS Output Graphics	
PLOTS=TRACE	Displays trace plots
Imputation Methods	
DISCRIM	Specifies the discriminant function method
LOGISTIC	Specifies the logistic regression method
REG	Specifies the regression method
REGPMM	Specifies the predictive mean matching method

The following options are available for the FCS statement in addition to the imputation methods specified (in alphabetical order):

NBITER=number

specifies the number of burn-in iterations before each imputation. The default is NBITER=20.

OUTITER <(options)> =SAS-data-set

creates an output SAS data set of TYPE=COV that contains parameters used in the imputation step for each iteration. The data set includes variables named `_Imputation_` and `_Iteration_` to identify the imputation number and iteration number.

The parameters in the output data set depend on the options specified. You can specify the options MEAN and STD to output parameters of means and standard deviations, respectively. When no options are specified, the output data set contains the mean parameters used in the imputation step for each iteration. See the section “[Output Data Sets](#)” on page 4767 for a description of this data set.

PLOTS <(LOG)> <= TRACE <(trace-options)>>

requests statistical graphics of trace plots from iterations via the Output Delivery System (ODS).

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc mi data=Fitness1 seed=501213 mu0=50 10 180;
    mcmc plots=(trace(mean(Oxygen)) acf(mean(Oxygen)));
    var Oxygen RunTime RunPulse;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The global plot option LOG requests that the logarithmic transformations of parameters be used. The default is PLOTS=TRACE(MEAN).

The available *trace-options* are as follows:

MEAN <(variables)>

displays plots of means for continuous variables in the list. When the MEAN option is specified without variables, all continuous variables are used.

STD <(variables)>

displays plots of standard deviations for continuous variables in the list. When the STD option is specified without variables, all continuous variables are used.

The discriminant function, logistic regression, regression, and predictive mean matching methods are available in the FCS statement. You specify each method with the syntax

```
method < (<imputed <= effects>> </ options>)>
```

That is, for each method, you can specify the imputed variables and, optionally, a set of effects to impute these variables. Each effect is a variable or a combination of variables in the VAR statement. The syntax for the specification of effects is the same as for the GLM procedure. See Chapter 42, “[The GLM Procedure](#),” for more information.

One general form of an effect involving several variables is

$$X1 * X2 * A * B * C (D E)$$

where A, B, C, D, and E are classification variables and X1 and X2 are continuous variables.

When an FCS statement is used without specifying any methods, the regression method is used for all continuous variables and the discriminant function method is used for all classification variables. For each imputed variable, all other variables in the VAR statement are used as the covariates.

When a method for continuous variables is specified without imputed variables, the method is used for all continuous variables in the VAR statement that are not specified in other methods. Similarly, when a method for classification variables is specified without imputed variables, the method is used for all classification variables in the VAR statement that are not specified in other methods.

For each imputed variable, if no covariates are specified, then all other variables in the VAR statement are used as the covariates. That is, each continuous variable is used as a regressor effect, and each classification variable is used as a main effect. For the discriminant function method, only the continuous variables can be used as covariate effects.

With an FCS statement, the variables are imputed sequentially in the order specified in the VAR statement. For a continuous variable, you can use a regression method or a regression predicted mean matching method to impute missing values. For a nominal classification variable, you can use a discriminant function method to impute missing values without using the ordering of the class levels. For an ordinal classification variable, you can use a logistic regression method to impute missing values by using the ordering of the class levels. For a binary classification variable, either a discriminant function method or a logistic regression method can be used. By default, a regression method is used for a continuous variable, and a discriminant function method is used for a classification variable.

Note that except for the regression method, all other methods impute values from the observed values. See the section “[FCS Methods for Data Sets with Arbitrary Missing Patterns](#)” on page 4755 for a detailed description of the FCS methods.

You can specify the following imputation methods in an FCS statement (in alphabetical order):

DISCRIM < (*imputed* < = *effects* > < / *options* >) >

specifies the discriminant function method of classification variables. The available options are DETAILS, PCOV=, PRIOR=, and CLASSEFFECTS=. The DETAILS option displays the group means and pooled covariance matrix used in each imputation. The PCOV= option specifies the pooled covariance used in the discriminant method. Valid values for the PCOV= option are as follows:

FIXED	uses the observed-data pooled covariance matrix for each imputation.
POSTERIOR	draws a pooled covariance matrix from its posterior distribution.

The default is PCOV=POSTERIOR. See the section “[Monotone and FCS Discriminant Function Methods](#)” on page 4752 for a detailed description of the method.

The PRIOR= option specifies the prior probabilities of group membership. Valid values for the PRIOR= option are as follows:

EQUAL	sets the prior probabilities equal for all groups.
PROPORTIONAL	sets the prior probabilities proportion to the group sample sizes.

JEFFREYS < = c > specifies a noninformative prior, $0 < c < 1$. If the number c is not specified, JEFFREYS=0.5.

RIDGE < = d > specifies a ridge prior, $d > 0$. If the number d is not specified, RIDGE=0.25.

The default is PRIOR=JEFFREYS. See the section “[Monotone and FCS Discriminant Function Methods](#)” on page 4752 for a detailed description of the method.

The CLASSEFFECTS= option specifies whether the CLASS variables are used as covariate effects. Valid values for the CLASSEFFECTS= option are as follows:

EXCLUDE excludes the CLASS variables from covariate effects.

INCLUDE includes the CLASS variables as covariate effects.

The default is CLASSEFFECTS=EXCLUDE.

LOGISTIC < (imputed < = effects > < / options >) >

specifies the logistic regression method of classification variables. The available options are DETAILS, ORDER=, and DESCENDING. The DETAILS option displays the regression coefficients in the logistic regression model used in each imputation.

When the imputed variable has more than two response levels, the ordinal logistic regression method is used. The ORDER= option specifies the sort order for the levels of the response variable. Valid values for the ORDER= option are as follows:

DATA sorts by the order of appearance in the input data set.

FORMATTED sorts by their external formatted values.

FREQ sorts by the descending frequency counts.

INTERNAL sorts by the unformatted values.

By default, ORDER=FORMATTED.

The option DESCENDING reverses the sort order for the levels of the response variables.

See the section “[Monotone and FCS Logistic Regression Methods](#)” on page 4754 for a detailed description of the method.

REG | REGRESSION < (imputed < = effects > < / DETAILS >) >

specifies the regression method of continuous variables. The DETAILS option displays the regression coefficients in the regression model used in each imputation.

With a regression method, the MAXIMUM=, MINIMUM=, and ROUND= options can be used to make the imputed values more consistent with the observed variable values.

See the section “[Monotone and FCS Regression Methods](#)” on page 4749 for a detailed description of the method.

REGPMM < (*imputed* < = *effects* > < *options* >) >

REGPREDMEANMATCH < (*imputed* < = *effects* > < *options* >) >

specifies the predictive mean matching method for continuous variables. This method is similar to the regression method except that it imputes a value randomly from a set of observed values whose predicted values are closest to the predicted value for the missing value from the simulated regression model (Heitjan and Little 1991; Schenker and Taylor 1996).

The available options are DETAILS and K=. The DETAILS option displays the regression coefficients in the regression model used in each imputation. The K= option specifies the number of closest observations to be used in the selection. The default is K=5.

See the section “[Monotone and FCS Predictive Mean Matching Methods](#)” on page 4750 for a detailed description of the method.

With an FCS statement, the missing values of variables in the VAR statement are imputed. After the initial filled in, these variables with missing values are imputed sequentially in the order specified in the VAR statement. For example, the following MI procedure statements use the regression method to impute variable y1 from effect y2, the regression method to impute variable y3 from effects y1 and y2, the logistic regression method to impute variable c1 from effects y1, y2, and y1 * y2, and the default regression method for continuous variables to impute variable y2 from effects y1, y3, and c1:

```
proc mi;
  class c1;
  fcs reg(y1= y2) reg(y3= y1 y2) logistic(c1= y1 y2 y1*y2);
  var y1 y2 y3 c1;
run;
```

FREQ Statement

FREQ *variable* ;

To run a procedure on an input data set that contains observations that occur multiple times, you can use a variable in the data set to represent how frequently observations occur and specify a FREQ statement with the name of that variable as its argument (*variable*) when you run the procedure.

When you specify a FREQ statement in other SAS procedures, they treat the data set as if each observation appeared *n* times, where *n* is the value of *variable* in the observation. However, PROC MI treats the data set differently because as PROC MI imputes each missing value in each observation, it generates only one imputed value for that missing value. That is, when you specify a FREQ *variable*, each imputed observation (with its imputed value in place of the missing value) is treated as if it appeared *n* times. In contrast, if an observation actually occurs *n* times in the data set, the missing value at each occurrence is imputed separately, and the resulting *n* observations are not identical.

PROC MI uses only the integer portion of each value of *variable*; if any value is less than 1, PROC MI does not use the corresponding observation in the analysis. When PROC MI calculates significance probabilities, it considers the total number of observations to be equal to the sum of the values of *variable*.

MCMC Statement

MCMC < options > ;

The MCMC statement specifies the details of the MCMC method for imputation.

Table 57.3 summarizes the options available for the MCMC statement.

Table 57.3 Summary of Options in MCMC

Option	Description
Data Sets	
INEST=	Inputs parameter estimates for imputations
OUTEST=	Outputs parameter estimates used in imputations
OUTITER=	Outputs parameter estimates used in iterations
Imputation Details	
IMPUTE=	Specifies monotone or full imputation
CHAIN=	Specifies single or multiple chain
NBITER=	Specifies the number of burn-in iterations for each chain
NITER=	Specifies the number of iterations between imputations in a chain
INITIAL=	Specifies initial parameter estimates for MCMC
PRIOR=	Specifies the prior parameter information
START=	Specifies starting parameters
ODS Output Graphics	
PLOTS=TRACE	Displays trace plots
PLOTS=ACF	Displays autocorrelation plots
Traditional Graphics	
TIMEPLOT	Displays trace plots
ACFPLOT	Displays autocorrelation plots
GOUT=	Specifies the graphics catalog name for saving graphics output
Printed Output	
WLF	Displays the worst linear function
DISPLAYINIT	Displays initial parameter values for MCMC

The following options are available for the MCMC statement (in alphabetical order).

ACFPLOT < (options < / display-options >) >

displays the traditional autocorrelation function plots of parameters from iterations. The ACFPLOT option is applicable only if ODS Graphics is not enabled.

The available options are as follows.

COV <(< *variables* > < *variable1*variable2* > < ... *variable1*variable2* >) >

displays plots of variances for variables in the list and covariances for pairs of variables in the list. When the option COV is specified without variables, variances for all variables and covariances for all pairs of variables are used.

MEAN <(*variables*) >

displays plots of means for variables in the list. When the option MEAN is specified without variables, all variables are used.

WLF

displays the plot for the worst linear function.

When the ACFPLOT is specified without the preceding options, the procedure displays plots of means for all variables that are used.

The display options provide additional information for the autocorrelation function plots. The available display options are as follows:

CCONF=*color*

specifies the color of the displayed confidence limits. The default is CCONF=BLACK.

CFRAME=*color*

specifies the color for filling the area enclosed by the axes and the frame. By default, this area is not filled.

CNEEDLES=*color*

specifies the color of the vertical line segments (needles) that connect autocorrelations to the reference line. The default is CNEEDLES=BLACK.

CREF=*color*

specifies the color of the displayed reference line. The default is CREF=BLACK.

CSYMBOL=*color*

specifies the color of the displayed data points. The default is CSYMBOL=BLACK.

HSYMBOL=*number*

specifies the height of data points in percentage screen units. The default is HSYMBOL=1.

LCONF=*linetype*

specifies the line type for the displayed confidence limits. The default is LCONF=1, a solid line.

LOG

requests that the logarithmic transformations of parameters be used to compute the autocorrelations; it is generally used for the variances of variables. When a parameter has values less than or equal to zero, the corresponding plot is not created.

LREF=*linetype*

specifies the line type for the displayed reference line. The default is LREF=3, a dashed line.

NAME='string'

specifies a descriptive name, up to eight characters, that appears in the name field of the PROC GREPLAY master menu. The default is NAME='MI'.

NLAG=number

specifies the maximum lag of the series. The default is NLAG=20. The autocorrelations at each lag are displayed in the graph.

SYMBOL=value

specifies the symbol for data points in percentage screen units. The default is SYMBOL=STAR.

TITLE='string'

specifies the title to be displayed in the autocorrelation function plots. The default is TITLE='Autocorrelation Plot'.

WCONF=number

specifies the width of the displayed confidence limits in percentage screen units. If you specify the WCONF=0 option, the confidence limits are not displayed. The default is WCONF=1.

WNEEDLES=number

specifies the width of the displayed needles that connect autocorrelations to the reference line, in percentage screen units. If you specify the WNEEDLES=0 option, the needles are not displayed. The default is WNEEDLES=1.

WREF=number

specifies the width of the displayed reference line in percentage screen units. If you specify the WREF=0 option, the reference line is not displayed. The default is WREF=1.

For example, the following statement requests autocorrelation function plots for the means and variances of the variable *y1*, respectively:

```
acfplot( mean( y1) cov(y1) /log);
```

Logarithmic transformations of both the means and variances are used in the plots. For a detailed description of the autocorrelation function plot, see the section “[Autocorrelation Function Plot](#)” on page 4765; see also Schafer (1997, pp. 120–126) and the *SAS/ETS User's Guide*.

CHAIN=SINGLE | MULTIPLE

specifies whether a single chain is used for all imputations or a separate chain is used for each imputation. The default is CHAIN=SINGLE.

DISPLAYINIT

displays initial parameter values in the MCMC method for each imputation.

GOUT=graphics-catalog

specifies the graphics catalog for saving graphics output from PROC MI. The default is WORK.GSEG. For more information, see “The GREPLAY Procedure” in *SAS/GRAPH: Reference*.

IMPUTE=FULL | MONOTONE

specifies whether a full-data imputation is used for all missing values or a monotone-data imputation is used for a subset of missing values to make the imputed data sets have a monotone missing pattern. The default is `IMPUTE=FULL`. When `IMPUTE=MONOTONE` is specified, the order in the `VAR` statement is used to complete the monotone pattern.

INEST=SAS-data-set

names a SAS data set of `TYPE=EST` that contains parameter estimates for imputations. These estimates are used to impute values for observations in the `DATA=` data set. A detailed description of the data set is provided in the section “[Input Data Sets](#)” on page 4766.

INITIAL=EM <(options)>**INITIAL=INPUT=SAS-data-set**

specifies the initial mean and covariance estimates for the MCMC method. The default is `INITIAL=EM`.

You can specify `INITIAL=INPUT=SAS-data-set` to read the initial estimates of the mean and covariance matrix for each imputation from a SAS data set. See the section “[Input Data Sets](#)” on page 4766 for a description of this data set.

With `INITIAL=EM`, `PROC MI` derives parameter estimates for a posterior mode, the highest observed-data posterior density, from the EM algorithm. The MLE from the EM algorithm is used to start the EM algorithm for the posterior mode, and the resulting EM estimates are used to begin the MCMC method. The prior information specified in the `PRIOR=` option is also used in the process to compute the posterior mode.

The following four options are available with `INITIAL=EM`:

BOOTSTRAP <=number>

requests bootstrap resampling, which uses a simple random sample with replacement from the input data set for the initial estimate. You can explicitly specify the number of observations in the random sample. Alternatively, you can implicitly specify the number of observations in the random sample by specifying the proportion p , $0 < p \leq 1$, to request $[np]$ observations in the random sample, where n is the number of observations in the data set and $[np]$ is the integer part of np . This produces an overdispersed initial estimate that provides different starting values for the MCMC method. If you specify the `BOOTSTRAP` option without the number, $p = 0.75$ is used by default.

CONVERGE= p **XCONV= p**

sets the convergence criterion. The value must be between 0 and 1. The iterations are considered to have converged when the change in the parameter estimates between iteration steps is less than p for each parameter—that is, for each of the means and covariances. For each parameter, the change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change. By default, `CONVERGE=1E-4`.

ITPRINT

prints the iteration history in the EM algorithm for the posterior mode.

MAXITER=number

specifies the maximum number of iterations used in the EM algorithm. The default is MAXITER=200.

NBITER=number

specifies the number of burn-in iterations before the first imputation in each chain. The default is NBITER=200.

NITER=number

specifies the number of iterations between imputations in a single chain. The default is NITER=100.

OUTEST=SAS-data-set

creates an output SAS data set of TYPE=EST. The data set contains parameter estimates used in each imputation. The data set also includes a variable named `_Imputation_` to identify the imputation number. See the section “[Output Data Sets](#)” on page 4767 for a description of this data set.

OUTITER < (options) > =SAS-data-set

creates an output SAS data set of TYPE=COV that contains parameters used in the imputation step for each iteration. The data set includes variables named `_Imputation_` and `_Iteration_` to identify the imputation number and iteration number.

The parameters in the output data set depend on the options specified. You can specify the options MEAN, STD, COV, LR, LR_POST, and WLF to output parameters of means, standard deviations, covariances, $-2 \log$ LR statistic, $-2 \log$ LR statistic of the posterior mode, and the worst linear function, respectively. When no options are specified, the output data set contains the mean parameters used in the imputation step for each iteration. See the section “[Output Data Sets](#)” on page 4767 for a description of this data set.

PLOTS < (LOG) > <= plot-request >**PLOTS < (LOG) > <= (plot-request < ... plot-request >) >**

requests statistical graphics via the Output Delivery System (ODS). To request these graphs, ODS Graphics must be enabled and you must specify options in the MCMC statement. For more information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).”

The global plot option LOG requests that the logarithmic transformations of parameters be used. The plot request options include the following:

ACF < (acf-options) >

displays plots of the autocorrelation function of parameters from iterations. The default is ACF(MEAN).

ALL

produces all appropriate plots.

NONE

suppresses all plots.

TRACE < (trace-options) >

displays trace plots of parameters from iterations. The default is TRACE(MEAN).

The available *acf-options* are as follows:

NLAG=*n*

specifies the maximum lag of the series. The default is NLAG=20. The autocorrelations at each lag are displayed in the graph.

COV < (< *variables* > < *variable1*variable2* > ...) >

displays plots of variances for variables in the list and covariances for pairs of variables in the list. When the option COV is specified without variables, variances for all variables and covariances for all pairs of variables are used.

MEAN < (*variables*) >

displays plots of means for variables in the list. When the option MEAN is specified without variables, all variables are used.

WLF

displays the plot for the worst linear function.

The available *trace-options* are as follows:

COV < (< *variables* > < *variable1*variable2* > ...) >

displays plots of variances for variables in the list and covariances for pairs of variables in the list. When the option COV is specified without variables, variances for all variables and covariances for all pairs of variables are used.

MEAN < (*variables*) >

displays plots of means for variables in the list. When the option MEAN is specified without variables, all variables are used.

WLF

displays the plot of the worst linear function.

PRIOR=*name*

specifies the prior information for the means and covariances. Valid values for *name* are as follows:

JEFFREYS specifies a noninformative prior.

RIDGE=*number* specifies a ridge prior.

INPUT=*SAS-data-set* specifies a data set that contains prior information.

For a detailed description of the prior information, see the section “[Bayesian Estimation of the Mean Vector and Covariance Matrix](#)” on page 4759 and the section “[Posterior Step](#)” on page 4759. If you do not specify the PRIOR= option, the default is PRIOR=JEFFREYS.

The PRIOR=INPUT= option specifies a TYPE=COV data set from which the prior information of the mean vector and the covariance matrix is read. See the section “[Input Data Sets](#)” on page 4766 for a description of this data set.

START=VALUE | DIST

specifies that the initial parameter estimates are used either as the starting value (START=VALUE) or as the starting distribution (START=DIST) in the first imputation step of each chain. If the IMPUTE=MONOTONE option is specified, then START=VALUE is used in the procedure. The default is START=VALUE.

TIMEPLOT < (*options* < / *display-options* >) >

displays the traditional trace (time series) plots of parameters from iterations. The TIMEPLOT option is applicable only if ODS Graphics is not enabled.

The available options are as follows:

COV < (< *variables* > < *variable1*variable2* > ...) >

displays plots of variances for variables in the list and covariances for pairs of variables in the list. When the option COV is specified without variables, variances for all variables and covariances for all pairs of variables are used.

MEAN < (*variables*)>

displays plots of means for variables in the list. When the option MEAN is specified without variables, all variables are used.

WLF

displays the plot of the worst linear function.

When the TIMEPLOT is specified without the preceding options, the procedure displays plots of means for all variables that are used.

The display options provide additional information for the trace plots. The available display options are as follows:

CCONNECT=*color*

specifies the color of the line segments that connect data points in the trace plots. The default is CCONNECT=BLACK.

CFRAME=*color*

specifies the color for filling the area enclosed by the axes and the frame. By default, this area is not filled.

CSYMBOL=*color*

specifies the color of the data points to be displayed in the trace plots. The default is CSYMBOL=BLACK.

HSYMBOL=*number*

specifies the height of data points in percentage screen units. The default is HSYMBOL=1.

LCONNECT=*linetype*

specifies the line type for the line segments that connect data points in the trace plots. The default is LCONNECT=1, a solid line.

LOG

requests that the logarithmic transformations of parameters be used; it is generally used for the variances of variables. When a parameter value is less than or equal to zero, the value is not displayed in the corresponding plot.

NAME='string'

specifies a descriptive name, up to eight characters, that appears in the name field of the PROC GREPLAY master menu. The default is NAME='MI'.

SYMBOL=value

specifies the symbol for data points in percentage screen units. The default is SYMBOL=PLUS.

TITLE='string'

specifies the title to be displayed in the trace plots. The default is TITLE='Trace Plot'.

WCONNECT=number

specifies the width of the line segments that connect data points in the trace plots, in percentage screen units. If you specify the WCONNECT=0 option, the data points are not connected. The default is WCONNECT=1.

For a detailed description of the trace plot, see the section “[Trace Plot](#)” on page 4765 and Schafer (1997, pp. 120–126).

WLF

displays the worst linear function of parameters. This scalar function of parameters μ and Σ is “worst” in the sense that its values from iterations converge most slowly among parameters. For a detailed description of this statistic, see the section “[Worst Linear Function of Parameters](#)” on page 4764.

MONOTONE Statement

```
MONOTONE <method <(<imputed <= effects>> </options>)>>
          <...method <(<imputed <= effects>> </options>)>> ;
```

The MONOTONE statement specifies imputation methods for data sets with monotone missingness. You must also specify a VAR statement, and the data set must have a monotone missing pattern with variables ordered in the VAR list.

Table 57.4 summarizes the options available for the MONOTONE statement.

Table 57.4 Summary of Imputation Methods in MONOTONE Statement

Option	Description
DISCRIM	Specifies the discriminant function method
LOGISTIC	Specifies the logistic regression method
PROPENSITY	Specifies the propensity scores method
REG	Specifies the regression method
REGPMM	Specifies the predictive mean matching method

For each method, you can specify the imputed variables and, optionally, a set of the effects to impute these variables. Each effect is a variable or a combination of variables preceding the imputed variable in the VAR statement. The syntax for specification of effects is the same as for the GLM procedure. See Chapter 42, “[The GLM Procedure](#),” for more information.

One general form of an effect involving several variables is

$$X1 * X2 * A * B * C (D E)$$

where A, B, C, D, and E are classification variables and X1 and X2 are continuous variables.

If no covariates are specified, then all preceding variables are used as the covariates. That is, each preceding continuous variable is used as a regressor effect, and each preceding classification variable is used as a main effect. For the discriminant function method, only the continuous variables can be used as covariate effects.

When a method for continuous variables is specified without imputed variables, the method is used for all continuous variables in the VAR statement that are not specified in other methods. Similarly, when a method for classification variables is specified without imputed variables, the method is used for all classification variables in the VAR statement that are not specified in other methods.

When a MONOTONE statement is used without specifying any methods, the regression method is used for all continuous variables and the discriminant function method is used for all classification variables. The preceding variables of each imputed variable in the VAR statement are used as the covariates.

With a MONOTONE statement, the variables are imputed sequentially in the order given by the VAR statement. For a continuous variable, you can use a regression method, a regression predicted mean matching method, or a propensity score method to impute missing values.

For a nominal classification variable, you can use a discriminant function method to impute missing values without using the ordering of the class levels. For an ordinal classification variable, you can use a logistic regression method to impute missing values by using the ordering of the class levels. For a binary classification variable, either a discriminant function method or a logistic regression method can be used.

Note that except for the regression method, all other methods impute values from the observed observation values. You can specify the following methods in a MONOTONE statement.

DISCRIM < (*imputed* < = *effects* > < / *options* >) >

specifies the discriminant function method of classification variables. The available options are DETAILS, PCOV=, PRIOR=, and CLASSEFFECTS=. The DETAILS option displays the group means and pooled covariance matrix used in each imputation. The PCOV= option specifies the pooled covariance used in the discriminant method. Valid values for the PCOV= option are as follows:

FIXED	uses the observed-data pooled covariance matrix for each imputation.
POSTERIOR	draws a pooled covariance matrix from its posterior distribution.

The default is PCOV=POSTERIOR. See the section “[Monotone and FCS Discriminant Function Methods](#)” on page 4752 for a detailed description of the method.

The PRIOR= option specifies the prior probabilities of group membership. Valid values for the PRIOR= option are as follows:

EQUAL	sets the prior probabilities equal for all groups.
PROPORTIONAL	sets the prior probabilities proportion to the group sample sizes.

JEFFREYS < =*c* > specifies a noninformative prior, $0 < c < 1$. If the number *c* is not specified, JEFFREYS=0.5.

RIDGE < =*d* > specifies a ridge prior, $d > 0$. If the number *d* is not specified, RIDGE=0.25.

The default is PRIOR=JEFFREYS. See the section “[Monotone and FCS Discriminant Function Methods](#)” on page 4752 for a detailed description of the method.

The CLASSEFFECTS= option specifies whether the CLASS variables are used as covariate effects. Valid values for the CLASSEFFECTS= option are as follows:

EXCLUDE excludes the CLASS variables from covariate effects.

INCLUDE includes the CLASS variables as covariate effects.

The default is CLASSEFFECTS=EXCLUDE.

LOGISTIC < (*imputed* < = *effects* > < / options >) >

specifies the logistic regression method of classification variables. The available options are DETAILS, ORDER=, and DESCENDING. The DETAILS option displays the regression coefficients in the logistic regression model used in each imputation.

When the imputed variable has more than two response levels, the ordinal logistic regression method is used. The ORDER= option specifies the sort order for the levels of the response variable. Valid values for the ORDER= option are as follows:

DATA sorts by the order of appearance in the input data set.

FORMATTED sorts by their external formatted values.

FREQ sorts by the descending frequency counts.

INTERNAL sorts by the unformatted values.

By default, ORDER=FORMATTED.

The option DESCENDING reverses the sort order for the levels of the response variables.

See the section “[Monotone and FCS Logistic Regression Methods](#)” on page 4754 for a detailed description of the method.

PROPENSITY < (*imputed* < = *effects* > < / options >) >

specifies the propensity scores method of variables. Each variable is either a classification variable or a continuous variable. The available options are DETAILS and NGROUPS=. The DETAILS option displays the regression coefficients in the logistic regression model for propensity scores. The NGROUPS= option specifies the number of groups created based on propensity scores. The default is NGROUPS=5.

See the section “[Monotone Propensity Score Method](#)” on page 4751 for a detailed description of the method.

REG | REGRESSION < (*imputed* < = *effects* > < / DETAILS >) >

specifies the regression method of continuous variables. The DETAILS option displays the regression coefficients in the regression model used in each imputation.

With a regression method, the MAXIMUM=, MINIMUM=, and ROUND= options can be used to make the imputed values more consistent with the observed variable values.

See the section “[Monotone and FCS Regression Methods](#)” on page 4749 for a detailed description of the method.

REGPM < (*imputed* < = *effects* > < *options* >) >

REGPREDMEANMATCH < (*imputed* < = *effects* > < *options* >) >

specifies the predictive mean matching method for continuous variables. This method is similar to the regression method except that it imputes a value randomly from a set of observed values whose predicted values are closest to the predicted value for the missing value from the simulated regression model (Heitjan and Little 1991; Schenker and Taylor 1996).

The available options are DETAILS and K=. The DETAILS option displays the regression coefficients in the regression model used in each imputation. The K= option specifies the number of closest observations to be used in the selection. The default is K=5.

See the section “[Monotone and FCS Predictive Mean Matching Methods](#)” on page 4750 for a detailed description of the method.

With a MONOTONE statement, the missing values of a variable are imputed when the variable is either explicitly specified in the method or implicitly specified when a method is specified without imputed variables. These variables are imputed sequentially in the order specified in the VAR statement. For example, the following MI procedure statements use the logistic regression method to impute variable c1 from effects y1, y2, and y1 * y2 first, and then use the regression method to impute variable y3 from effects y1, y2, and c1:

```
proc mi;
  class c1;
  var y1 y2 c1 y3;
  monotone reg(y3= y1 y2 c1) logistic(c1= y1 y2 y1*y2);
run;
```

The variables y1 and y2 are not imputed since y1 is the leading variable in the VAR statement and y2 is not specified as an imputed variable in the MONOTONE statement.

TRANSFORM Statement

TRANSFORM *transform* (*variables* < / *options* >) < ... *transform* (*variables* < / *options* >) > ;

The TRANSFORM statement lists the transformations and their associated variables to be transformed. The options are transformation options that provide additional information for the transformation.

The MI procedure assumes that the data are from a multivariate normal distribution when either the regression method or the MCMC method is used. When some variables in a data set are clearly non-normal, it is useful to transform these variables to conform to the multivariate normality assumption. With a TRANSFORM statement, variables are transformed before the imputation process, and these transformed variable values are displayed in all of the results. When you specify an OUT= option, the variable values are back-transformed to create the imputed data set.

The following transformations can be used in the TRANSFORM statement:

BOXCOX

specifies the Box-Cox transformation of variables. The variable Y is transformed to $\frac{(Y+c)^\lambda - 1}{\lambda}$, where c is a constant such that each value of $Y + c$ must be positive. If the specified constant $\lambda = 0$, the logarithmic transformation is used.

EXP

specifies the exponential transformation of variables. The variable Y is transformed to $e^{(Y+c)}$, where c is a constant.

LOG

specifies the logarithmic transformation of variables. The variable Y is transformed to $\log(Y + c)$, where c is a constant such that each value of $Y + c$ must be positive.

LOGIT

specifies the logit transformation of variables. The variable Y is transformed to $\log(\frac{Y/c}{1-Y/c})$, where the constant $c > 0$ and the values of Y/c must be between 0 and 1.

POWER

specifies the power transformation of variables. The variable Y is transformed to $(Y + c)^\lambda$, where c is a constant such that each value of $Y + c$ must be positive and the constant $\lambda \neq 0$.

The following options provide the constant c and λ values in the transformations.

C=number

specifies the c value in the transformation. The default is $c = 1$ for logit transformation and $c = 0$ for other transformations.

LAMBDA=number

specifies the λ value in the power and Box-Cox transformations. You must specify the λ value for these two transformations.

For example, the following statement requests that variables $\log(y1)$, a logarithmic transformation for the variable $y1$, and $\sqrt{y2 + 1}$, a power transformation for the variable $y2$, be used in the imputation:

```
transform log(y1) power(y2/c=1 lambda=.5);
```

If the MU0= option is used to specify a parameter value μ_0 for a transformed variable, the same transformation for the variable is also applied to its corresponding MU0= value in the t test. Otherwise, $\mu_0 = 0$ is used for the transformed variable. See [Example 57.10](#) for a usage of the TRANSFORM statement.

VAR Statement

VAR *variables* ;

The VAR statement lists the variables to be analyzed. The variables can be either character or numeric. If you omit the VAR statement, all continuous variables not mentioned in other statements are used. The VAR statement is required if you specify either an FCS statement, a MONOTONE statement, an IMPUTE=MONOTONE option in the MCMC statement, or more than one number in the MU0=, MAXIMUM=, MINIMUM=, or ROUND= option.

The classification variables in the VAR statement, which can be either character or numeric, are further specified in the CLASS statement.

Details: MI Procedure

Descriptive Statistics

Suppose $\mathbf{Y} = (\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n)'$ is the $(n \times p)$ matrix of complete data, which might not be fully observed, n_0 is the number of observations fully observed, and n_j is the number of observations with observed values for variable Y_j .

With complete cases, the sample mean vector is

$$\bar{\mathbf{y}} = \frac{1}{n_0} \sum \mathbf{y}_i$$

and the CSSCP matrix is

$$\sum (\mathbf{y}_i - \bar{\mathbf{y}})(\mathbf{y}_i - \bar{\mathbf{y}})'$$

where each summation is over the fully observed observations.

The sample covariance matrix is

$$\mathbf{S} = \frac{1}{n_0 - 1} \sum (\mathbf{y}_i - \bar{\mathbf{y}})(\mathbf{y}_i - \bar{\mathbf{y}})'$$

and is an unbiased estimate of the covariance matrix.

The correlation matrix \mathbf{R} , which contains the Pearson product-moment correlations of the variables, is derived by scaling the corresponding covariance matrix:

$$\mathbf{R} = \mathbf{D}^{-1} \mathbf{S} \mathbf{D}^{-1}$$

where \mathbf{D} is a diagonal matrix whose diagonal elements are the square roots of the diagonal elements of \mathbf{S} .

With available cases, the corrected sum of squares for variable Y_j is

$$\sum (y_{ji} - \bar{y}_j)^2$$

where $\bar{y}_j = \frac{1}{n_j} \sum y_{ji}$ is the sample mean and each summation is over observations with observed values for variable Y_j .

The variance is

$$s_{jj}^2 = \frac{1}{n_j - 1} \sum (y_{ji} - \bar{y}_j)^2$$

The correlations for available cases contain pairwise correlations for each pair of variables. Each correlation is computed from all observations that have nonmissing values for the corresponding pair of variables.

EM Algorithm for Data with Missing Values

The EM algorithm (Dempster, Laird, and Rubin 1977) is a technique that finds maximum likelihood estimates in parametric models for incomplete data. For a detailed description and applications of the EM algorithm, see the books by Little and Rubin (2002); Schafer (1997); McLachlan and Krishnan (1997).

The EM algorithm is an iterative procedure that finds the MLE of the parameter vector by repeating the following steps:

1. The expectation E-step

Given a set of parameter estimates, such as a mean vector and covariance matrix for a multivariate normal distribution, the E-step calculates the conditional expectation of the complete-data log likelihood given the observed data and the parameter estimates.

2. The maximization M-step

Given a complete-data log likelihood, the M-step finds the parameter estimates to maximize the complete-data log likelihood from the E-step.

The two steps are iterated until the iterations converge.

In the EM process, the observed-data log likelihood is nondecreasing at each iteration. For multivariate normal data, suppose there are G groups with distinct missing patterns. Then the observed-data log likelihood being maximized can be expressed as

$$\log L(\theta|Y_{obs}) = \sum_{g=1}^G \log L_g(\theta|Y_{obs})$$

where $\log L_g(\theta|Y_{obs})$ is the observed-data log likelihood from the g th group, and

$$\log L_g(\theta|Y_{obs}) = -\frac{n_g}{2} \log |\Sigma_g| - \frac{1}{2} \sum_{ig} (\mathbf{y}_{ig} - \boldsymbol{\mu}_g)' \Sigma_g^{-1} (\mathbf{y}_{ig} - \boldsymbol{\mu}_g)$$

where n_g is the number of observations in the g th group, the summation is over observations in the g th group, \mathbf{y}_{ig} is a vector of observed values corresponding to observed variables, $\boldsymbol{\mu}_g$ is the corresponding mean vector, and Σ_g is the associated covariance matrix.

A sample covariance matrix is computed at each step of the EM algorithm. If the covariance matrix is singular, the linearly dependent variables for the observed data are excluded from the likelihood function. That is, for each observation with linear dependency among its observed variables, the dependent variables are excluded from the likelihood function. Note that this can result in an unexpected change in the likelihood between iterations prior to the final convergence.

See Schafer (1997, pp. 163–181) for a detailed description of the EM algorithm for multivariate normal data.

PROC MI uses the means and standard deviations from available cases as the initial estimates for the EM algorithm. The correlations are set to zero. These initial estimates provide a good starting value with positive definite covariance matrix. For a discussion of suggested starting values for the algorithm, see Schafer (1997, p. 169).

You can specify the convergence criterion with the `CONVERGE=` option in the `EM` statement. The iterations are considered to have converged when the maximum change in the parameter estimates between iteration steps is less than the value specified. You can also specify the maximum number of iterations used in the `EM` algorithm with the `MAXITER=` option.

The `MI` procedure displays tables of the initial parameter estimates used to begin the `EM` process and the MLE parameter estimates derived from `EM`. You can also display the `EM` iteration history with the `ITPRINT` option. `PROC MI` lists the iteration number, the likelihood $-2 \log L$, and the parameter values μ at each iteration. You can also save the MLE derived from the `EM` algorithm in a SAS data set by specifying the `OUTEM=` option.

Statistical Assumptions for Multiple Imputation

The `MI` procedure assumes that the data are from a continuous multivariate distribution and contain missing values that can occur for any of the variables. It also assumes that the data are from a multivariate normal distribution when either the regression method or the MCMC method is used.

Suppose \mathbf{Y} is the $n \times p$ matrix of complete data, which is not fully observed, and denote the observed part of \mathbf{Y} by \mathbf{Y}_{obs} and the missing part by \mathbf{Y}_{mis} . The `MI` and `MIANALYZE` procedures assume that the missing data are missing at random (MAR); that is, the probability that an observation is missing can depend on \mathbf{Y}_{obs} , but not on \mathbf{Y}_{mis} (Rubin 1976, 1987, p. 53).

To be more precise, suppose that \mathbf{R} is the $n \times p$ matrix of response indicators whose elements are zero or one depending on whether the corresponding elements of \mathbf{Y} are missing or observed. Then the MAR assumption is that the distribution of \mathbf{R} can depend on \mathbf{Y}_{obs} but not on \mathbf{Y}_{mis} :

$$\text{pr}(\mathbf{R} | \mathbf{Y}_{obs}, \mathbf{Y}_{mis}) = \text{pr}(\mathbf{R} | \mathbf{Y}_{obs})$$

For example, consider a trivariate data set with variables Y_1 and Y_2 fully observed, and a variable Y_3 that has missing values. MAR assumes that the probability that Y_3 is missing for an individual can be related to the individual's values of variables Y_1 and Y_2 , but not to its value of Y_3 . On the other hand, if a complete case and an incomplete case for Y_3 with exactly the same values for variables Y_1 and Y_2 have systematically different values, then there exists a response bias for Y_3 , and MAR is violated.

The MAR assumption is not the same as missing completely at random (MCAR), which is a special case of MAR. Under the MCAR assumption, the missing data values are a simple random sample of all data values; the missingness does not depend on the values of any variables in the data set.

Although the MAR assumption cannot be verified with the data and it can be questionable in some situations, the assumption becomes more plausible as more variables are included in the imputation model (Schafer 1997, pp. 27–28; van Buuren, Boshuizen, and Knook 1999, p. 687).

Furthermore, the `MI` and `MIANALYZE` procedures assume that the parameters θ of the data model and the parameters ϕ of the model for the missing-data indicators are distinct. That is, knowing the values of θ does not provide any additional information about ϕ , and vice versa. If both the MAR and distinctness assumptions are satisfied, the missing-data mechanism is said to be ignorable (Rubin 1987, pp. 50–54; Schafer 1997, pp. 10–11).

Missing Data Patterns

The MI procedure sorts the data into groups based on whether the analysis variables are observed or missing. Note that the input data set does not need to be sorted in any order.

For example, with variables Y_1 , Y_2 , and Y_3 (in that order) in a data set, up to eight groups of observations can be formed from the data set. Figure 57.6 displays the eight groups of observations and an unique missing pattern for each group.

Figure 57.6 Missing Data Patterns

Missing Data Patterns				
Group	Y1	Y2	Y3	
1	X	X	X	
2	X	X	.	
3	X	.	X	
4	X	.	.	
5	.	X	X	
6	.	X	.	
7	.	.	X	
8	.	.	.	

Here, an “X” means that the variable is observed in the corresponding group and a “.” means that the variable is missing.

The variable order is used to derive the order of the groups from the data set, and thus determines the order of missing values in the data to be imputed. If you specify a different order of variables in the VAR statement, then the results are different even if the other specifications remain the same.

A data set with variables Y_1, Y_2, \dots, Y_p (in that order) is said to have a *monotone missing pattern* when the event that a variable Y_j is missing for a particular individual implies that all subsequent variables $Y_k, k > j$, are missing for that individual. Alternatively, when a variable Y_j is observed for a particular individual, it is assumed that all previous variables $Y_k, k < j$, are also observed for that individual.

For example, Figure 57.7 displays a data set of three variables with a monotone missing pattern.

Figure 57.7 Monotone Missing Patterns

Monotone Missing Data Patterns				
Group	Y1	Y2	Y3	
1	X	X	X	
2	X	X	.	
3	X	.	.	

Figure 57.8 displays a data set of three variables with a non-monotone missing pattern.

Figure 57.8 Non-monotone Missing Patterns

Non-monotone Missing Data Patterns				
Group	Y1	Y2	Y3	
1	X	X	X	
2	X	.	X	
3	.	X	.	
4	.	.	X	

A data set with an *arbitrary missing pattern* is a data set with either a monotone missing pattern or a non-monotone missing pattern.

Imputation Methods

This section describes the methods for multiple imputation that are available in the MI procedure. The method of choice depends on the pattern of missingness in the data and the type of the imputed variable, as summarized in Table 57.5.

Table 57.5 Imputation Methods in PROC MI

Pattern of Missingness	Type of Imputed Variable	Type of Covariates	Available Methods
Monotone	Continuous	Arbitrary	<ul style="list-style-type: none"> • Monotone regression • Monotone predicted mean matching • Monotone propensity score
Monotone	Classification (ordinal)	Arbitrary	<ul style="list-style-type: none"> • Monotone logistic regression
Monotone	Classification (nominal)	Arbitrary	<ul style="list-style-type: none"> • Monotone discriminant function
Arbitrary	Continuous	Continuous	<ul style="list-style-type: none"> • MCMC full-data imputation • MCMC monotone-data imputation
Arbitrary	Continuous	Arbitrary	<ul style="list-style-type: none"> • FCS regression • FCS predicted mean matching
Arbitrary	Classification (ordinal)	Arbitrary	<ul style="list-style-type: none"> • FCS logistic regression
Arbitrary	Classification (nominal)	Arbitrary	<ul style="list-style-type: none"> • FCS discriminant function

To impute missing values for a continuous variable in data sets with monotone missing patterns, you should use either a parametric method that assumes multivariate normality or a nonparametric method that uses propensity scores (Rubin 1987, pp. 124, 158; Lavori, Dawson, and Shera 1995). Parametric methods available include the regression method (Rubin 1987, pp. 166–167) and the predictive mean matching method (Heitjan and Little 1991; Schenker and Taylor 1996).

To impute missing values for a classification variable in data sets with monotone missing patterns, you should use the logistic regression method or the discriminant function method. Use the logistic regression method when the classification variable has a binary or ordinal response, and use the discriminant function method when the classification variable has a binary or nominal response.

For data sets with arbitrary missing patterns, you can use either of the following methods to impute missing values: a Markov chain Monte Carlo (MCMC) method (Schafer 1997) that assumes multivariate normality, or a fully conditional specification (FCS) method (van Buuren 2007; Brand 1999) that assumes the existence of a joint distribution for all variables.

For continuous variables in data sets with arbitrary missing patterns, you can use the MCMC method to impute either all the missing values or just enough missing values to make the imputed data sets have monotone missing patterns. With a monotone missing data pattern, you have greater flexibility in your choice of imputation models. In addition to the MCMC method, you can implement other methods, such as the regression method, that do not use Markov chains. You can also specify a different set of covariates for each imputed variable.

Although the regression and MCMC methods assume multivariate normality, inferences based on multiple imputation can be robust to departures from multivariate normality if the amount of missing information is not large, because the imputation model is effectively applied not to the entire data set but only to its missing part (Schafer 1997, pp.147–148).

To impute missing values for both continuous and classification variables in data sets with arbitrary missing patterns, you can use FCS methods to impute missing values for all variables assuming a joint distribution for these variables exists (Brand 1999; van Buuren 2007). Similar to the methods of imputing missing values for variables in data sets with monotone missing patterns, you can use the regression and predictive mean matching methods to impute missing values for a continuous variable, and use the logistic regression method to impute missing values for a classification variable when the variable has a binary or ordinal response, or use the discriminant function method when the variable has a binary or nominal response.

You can also use a TRANSFORM statement to transform variables to conform to the multivariate normality assumption. Variables are transformed before the imputation process and then are reverse-transformed to create the imputed data set. All continuous variables are standardized before the imputation process and then are transformed back to the original scale after the imputation process.

Li (1988) presents a theoretical argument for convergence of the MCMC method in the continuous case and uses it to create imputations for incomplete multivariate continuous data. In practice, however, it is not easy to check the convergence of a Markov chain, especially for a large number of parameters. PROC MI generates statistics and plots that you can use to check for convergence of the MCMC method. The details are described in the section “[Checking Convergence in MCMC](#)” on page 4764.

Monotone Methods for Data Sets with Monotone Missing Patterns

For data sets with monotone missing data patterns, you can use monotone methods to impute missing values for the variables. A monotone method creates multiple imputations by imputing missing values sequentially over the variables taken one at a time.

For example, with variables Y_1, Y_2, \dots, Y_p (in that order) in the VAR statement, a monotone method sequentially simulates a draw for missing values for variables Y_2, \dots, Y_p . That is, the missing values are imputed by using the sequence

$$\begin{aligned}
\theta_2^{(*)} &\sim P(\theta_2 | Y_{1(obs)}, Y_{2(obs)}) \\
Y_2^{(*)} &\sim P(Y_2 | \theta_2^{(*)}) \\
&\dots \\
&\dots \\
\theta_p^{(*)} &\sim P(\theta_p | Y_{1(obs)}, \dots, Y_{p(obs)}) \\
Y_p^{(*)} &\sim P(Y_p | \theta_p^{(*)})
\end{aligned}$$

where $Y_{j(obs)}$ is the set of observed Y_j values, $\theta_j^{(*)}$ is the set of simulated parameters for the conditional distribution of Y_j given covariates constructed from variables Y_1, Y_2, \dots, Y_{j-1} , and $Y_j^{(*)}$ is the set of imputed Y_j values.

The missing values for the leading variable Y_1 are not imputed, and missing values for Y_2, \dots, Y_p are not imputed for those observations with missing Y_1 values. For each subsequent variable Y_j with missing values, the corresponding imputation method is used to fit a model with covariates constructed from its preceding variables Y_1, Y_2, \dots, Y_{j-1} . The observed observations for Y_j , which include only observations with observed values for Y_1, Y_2, \dots, Y_{j-1} , are used in the model fitting. With this resulting model, a new model is drawn and then used to impute missing values for Y_j .

You can specify a separate monotone method for each imputed variable. If a method is not specified for the variable, then the default method is used. That is, a regression method is used for a continuous variable and a discriminant function method is used for a classification variable. For each imputed variable, you can also specify a set of covariates that are constructed from its preceding variables. If a set of covariates is not specified for the variable, all preceding variables in the VAR list are used as covariates.

You can use a regression method, a predictive mean matching method, or a propensity score method to impute missing values for a continuous variable; a logistic regression method for a classification variable with a binary or ordinal response; and a discriminant function method for a classification variable with a binary or nominal response. See the sections “[Monotone and FCS Regression Methods](#)” on page 4749, “[Monotone and FCS Predictive Mean Matching Methods](#)” on page 4750, “[Monotone Propensity Score Method](#)” on page 4751, “[Monotone and FCS Discriminant Function Methods](#)” on page 4752, and “[Monotone and FCS Logistic Regression Methods](#)” on page 4754 for these methods.

Monotone and FCS Regression Methods

The regression method is the default imputation method in the MONOTONE and FCS statements for continuous variables.

In the regression method, a regression model is fitted for a continuous variable with the covariates constructed from a set of effects. Based on the fitted regression model, a new regression model is simulated from the posterior predictive distribution of the parameters and is used to impute the missing values for each variable (Rubin 1987, pp. 166–167). That is, for a continuous variable Y_j with missing values, a model

$$Y_j = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

is fitted using observations with observed values for the variable Y_j and its covariates X_1, X_2, \dots, X_k .

The fitted model includes the regression parameter estimates $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_k)$ and the associated covariance matrix $\hat{\sigma}_j^2 \mathbf{V}_j$, where \mathbf{V}_j is the usual $\mathbf{X}'\mathbf{X}$ inverse matrix derived from the intercept and covariates X_1, X_2, \dots, X_k .

The following steps are used to generate imputed values for each imputation:

1. New parameters $\beta_* = (\beta_{*0}, \beta_{*1}, \dots, \beta_{*(k)})$ and σ_{*j}^2 are drawn from the posterior predictive distribution of the parameters. That is, they are simulated from $(\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_k)$, σ_j^2 , and \mathbf{V}_j . The variance is drawn as

$$\sigma_{*j}^2 = \hat{\sigma}_j^2 (n_j - k - 1) / g$$

where g is a $\chi_{n_j - k - 1}^2$ random variate and n_j is the number of nonmissing observations for Y_j . The regression coefficients are drawn as

$$\beta_* = \hat{\beta} + \sigma_{*j} \mathbf{V}_{hj}' \mathbf{Z}$$

where \mathbf{V}_{hj} is the upper triangular matrix in the Cholesky decomposition, $\mathbf{V}_j = \mathbf{V}_{hj}' \mathbf{V}_{hj}$, and \mathbf{Z} is a vector of $k + 1$ independent random normal variates.

2. The missing values are then replaced by

$$\beta_{*0} + \beta_{*1} x_1 + \beta_{*2} x_2 + \dots + \beta_{*(k)} x_k + z_i \sigma_{*j}$$

where x_1, x_2, \dots, x_k are the values of the covariates and z_i is a simulated normal deviate.

Monotone and FCS Predictive Mean Matching Methods

The predictive mean matching method is also an imputation method available for continuous variables. It is similar to the regression method except that for each missing value, it imputes a value randomly from a set of observed values whose predicted values are closest to the predicted value for the missing value from the simulated regression model (Heitjan and Little 1991; Schenker and Taylor 1996).

Following the description of the model in the section “[Monotone and FCS Regression Methods](#)” on page 4749, the following steps are used to generate imputed values:

1. New parameters $\beta_* = (\beta_{*0}, \beta_{*1}, \dots, \beta_{*(k)})$ and σ_{*j}^2 are drawn from the posterior predictive distribution of the parameters. That is, they are simulated from $(\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_k)$, σ_j^2 , and \mathbf{V}_j . The variance is drawn as

$$\sigma_{*j}^2 = \hat{\sigma}_j^2 (n_j - k - 1) / g$$

where g is a $\chi_{n_j - k - 1}^2$ random variate and n_j is the number of nonmissing observations for Y_j . The regression coefficients are drawn as

$$\beta_* = \hat{\beta} + \sigma_{*j} \mathbf{V}_{hj}' \mathbf{Z}$$

where \mathbf{V}_{hj} is the upper triangular matrix in the Cholesky decomposition, $\mathbf{V}_j = \mathbf{V}_{hj}' \mathbf{V}_{hj}$, and \mathbf{Z} is a vector of $k + 1$ independent random normal variates.

2. For each missing value, a predicted value

$$y_{i*} = \beta_{*0} + \beta_{*1} x_1 + \beta_{*2} x_2 + \dots + \beta_{*(k)} x_k$$

is computed with the covariate values x_1, x_2, \dots, x_k .

3. A set of k_0 observations whose corresponding predicted values are closest to y_{i*} is generated. You can specify k_0 with the K= option.
4. The missing value is then replaced by a value drawn randomly from these k_0 observed values.

The predictive mean matching method requires the number of closest observations to be specified. A smaller k_0 tends to increase the correlation among the multiple imputations for the missing observation and results in a higher variability of point estimators in repeated sampling. On the other hand, a larger k_0 tends to lessen the effect from the imputation model and results in biased estimators (Schenker and Taylor 1996, p. 430).

The predictive mean matching method ensures that imputed values are plausible; it might be more appropriate than the regression method if the normality assumption is violated (Horton and Lipsitz 2001, p. 246).

Monotone Propensity Score Method

The propensity score method is another imputation method available for continuous variables when the data set has a monotone missing pattern.

A propensity score is generally defined as the conditional probability of assignment to a particular treatment given a vector of observed covariates (Rosenbaum and Rubin 1983). In the propensity score method, for a variable with missing values, a propensity score is generated for each observation to estimate the probability that the observation is missing. The observations are then grouped based on these propensity scores, and an approximate Bayesian bootstrap imputation (Rubin 1987, p. 124) is applied to each group (Lavori, Dawson, and Shera 1995).

The propensity score method uses the following steps to impute values for variable Y_j with missing values:

1. Creates an indicator variable R_j with the value 0 for observations with missing Y_j and 1 otherwise.
2. Fits a logistic regression model

$$\text{logit}(p_j) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

where X_1, X_2, \dots, X_k are covariates for Y_j , $p_j = \Pr(R_j = 0 | X_1, X_2, \dots, X_k)$, and $\text{logit}(p) = \log(p/(1-p))$.

3. Creates a propensity score for each observation to estimate the probability that it is missing.
4. Divides the observations into a fixed number of groups (typically assumed to be five) based on these propensity scores.
5. Applies an approximate Bayesian bootstrap imputation to each group. In group k , suppose that Y_{obs} denotes the n_1 observations with nonmissing Y_j values and Y_{mis} denotes the n_0 observations with missing Y_j . The approximate Bayesian bootstrap imputation first draws n_1 observations randomly with replacement from Y_{obs} to create a new data set Y_{obs}^* . This is a nonparametric analog of drawing parameters from the posterior predictive distribution of the parameters. The process then draws the n_0 values for Y_{mis} randomly with replacement from Y_{obs}^* .

Steps 1 through 5 are repeated sequentially for each variable with missing values.

The propensity score method was originally designed for a randomized experiment with repeated measures on the response variables. The goal was to impute the missing values on the response variables. The method uses only the covariate information that is associated with whether the imputed variable values are missing; it does not use correlations among variables. It is effective for inferences about the distributions of individual imputed variables, such as a univariate analysis, but it is not appropriate for analyses that involve relationship among variables, such as a regression analysis (Schafer 1999, p. 11). It can also produce badly biased estimates of regression coefficients when data on predictor variables are missing (Allison 2000).

Monotone and FCS Discriminant Function Methods

The discriminant function method is the default imputation method in the MONOTONE and FCS statements for classification variables.

For a nominal classification variable Y_j with responses $1, \dots, g$ and a set of effects from its preceding variables, if the covariates X_1, X_2, \dots, X_k associated with these effects within each group are approximately multivariate normal and the within-group covariance matrices are approximately equal, the discriminant function method (Brand 1999, pp. 95–96) can be used to impute missing values for the variable Y_j .

Denote the group-specific means for covariates X_1, X_2, \dots, X_k by

$$\bar{\mathbf{X}}_t = (\bar{X}_{t1}, \bar{X}_{t2}, \dots, \bar{X}_{tk}), t = 1, 2, \dots, g$$

then the pooled covariance matrix is computed as

$$\mathbf{S} = \frac{1}{n - g} \sum_{t=1}^g (n_t - 1) \mathbf{S}_t$$

where \mathbf{S}_t is the within-group covariance matrix, n_t is the group-specific sample size, and $n = \sum_{t=1}^g n_t$ is the total sample size.

In each imputation, new parameters of the group-specific means (\mathbf{m}_{*t}), pooled covariance matrix (\mathbf{S}_*), and prior probabilities of group membership (q_{*t}) can be drawn from their corresponding posterior distributions (Schafer 1997, p. 356).

Pooled Covariance Matrix and Group-Specific Means

For each imputation, the MI procedure uses either the fixed observed pooled covariance matrix (PCOV=FIXED) or a drawn pooled covariance matrix (PCOV=POSTERIOR) from its posterior distribution with a noninformative prior. That is,

$$\Sigma | \mathbf{X} \sim W^{-1}(n - g, (n - g)\mathbf{S})$$

where W^{-1} is an inverted Wishart distribution.

The group-specific means are then drawn from their posterior distributions with a noninformative prior

$$\mu_t | (\Sigma, \bar{\mathbf{X}}_t) \sim N\left(\bar{\mathbf{X}}_t, \frac{1}{n_t} \Sigma\right)$$

See the section “Bayesian Estimation of the Mean Vector and Covariance Matrix” on page 4759 for a complete description of the inverted Wishart distribution and posterior distributions that use a noninformative prior.

Prior Probabilities of Group Membership

The prior probabilities are computed through the drawing of new group sample sizes. When the total sample size n is considered fixed, the group sample sizes (n_1, n_2, \dots, n_g) have a multinomial distribution. New multinomial parameters (group sample sizes) can be drawn from their posterior distribution by using a Dirichlet prior with parameters $(\alpha_1, \alpha_2, \dots, \alpha_g)$.

After the new sample sizes are drawn from the posterior distribution of (n_1, n_2, \dots, n_g) , the prior probabilities q_{*t} are computed proportionally to the drawn sample sizes.

See Schafer (1997, pp. 247–255) for a complete description of the Dirichlet prior.

Imputation Steps

The discriminant function method uses the following steps in each imputation to impute values for a nominal classification variable Y_j with g responses:

1. Draw a pooled covariance matrix S_* from its posterior distribution if the PCOV=POSTERIOR option is used.
2. For each group, draw group means \mathbf{m}_{*t} from the observed group mean $\bar{\mathbf{X}}_t$ and either the observed pooled covariance matrix (PCOV=FIXED) or the drawn pooled covariance matrix S_* (PCOV=POSTERIOR).
3. For each group, compute or draw q_{*t} , prior probabilities of group membership, based on the PRIOR=option:
 - PRIOR=EQUAL, $q_{*t} = 1/g$, prior probabilities of group membership are all equal.
 - PRIOR=PROPORTIONAL, $q_{*t} = n_t/n$, prior probabilities are proportional to their group sample sizes.
 - PRIOR=JEFFREYS= c , a noninformative Dirichlet prior with $\alpha_t = c$ is used.
 - PRIOR=RIDGE= d , a ridge prior is used with $\alpha_t = d * n_t/n$ for $d \geq 1$ and $\alpha_t = d * n_t$ for $d < 1$.
4. With the group means \mathbf{m}_{*t} , the pooled covariance matrix S_* , and the prior probabilities of group membership q_{*t} , the discriminant function method derives linear discriminant function and computes the posterior probabilities of an observation belonging to each group

$$p_t(\mathbf{x}) = \frac{\exp(-0.5D_t^2(\mathbf{x}))}{\sum_{u=1}^g \exp(-0.5D_u^2(\mathbf{x}))}$$

where $D_t^2(\mathbf{x}) = (\mathbf{x} - \mathbf{m}_{*t})'S_*^{-1}(\mathbf{x} - \mathbf{m}_{*t}) - 2\log(q_{*t})$ is the generalized squared distance from \mathbf{x} to group t .

5. Draw a random uniform variate u , between 0 and 1, for each observation with missing group value. With the posterior probabilities, $p_1(\mathbf{x}) + p_2(\mathbf{x}) + \dots + p_g(\mathbf{x}) = 1$, the discriminant function method imputes $Y_j = 1$ if the value of u is less than $p_1(\mathbf{x})$, $Y_j = 2$ if the value is greater than or equal to $p_1(\mathbf{x})$ but less than $p_1(\mathbf{x}) + p_2(\mathbf{x})$, and so on.

Monotone and FCS Logistic Regression Methods

The logistic regression method is another imputation method available for classification variables. In the logistic regression method, a logistic regression model is fitted for a classification variable with a set of covariates constructed from the effects. For a binary classification variable, based on the fitted regression model, a new logistic regression model is simulated from the posterior predictive distribution of the parameters and is used to impute the missing values for each variable (Rubin 1987, pp. 167–170).

For a binary variable Y_j with responses 1 and 2, a logistic regression model is fitted using observations with observed values for the imputed variable Y_j and its covariates X_1, X_2, \dots, X_k :

$$\text{logit}(p_j) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

where X_1, X_2, \dots, X_k are covariates for Y_j , $p_j = \Pr(R_j = 1|X_1, X_2, \dots, X_k)$, and $\text{logit}(p) = \log(p/(1-p))$.

The fitted model includes the regression parameter estimates $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_k)$ and the associated covariance matrix \mathbf{V}_j .

The following steps are used to generate imputed values for a binary variable Y_j with responses 1 and 2:

1. New parameters $\beta_* = (\beta_{*0}, \beta_{*1}, \dots, \beta_{*(k)})$ are drawn from the posterior predictive distribution of the parameters.

$$\beta_* = \hat{\beta} + \mathbf{V}_{hj}' \mathbf{Z}$$

where \mathbf{V}_{hj} is the upper triangular matrix in the Cholesky decomposition, $\mathbf{V}_j = \mathbf{V}_{hj}' \mathbf{V}_{hj}$, and \mathbf{Z} is a vector of $k+1$ independent random normal variates.

2. For an observation with missing Y_j and covariates x_1, x_2, \dots, x_k , compute the expected probability that $Y_j = 1$:

$$p_j = \frac{\exp(\mu_j)}{1 + \exp(\mu_j)}$$

where $\mu_j = \beta_{*0} + \beta_{*1} x_1 + \beta_{*2} x_2 + \dots + \beta_{*(k)} x_k$.

3. Draw a random uniform variate, u , between 0 and 1. If the value of u is less than p_j , impute $Y_j = 1$; otherwise impute $Y_j = 2$.

The preceding logistic regression method can be extended to include the ordinal classification variables with more than two levels of responses. The options ORDER= and DESCENDING can be used to specify the sort order for the levels of the imputed variables.

FCS Methods for Data Sets with Arbitrary Missing Patterns

For a data set with an arbitrary missing data pattern, you can use FCS methods to impute missing values for all variables, assuming the existence of a joint distribution for these variables (Brand 1999; van Buuren 2007). FCS method involves two phases in each imputation: the preliminary filled-in phase followed by the imputation phase.

At the filled-in phase, the missing values for all variables are filled in sequentially over the variables taken one at a time. The missing values for each variable are filled in using the specified method, or the default method for the variable if a method is not specified, with preceding variables serving as the covariates. These filled-in values provide starting values for these missing values at the imputation phase.

At the imputation phase, the missing values for each variable are imputed using the specified method and covariates at each iteration. The default method for the variable is used if a method is not specified, and the remaining variables are used as covariates if the set of covariates is not specified. After a number of iterations, as specified with the NBITER= option, the imputed values in each variable are used for the imputation. At each iteration, the missing values are imputed sequentially over the variables taken one at a time.

The MI procedure orders the variables as they are ordered in the VAR statement. For example, if the order of the p variables in the VAR statement is Y_1, Y_2, \dots, Y_p , then Y_1, Y_2, \dots, Y_p (in that order) are used in the filled-in and imputation phases.

The filled-in phase replaces missing values with filled-in values for each variable. That is, with p variables Y_1, Y_2, \dots, Y_p (in that order), the missing values are filled in by using the sequence,

$$\begin{aligned}
 \theta_1^{(0)} &\sim P(\theta_1 | Y_{1(obs)}) \\
 Y_{1(*)}^{(0)} &\sim P(Y_1 | \theta_1^{(0)}) \\
 Y_1^{(0)} &= (Y_{1(obs)}, Y_{1(*)}^{(0)}) \\
 &\dots \\
 &\dots \\
 \theta_p^{(0)} &\sim P(\theta_p | Y_1^{(0)}, \dots, Y_{p-1}^{(0)}, Y_{p(obs)}) \\
 Y_{p(*)}^{(0)} &\sim P(Y_p | \theta_p^{(0)}) \\
 Y_p^{(0)} &= (Y_{p(obs)}, Y_{p(*)}^{(0)})
 \end{aligned}$$

where $Y_{j(obs)}$ is the set of observed Y_j values, $Y_{j(*)}^{(0)}$ is the set of filled-in Y_j values, $Y_j^{(0)}$ is the set of both observed and filled-in Y_j values, and $\theta_j^{(0)}$ is the set of simulated parameters for the conditional distribution of Y_j given variables Y_1, Y_2, \dots, Y_{j-1} .

For each variable Y_j with missing values, the corresponding imputation method is used to fit the model with covariates Y_1, Y_2, \dots, Y_{j-1} . The observed observations for Y_j , which might include observations with filled-in values for Y_1, Y_2, \dots, Y_{j-1} , are used in the model fitting. With this resulting model, a new model is drawn and then used to impute missing values for Y_j .

The imputation phase replaces these filled-in values $Y_{j(*)}^{(0)}$ with imputed values for each variable sequentially at each iteration. That is, with p variables Y_1, Y_2, \dots, Y_p (in that order), the missing values are imputed with the sequence at iteration $t + 1$,

$$\begin{aligned}\theta_1^{(t+1)} &\sim P(\theta_1 | Y_{1(obs)}, Y_2^{(t)}, \dots, Y_p^{(t)}) \\ Y_{1(*)}^{(t+1)} &\sim P(Y_1 | \theta_1^{(t+1)}) \\ Y_1^{(t+1)} &= (Y_{1(obs)}, Y_{1(*)}^{(t+1)}) \\ &\dots \\ &\dots \\ \theta_p^{(t+1)} &\sim P(\theta_p | Y_1^{(t+1)}, \dots, Y_{p-1}^{(t+1)}, Y_{p(obs)}) \\ Y_{p(*)}^{(t+1)} &\sim P(Y_p | \theta_p^{(t+1)}) \\ Y_p^{(t+1)} &= (Y_{p(obs)}, Y_{p(*)}^{(t+1)})\end{aligned}$$

where $Y_{j(obs)}$ is the set of observed Y_j values, $Y_{j(*)}^{(t+1)}$ is the set of imputed Y_j values at iteration $t + 1$, $Y_{j(*)}^{(t)}$ is the set of filled-in Y_j values ($t = 0$) or the set of imputed Y_j values at iteration t ($t > 0$), $Y_j^{(t+1)}$ is the set of both observed and imputed Y_j values at iteration $t + 1$, and $\theta_j^{(t+1)}$ is the set of simulated parameters for the conditional distribution of Y_j given covariates constructed from $Y_1, \dots, Y_{j-1}, Y_{j+1}, \dots, Y_p$.

At each iteration, a specified model is fitted for each variable with missing values by using observed observations for that variable, which might include observations with imputed values for other variables. With this resulting model, a new model is drawn and then used to impute missing values for the imputed variable.

The steps are iterated long enough for the results to reliably simulate an approximately independent draw of the missing values for an imputed data set.

The imputation methods used in the filled-in and imputation phases are similar to the corresponding monotone methods for monotone missing data. You can use a regression method or a predictive mean matching method to impute missing values for a continuous variable, a logistic regression method for a classification variable with a binary or ordinal response, and a discriminant function method for a classification variable with a binary or nominal response. See the sections “[Monotone and FCS Regression Methods](#)” on page 4749, “[Monotone and FCS Predictive Mean Matching Methods](#)” on page 4750, “[Monotone and FCS Discriminant Function Methods](#)” on page 4752, and “[Monotone and FCS Logistic Regression Methods](#)” on page 4754 for these methods.

The FCS method requires fewer iterations than the MCMC method (van Buuren 2007). Often, as few as five or 10 iterations are enough to produce satisfactory results (van Buuren 2007; Brand 1999).

Checking Convergence in FCS Methods

The parameters used in the imputation step at each iteration can be saved in an output data set with the `OUTITER=` option. These include the means and standard deviations. You can then monitor the convergence by displaying trace plots for those parameter values with the `PLOTS=TRACE` option.

A trace plot for a parameter ξ is a scatter plot of successive parameter estimates ξ_i against the iteration number i . The plot provides a simple way to examine the convergence behavior of the estimation algorithm

for ξ . Long-term trends in the plot indicate that successive iterations are highly correlated and that the series of iterations has not converged.

You can display trace plots for the variable means and standard deviations. You can also request logarithmic transformations for positive parameters in the plots with the LOG option. With the LOG option, if a parameter value is less than or equal to zero, then the value is not displayed in the corresponding plot.

See [Example 57.8](#) for a usage of the trace plot.

MCMC Method for Arbitrary Missing Multivariate Normal Data

The Markov chain Monte Carlo (MCMC) method originated in physics as a tool for exploring equilibrium distributions of interacting molecules. In statistical applications, it is used to generate pseudorandom draws from multidimensional and otherwise intractable probability distributions via Markov chains. A Markov chain is a sequence of random variables in which the distribution of each element depends only on the value of the previous element.

In MCMC simulation, you construct a Markov chain long enough for the distribution of the elements to stabilize to a stationary distribution, which is the distribution of interest. Repeatedly simulating steps of the chain simulates draws from the distribution of interest. See Schafer (1997) for a detailed discussion of this method.

In Bayesian inference, information about unknown parameters is expressed in the form of a posterior probability distribution. This posterior distribution is computed using Bayes' theorem,

$$p(\theta|y) = \frac{p(y|\theta)p(\theta)}{\int p(y|\theta)p(\theta)d\theta}$$

MCMC has been applied as a method for exploring posterior distributions in Bayesian inference. That is, through MCMC, you can simulate the entire joint posterior distribution of the unknown quantities and obtain simulation-based estimates of posterior parameters that are of interest.

In many incomplete-data problems, the observed-data posterior $p(\theta|Y_{obs})$ is intractable and cannot easily be simulated. However, when Y_{obs} is augmented by an estimated or simulated value of the missing data Y_{mis} , the complete-data posterior $p(\theta|Y_{obs}, Y_{mis})$ is much easier to simulate. Assuming that the data are from a multivariate normal distribution, data augmentation can be applied to Bayesian inference with missing data by repeating the following steps:

1. The imputation I-step

Given an estimated mean vector and covariance matrix, the I-step simulates the missing values for each observation independently. That is, if you denote the variables with missing values for observation i by $Y_{i(mis)}$ and the variables with observed values by $Y_{i(obs)}$, then the I-step draws values for $Y_{i(mis)}$ from a conditional distribution for $Y_{i(mis)}$ given $Y_{i(obs)}$.

2. The posterior P-step

Given a complete sample, the P-step simulates the posterior population mean vector and covariance matrix. These new estimates are then used in the next I-step. Without prior information about the parameters, a noninformative prior is used. You can also use other informative priors. For example, a prior information about the covariance matrix can help to stabilize the inference about the mean vector for a near singular covariance matrix.

That is, with a current parameter estimate $\theta^{(t)}$ at the t th iteration, the I-step draws $Y_{mis}^{(t+1)}$ from $p(Y_{mis}|Y_{obs}, \theta^{(t)})$ and the P-step draws $\theta^{(t+1)}$ from $p(\theta|Y_{obs}, Y_{mis}^{(t+1)})$. The two steps are iterated long enough for the results to reliably simulate an approximately independent draw of the missing values for a multiply imputed data set (Schafer 1997).

This creates a Markov chain $(Y_{mis}^{(1)}, \theta^{(1)})$, $(Y_{mis}^{(2)}, \theta^{(2)})$, ..., which converges in distribution to $p(Y_{mis}, \theta|Y_{obs})$. Assuming the iterates converge to a stationary distribution, the goal is to simulate an approximately independent draw of the missing values from this distribution.

To validate the imputation results, you should repeat the process with different random number generators and starting values based on different initial parameter estimates.

The next three sections provide details for the imputation step, Bayesian estimation of the mean vector and covariance matrix, and the posterior step.

Imputation Step

In each iteration, starting with a given mean vector μ and covariance matrix Σ , the imputation step draws values for the missing data from the conditional distribution Y_{mis} given Y_{obs} .

Suppose $\mu = [\mu'_1, \mu'_2]'$ is the partitioned mean vector of two sets of variables, Y_{obs} and Y_{mis} , where μ_1 is the mean vector for variables Y_{obs} and μ_2 is the mean vector for variables Y_{mis} .

Also suppose

$$\Sigma = \begin{bmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma'_{12} & \Sigma_{22} \end{bmatrix}$$

is the partitioned covariance matrix for these variables, where Σ_{11} is the covariance matrix for variables Y_{obs} , Σ_{22} is the covariance matrix for variables Y_{mis} , and Σ_{12} is the covariance matrix between variables Y_{obs} and variables Y_{mis} .

By using the sweep operator (Goodnight 1979) on the pivots of the Σ_{11} submatrix, the matrix becomes

$$\begin{bmatrix} \Sigma_{11}^{-1} & \Sigma_{11}^{-1}\Sigma_{12} \\ -\Sigma'_{12}\Sigma_{11}^{-1} & \Sigma_{22.1} \end{bmatrix}$$

where $\Sigma_{22.1} = \Sigma_{22} - \Sigma'_{12}\Sigma_{11}^{-1}\Sigma_{12}$ can be used to compute the conditional covariance matrix of Y_{mis} after controlling for Y_{obs} .

For an observation with the preceding missing pattern, the conditional distribution of Y_{mis} given $Y_{obs} = \mathbf{y}_1$ is a multivariate normal distribution with the mean vector

$$\mu_{2.1} = \mu_2 + \Sigma'_{12}\Sigma_{11}^{-1}(\mathbf{y}_1 - \mu_1)$$

and the conditional covariance matrix

$$\Sigma_{22.1} = \Sigma_{22} - \Sigma'_{12}\Sigma_{11}^{-1}\Sigma_{12}$$

Bayesian Estimation of the Mean Vector and Covariance Matrix

Suppose that $\mathbf{Y} = (\mathbf{y}'_1, \mathbf{y}'_2, \dots, \mathbf{y}'_n)'$ is an $(n \times p)$ matrix made up of n ($p \times 1$) independent vectors \mathbf{y}_i , each of which has a multivariate normal distribution with mean zero and covariance matrix $\mathbf{\Lambda}$. Then the SSCP matrix

$$\mathbf{A} = \mathbf{Y}'\mathbf{Y} = \sum_i \mathbf{y}_i \mathbf{y}'_i$$

has a Wishart distribution $W(n, \mathbf{\Lambda})$.

When each observation \mathbf{y}_i is distributed with a multivariate normal distribution with an unknown mean $\boldsymbol{\mu}$, then the CSSCP matrix

$$\mathbf{A} = \sum_i (\mathbf{y}_i - \bar{\mathbf{y}})(\mathbf{y}_i - \bar{\mathbf{y}})'$$

has a Wishart distribution $W(n - 1, \mathbf{\Lambda})$.

If \mathbf{A} has a Wishart distribution $W(n, \mathbf{\Lambda})$, then $\mathbf{B} = \mathbf{A}^{-1}$ has an inverted Wishart distribution $W^{-1}(n, \boldsymbol{\Psi})$, where n is the degrees of freedom and $\boldsymbol{\Psi} = \mathbf{\Lambda}^{-1}$ is the precision matrix (Anderson 1984).

Note that, instead of using the parameter $\boldsymbol{\Psi} = \mathbf{\Lambda}^{-1}$ for the inverted Wishart distribution, Schafer (1997) uses the parameter $\mathbf{\Lambda}$.

Suppose that each observation in the data matrix \mathbf{Y} has a multivariate normal distribution with mean $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$. Then with a prior inverted Wishart distribution for $\boldsymbol{\Sigma}$ and a prior normal distribution for $\boldsymbol{\mu}$

$$\begin{aligned} \boldsymbol{\Sigma} &\sim W^{-1}(m, \boldsymbol{\Psi}) \\ \boldsymbol{\mu} | \boldsymbol{\Sigma} &\sim N\left(\boldsymbol{\mu}_0, \frac{1}{\tau} \boldsymbol{\Sigma}\right) \end{aligned}$$

where $\tau > 0$ is a fixed number.

The posterior distribution (Anderson 1984, p. 270; Schafer 1997, p. 152) is

$$\begin{aligned} \boldsymbol{\Sigma} | \mathbf{Y} &\sim W^{-1}\left(n + m, (n - 1)\mathbf{S} + \boldsymbol{\Psi} + \frac{n\tau}{n + \tau}(\bar{\mathbf{y}} - \boldsymbol{\mu}_0)(\bar{\mathbf{y}} - \boldsymbol{\mu}_0)'\right) \\ \boldsymbol{\mu} | (\boldsymbol{\Sigma}, \mathbf{Y}) &\sim N\left(\frac{1}{n + \tau}(n\bar{\mathbf{y}} + \tau\boldsymbol{\mu}_0), \frac{1}{n + \tau}\boldsymbol{\Sigma}\right) \end{aligned}$$

where $(n - 1)\mathbf{S}$ is the CSSCP matrix.

Posterior Step

In each iteration, the posterior step simulates the posterior population mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$ from prior information for $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$, and the complete sample estimates.

You can specify the prior parameter information by using one of the following methods:

- PRIOR=JEFFREYS, which uses a noninformative prior
- PRIOR=INPUT=, which provides a prior information for $\boldsymbol{\Sigma}$ in the data set. Optionally, it also provides a prior information for $\boldsymbol{\mu}$ in the data set.
- PRIOR=RIDGE=, which uses a ridge prior

The next four subsections provide details of the posterior step for different prior distributions.

1. A Noninformative Prior

Without prior information about the mean and covariance estimates, you can use a noninformative prior by specifying the PRIOR=JEFFREYS option. The posterior distributions (Schafer 1997, p. 154) are

$$\begin{aligned}\Sigma^{(t+1)}|\mathbf{Y} &\sim W^{-1}(n-1, (n-1)\mathbf{S}) \\ \mu^{(t+1)}|(\Sigma^{(t+1)}, \mathbf{Y}) &\sim N\left(\bar{\mathbf{y}}, \frac{1}{n}\Sigma^{(t+1)}\right)\end{aligned}$$

2. An Informative Prior for μ and Σ

When prior information is available for the parameters μ and Σ , you can provide it with a SAS data set that you specify with the PRIOR=INPUT= option:

$$\begin{aligned}\Sigma &\sim W^{-1}(d^*, d^*\mathbf{S}^*) \\ \mu|\Sigma &\sim N\left(\mu_0, \frac{1}{n_0}\Sigma\right)\end{aligned}$$

To obtain the prior distribution for Σ , PROC MI reads the matrix \mathbf{S}^* from observations in the data set with _TYPE_='COV', and it reads $n^* = d^* + 1$ from observations with _TYPE_='N'.

To obtain the prior distribution for μ , PROC MI reads the mean vector μ_0 from observations with _TYPE_='MEAN', and it reads n_0 from observations with _TYPE_='N_MEAN'. When there are no observations with _TYPE_='N_MEAN', PROC MI reads n_0 from observations with _TYPE_='N'.

The resulting posterior distribution, as described in the section “[Bayesian Estimation of the Mean Vector and Covariance Matrix](#)” on page 4759, is given by

$$\begin{aligned}\Sigma^{(t+1)}|\mathbf{Y} &\sim W^{-1}(n+d^*, (n-1)\mathbf{S} + d^*\mathbf{S}^* + \mathbf{S}_m) \\ \mu^{(t+1)}|(\Sigma^{(t+1)}, \mathbf{Y}) &\sim N\left(\frac{1}{n+n_0}(n\bar{\mathbf{y}} + n_0\mu_0), \frac{1}{n+n_0}\Sigma^{(t+1)}\right)\end{aligned}$$

where

$$\mathbf{S}_m = \frac{nn_0}{n+n_0}(\bar{\mathbf{y}} - \mu_0)(\bar{\mathbf{y}} - \mu_0)'$$

3. An Informative Prior for Σ

When the sample covariance matrix \mathbf{S} is singular or near singular, prior information about Σ can also be used without prior information about μ to stabilize the inference about μ . You can provide it with a SAS data set that you specify with the PRIOR=INPUT= option.

To obtain the prior distribution for Σ , PROC MI reads the matrix \mathbf{S}^* from observations in the data set with _TYPE_='COV', and it reads n^* from observations with _TYPE_='N'.

The resulting posterior distribution for (μ, Σ) (Schafer 1997, p. 156) is

$$\begin{aligned}\Sigma^{(t+1)}|\mathbf{Y} &\sim W^{-1}(n+d^*, (n-1)\mathbf{S} + d^*\mathbf{S}^*) \\ \mu^{(t+1)}|(\Sigma^{(t+1)}, \mathbf{Y}) &\sim N\left(\bar{\mathbf{y}}, \frac{1}{n}\Sigma^{(t+1)}\right)\end{aligned}$$

Note that if the PRIOR=INPUT= data set also contains observations with _TYPE_='MEAN', then a complete informative prior for both μ and Σ will be used.

4. A Ridge Prior

A special case of the preceding adjustment is a ridge prior with $S^* = \text{Diag}(S)$ (Schafer 1997, p. 156). That is, S^* is a diagonal matrix with diagonal elements equal to the corresponding elements in S .

You can request a ridge prior by using the PRIOR=RIDGE= option. You can explicitly specify the number $d^* \geq 1$ in the PRIOR=RIDGE= d^* option. Or you can implicitly specify the number by specifying the proportion p in the PRIOR=RIDGE= p option to request $d^* = (n - 1)p$.

The posterior is then given by

$$\begin{aligned} \Sigma^{(t+1)} | Y &\sim W^{-1} (n + d^*, (n - 1)S + d^* \text{Diag}(S)) \\ \mu^{(t+1)} | (\Sigma^{(t+1)}, Y) &\sim N \left(\bar{y}, \frac{1}{n} \Sigma^{(t+1)} \right) \end{aligned}$$

Producing Monotone Missingness with the MCMC Method

The monotone data MCMC method was first proposed by Li (1988) and Liu (1993) described the algorithm. The method is useful especially when a data set is close to having a monotone missing pattern. In this case, the method needs to impute only a few missing values to the data set to have a monotone missing pattern in the imputed data set. Compared to a full data imputation that imputes all missing values, the monotone data MCMC method imputes fewer missing values in each iteration and achieves approximate stationarity in fewer iterations (Schafer 1997, p. 227).

You can request the monotone MCMC method by specifying the option IMPUTE=MONOTONE in the MCMC statement. The “Missing Data Patterns” table now denotes the variables with missing values by “.” or “O”. The value “.” means that the variable is missing and will be imputed, and the value “O” means that the variable is missing and will not be imputed. The “Variance Information” and “Parameter Estimates” tables are not created.

You must specify the variables in the VAR statement. The variable order in the list determines the monotone missing pattern in the imputed data set. With a different order in the VAR list, the results will be different because the monotone missing pattern to be constructed will be different.

Assuming that the data are from a multivariate normal distribution, then like the MCMC method, the monotone MCMC method repeats the following steps:

1. The imputation I-step

Given an estimated mean vector and covariance matrix, the I-step simulates the missing values for each observation independently. Only a subset of missing values are simulated to achieve a monotone pattern of missingness.

2. The posterior P-step

Given a new sample with a monotone pattern of missingness, the P-step simulates the posterior population mean vector and covariance matrix with a noninformative Jeffreys prior. These new estimates are then used in the next I-step.

Imputation Step

The I-step is almost identical to the I-step described in the section “MCMC Method for Arbitrary Missing Multivariate Normal Data” on page 4757 except that only a subset of missing values need to be simulated. To state this precisely, denote the variables with observed values for observation i by $Y_{i(obs)}$ and the variables with missing values by $Y_{i(mis)} = (Y_{i(m1)}, Y_{i(m2)})$, where $Y_{i(m1)}$ is a subset of the missing variables that will cause a monotone missingness when their values are imputed. Then the I-step draws values for $Y_{i(m1)}$ from a conditional distribution for $Y_{i(m1)}$ given $Y_{i(obs)}$.

Posterior Step

The P-step is different from the P-step described in the section “MCMC Method for Arbitrary Missing Multivariate Normal Data” on page 4757. Instead of simulating the μ and Σ parameters from the full imputed data set, this P-step simulates the μ and Σ parameters through simulated regression coefficients from regression models based on the imputed data set with a monotone pattern of missingness. The step is similar to the process described in the section “Monotone and FCS Regression Methods” on page 4749.

That is, for the variable Y_j , a model

$$Y_j = \beta_0 + \beta_1 Y_1 + \beta_2 Y_2 + \dots + \beta_{j-1} Y_{j-1}$$

is fitted using n_j nonmissing observations for variable Y_j in the imputed data sets.

The fitted model consists of the regression parameter estimates $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_{j-1})$ and the associated covariance matrix $\hat{\sigma}_j^2 \mathbf{V}_j$, where \mathbf{V}_j is the usual $\mathbf{X}'\mathbf{X}$ inverse matrix from the intercept and variables Y_1, Y_2, \dots, Y_{j-1} .

For each imputation, new parameters $\beta_* = (\beta_{*0}, \beta_{*1}, \dots, \beta_{*(j-1)})$ and σ_{*j}^2 are drawn from the posterior predictive distribution of the parameters. That is, they are simulated from $(\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_{j-1})$, σ_j^2 , and \mathbf{V}_j . The variance is drawn as

$$\sigma_{*j}^2 = \hat{\sigma}_j^2(n_j - j)/g$$

where g is a $\chi_{n_j - p + j - 1}^2$ random variate and n_j is the number of nonmissing observations for Y_j . The regression coefficients are drawn as

$$\beta_* = \hat{\beta} + \sigma_{*j} \mathbf{V}_{hj}' \mathbf{Z}$$

where \mathbf{V}_{hj} is the upper triangular matrix in the Cholesky decomposition, $\mathbf{V}_j = \mathbf{V}_{hj}' \mathbf{V}_{hj}$, and \mathbf{Z} is a vector of j independent random normal variates.

These simulated values of β_* and σ_{*j}^2 are then used to re-create the parameters μ and Σ . For a detailed description of how to produce monotone missingness with the MCMC method for a multivariate normal data, see Schafer (1997, pp. 226–235).

MCMC Method Specifications

With the MCMC method, you can impute either all missing values (IMPUTE=FULL) or just enough missing values to make the imputed data set have a monotone missing pattern (IMPUTE=MONOTONE). In the process, either a single chain for all imputations (CHAIN=SINGLE) or a separate chain for each imputation

(CHAIN=MULTIPLE) is used. The single chain might be somewhat more precise for estimating a single quantity such as a posterior mean (Schafer 1997, p. 138). See Schafer (1997, pp. 137–138) for a discussion of single versus multiple chains.

You can specify the number of initial burn-in iterations before the first imputation with the NBITER= option. This number is also used for subsequent chains for multiple chains. For a single chain, you can also specify the number of iterations between imputations with the NITER= option.

You can explicitly specify initial parameter values for the MCMC method with the INITIAL=INPUT= data set option. Alternatively, you can use the EM algorithm to derive a set of initial parameter values for MCMC with the option INITIAL=EM. These estimates are used as either the starting value (START=VALUE) or the starting distribution (START=DIST) for the MCMC method. For multiple chains, these estimates are used again as either the starting value (START=VALUE) or the starting distribution (START=DIST) for the subsequent chains.

You can specify the prior parameter information in the PRIOR= option. You can use a noninformative prior (PRIOR=JEFFREYS), a ridge prior (PRIOR=RIDGE), or an informative prior specified in a data set (PRIOR=INPUT).

The parameter estimates used to generate imputed values in each imputation can be saved in a data set with the OUTEST= option. Later, this data set can be read with the INEST= option to provide the reference distribution for imputing missing values for a new data set.

By default, the MCMC method uses a single chain to produce five imputations. It completes 200 burn-in iterations before the first imputation and 100 iterations between imputations. The posterior mode computed from the EM algorithm with a noninformative prior is used as the starting values for the MCMC method.

INITIAL=EM Specifications

The EM algorithm is used to find the maximum likelihood estimates for incomplete data in the EM statement. You can also use the EM algorithm to find a posterior mode, the parameter estimates that maximize the observed-data posterior density. The resulting posterior mode provides a good starting value for the MCMC method.

With the INITIAL=EM option, PROC MI uses the MLE of the parameter vector as the initial estimates in the EM algorithm for the posterior mode. You can use the ITPRINT option within the INITIAL=EM option to display the iteration history for the EM algorithm.

You can use the CONVERGE= option to specify the convergence criterion in deriving the EM posterior mode. The iterations are considered to have converged when the maximum change in the parameter estimates between iteration steps is less than the value specified. By default, CONVERGE=1E-4.

You can also use the MAXITER= option to specify the maximum number of iterations of the EM algorithm. By default, MAXITER=200.

With the BOOTSTRAP option, you can use overdispersed starting values for the MCMC method. In this case, PROC MI applies the EM algorithm to a bootstrap sample, a simple random sample with replacement from the input data set, to derive the initial estimates for each chain (Schafer 1997, p. 128).

Checking Convergence in MCMC

The theoretical convergence of the MCMC method has been explored under various conditions, as described in Schafer (1997, p. 70). However, in practice, verification of convergence is not a simple matter.

The parameters used in the imputation step for each iteration can be saved in an output data set with the OUTITER= option. These include the means, standard deviations, covariances, worst linear function, and observed-data LR statistics. You can then monitor the convergence in a single chain by displaying trace plots and autocorrelations for those parameter values (Schafer 1997, p. 120). The trace and autocorrelation function plots for parameters such as variable means, covariances, and the worst linear function can be displayed by specifying the TIMEPLOT and ACFPLOT options, respectively.

You can apply the EM algorithm to a bootstrap sample to obtain overdispersed starting values for multiple chains (Gelman and Rubin 1992). This provides a conservative estimate of the number of iterations needed before each imputation.

The next four subsections describe useful statistics and plots that can be used to check the convergence of the MCMC method.

LR Statistics

You can save the observed-data likelihood ratio (LR) statistic in each iteration with the LR option in the OUTITER= data set. The statistic is based on the observed-data likelihood with parameter values used in the iteration and the observed-data maximum likelihood derived from the EM algorithm.

In each iteration, the LR statistic is given by

$$-2 \log \left(\frac{f(\hat{\theta}_i)}{f(\hat{\theta})} \right)$$

where $f(\hat{\theta})$ is the observed-data maximum likelihood derived from the EM algorithm and $f(\hat{\theta}_i)$ is the observed-data likelihood for $\hat{\theta}_i$ used in the iteration.

Similarly, you can also save the observed-data LR posterior mode statistic for each iteration with the LR_POST option. This statistic is based on the observed-data posterior density with parameter values used in each iteration and the observed-data posterior mode derived from the EM algorithm for posterior mode.

For large samples, these LR statistics tends to be approximately χ^2 distributed with degrees of freedom equal to the dimension of θ (Schafer 1997, p. 131). For example, with a large number of iterations, if the values of the LR statistic do not behave like a random sample from the described χ^2 distribution, then there is evidence that the MCMC method has not converged.

Worst Linear Function of Parameters

The worst linear function (WLF) of parameters (Schafer 1997, pp. 129–131) is a scalar function of parameters μ and Σ that is “worst” in the sense that its function values converge most slowly among parameters in the MCMC method. The convergence of this function is evidence that other parameters are likely to converge as well.

For linear functions of parameters $\theta = (\mu, \Sigma)$, a worst linear function of θ has the highest asymptotic rate of missing information. The function can be derived from the iterative values of θ near the posterior mode in the EM algorithm. That is, an estimated worst linear function of θ is

$$w(\theta) = \mathbf{v}'(\theta - \hat{\theta})$$

where $\hat{\theta}$ is the posterior mode and the coefficients $\mathbf{v} = \hat{\theta}_{(-1)} - \hat{\theta}$ are the difference between the estimated value of θ one step prior to convergence and the converged value $\hat{\theta}$.

You can display the coefficients of the worst linear function, \mathbf{v} , by specifying the WLF option in the MCMC statement. You can save the function value from each iteration in an OUTITER= data set by specifying the WLF option within the OUTITER option. You can also display the worst linear function values from iterations in an autocorrelation plot or a trace plot by specifying WLF as an ACFPLOT or TIMEPLOT option, respectively.

Note that when the observed-data posterior is nearly normal, the WLF is one of the slowest functions to approach stationarity. When the posterior is not close to normal, other functions might take much longer than the WLF to converge, as described in Schafer (1997, p.130).

Trace Plot

A trace plot for a parameter ξ is a scatter plot of successive parameter estimates ξ_i against the iteration number i . The plot provides a simple way to examine the convergence behavior of the estimation algorithm for ξ . Long-term trends in the plot indicate that successive iterations are highly correlated and that the series of iterations has not converged.

You can display trace plots for worst linear function, variable means, variable variances, and covariances of variables. You can also request logarithmic transformations for positive parameters in the plots with the LOG option. When a parameter value is less than or equal to zero, the value is not displayed in the corresponding plot.

By default, the MI procedure uses solid line segments to connect data points in a trace plot. You can use the CCONNECT=, LCONNECT=, and WCONNECT= options to change the color, line type, and width of the line segments, respectively. When WCONNECT=0 is specified, the data points are not connected, and the procedure uses the plus sign (+) as the plot symbol to display the points with a height of one (percentage screen unit) in a trace plot. You can use the SYMBOL=, CSYMBOL=, and HSYMBOL= options to change the shape, color, and height of the plot symbol, respectively.

By default, the plot title “Trace Plot” is displayed in a trace plot. You can request another title by using the TITLE= option in the TIMEPLOT option. When another title is also specified in a TITLE statement, this title is displayed as the main title and the plot title is displayed as a subtitle in the plot.

You can use options in the GOPTIONS statement to change the color and height of the title. See the chapter “The SAS/GRAPH Statements” in *SAS/GRAPH: Reference* for an illustration of title options. See [Example 57.11](#) for a usage of the trace plot.

Autocorrelation Function Plot

To examine relationships of successive parameter estimates ξ , the autocorrelation function (ACF) can be used. For a stationary series, $\xi_i, i \geq 1$, in trace data, the autocorrelation function at lag k is

$$\rho_k = \frac{\text{Cov}(\xi_i, \xi_{i+k})}{\text{Var}(\xi_i)}$$

The sample k th order autocorrelation is computed as

$$r_k = \frac{\sum_{i=1}^{n-k} (\xi_i - \bar{\xi})(\xi_{i+k} - \bar{\xi})}{\sum_{i=1}^n (\xi_i - \bar{\xi})^2}$$

You can display autocorrelation function plots for the worst linear function, variable means, variable variances, and covariances of variables. You can also request logarithmic transformations for parameters in the plots with the LOG option. When a parameter has values less than or equal to zero, the corresponding plot is not created.

You specify the maximum number of lags of the series with the NLAG= option. The autocorrelations at each lag less than or equal to the specified lag are displayed in the graph. In addition, the plot also displays approximate 95% confidence limits for the autocorrelations. At lag k , the confidence limits indicate a set of approximate 95% critical values for testing the hypothesis $\rho_j = 0$, $j \geq k$.

By default, the MI procedure uses the star (*) as the plot symbol to display the points with a height of one (percentage screen unit) in the plot, a solid line to display the reference line of zero autocorrelation, vertical line segments to connect autocorrelations to the reference line, and a pair of dashed lines to display approximately 95% confidence limits for the autocorrelations.

You can use the SYMBOL=, CSYMBOL=, and HSYMBOL= options to change the shape, color, and height of the plot symbol, respectively, and the CNEEDLES= and WNEEDLES= options to change the color and width of the needles, respectively. You can also use the LREF=, CREF=, and WREF= options to change the line type, color, and width of the reference line, respectively. Similarly, you can use the LCONF=, CCONF=, and WCONF= options to change the line type, color, and width of the confidence limits, respectively.

By default, the plot title “Autocorrelation Plot” is displayed in a autocorrelation function plot. You can request another title by using the TITLE= option within the ACFPLOT option. When another title is also specified in a TITLE statement, this title is displayed as the main title and the plot title is displayed as a subtitle in the plot.

You can use options in the GOPTIONS statement to change the color and height of the title. See the chapter “The SAS/GRAPH Statements” in *SAS/GRAPH: Reference* for a description of title options. See [Example 57.8](#) for an illustration of the autocorrelation function plot.

Input Data Sets

You can specify the input data set with missing values by using the DATA= option in the PROC MI statement. When an MCMC method is used, you can specify the data set that contains the reference distribution information for imputation with the INEST= option, the data set that contains initial parameter estimates for the MCMC method with the INITIAL=INPUT= option, and the data set that contains information for the prior distribution with the PRIOR=INPUT= option in the MCMC statement.

DATA=SAS-data-set

The input DATA= data set is an ordinary SAS data set that contains multivariate data with missing values.

INEST=SAS-data-set

The input INEST= data set is a TYPE=EST data set and contains a variable `_Imputation_` to identify the imputation number. For each imputation, PROC MI reads the point estimate from the observations with `_TYPE_='PARM'` or `_TYPE_='PARMS'` and the associated covariances from the observations with `_TYPE_='COV'` or `_TYPE_='COVB'`. These estimates are used as the reference distribution to impute values for observations in the DATA= data set. When the input INEST= data set also contains observations with `_TYPE_='SEED'`, PROC MI reads the seed information for the random number generator from these observations. Otherwise, the SEED= option provides the seed information.

INITIAL=INPUT=SAS-data-set

The input INITIAL=INPUT= data set is a TYPE=COV or CORR data set and provides initial parameter estimates for the MCMC method. The covariances derived from the TYPE=COV/CORR data set are divided by the number of observations to get the correct covariance matrix for the point estimate (sample mean).

If TYPE=COV, PROC MI reads the number of observations from the observations with `_TYPE_='N'`, the point estimate from the observations with `_TYPE_='MEAN'`, and the covariances from the observations with `_TYPE_='COV'`.

If TYPE=CORR, PROC MI reads the number of observations from the observations with `_TYPE_='N'`, the point estimate from the observations with `_TYPE_='MEAN'`, the correlations from the observations with `_TYPE_='CORR'`, and the standard deviations from the observations with `_TYPE_='STD'`.

PRIOR=INPUT=SAS-data-set

The input PRIOR=INPUT= data set is a TYPE=COV data set that provides information for the prior distribution. You can use the data set to specify a prior distribution for Σ of the form

$$\Sigma \sim W^{-1}(d^*, d^*S^*)$$

where $d^* = n^* - 1$ is the degrees of freedom. PROC MI reads the matrix S^* from observations with `_TYPE_='COV'` and reads n^* from observations with `_TYPE_='N'`.

You can also use this data set to specify a prior distribution for μ of the form

$$\mu \sim N\left(\mu_0, \frac{1}{n_0}\Sigma\right)$$

PROC MI reads the mean vector μ_0 from observations with `_TYPE_='MEAN'` and reads n_0 from observations with `_TYPE_='N_MEAN'`. When there are no observations with `_TYPE_='N_MEAN'`, PROC MI reads n_0 from observations with `_TYPE_='N'`.

Output Data Sets

You can specify the output data set of imputed values with the OUT= option in the PROC MI statement. When an EM statement is used, you can specify the data set that contains the original data set with missing values being replaced by the expected values from the EM algorithm by using the OUT= option in the EM statement. You can also specify the data set that contains MLE computed with the EM algorithm by using the OUTEM= option.

When an MCMC method is used, you can specify the data set that contains parameter estimates used in each imputation with the `OUTEST=` option in the MCMC statement, and you can specify the data set that contains parameters used in the imputation step for each iteration with the `OUTITER` option in the MCMC statement.

OUT=SAS-data-set in the PROC MI statement

The `OUT=` data set contains all the variables in the original data set and a new variable named `_Imputation_` that identifies the imputation. For each imputation, the data set contains all variables in the input `DATA=` data set with missing values being replaced by imputed values. Note that when the `NIMPUTE=1` option is specified, the variable `_Imputation_` is not created.

OUT=SAS-data-set in an EM statement

The `OUT=` data set contains the original data set with missing values being replaced by expected values from the EM algorithm.

OUTEM=SAS-data-set

The `OUTEM=` data set is a `TYPE=COV` data set and contains the MLE computed with the EM algorithm. The observations with `_TYPE_='MEAN'` contain the estimated mean and the observations with `_TYPE_='COV'` contain the estimated covariances.

OUTEST=SAS-data-set

The `OUTEST=` data set is a `TYPE=EST` data set and contains parameter estimates used in each imputation in the MCMC method. It also includes an index variable named `_Imputation_`, which identifies the imputation.

The observations with `_TYPE_='SEED'` contain the seed information for the random number generator. The observations with `_TYPE_='PARM'` or `_TYPE_='PARMS'` contain the point estimate, and the observations with `_TYPE_='COV'` or `_TYPE_='COVB'` contain the associated covariances. These estimates are used as the parameters of the reference distribution to impute values for observations in the `DATA=` dataset.

Note that these estimates are the values used in the I-step before each imputation. These are not the parameter values simulated from the P-step in the same iteration. See [Example 57.12](#) for a usage of this option.

OUTITER <(options)> =SAS-data-set in an EM statement

The `OUTITER=` data set in an EM statement is a `TYPE=COV` data set and contains parameters for each iteration. It also includes a variable `_Iteration_` that provides the iteration number.

The parameters in the output data set depend on the options specified. You can specify the `MEAN` and `COV` options for `OUTITER`. With the `MEAN` option, the output data set contains the mean parameters in observations with the variable `_TYPE_='MEAN'`. Similarly, with the `COV` option, the output data set contains the covariance parameters in observations with the variable `_TYPE_='COV'`. When no options are specified, the output data set contains the mean parameters for each iteration.

OUTITER <(options)> =SAS-data-set in an FCS statement

The OUTITER= data set in an FCS statement is a TYPE=COV data set and contains parameters for each iteration. It also includes variables named `_Imputation_` and `_Iteration_`, which provide the imputation number and iteration number.

The parameters in the output data set depend on the options specified. You can specify the MEAN and STD options for OUTITER. With the MEAN option, the output data set contains the mean parameters used in the imputation in observations with the variable `_TYPE_='MEAN'`. Similarly, with the STD option, the output data set contains the standard deviation parameters used in the imputation in observations with the variable `_TYPE_='STD'`. When no options are specified, the output data set contains the mean parameters for each iteration.

OUTITER <(options)> =SAS-data-set in an MCMC statement

The OUTITER= data set in an MCMC statement is a TYPE=COV data set and contains parameters used in the imputation step for each iteration. It also includes variables named `_Imputation_` and `_Iteration_`, which provide the imputation number and iteration number.

The parameters in the output data set depend on the options specified. [Table 57.6](#) summarizes the options available for OUTITER and the corresponding values for the output variable `_TYPE_`.

Table 57.6 Summary of Options for OUTITER in an MCMC statement

Option	Output Parameters	<code>_TYPE_</code>
MEAN	mean parameters	MEAN
STD	standard deviations	STD
COV	covariances	COV
LR	-2 log LR statistic	LOG_LR
LR_POST	-2 log LR statistic of the posterior mode	LOG_POST
WLF	worst linear function	WLF

When no options are specified, the output data set contains the mean parameters used in the imputation step for each iteration. For a detailed description of the worst linear function and LR statistics, see the section “[Checking Convergence in MCMC](#)” on page 4764.

Combining Inferences from Multiply Imputed Data Sets

With m imputations, m different sets of the point and variance estimates for a parameter Q can be computed. Suppose \hat{Q}_i and \hat{W}_i are the point and variance estimates from the i th imputed data set, $i = 1, 2, \dots, m$. Then the combined point estimate for Q from multiple imputation is the average of the m complete-data estimates:

$$\bar{Q} = \frac{1}{m} \sum_{i=1}^m \hat{Q}_i$$

Suppose \overline{W} is the within-imputation variance, which is the average of the m complete-data estimates,

$$\overline{W} = \frac{1}{m} \sum_{i=1}^m \hat{W}_i$$

and B is the between-imputation variance

$$B = \frac{1}{m-1} \sum_{i=1}^m (\hat{Q}_i - \overline{Q})^2$$

Then the variance estimate associated with \overline{Q} is the total variance (Rubin 1987)

$$T = \overline{W} + (1 + \frac{1}{m})B$$

The statistic $(Q - \overline{Q})T^{-(1/2)}$ is approximately distributed as t with v_m degrees of freedom (Rubin 1987), where

$$v_m = (m-1) \left[1 + \frac{\overline{W}}{(1 + m^{-1})B} \right]^2$$

The degrees of freedom v_m depend on m and the ratio

$$r = \frac{(1 + m^{-1})B}{\overline{W}}$$

The ratio r is called the relative increase in variance due to nonresponse (Rubin 1987). When there is no missing information about Q , the values of r and B are both zero. With a large value of m or a small value of r , the degrees of freedom v_m will be large and the distribution of $(Q - \overline{Q})T^{-(1/2)}$ will be approximately normal.

Another useful statistic is the fraction of missing information about Q :

$$\hat{\lambda} = \frac{r + 2/(v_m + 3)}{r + 1}$$

Both statistics r and λ are helpful diagnostics for assessing how the missing data contribute to the uncertainty about Q .

When the complete-data degrees of freedom v_0 are small, and there is only a modest proportion of missing data, the computed degrees of freedom, v_m , can be much larger than v_0 , which is inappropriate. For example, with $m = 5$ and $r = 10\%$, the computed degrees of freedom $v_m = 484$, which is inappropriate for data sets with complete-data degrees of freedom less than 484.

Barnard and Rubin (1999) recommend the use of adjusted degrees of freedom

$$v_m^* = \left[\frac{1}{v_m} + \frac{1}{\hat{v}_{obs}} \right]^{-1}$$

where $\hat{v}_{obs} = (1 - \gamma) v_0 (v_0 + 1) / (v_0 + 3)$ and $\gamma = (1 + m^{-1})B/T$.

Note that the MI procedure uses the adjusted degrees of freedom, v_m^* , for inference.

Multiple Imputation Efficiency

The relative efficiency (RE) of using the finite m imputation estimator, rather than using an infinite number for the fully efficient imputation, in units of variance, is approximately a function of m and λ (Rubin 1987, p. 114):

$$\text{RE} = \left(1 + \frac{\lambda}{m}\right)^{-1}$$

Table 57.7 shows relative efficiencies with different values of m and λ .

Table 57.7 Relative Efficiencies

m	λ				
	10%	20%	30%	50%	70%
3	0.9677	0.9375	0.9091	0.8571	0.8108
5	0.9804	0.9615	0.9434	0.9091	0.8772
10	0.9901	0.9804	0.9709	0.9524	0.9346
20	0.9950	0.9901	0.9852	0.9756	0.9662

The table shows that for situations with little missing information, only a small number of imputations are necessary. In practice, the number of imputations needed can be informally verified by replicating sets of m imputations and checking whether the estimates are stable between sets (Horton and Lipsitz 2001, p. 246).

Imputer's Model Versus Analyst's Model

Multiple imputation inference assumes that the model you used to analyze the multiply imputed data (the analyst's model) is the same as the model used to impute missing values in multiple imputation (the imputer's model). But in practice, the two models might not be the same (Schafer 1997, p. 139).

Schafer (1997, pp. 139–143) provides comprehensive coverage of this topic, and the following example is based on his work.

Consider a trivariate data set with variables Y_1 and Y_2 fully observed, and a variable Y_3 with missing values. An imputer creates multiple imputations with the model $Y_3 = Y_1 Y_2$. However, the analyst can later use the simpler model $Y_3 = Y_1$. In this case, the analyst assumes more than the imputer. That is, the analyst assumes there is no relationship between variables Y_3 and Y_2 .

The effect of the discrepancy between the models depends on whether the analyst's additional assumption is true. If the assumption is true, the imputer's model still applies. The inferences derived from multiple imputations will still be valid, although they might be somewhat conservative because they reflect the additional uncertainty of estimating the relationship between Y_3 and Y_2 .

On the other hand, suppose that the analyst models $Y_3 = Y_1$, and there is a relationship between variables Y_3 and Y_2 . Then the model $Y_3 = Y_1$ will be biased and is inappropriate. Appropriate results can be generated only from appropriate analyst models.

Another type of discrepancy occurs when the imputer assumes more than the analyst. For example, suppose that an imputer creates multiple imputations with the model $Y_3 = Y_1$, but the analyst later fits a model $Y_3 = Y_1 Y_2$. When the assumption is true, the imputer's model is a correct model and the inferences still hold.

On the other hand, suppose there is a relationship between Y_3 and Y_2 . Imputations created under the incorrect assumption that there is no relationship between Y_3 and Y_2 will make the analyst's estimate of the relationship biased toward zero. Multiple imputations created under an incorrect model can lead to incorrect conclusions.

Thus, generally you should include as many variables as you can when doing multiple imputation. The precision you lose with included unimportant predictors is usually a relatively small price to pay for the general validity of analyses of the resultant multiply imputed data set (Rubin 1996). But at the same time, you need to keep the model building and fitting feasible (Barnard and Meng 1999, pp. 19–20).

To produce high-quality imputations for a particular variable, the imputation model should also include variables that are potentially related to the imputed variable and variables that are potentially related to the missingness of the imputed variable (Schafer 1997, p. 143).

Similar suggestions were also given by van Buuren, Boshuizen, and Knook (1999, p. 687). They recommend that the imputation model include three sets of covariates: variables in the analyst's model, variables associated with the missingness of the imputed variable, and variables correlated with the imputed variable. They also recommend the removal of the covariates not in the analyst's model if they have too many missing values for observations with missing imputed variables.

Note that it is good practice to include a description of the imputer's model with the multiply imputed data set (Rubin 1996, p. 479). That way, the analysts will have information about the variables involved in the imputation and which relationships among the variables have been implicitly set to zero.

Parameter Simulation versus Multiple Imputation

As an alternative to multiple imputation, parameter simulation can also be used to analyze the data for many incomplete-data problems. Although the MI procedure does not offer parameter simulation, the trade-offs between the two methods (Schafer 1997, pp. 89–90, 135–136) are examined in this section.

The parameter simulation method simulates random values of parameters from the observed-data posterior distribution and makes simple inferences about these parameters (Schafer 1997, p. 89). When a set of well-defined population parameters θ are of interest, parameter simulation can be used to directly examine and summarize simulated values of θ . This usually requires a large number of iterations, and involves calculating appropriate summaries of the resulting dependent sample of the iterates of the θ . If only a small set of parameters are involved, parameter simulation is suitable (Schafer 1997).

Multiple imputation requires only a small number of imputations. Generating and storing a few imputations can be more efficient than generating and storing a large number of iterations for parameter simulation.

When fractions of missing information are low, methods that average over simulated values of the missing data, as in multiple imputation, can be much more efficient than methods that average over simulated values of θ as in parameter simulation (Schafer 1997).

Summary of Issues in Multiple Imputation

This section summarizes issues that are encountered in applications of the MI procedure.

The MAR Assumption

The missing at random (MAR) assumption is needed for the imputation methods in the MI procedure. Although this assumption cannot be verified with the data, it becomes more plausible as more variables are included in the imputation model (Schafer 1997, pp. 27–28; van Buuren, Boshuizen, and Knook 1999, p. 687).

Number of Imputations

Based on the theory of multiple imputation, only a small number of imputations are needed for a data set with little missing information (Rubin 1987, p. 114). The number of imputations can be informally verified by replicating sets of m imputations and checking whether the estimates are stable (Horton and Lipsitz 2001, p. 246).

Imputation Model

Generally you should include as many variables as you can in the imputation model (Rubin 1996). At the same time, however, it is important to keep the number of variables in control, as discussed by Barnard and Meng (1999, pp. 19–20). For the imputation of a particular variable, the model should include variables in the complete-data model, variables that are correlated with the imputed variable, and variables that are associated with the missingness of the imputed variable (Schafer 1997, p. 143; van Buuren, Boshuizen, and Knook 1999, p. 687).

Multivariate Normality Assumption

Although the regression and MCMC methods assume multivariate normality, inferences based on multiple imputation can be robust to departures from the multivariate normality if the amount of missing information is not large (Schafer 1997, pp. 147–148).

You can use variable transformations to make the normality assumption more tenable. Variables are transformed before the imputation process and then back-transformed to create imputed values.

Monotone Regression Method

With the multivariate normality assumption, either the regression method or the predictive mean matching method can be used to impute continuous variables in data sets with monotone missing patterns.

The predictive mean matching method ensures that imputed values are plausible and might be more appropriate than the regression method if the normality assumption is violated (Horton and Lipsitz 2001, p. 246).

Monotone Propensity Score Method

The propensity score method can also be used to impute continuous variables in data sets with monotone missing patterns.

The propensity score method does not use correlations among variables and is not appropriate for analyses involving relationship among variables, such as a regression analysis (Schafer 1999, p. 11). It can also produce badly biased estimates of regression coefficients when data on predictor variables are missing (Allison 2000).

MCMC Monotone-Data Imputation

The MCMC method is used to impute continuous variables in data sets with arbitrary missing patterns, assuming a multivariate normal distribution for the data. It can also be used to impute just enough missing values to make the imputed data sets have a monotone missing pattern. Then, a more flexible monotone imputation method can be used for the remaining missing values.

Checking Convergence in MCMC

In an MCMC method, parameters are drawn after the MCMC is run long enough to converge to its stationary distribution. In practice, however, it is not simple to verify the convergence of the process, especially for a large number of parameters.

You can check for convergence by examining the observed-data likelihood ratio statistic and worst linear function of the parameters in each iteration. You can also check for convergence by examining a plot of autocorrelation function, as well as a trace plot of parameters (Schafer 1997, p. 120).

EM Estimates

The EM algorithm can be used to compute the MLE of the mean vector and covariance matrix of the data with missing values, assuming a multivariate normal distribution for the data. However, the covariance matrix associated with the estimate of the mean vector cannot be derived from the EM algorithm.

In the MI procedure, you can use the EM algorithm to compute the posterior mode, which provides a good starting value for the MCMC method (Schafer 1997, p. 169).

ODS Table Names

PROC MI assigns a name to each table it creates. You must use these names to reference tables when using the Output Delivery System (ODS). These names are listed in Table 57.8. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 57.8 ODS Tables Produced by PROC MI

ODS Table Name	Description	Statement	Option

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS.](#)”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS.](#)”

PROC MI assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. To request these graphs, ODS Graphics must be enabled and you must specify the options indicated in [Table 57.9](#).

Table 57.9 Graphs Produced by PROC MI

ODS Graph Name	Description	Statement	Option
ACFPlot	ACF plot	MCMC	PLOTS=ACF
TracePlot	Trace plot	MCMC	PLOTS= TRACE
		FCS	PLOTS= TRACE

Examples: MI Procedure

The Fish data described in the STEPDISC procedure are measurements of 159 fish of seven species caught in Finland's lake Laengelmavesi. For each fish, the length, height, and width are measured. Three different length measurements are recorded: from the nose of the fish to the beginning of its tail (Length1), from the nose to the notch of its tail (Length2), and from the nose to the end of its tail (Length3). See Chapter 89, "The STEPDISC Procedure," for more information.

The Fish1 data set is constructed from the Fish data set and contains only one species of the fish and the three length measurements. Some values have been set to missing, and the resulting data set has a monotone missing pattern in the variables Length1, Length2, and Length3. The Fish1 data set is used in [Example 57.2](#) with the propensity score method and in [Example 57.3](#) with the regression method.

The Fish2 data set is also constructed from the Fish data set and contains two species of fish. Some values have been set to missing, and the resulting data set has a monotone missing pattern in the variables Length, Height, Width, and Species. The Fish2 data set is used in [Example 57.4](#) with the logistic regression method and in [Example 57.5](#) with the discriminant function method. Note that some values of the variable Species have also been altered in the data set.

The Fish3 data set is similar to the data set Fish2 except some additional values have been set to missing and the resulting data set has an arbitrary missing pattern. The Fish3 data set is used in [Example 57.7](#) and in [Example 57.8](#).

The Fitness1 data set created in the section "Getting Started: MI Procedure" on page 4716 is used in other examples.

The following statements create the Fish1 data set:

```

Example 57.1: EM Algorithm for MLE

This example uses the EM algorithm to compute the maximum likelihood estimates for parameters of multivariate normally distributed data with missing values. The following statements invoke the MI procedure and request the EM algorithm to compute the MLE for (μ, Σ) of a multivariate normal distribution from the input data set Fitness1:

```

proc mi data=Fitness1 seed=1518971 simple nimpute=0;
  em itprint outem=outem;
  var Oxygen RunTime RunPulse;
run;

```

Note that when you specify the NIMPUTE=0 option, the missing values are not imputed.

The “Model Information” table in [Output 57.1.1](#) describes the method and options used in the procedure if a positive number is specified in the NIMPUTE= option.

Output 57.1.1 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FITNESS1
Method	MCMC
Multiple Imputation Chain	Single Chain
Initial Estimates for MCMC	EM Posterior Mode
Start	Starting Value
Prior	Jeffreys
Number of Imputations	0
Number of Burn-in Iterations	200
Number of Iterations	100
Seed for random number generator	1518971

The “Missing Data Patterns” table in [Output 57.1.2](#) lists distinct missing data patterns with corresponding frequencies and percentages. Here, a value of “X” means that the variable is observed in the corresponding group and a value of “.” means that the variable is missing. The table also displays group-specific variable means.

Output 57.1.2 Missing Data Patterns

Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	.	4	12.90
3	X	.	.	3	9.68
4	.	X	X	1	3.23
5	.	X	.	2	6.45

Missing Data Patterns			
-----Group Means-----			
Group	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

With the SIMPLE option, the procedure displays simple descriptive univariate statistics for available cases in the “Univariate Statistics” table in [Output 57.1.3](#) and correlations from pairwise available cases in the “Pairwise Correlations” table in [Output 57.1.4](#).

Output 57.1.3 Univariate Statistics

Univariate Statistics					
Variable	N	Mean	Std Dev	Minimum	Maximum
Oxygen	28	47.11618	5.41305	37.38800	60.05500
RunTime	28	10.68821	1.37988	8.63000	14.03000
RunPulse	22	171.86364	10.14324	148.00000	186.00000

Univariate Statistics			
---Missing Values---			
Variable	Count	Percent	
Oxygen	3	9.68	
RunTime	3	9.68	
RunPulse	9	29.03	

Output 57.1.4 Pairwise Correlations

Pairwise Correlations				
	Oxygen	RunTime	RunPulse	
Oxygen	1.000000000	-0.849118562	-0.343961742	
RunTime	-0.849118562	1.000000000	0.247258191	
RunPulse	-0.343961742	0.247258191	1.000000000	

When you use the EM statement, the MI procedure displays the initial parameter estimates for the EM algorithm in the “Initial Parameter Estimates for EM” table in [Output 57.1.5](#).

Output 57.1.5 Initial Parameter Estimates for EM

Initial Parameter Estimates for EM				
TYPE	_NAME_	Oxygen	RunTime	RunPulse
MEAN		47.116179	10.688214	171.863636
COV	Oxygen	29.301078	0	0
COV	RunTime	0	1.904067	0
COV	RunPulse	0	0	102.885281

When you use the ITPRINT option in the EM statement, the “EM (MLE) Iteration History” table in [Output 57.1.6](#) displays the iteration history for the EM algorithm.

Output 57.1.6 EM (MLE) Iteration History

EM (MLE) Iteration History				
<u>_Iteration_</u>	<u>-2 Log L</u>	<u>Oxygen</u>	<u>RunTime</u>	<u>RunPulse</u>
0	289.544782	47.116179	10.688214	171.863636
1	263.549489	47.116179	10.688214	171.863636
2	255.851312	47.139089	10.603506	171.538203
3	254.616428	47.122353	10.571685	171.426790
4	254.494971	47.111080	10.560585	171.398296
5	254.483973	47.106523	10.556768	171.389208
6	254.482920	47.104899	10.555485	171.385257
7	254.482813	47.104348	10.555062	171.383345
8	254.482801	47.104165	10.554923	171.382424
9	254.482800	47.104105	10.554878	171.381992
10	254.482800	47.104086	10.554864	171.381796
11	254.482800	47.104079	10.554859	171.381708
12	254.482800	47.104077	10.554858	171.381669

The “EM (MLE) Parameter Estimates” table in [Output 57.1.7](#) displays the maximum likelihood estimates for μ and Σ of a multivariate normal distribution from the data set Fitness1.

Output 57.1.7 EM (MLE) Parameter Estimates

EM (MLE) Parameter Estimates				
<u>_TYPE_</u>	<u>_NAME_</u>	<u>Oxygen</u>	<u>RunTime</u>	<u>RunPulse</u>
MEAN		47.104077	10.554858	171.381669
COV	Oxygen	27.797931	-6.457975	-18.031298
COV	RunTime	-6.457975	2.015514	3.516287
COV	RunPulse	-18.031298	3.516287	97.766857

You can also output the EM (MLE) parameter estimates to an output data set with the OUTEM= option. The following statements list the observations in the output data set outem:

```
proc print data=outem;
  title 'EM Estimates';
run;
```

The output data set outem in [Output 57.1.8](#) is a TYPE=COV data set. The observation with _TYPE_='MEAN' contains the MLE for the parameter μ , and the observations with _TYPE_='COV' contain the MLE for the parameter Σ of a multivariate normal distribution from the data set Fitness1.

Output 57.1.8 EM Estimates

EM Estimates					
Obs	_TYPE_	_NAME_	Oxygen	RunTime	RunPulse
1	MEAN		47.1041	10.5549	171.382
2	COV	Oxygen	27.7979	-6.4580	-18.031
3	COV	RunTime	-6.4580	2.0155	3.516
4	COV	RunPulse	-18.0313	3.5163	97.767

Example 57.2: Monotone Propensity Score Method

This example uses the propensity score method to impute missing values for variables in a data set with a monotone missing pattern. The following statements invoke the MI procedure and request the propensity score method. The resulting data set is named outex2.

```
proc mi data=Fish1 seed=899603 out=outex2;
  monotone propensity;
  var Length1 Length2 Length3;
run;
```

Note that the VAR statement is required and the data set must have a monotone missing pattern with variables as ordered in the VAR statement.

The “Model Information” table in [Output 57.2.1](#) describes the method and options used in the multiple imputation process. By default, five imputations are created for the missing data.

Output 57.2.1 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FISH1
Method	Monotone
Number of Imputations	5
Seed for random number generator	899603

When monotone methods are used in the imputation, MONOTONE is displayed as the method. The “Monotone Model Specification” table in [Output 57.2.2](#) displays the detailed model specification. By default, the observations are sorted into five groups based on their propensity scores.

Output 57.2.2 Monotone Model Specification

Monotone Model Specification		
Method	Imputed Variables	
Propensity(Groups= 5)	Length2	Length3

Without covariates specified for imputed variables Length2 and Length3, the variable Length1 is used as the covariate for Length2, and the variables Length1 and Length2 are used as covariates for Length3.

The “Missing Data Patterns” table in [Output 57.2.3](#) lists distinct missing data patterns with corresponding frequencies and percentages. Here, values of “X” and “.” indicate that the variable is observed or missing, respectively, in the corresponding group. The table confirms a monotone missing pattern for these three variables.

Output 57.2.3 Missing Data Patterns

Missing Data Patterns					
Group	Length1	Length2	Length3	Freq	Percent
1	X	X	X	30	85.71
2	X	X	.	3	8.57
3	X	.	.	2	5.71

Missing Data Patterns			
Group	-----Group Means-----		
	Length1	Length2	Length3
1	30.603333	33.436667	38.720000
2	29.033333	31.666667	.
3	27.750000	.	.

For the imputation process, first, missing values of Length2 in group 3 are imputed using observed values of Length1. Then the missing values of Length3 in group 2 are imputed using observed values of Length1 and Length2. And finally, the missing values of Length3 in group 3 are imputed using observed values of Length1 and imputed values of Length2.

After the completion of m imputations, the “Variance Information” table in [Output 57.2.4](#) displays the between-imputation variance, within-imputation variance, and total variance for combining complete-data inferences. It also displays the degrees of freedom for the total variance. The relative increase in variance due to missingness, the fraction of missing information, and the relative efficiency for each variable are also displayed. A detailed description of these statistics is provided in the section “[Combining Inferences from Multiply Imputed Data Sets](#)” on page 4769.

Output 57.2.4 Variance Information

Variance Information				
-----Variance-----				
Variable	Between	Within	Total	DF
Length2	0.001500	0.465422	0.467223	32.034
Length3	0.049725	0.547434	0.607104	27.103

Variance Information				
Variable	Relative Increase in Variance	Fraction Missing Information	Relative Efficiency	
Length2	0.003869	0.003861	0.999228	
Length3	0.108999	0.102610	0.979891	

The “Parameter Estimates” table in [Output 57.2.5](#) displays the estimated mean and standard error of the mean for each variable. The inferences are based on the t distributions. For each variable, the table also displays a 95% mean confidence interval and a t statistic with the associated p -value for the hypothesis that the population mean is equal to the value specified in the MU0= option, which is zero by default.

Output 57.2.5 Parameter Estimates

Parameter Estimates					
Variable	Mean	Std Error	95% Confidence Limits		DF
Length2	33.006857	0.683537	31.61460	34.39912	32.034
Length3	38.361714	0.779169	36.76328	39.96015	27.103

Parameter Estimates					
Variable	Minimum	Maximum	Mu0	t for H0: Mean=Mu0	Pr > t
Length2	32.957143	33.060000	0	48.29	<.0001
Length3	38.080000	38.545714	0	49.23	<.0001

The following statements list the first 10 observations of the data set outex2, as shown in [Output 57.2.6](#). The missing values are imputed from observed values with similar propensity scores.

```
proc print data=outex2(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 57.2.6 Imputed Data Set

First 10 Observations of the Imputed Data Set				
Obs	_Imputation_	Length1	Length2	Length3
1	1	23.2	25.4	30.0
2	1	24.0	26.3	31.2
3	1	23.9	26.5	31.1
4	1	26.3	29.0	33.5
5	1	26.5	29.0	38.6
6	1	26.8	29.7	34.7
7	1	26.8	29.0	35.0
8	1	27.6	30.0	35.0
9	1	27.6	30.0	35.1
10	1	28.5	30.7	36.2

Example 57.3: Monotone Regression Method

This example uses the regression method to impute missing values for all variables in a data set with a monotone missing pattern. The following statements invoke the MI procedure and request the regression method for the variable Length2 and the predictive mean matching method for variable Length3. The resulting data set is named outex3.

```
proc mi data=Fish1 round=.1 mu0= 0 35 45
    seed=13951639 out=outex3;
    monotone reg(Length2/ details)
        regpmm(Length3= Length1 Length2 Length1*Length2/ details);
    var Length1 Length2 Length3;
run;
```

The ROUND= option is used to round the imputed values to the same precision as observed values. The values specified with the ROUND= option are matched with the variables Length1, Length2, and Length3 in the order listed in the VAR statement. The MU0= option requests t tests for the hypotheses that the population means corresponding to the variables in the VAR statement are Length2=35 and Length3=45.

The “Missing Data Patterns” table lists distinct missing data patterns with corresponding frequencies and percentages. It is identical to the table in [Output 57.2.3](#) in [Example 57.2](#).

The “Monotone Model Specification” table in [Output 57.3.1](#) displays the model specification.

Output 57.3.1 Monotone Model Specification

The MI Procedure	
Monotone Model Specification	
Method	Imputed Variables
Regression	Length2
Regression-PMM(K= 5)	Length3

When you use the DETAILS option, the parameters estimated from the observed data and the parameters used in each imputation are displayed in [Output 57.3.2](#) and [Output 57.3.3](#).

Output 57.3.2 Regression Model

Regression Models for Monotone Method					
Imputed Variable	Effect	Obs-Data	-----Imputation-----		
			1	2	3
Length2	Intercept	-0.04249	-0.049184	-0.055470	-0.051346
Length2	Length1	0.98587	1.001934	0.995275	0.992294
Regression Models for Monotone Method					
Imputed Variable	Effect		-----Imputation-----		
			4	5	
Length2	Intercept		-0.064193	-0.030719	
Length2	Length1		0.983122	0.995883	

Output 57.3.3 Regression Predicted Mean Matching Model

Regression Models for Monotone Predicted Mean Matching Method					
Imputed Variable	Effect	Obs Data	-----Imputation-----		
			1	2	3
Length3	Intercept	-0.01304	0.004134	-0.011417	-0.034177
Length3	Length1	-0.01332	0.025320	-0.037494	0.308765
Length3	Length2	0.98918	0.955510	1.025741	0.673374
Length3	Length1*Length2	-0.02521	-0.034964	-0.022017	-0.017919

Regression Models for Monotone Predicted Mean Matching Method			
Imputed Variable	Effect	-----Imputation-----	
		4	5
Length3	Intercept	-0.010532	0.004685
Length3	Length1	0.156606	-0.147118
Length3	Length2	0.828384	1.146440
Length3	Length1*Length2	-0.029335	-0.034671

After the completion of five imputations by default, the “Variance Information” table in [Output 57.3.4](#) displays the between-imputation variance, within-imputation variance, and total variance for combining complete-data inferences. The relative increase in variance due to missingness, the fraction of missing information, and the relative efficiency for each variable are also displayed. These statistics are described in the section “[Combining Inferences from Multiply Imputed Data Sets](#)” on page 4769.

Output 57.3.4 Variance Information

Variance Information				
Variable	-----Variance-----			DF
	Between	Within	Total	
Length2	0.000133	0.439512	0.439672	32.15
Length3	0.000386	0.486913	0.487376	32.131

Variance Information			
Variable	Relative Increase in Variance	Fraction Missing Information	Relative Efficiency
Length2	0.000363	0.000363	0.999927
Length3	0.000952	0.000951	0.999810

The “Parameter Estimates” table in [Output 57.3.5](#) displays a 95% mean confidence interval and a t statistic with its associated p -value for each of the hypotheses requested with the MU0= option.

Output 57.3.5 Parameter Estimates

Parameter Estimates					
Variable	Mean	Std Error	95% Confidence Limits		DF
Length2	33.104571	0.663078	31.75417	34.45497	32.15
Length3	38.424571	0.698123	37.00277	39.84637	32.131
Parameter Estimates					
Variable	Minimum	Maximum	Mu0	t for H0: Mean=Mu0	Pr > t
Length2	33.088571	33.117143	35.000000	-2.86	0.0074
Length3	38.397143	38.445714	45.000000	-9.42	<.0001

The following statements list the first 10 observations of the data set outex3 in [Output 57.3.6](#). Note that the imputed values of Length2 are rounded to the same precision as the observed values.

```
proc print data=outex3(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 57.3.6 Imputed Data Set

First 10 Observations of the Imputed Data Set				
Obs	_Imputation_	Length1	Length2	Length3
1	1	23.2	25.4	30.0
2	1	24.0	26.3	31.2
3	1	23.9	26.5	31.1
4	1	26.3	29.0	33.5
5	1	26.5	29.0	34.7
6	1	26.8	29.7	34.7
7	1	26.8	28.8	34.7
8	1	27.6	30.0	35.0
9	1	27.6	30.0	35.1
10	1	28.5	30.7	36.2

Example 57.4: Monotone Logistic Regression Method for CLASS Variables

This example uses logistic regression method to impute values for a binary variable in a data set with a monotone missing pattern.

In the following statements, the logistic regression method is used for the binary CLASS variable Species:

```
proc mi data=Fish2 seed=1305417 out=outex4;
  class Species;
  monotone reg( Length Width/ details)
    logistic( Species= Length Height Width Height*Width/ details);
  var Length Height Width Species;
run;
```

The “Model Information” table in [Output 57.4.1](#) describes the method and options used in the multiple imputation process.

Output 57.4.1 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FISH2
Method	Monotone
Number of Imputations	5
Seed for random number generator	1305417

The “Monotone Model Specification” table in [Output 57.4.2](#) describes methods and imputed variables in the imputation model. The procedure uses the logistic regression method to impute the variable Species in the model. Missing values in other variables are not imputed.

Output 57.4.2 Monotone Model Specification

Monotone Model Specification	
Method	Imputed Variables
Regression	Height Width
Logistic Regression	Species

The “Missing Data Patterns” table in [Output 57.4.3](#) lists distinct missing data patterns with corresponding frequencies and percentages. The table confirms a monotone missing pattern for these variables.

Output 57.4.3 Missing Data Patterns

Missing Data Patterns						
Group	Length	Height	Width	Species	Freq	Percent
1	X	X	X	X	43	82.69
2	X	X	X	.	3	5.77
3	X	X	.	.	4	7.69
4	X	.	.	.	2	3.85

Missing Data Patterns				
-----Group Means-----				
Group	Length	Height	Width	
1	41.997674	12.819512	5.359860	
2	38.433333	11.797667	4.587667	
3	42.275000	13.346750	.	
4	40.150000	.	.	

When you use the DETAILS option, parameters estimated from the observed data and the parameters used in each imputation are displayed in the “Logistic Models for Monotone Method” table in [Output 57.4.4](#).

Output 57.4.4 Regression Model

Regression Models for Monotone Method					
Imputed Variable	Effect	Obs-Data	-----Imputation-----		
			1	2	3
Width	Intercept	0.00682	0.054140	0.018049	-0.015137
Width	Length	0.75519	0.838485	0.768945	0.789577
Width	Height	0.73890	0.832117	0.831748	0.809482

Regression Models for Monotone Method			
Imputed Variable	Effect	-----Imputation-----	
		4	5
Width	Intercept	0.024027	0.084643
Width	Length	0.728779	0.631217
Width	Height	0.747734	0.745232

Output 57.4.5 Logistic Regression Model

Logistic Models for Monotone Method					
Imputed Variable	Effect	Obs-Data	-----Imputation-----		
			1	2	3
Species	Intercept	22.80713	22.807129	22.807129	22.807129
Species	Length	-14.44698	-14.446980	-14.446980	-14.446980
Species	Height	43.11236	43.112363	43.112363	43.112363
Species	Width	-9.64352	-9.643524	-9.643524	-9.643524
Species	Height*Width	-9.73015	-9.730154	-9.730154	-9.730154

Logistic Models for Monotone Method					
Imputed Variable	Effect		-----Imputation-----		
			4	5	
Species	Intercept		22.807129	22.807129	
Species	Length		-14.446980	-14.446980	
Species	Height		43.112363	43.112363	
Species	Width		-9.643524	-9.643524	
Species	Height*Width		-9.730154	-9.730154	

The following statements list the first 10 observations of the data set outex4 in [Output 57.4.5](#):

```
proc print data=outex4(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 57.4.6 Imputed Data Set

First 10 Observations of the Imputed Data Set					
Obs	_Imputation_	Species	Length	Height	Width
1	1	Bream	30.0	11.520	4.02000
2	1	Bream	31.2	12.480	4.30600
3	1	Bream	31.1	12.378	4.69600
4	1	Bream	33.5	12.730	4.45600
5	1	Bream	34.0	12.444	4.62964
6	1	Bream	34.7	13.602	4.92700
7	1	Bream	34.5	14.180	5.27900
8	1	Bream	35.0	12.670	4.69000
9	1	Bream	35.1	14.005	4.84400
10	1	Bream	36.2	14.227	4.95900

Note that a missing value of the variable Species is not imputed if the corresponding covariates are missing and not imputed, as shown by observation 4 in the table.

Example 57.5: Monotone Discriminant Function Method for CLASS Variables

This example uses discriminant monotone methods to impute values of a CLASS variable from the observed observation values in a data set with a monotone missing pattern.

The following statements impute the continuous variables Height and Width with the regression method and the classification variable Species with the discriminant function method:

```
proc mi data=Fish2 seed=7545417 nimpute=3 out=outex5;
  class Species;
  monotone reg( Height Width)
           discrim( Species= Length Height Width/ details);
  var Length Height Width Species;
run;
```

The “Model Information” table in [Output 57.5.1](#) describes the method and options used in the multiple imputation process.

Output 57.5.1 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FISH2
Method	Monotone
Number of Imputations	3
Seed for random number generator	7545417

The “Monotone Model Specification” table in [Output 57.5.2](#) describes methods and imputed variables in the imputation model. The procedure uses the regression method to impute the variables Height and Width, and uses the logistic regression method to impute the variable Species in the model.

Output 57.5.2 Monotone Model Specification

Monotone Model Specification	
Method	Imputed Variables
Regression	Height Width
Discriminant Function	Species

The “Missing Data Patterns” table in [Output 57.5.3](#) lists distinct missing data patterns with corresponding frequencies and percentages. The table confirms a monotone missing pattern for these variables.

Output 57.5.3 Missing Data Patterns

Missing Data Patterns						
Group	Length	Height	Width	Species	Freq	Percent
1	X	X	X	X	43	82.69
2	X	X	X	.	3	5.77
3	X	X	.	.	4	7.69
4	X	.	.	.	2	3.85

Missing Data Patterns						
-----Group Means-----						
Group	Length	Height	Width			
1	41.997674	12.819512	5.359860			
2	38.433333	11.797667	4.587667			
3	42.275000	13.346750	.			
4	40.150000	.	.			

When you use the DETAILS option, the parameters estimated from the observed data and the parameters used in each imputation are displayed in [Output 57.5.4](#).

Output 57.5.4 Discriminant Model

Group Means for Monotone Discriminant Method					
Species	Variable	Obs-Data	-----Imputation-----		
			1	2	3
Bream	Length	-0.36712	-0.198907	-0.375696	-0.307771
Bream	Height	0.64051	0.756448	0.684845	0.658337
Bream	Width	0.20882	0.465034	0.254438	0.252637
Pike	Length	0.85554	0.656521	0.677957	1.024069
Pike	Height	-1.31185	-1.431954	-1.436355	-1.119520
Pike	Width	-0.25768	-0.381503	-0.420441	-0.136188

The following statements list the first 10 observations of the data set outex5 in [Output 57.5.5](#). Note that all missing values of the variables Width and Species are imputed.

```
proc print data=outex5(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 57.5.5 Imputed Data Set

First 10 Observations of the Imputed Data Set					
Obs	_Imputation_	Species	Length	Height	Width
1	1	Bream	30.0	11.520	4.02000
2	1	Bream	31.2	12.480	4.30600
3	1	Bream	31.1	12.378	4.69600
4	1	Bream	33.5	12.730	4.45600
5	1	Bream	34.0	12.444	4.46687
6	1	Bream	34.7	13.602	4.92700
7	1	Bream	34.5	14.180	5.27900
8	1	Bream	35.0	12.670	4.69000
9	1	Bream	35.1	14.005	4.84400
10	1	Bream	36.2	14.227	4.95900

Example 57.6: FCS Method for Continuous Variables

This example uses FCS regression methods to impute values for all continuous variables in a data set with an arbitrary missing pattern.

The following statements invoke the MI procedure and impute missing values for the Fitness1 data set:

```
proc mi data=Fitness1 seed=1213 nimpute=4 mu0=50 10 180 out=outex6;
  fcs nbiter=20 reg(/details);
  var Oxygen RunTime RunPulse;
run;
```

The NIMPUTE=4 option specifies the total number of imputations. The FCS statement requests multivariate imputations by FCS methods, and the NBITER=20 option (which is the default) specifies the number of burn-in iterations before each imputation.

The “Model Information” table in [Output 57.6.1](#) describes the method and options used in the multiple imputation process.

Output 57.6.1 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FITNESS1
Method	FCS
Number of Imputations	4
Number of Burn-in Iterations	20
Seed for random number generator	1213

The “FCS Model Specification” table in [Output 57.6.2](#) describes methods and imputed variables in the imputation model. With the REG option in the FCS statement, the procedure uses the regression method to

impute variables RunTime, RunPulse, and Oxygen in the model.

Output 57.6.2 FCS Model Specification

FCS Model Specification			
Method	Imputed Variables		
Regression	Oxygen	RunTime	RunPulse

The “Missing Data Patterns” table in [Output 57.6.3](#) lists distinct missing data patterns with corresponding frequencies and percentages.

Output 57.6.3 Missing Data Patterns

Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	.	4	12.90
3	X	.	.	3	9.68
4	.	X	X	1	3.23
5	.	X	.	2	6.45

Missing Data Patterns			
Group	-----Group Means-----		
	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

When you use the DETAILS option, the parameters used in each imputation are displayed in [Output 57.6.4](#), [Output 57.6.5](#), and [Output 57.6.6](#).

Output 57.6.4 FCS Regression Model for Oxygen

Regression Models for FCS Method					
Imputed Variable	Effect	-----Imputation-----			
		1	2	3	4
Oxygen	Intercept	-0.132359	0.093555	0.078587	0.063256
Oxygen	RunTime	-0.908663	-0.753423	-1.125549	-0.634844
Oxygen	RunPulse	-0.134745	0.052640	-0.135864	-0.158692

Output 57.6.5 FCS Regression Model for RunTime

The MI Procedure					
Regression Models for FCS Method					
Imputed Variable	Effect	-----Imputation-----			
		1	2	3	4
RunTime	Intercept	-0.127880	-0.125666	-0.074802	0.058724
RunTime	Oxygen	-0.592047	-1.067554	-1.020216	-0.827592
RunTime	RunPulse	0.110865	-0.311273	-0.158049	0.060715

Output 57.6.6 FCS Regression Model for RunPulse

The MI Procedure					
Regression Models for FCS Method					
Imputed Variable	Effect	-----Imputation-----			
		1	2	3	4
RunPulse	Intercept	-0.072862	-0.089964	0.049778	0.082088
RunPulse	Oxygen	0.226951	-0.439850	-0.440705	-0.353438
RunPulse	RunTime	0.545914	0.067482	0.234528	-0.273761

The following statements list the first 10 observations of the data set outex6 in [Output 57.6.7](#). Note that all missing values of all variables are imputed.

```
proc print data=outex6(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 57.6.7 Imputed Data Set

First 10 Observations of the Imputed Data Set				
Obs	_Imputation_	Oxygen	RunTime	Run Pulse
1	1	44.6090	11.3700	178.000
2	1	45.3130	10.0700	185.000
3	1	54.2970	8.6500	156.000
4	1	59.5710	10.1985	185.842
5	1	49.8740	9.2200	173.379
6	1	44.8110	11.6300	176.000
7	1	44.6299	11.9500	176.000
8	1	47.4258	10.8500	183.926
9	1	39.4420	13.0800	174.000
10	1	60.0550	8.6300	170.000

After the completion of the specified four imputations, the “Variance Information” table in [Output 57.6.8](#) displays the between-imputation variance, within-imputation variance, and total variance for combining complete-data inferences. The relative increase in variance due to missingness, the fraction of missing information, and the relative efficiency for each variable are also displayed. These statistics are described in the section “Combining Inferences from Multiply Imputed Data Sets” on page 4769.

Output 57.6.8 Variance Information

Variance Information				
Variable	-----Variance-----			DF
	Between	Within	Total	
Oxygen	0.044012	0.936794	0.991809	25.911
RunTime	0.002518	0.063583	0.066730	26.328
RunPulse	3.552893	3.488832	7.929948	5.3995

Variance Information			
Variable	Relative Increase in Variance	Fraction Missing Information	Relative Efficiency
Oxygen	0.058727	0.057401	0.985853
RunTime	0.049500	0.048575	0.988002
RunPulse	1.272952	0.630073	0.863917

The “Parameter Estimates” table in [Output 57.6.9](#) displays a 95% mean confidence interval and a t statistic with its associated p -value for each of the hypotheses requested with the MU0= option.

Output 57.6.9 Parameter Estimates

Parameter Estimates					
Variable	Mean	Std Error	95% Confidence Limits		DF
Oxygen	47.200681	0.995896	45.1532	49.2481	25.911
RunTime	10.578418	0.258322	10.0478	11.1091	26.328
RunPulse	171.368390	2.816016	164.2877	178.4490	5.3995

Parameter Estimates					
Variable	Minimum	Maximum	Mu0	t for H0:	Pr > t
				Mean=Mu0	
Oxygen	47.075129	47.512585	50.000000	-2.81	0.0093
RunTime	10.526891	10.627704	10.000000	2.24	0.0338
RunPulse	168.633931	172.932612	180.000000	-3.07	0.0253

Example 57.7: FCS Method for CLASS Variables

This example uses FCS methods to impute missing values in both continuous and CLASS variables in a data set with an arbitrary missing pattern. The following statements invoke the MI procedure and impute missing values for the Fish3 data set:

```
proc mi data=Fish3 seed=1305417 out=outex7;
  class Species;
  fcs nbiter=10 discrim(Species/details) reg(Height/details);
  var Species Length Height Width;
run;
```

The DISCRIM option uses the discriminant function method to impute the classification variable Species, and the REG option uses the regression method to impute the continuous variable Height. By default, the regression method is also used to impute other continuous variables, Length and Width.

The “Model Information” table in [Output 57.7.1](#) describes the method and options used in the multiple imputation process.

Output 57.7.1 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FISH3
Method	FCS
Number of Imputations	5
Number of Burn-in Iterations	10
Seed for random number generator	1305417

The “FCS Model Specification” table in [Output 57.7.2](#) describes methods and imputed variables in the imputation model. The procedure uses the discriminant function method to impute the variable Species, and the regression method to impute other variables.

Output 57.7.2 FCS Model Specification

FCS Model Specification		
Method	Imputed Variables	
Regression	Length	Height Width
Discriminant Function	Species	

The “Missing Data Patterns” table in [Output 57.7.3](#) lists distinct missing data patterns with corresponding frequencies and percentages.

Output 57.7.3 Missing Data Patterns

Missing Data Patterns						
Group	Species	Length	Height	Width	Freq	Percent
1	X	X	X	X	38	73.08
2	X	.	X	X	2	3.85
3	X	.	X	.	1	1.92
4	.	X	X	X	3	5.77
5	.	X	X	.	3	5.77
6	.	X	.	X	2	3.85
7	.	X	.	.	2	3.85
8	.	.	X	.	1	1.92

Missing Data Patterns			
-----Group Means-----			
Group	Length	Height	Width
1	41.515789	12.531526	5.266474

		4	5
Height	Intercept	-0.353772	-0.357781
Height	Species	1.035374	0.963826
Height	Length	0.187469	0.090964
Height	Width	0.299173	0.325195

The following statements list the first 10 observations of the data set outex7 in [Output 57.7.6](#):

```
proc print data=outex7(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 57.7.6 Imputed Data Set

First 10 Observations of the Imputed Data Set					
Obs	_Imputation_	Species	Length	Height	Width
1	1	Bream	30.0000	11.5200	4.02000
2	1	Bream	31.2000	12.4800	4.30600
3	1	Bream	31.1000	12.3780	4.69600
4	1	Bream	33.5000	12.7300	4.45600
5	1	Pike	68.6009	12.4440	7.65040
6	1	Bream	34.7000	13.6020	4.92700
7	1	Bream	34.5000	14.1800	5.27900
8	1	Pike	35.0000	5.7684	4.69000
9	1	Bream	35.1000	14.0050	4.84400
10	1	Bream	36.2000	14.2270	4.95900

After the completion of five imputations by default, the “Variance Information” table in [Output 57.7.7](#) displays the between-imputation variance, within-imputation variance, and total variance for combining complete-data inferences for continuous variables. The relative increase in variance due to missingness, the fraction of missing information, and the relative efficiency for each variable are also displayed. These statistics are described in the section “[Combining Inferences from Multiply Imputed Data Sets](#)” on page 4769.

Output 57.7.7 Variance Information

Variance Information				
Variable	-----Variance-----			DF
	Between	Within	Total	
Length	0.076551	1.351968	1.443828	43.942
Height	0.024597	0.311347	0.340863	41.379
Width	0.000307	0.015361	0.015730	47.645
Variance Information				
Variable	Relative Increase in Variance	Fraction Missing Information	Relative Efficiency	
Length	0.067946	0.065513	0.987067	
Height	0.094801	0.089997	0.982319	
Width	0.024018	0.023723	0.995278	

The “Parameter Estimates” table in [Output 57.7.8](#) displays a 95% mean confidence interval and a t statistic with its associated p -value for each of the hypotheses requested with the default MU0=0 option.

Output 57.7.8 Parameter Estimates

Parameter Estimates					
Variable	Mean	Std Error	95% Confidence Limits		DF
Length	41.952213	1.201594	39.53047	44.37396	43.942
Height	12.785938	0.583835	11.60719	13.96469	41.379
Width	5.345132	0.125420	5.09291	5.59735	47.645
Parameter Estimates					
Variable	Minimum	Maximum	t for H0:		
			Mu0	Mean=Mu0	Pr > t
Length	41.702410	42.286360	0	34.91	<.0001
Height	12.555560	12.988405	0	21.90	<.0001
Width	5.324639	5.366759	0	42.62	<.0001

Example 57.8: FCS Method with Trace Plot

This example uses FCS methods to impute missing values in both continuous and classification variables in a data set with an arbitrary missing pattern. The following statements use a logistic regression method to impute values of the classification variable Species:

```
ods graphics on;
proc mi data=Fish3 seed=1305417 out=outex8;
  class Species;
  fcs plots=trace
    logistic(Species= Height Width Height*Width /details);
  var Species Height Width;
run;
ods graphics off;
```

The “Model Information” table in [Output 57.8.1](#) describes the method and options used in the multiple imputation process. By default, a regression method is used to impute missing values in each continuous variable.

Output 57.8.1 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FISH3
Method	FCS
Number of Imputations	5
Number of Burn-in Iterations	20
Seed for random number generator	1305417

The “FCS Model Specification” table in [Output 57.8.2](#) describes methods and imputed variables in the imputation model. The procedure uses the logistic regression method to impute the variable Species, and the regression method to impute variables Height and Width.

Output 57.8.2 FCS Model Specification

FCS Model Specification	
Method	Imputed Variables
Regression	Height Width
Logistic Regression	Species

The “Missing Data Patterns” table in [Output 57.8.3](#) lists distinct missing data patterns with corresponding frequencies and percentages.

Output 57.8.3 Missing Data Patterns

Missing Data Patterns							
Group	Species	Height	Width	Freq	Percent	-----Group Means-----	
						Height	Width
1	X	X	X	40	76.92	12.627350	5.347450
2	X	X	.	1	1.92	18.037000	.
3	.	X	X	3	5.77	11.797667	4.587667
4	.	X	.	4	7.69	13.346750	.
5	.	.	X	2	3.85	.	5.135000
6	O	O	O	2	3.85	.	.

When you use the DETAILS keyword in the LOGISTIC option, parameters estimated from the observed data and the parameters used in each imputation are displayed in the “Logistic Models for FCS Method” table in [Output 57.8.4](#).

Output 57.8.4 FCS Logistic Regression Model for Species

Logistic Models for FCS Method					
Imputed Variable	Effect	-----Imputation-----			
		1	2	3	4
Species	Intercept	27.250540	27.240843	27.242699	27.254682
Species	Height	59.970974	59.962249	59.964027	59.980855
Species	Width	-26.032805	-26.021304	-26.023556	-26.028866
Species	Height*Width	-6.760308	-6.739118	-6.742934	-6.754780

Logistic Models for FCS Method		
Imputed Variable	Effect	-Imputation- 5
Species	Intercept	27.251468
Species	Height	59.971742
Species	Width	-26.033865
Species	Height*Width	-6.762477

With ODS Graphics enabled, the PLOTS=TRACE option displays trace plots of means for all continuous variables by default, as shown in [Output 57.8.5](#) and [Output 57.8.6](#). The dashed vertical lines indicate the imputed iterations—that is, the variable values used in the imputations. The plot shows no apparent trends for the two variables.

Output 57.8.5 Trace Plot for Height

Output 57.8.6 Trace Plot for Width

The following statements list the first 10 observations of the data set outex8 in [Output 57.8.7](#):

```
proc print data=outex8(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 57.8.7 Imputed Data Set

First 10 Observations of the Imputed Data Set					
Obs	_Imputation_	Species	Length	Height	Width
1	1	Bream	30.0000	11.5200	4.02000
2	1	Bream	31.2000	12.4800	4.30600
3	1	Bream	31.1000	12.3780	4.69600
4	1	Bream	33.5000	12.7300	4.45600
5	1	Pike	68.0455	12.4440	6.46920
6	1	Bream	34.7000	13.6020	4.92700
7	1	Bream	34.5000	14.1800	5.27900
8	1	Pike	35.0000	4.9290	4.69000
9	1	Bream	35.1000	14.0050	4.84400
10	1	Bream	36.2000	14.2270	4.95900

After the completion of five imputations by default, the “Variance Information” table in [Output 57.8.8](#) displays the between-imputation variance, within-imputation variance, and total variance for combining complete-data inferences for continuous variables. The relative increase in variance due to missingness, the fraction of missing information, and the relative efficiency for each variable are also displayed. These statistics are described in the section “[Combining Inferences from Multiply Imputed Data Sets](#)” on page 4769.

Output 57.8.8 Variance Information

Variance Information				
Variable	-----Variance-----			DF
	Between	Within	Total	
Height	0.003691	0.318783	0.323212	46.369
Width	0.001464	0.017777	0.019534	39.458
Variance Information				
Variable	Relative Increase in Variance	Fraction Missing Information	Relative Efficiency	
Height	0.013894	0.013797	0.997248	
Width	0.098807	0.093580	0.981628	

The “Parameter Estimates” table in [Output 57.8.9](#) displays a 95% mean confidence interval and a t statistic with its associated p -value for each of the hypotheses requested with the default MU0=0 option.

Output 57.8.9 Parameter Estimates

Parameter Estimates					
Variable	Mean	Std Error	95% Confidence Limits		DF
Height	12.710577	0.568517	11.56646	13.85470	46.369
Width	5.331652	0.139764	5.04906	5.61425	39.458
Parameter Estimates					
Variable	Minimum	Maximum	t for H0: Mu0 Mean=Mu0 Pr > t		
Height	12.677842	12.819080	0	22.36	<.0001
Width	5.287861	5.393360	0	38.15	<.0001

Example 57.9: MCMC Method

This example uses the MCMC method to impute missing values for a data set with an arbitrary missing pattern. The following statements invoke the MI procedure and specify the MCMC method with six imputations:

```
proc mi data=Fitness1 seed=21355417 nimpute=6 mu0=50 10 180 ;
  mcmc chain=multiple displayinit initial=em(itprint);
  var Oxygen RunTime RunPulse;
run;
```

The “Model Information” table in [Output 57.9.1](#) describes the method used in the multiple imputation process. When you use the CHAIN=MULTIPLE option, the procedure uses multiple chains and completes the default 200 burn-in iterations before each imputation. The 200 burn-in iterations are used to make the iterations converge to the stationary distribution before the imputation.

Output 57.9.1 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FITNESS1
Method	MCMC
Multiple Imputation Chain	Multiple Chains
Initial Estimates for MCMC	EM Posterior Mode
Start	Starting Value
Prior	Jeffreys
Number of Imputations	6
Number of Burn-in Iterations	200
Seed for random number generator	21355417

By default, the procedure uses a noninformative Jeffreys prior to derive the posterior mode from the EM algorithm as the starting values for the MCMC method.

The “Missing Data Patterns” table in [Output 57.9.2](#) lists distinct missing data patterns with corresponding statistics.

Output 57.9.2 Missing Data Patterns

Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	.	4	12.90
3	X	.	.	3	9.68
4	.	X	X	1	3.23
5	.	X	.	2	6.45

Missing Data Patterns			
-----Group Means-----			
Group	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

When you use the ITPRINT option within the INITIAL=EM option, the procedure displays the “EM (Posterior Mode) Iteration History” table in [Output 57.9.3](#).

Output 57.9.3 EM (Posterior Mode) Iteration History

EM (Posterior Mode) Iteration History				
Iteration	-2 Log L	-2 Log Posterior	Oxygen	RunTime
0	254.482800	282.909549	47.104077	10.554858
1	255.081168	282.051584	47.104077	10.554857
2	255.271408	282.017488	47.104077	10.554857
3	255.318622	282.015372	47.104002	10.554523
4	255.330259	282.015232	47.103861	10.554388
5	255.333161	282.015222	47.103797	10.554341
6	255.333896	282.015222	47.103774	10.554325
7	255.334085	282.015222	47.103766	10.554320

EM (Posterior Mode) Iteration History	
Iteration	RunPulse
0	171.381669
1	171.381652
2	171.381644
3	171.381842
4	171.382053
5	171.382150
6	171.382185
7	171.382196

When you use the `DISPLAYINIT` option in the `MCMC` statement, the “Initial Parameter Estimates for MCMC” table in [Output 57.9.4](#) displays the starting mean and covariance estimates used in the MCMC method. The same starting estimates are used in the MCMC method for multiple chains because the EM algorithm is applied to the same data set in each chain. You can explicitly specify different initial estimates for different imputations, or you can use the bootstrap method to generate different parameter estimates from the EM algorithm for the MCMC method.

Output 57.9.4 Initial Parameter Estimates

Initial Parameter Estimates for MCMC				
TYPE	_NAME_	Oxygen	RunTime	RunPulse
MEAN		47.103766	10.554320	171.382196
COV	Oxygen	24.549967	-5.726112	-15.926036
COV	RunTime	-5.726112	1.781407	3.124798
COV	RunPulse	-15.926036	3.124798	83.164045

[Output 57.9.5](#) and [Output 57.9.6](#) display variance information and parameter estimates, respectively, from the multiple imputation.

Output 57.9.5 Variance Information

Variance Information				
-----Variance-----				
Variable	Between	Within	Total	DF
Oxygen	0.051560	0.928170	0.988323	25.958
RunTime	0.003979	0.070057	0.074699	25.902
RunPulse	4.118578	4.260631	9.065638	7.5938

Variance Information			
Variable	Relative Increase in Variance	Fraction Missing Information	Relative Efficiency
Oxygen	0.064809	0.062253	0.989731
RunTime	0.066262	0.063589	0.989513
RunPulse	1.127769	0.575218	0.912517

Output 57.9.6 Parameter Estimates

Parameter Estimates					
Variable	Mean	Std Error	95% Confidence Limits		DF
Oxygen	47.164819	0.994145	45.1212	49.2085	25.958
RunTime	10.549936	0.273312	9.9880	11.1118	25.902
RunPulse	170.969836	3.010920	163.9615	177.9782	7.5938

Parameter Estimates					
Variable	Minimum	Maximum	Mu0	t for H0: Mean=Mu0	Pr > t
Oxygen	46.858020	47.363540	50.000000	-2.85	0.0084
RunTime	10.476886	10.659412	10.000000	2.01	0.0547
RunPulse	168.252615	172.894991	180.000000	-3.00	0.0182

Example 57.10: Producing Monotone Missingness with MCMC

This example uses the MCMC method to impute just enough missing values for a data set with an arbitrary missing pattern so that each imputed data set has a monotone missing pattern based on the order of variables in the VAR statement.

The following statements invoke the MI procedure and specify the IMPUTE=MONOTONE option to create the imputed data set with a monotone missing pattern. You must specify a VAR statement to provide the order of variables in order for the imputed data to achieve a monotone missing pattern.

```
proc mi data=Fitness1 seed=17655417 out=outex10;
  mcmc impute=monotone;
  var Oxygen RunTime RunPulse;
run;
```

The “Model Information” table in [Output 57.10.1](#) describes the method used in the multiple imputation process.

Output 57.10.1 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FITNESS1
Method	Monotone-data MCMC
Multiple Imputation Chain	Single Chain
Initial Estimates for MCMC	EM Posterior Mode
Start	Starting Value
Prior	Jeffreys
Number of Imputations	5
Number of Burn-in Iterations	200
Number of Iterations	100
Seed for random number generator	17655417

The “Missing Data Patterns” table in [Output 57.10.2](#) lists distinct missing data patterns with corresponding statistics. Here, an “X” means that the variable is observed in the corresponding group, a “.” means that the variable is missing and will be imputed to achieve the monotone missingness for the imputed data set, and an “O” means that the variable is missing and will not be imputed. The table also displays group-specific variable means.

Output 57.10.2 Missing Data Patterns

Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	O	4	12.90
3	X	O	O	3	9.68
4	.	X	X	1	3.23
5	.	X	O	2	6.45

Missing Data Patterns			
-----Group Means-----			
Group	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

As shown in the table in [Output 57.10.2](#), the MI procedure needs to impute only three missing values from group 4 and group 5 to achieve a monotone missing pattern for the imputed data set.

When you use the MCMC method to produce an imputed data set with a monotone missing pattern, tables of variance information and parameter estimates are not created.

The following statements are used just to show the monotone missingness of the output data set outex10:

```
proc mi data=outex10 seed=15541 nimpute=0;
  var Oxygen RunTime RunPulse;
run;
```

The “Missing Data Patterns” table in [Output 57.10.3](#) displays a monotone missing data pattern.

Output 57.10.3 Monotone Missing Data Patterns

The MI Procedure					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	110	70.97
2	X	X	.	30	19.35
3	X	.	.	15	9.68

Missing Data Patterns			
-----Group Means-----			
Group	Oxygen	RunTime	RunPulse
1	46.152428	10.861364	171.863636
2	47.796038	10.053333	.
3	52.461667	.	.

The following statements impute one value for each missing value in the monotone missingness data set outex10:

```
proc mi data=outex10 nimpute=1 seed=51343672 out=outex10a;
  monotone method=reg;
  var Oxygen RunTime RunPulse;
  by _Imputation_;
run;
```

You can then analyze these data sets by using other SAS procedures and combine these results by using the MIANALYZE procedure. Note that the VAR statement is required with a MONOTONE statement to provide the variable order for the monotone missing pattern.

Example 57.11: Checking Convergence in MCMC

This example uses the MCMC method with a single chain. It also displays trace and autocorrelation plots to check convergence for the single chain.

The following statements use the MCMC method to create an iteration plot for the successive estimates of the mean of Oxygen. These statements also create an autocorrelation function plot for the variable Oxygen.

```
ods graphics on;
proc mi data=Fitness1 seed=501213 mu0=50 10 180;
  mcmc plots=(trace(mean(Oxygen)) acf(mean(Oxygen))) ;
  var Oxygen RunTime RunPulse;
run;
ods graphics off;
```

With ODS Graphics enabled, the TRACE(MEAN(OXYGEN)) option in the PLOTS= option displays the trace plot of means for the variable Oxygen, as shown in [Output 57.11.1](#). The dashed vertical lines indicate the imputed iterations—that is, the Oxygen values used in the imputations. The plot shows no apparent trends for the variable Oxygen.

Output 57.11.1 Trace Plot for Oxygen

The ACF(MEAN(OXYGEN)) option in the PLOTS= option displays the autocorrelation plot of means for the variable Oxygen, as shown in [Output 57.11.2](#). The autocorrelation function plot shows no significant positive or negative autocorrelation.

Output 57.11.2 Autocorrelation Function Plot for Oxygen

You can also create plots for the worst linear function, the means of other variables, the variances of variables, and the covariances between variables. Alternatively, you can use the OUTITER option to save statistics such as the means, standard deviations, covariances, $-2 \log LR$ statistic, $-2 \log LR$ statistic of the posterior mode, and worst linear function from each iteration in an output data set. Then you can do a more in-depth trace (time series) analysis of the iterations with other procedures, such as PROC AUTOREG and PROC ARIMA in the *SAS/ETS User's Guide*.

For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For specific information about the graphics available in the MI procedure, see the section “[ODS Graphics](#)” on page 4775.

Example 57.12: Saving and Using Parameters for MCMC

This example uses the MCMC method with multiple chains as specified in [Example 57.9](#). It saves the parameter values used for each imputation in an output data set of type EST called `miest`. This output data set can then be used to impute missing values in other similar input data sets. The following statements invoke the MI procedure and specify the MCMC method with multiple chains to create three imputations:

```
proc mi data=Fitness1 seed=21355417 nimpute=6 mu0=50 10 180;
  mcmc chain=multiple initial=em outest=miest;
  var Oxygen RunTime RunPulse;
run;
```

The following statements list the parameters used for the imputations in [Output 57.12.1](#). Note that the data set includes observations with `_TYPE_='SEED'` which contains the seed to start the next random number generator.

```
proc print data=miest(obs=15);
  title 'Parameters for the Imputations';
run;
```

Output 57.12.1 OUTEST Data Set

Parameters for the Imputations						
Obs	_Imputation_	_TYPE_	_NAME_	Oxygen	RunTime	RunPulse

14	3	COV	RunTime	-5.25	1.66	5.00
15	3	COV	RunPulse	-19.76	5.00	110.99

The following statements invoke the MI procedure and use the `INEST=` option in the MCMC statement:

```
proc mi data=Fitness1 mu0=50 10 180;
  mcmc inest=miest;
  var Oxygen RunTime RunPulse;
run;
```

The “Model Information” table in [Output 57.12.2](#) describes the method used in the multiple imputation process. The remaining tables for the example are identical to the tables in [Output 57.9.2](#), [Output 57.9.4](#), [Output 57.9.5](#), and [Output 57.9.6](#) in [Example 57.9](#).

Output 57.12.2 Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FITNESS1
Method	MCMC
INEST Data Set	WORK.MIEST
Number of Imputations	6

Example 57.13: Transforming to Normality

This example applies the MCMC method to the Fitness1 data set in which the variable Oxygen is transformed. Assume that Oxygen is skewed and can be transformed to normality with a logarithmic transformation. The following statements invoke the MI procedure and specify the transformation. The TRANSFORM statement specifies the log transformation for Oxygen. Note that the values displayed for Oxygen in all of the results correspond to transformed values.

```
proc mi data=Fitness1 seed=32937921 mu0=50 10 180 out=outex13;
  transform log(Oxygen);
  mcmc chain=multiple displayinit;
  var Oxygen RunTime RunPulse;
run;
```

The “Missing Data Patterns” table in [Output 57.13.1](#) lists distinct missing data patterns with corresponding statistics for the Fitness1 data. Note that the values of Oxygen shown in the tables are transformed values.

Output 57.13.1 Missing Data Patterns

The MI Procedure					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	.	4	12.90
3	X	.	.	3	9.68
4	.	X	X	1	3.23

RunPulse	171.251777	172.498626	180.000000	-4.47	0.0001
* Transformed Variables					

The following statements list the first 10 observations of the data set outex13 in [Output 57.13.6](#). Note that the values for Oxygen are in the original scale.

```
proc print data=outex13(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 57.13.6 Imputed Data Set in Original Scale

First 10 Observations of the Imputed Data Set				
Obs	_Imputation_	Oxygen	RunTime	Run Pulse
1	1	44.6090	11.3700	178.000
2	1	45.3130	10.0700	185.000
3	1	54.2970	8.6500	156.000
4	1	59.5710	7.1440	167.012
5	1	49.8740	9.2200	170.092
6	1	44.8110	11.6300	176.000
7	1	38.5834	11.9500	176.000
8	1	43.7376	10.8500	158.851
9	1	39.4420	13.0800	174.000
10	1	60.0550	8.6300	170.000

Note that the results in [Output 57.13.6](#) can also be produced from the following statements without using a TRANSFORM statement. A transformed value of $\log(50)=3.91202$ is used in the MU0= option.

```
data temp;
    set Fitness1;
    LogOxygen= log(Oxygen);
run;
proc mi data=temp seed=14337921 mu0=3.91202 10 180 out=outtemp;
    mcmc chain=multiple displayinit;
    var LogOxygen RunTime RunPulse;
run;
data outex13;
    set outtemp;
    Oxygen= exp(LogOxygen);
run;
```

Example 57.14: Multistage Imputation

This example uses two separate imputation procedures to complete the imputation process. In the first case, the MI procedure statements use the MCMC method to impute just enough missing values for a data set with an arbitrary missing pattern so that each imputed data set has a monotone missing pattern. In the second case, the MI procedure statements use a MONOTONE statement to impute missing values for data sets with monotone missing patterns.

The following statements are identical to those in [Example 57.10](#). The statements invoke the MI procedure and specify the IMPUTE=MONOTONE option to create the imputed data set with a monotone missing pattern.

```
proc mi data=Fitness1 seed=17655417 out=outex14;
    mcmc impute=monotone;
    var Oxygen RunTime RunPulse;
run;
```

The “Missing Data Patterns” table in [Output 57.14.1](#) lists distinct missing data patterns with corresponding statistics. Here, an “X” means that the variable is observed in the corresponding group, a “.” means that the variable is missing and will be imputed to achieve the monotone missingness for the imputed data set, and an “O” means that the variable is missing and will not be imputed. The table also displays group-specific variable means.

Output 57.14.1 Missing Data Patterns

The MI Procedure					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	O	4	12.90
3	X	O	O	3	9.68
4	.	X	X	1	3.23
5	.	X	O	2	6.45

Missing Data Patterns			
-----Group Means-----			
Group	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

As shown in the table, the MI procedure needs to impute only three missing values from group 4 and group 5 to achieve a monotone missing pattern for the imputed data set. When the MCMC method is used to produce an imputed data set with a monotone missing pattern, tables of variance information and parameter estimates are not created.

The following statements impute one value for each missing value in the monotone missingness data set outex14:

```
proc mi data=outex14
  nimpute=1 seed=51343672
  out=outex14a;
  monotone reg;
  var Oxygen RunTime RunPulse;
  by _Imputation_;
run;
```

You can then analyze these data sets by using other SAS procedures and combine these results by using the MIANALYZE procedure. Note that the VAR statement is required with a MONOTONE statement to provide the variable order for the monotone missing pattern.

The “Model Information” table in [Output 57.14.2](#) shows that a monotone method is used to generate imputed values in the first BY group.

Output 57.14.2 Model Information

----- Imputation Number=1 -----	
The MI Procedure	
Model Information	
Data Set	WORK.OUTEX14
Method	Monotone
Number of Imputations	1
Seed for random number generator	51343672

The “Monotone Model Specification” table in [Output 57.14.3](#) describes methods and imputed variables in the imputation model. The MI procedure uses the regression method to impute the variables RunTime and RunPulse in the model.

Output 57.14.3 Monotone Model Specification

----- Imputation Number=1 -----		
Monotone Model Specification		
Method	Imputed Variables	
Regression	RunTime	RunPulse

The “Missing Data Patterns” table in [Output 57.14.4](#) lists distinct missing data patterns with corresponding statistics. It shows a monotone missing pattern for the imputed data set.

Output 57.14.4 Missing Data Patterns

----- Imputation Number=1 -----					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	22	70.97
2	X	X	.	6	19.35
3	X	.	.	3	9.68
Missing Data Patterns					
-----Group Means-----					
Group	Oxygen	RunTime	RunPulse		
1	46.057479	10.861364	171.863636		
2	46.745227	10.053333	.		
3	52.461667	.	.		

The following statements list the first 10 observations of the data set outex14a in [Output 57.14.5](#):

```
proc print data=outex14a(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 57.14.5 Imputed Data Set

First 10 Observations of the Imputed Data Set				
Obs	_Imputation_	Oxygen	RunTime	Run Pulse
1	1	44.6090	11.3700	178.000
2	1	45.3130	10.0700	185.000
3	1	54.2970	8.6500	156.000
4	1	59.5710	7.1569	169.914
5	1	49.8740	9.2200	159.315
6	1	44.8110	11.6300	176.000
7	1	39.8345	11.9500	176.000
8	1	45.3196	10.8500	151.252
9	1	39.4420	13.0800	174.000
10	1	60.0550	8.6300	170.000

This example presents an alternative to the full-data MCMC imputation, in which imputation of only a few missing values is needed to achieve a monotone missing pattern for the imputed data set. The example uses a monotone MCMC method that imputes fewer missing values in each iteration and achieves approximate stationarity in fewer iterations (Schafer 1997, p. 227). The example also demonstrates how to combine the monotone MCMC method with a method for monotone missing data, which does not rely on iterations of steps.

Overview: MIANALYZE Procedure

The MIANALYZE procedure combines the results of the analyses of imputations and generates valid statistical inferences. Multiple imputation provides a useful strategy for analyzing data sets with missing values. Instead of filling in a single value for each missing value, Rubin's (1976, 1987) multiple imputation strategy replaces each missing value with a set of plausible values that represent the uncertainty about the right value to impute.

Multiple imputation inference involves three distinct phases:

1. The missing data are filled in m times to generate m complete data sets.
2. The m complete data sets are analyzed using standard statistical analyses.
3. The results from the m complete data sets are combined to produce inferential results.

A companion procedure, PROC MI, creates multiply imputed data sets for incomplete multivariate data. It uses methods that incorporate appropriate variability across the m imputations.

The analyses of imputations are obtained by using standard SAS procedures (such as PROC REG) for complete data. No matter which complete-data analysis is used, the process of combining results from different imputed data sets is essentially the same and results in valid statistical inferences that properly reflect the uncertainty due to missing values. These results of analyses are combined in the MIANALYZE procedure to derive valid inferences.

The MIANALYZE procedure reads parameter estimates and associated standard errors or covariance matrix that are computed by the standard statistical procedure for each imputed data set. The MIANALYZE procedure then derives valid univariate inference for these parameters. With an additional assumption about the population between and within imputation covariance matrices, multivariate inference based on Wald tests can also be derived.

The MODELEFFECTS statement lists the effects to be analyzed, and the CLASS statement lists the classification variables in the MODELEFFECTS statement. The variables in the MODELEFFECTS statement that are not specified in a CLASS statement are assumed to be continuous.

When each effect in the MODELEFFECTS statement is a continuous variable by itself, a STDERR statement specifies the standard errors when both parameter estimates and associated standard errors are stored as variables in the same data set.

For some parameters of interest, you can use TEST statements to test linear hypotheses about the parameters. For others, it is not straightforward to compute estimates and associated covariance matrices with standard statistical SAS procedures. Examples include correlation coefficients between two variables and ratios of variable means. These special cases are described in the section [“Examples of the Complete-Data Inferences”](#) on page 4848.

Getting Started: MIANALYZE Procedure

The Fitness data described in the REG procedure are measurements of 31 individuals in a physical fitness course. See Chapter 79, “The REG Procedure,” for more information. The Fitness1 data set is constructed from the Fitness data set and contains three variables: Oxygen, RunTime, and RunPulse. Some values have been set to missing, and the resulting data set has an arbitrary pattern of missingness in these three variables.

```
*----- Data on Physical Fitness -----*
| These measurements were made on men involved in a physical |
| fitness course at N.C. State University.                    |
| Only selected variables of                                  |
| Oxygen (oxygen intake, ml per kg body weight per minute),  |
| Runtime (time to run 1.5 miles in minutes), and            |
| RunPulse (heart rate while running) are used.              |
| Certain values were changed to missing for the analysis.   |

48.673 9.40 186      47.920 11.50 170
47.467 10.50 170
;
```

Suppose that the data are multivariate normally distributed and that the missing data are missing at random (see the “Statistical Assumptions for Multiple Imputation” section in the chapter “The MI Procedure” for a description of these assumptions). The following statements use the MI procedure to impute missing values for the Fitness1 data set:

```
proc mi data=Fitness1 seed=3237851 noprint out=outmi;
  var Oxygen RunTime RunPulse;
run;
```

The MI procedure creates imputed data sets, which are stored in the outmi data set. A variable named `_Imputation_` indicates the imputation numbers. Based on m imputations, m different sets of the point and variance estimates for a parameter can be computed. In this example, $m = 5$ is the default.

The following statements generate regression coefficients for each of the five imputed data sets:

```
proc reg data=outmi outest=outreg covout noprint;
  model Oxygen= RunTime RunPulse;
  by _Imputation_;
run;
```

The following statements display (in [Figure 58.1](#)) output parameter estimates and covariance matrices from PROC REG for the first two imputed data sets:

```
proc print data=outreg (obs=8);
  var _Imputation_ _Type_ _Name_
      Intercept RunTime RunPulse;
  title 'Parameter Estimates from Imputed Data Sets';
run;
```

8	2	COV	RunPulse	-0.419	-0.00313	0.00264

The following statements combine the five sets of regression coefficients:

```
proc mianalyze data=outreg;
  modeleffects Intercept RunTime RunPulse;
run;
```

The “Model Information” table in [Figure 58.2](#) lists the input data set(s) and the number of imputations.

Figure 58.2 Model Information Table

The MIANALYZE Procedure	
Model Information	
Data Set	WORK.OUTREG
Number of Imputations	5

The “Variance Information” table in [Figure 58.3](#) displays the between-imputation, within-imputation, and total variances for combining complete-data inferences. It also displays the degrees of freedom for the total variance, the relative increase in variance due to missing values, the fraction of missing information, and the relative efficiency for each parameter estimate.

Figure 58.3 Variance Information Table

Variance Information				
-----Variance-----				
Parameter	Between	Within	Total	DF
Intercept	45.529229	76.543614	131.178689	23.059
RunTime	0.019390	0.106220	0.129487	123.88
RunPulse	0.001007	0.002537	0.003746	38.419

Variance Information			
Parameter	Relative Increase in Variance	Fraction Missing Information	Relative Efficiency
Intercept	0.713777	0.461277	0.915537
RunTime	0.219051	0.192620	0.962905
RunPulse	0.476384	0.355376	0.933641

The “Parameter Estimates” table in [Figure 58.4](#) displays a combined estimate and standard error for each regression coefficient (parameter). Inferences are based on t distributions. The table displays a 95% confidence interval and a t test with the associated p -value for the hypothesis that the parameter is equal to the value specified with the THETA0= option (in this case, zero by default). The minimum and maximum parameter estimates from the imputed data sets are also displayed.

Figure 58.4 Parameter Estimates

Parameter Estimates					
Parameter	Estimate	Std Error	95% Confidence Limits		DF
Intercept	90.837440	11.453327	67.14779	114.5271	23.059

Syntax: MIANALYZE Procedure

The following statements are available in the MIANALYZE procedure:

```
PROC MIANALYZE < options > ;
    BY variables ;
    CLASS variables ;
    MODELEFFECTS effects ;
    < label > TEST equation1 < , ... , < equationk > > < / options > ;
    STDERR variables ;
```

The BY statement specifies groups in which separate analyses are performed.

The CLASS statement lists the classification variables in the MODELEFFECTS statement. Classification variables can be either character or numeric.

The required MODELEFFECTS statement lists the effects to be analyzed. The variables in the statement that are not specified in a CLASS statement are assumed to be continuous.

The STDERR statement lists the standard errors associated with the effects in the MODELEFFECTS statement when both parameter estimates and standard errors are saved as variables in the same DATA= data set. The STDERR statement can be used only when each effect in the MODELEFFECTS statement is a continuous variable by itself.

The TEST statement tests linear hypotheses about the parameters. An F statistic is used to jointly test the null hypothesis ($H_0 : \mathbf{L}_\epsilon = \mathbf{c}$) specified in a single TEST statement. Several TEST statements can be used.

The PROC MIANALYZE and MODELEFFECTS statements are required for the MIANALYZE procedure. The rest of this section provides detailed syntax information for each of these statements, beginning with the PROC MIANALYZE statement. The remaining statements are in alphabetical order.

PROC MIANALYZE Statement

```
PROC MIANALYZE < options > ;
```

The PROC MIANALYZE statement invokes the MIANALYZE procedure. [Table 58.1](#) summarizes the options available in the PROC MIANALYZE statement.

Table 58.1 Summary of PROC MIANALYZE Options

Option	Description
Input Data Sets	
DATA=	Specifies the COV, CORR, or EST type data set
DATA=	Specifies the data set for parameter estimates and standard errors
PARMS=	Specifies the data set for parameter estimates
PARMINFO=	Specifies the data set for parameter information
COVB=	Specifies the data set for covariance matrices
XPXI=	Specifies the data set for $(\mathbf{X}'\mathbf{X})^{-1}$ matrices

Table 58.1 *continued*

Option	Description
Statistical Analysis	
THETA0=	Specifies parameters under the null hypothesis
ALPHA=	Specifies the level for the confidence interval
EDF=	Specifies the complete-data degrees of freedom
Printed Output	
WCOV	Displays the within-imputation covariance matrix
BCOV	Displays the between-imputation covariance matrix
TCOV	Displays the total covariance matrix
MULT	Displays multivariate inferences

The following options can be used in the PROC MIANALYZE statement. They are listed in alphabetical order.

ALPHA= α

specifies that confidence limits are to be constructed for the parameter estimates with confidence level $100(1 - \alpha)\%$, where $0 < \alpha < 1$. The default is ALPHA=0.05.

BCOV

displays the between-imputation covariance matrix.

COVB <(EFFECTVAR=STACKING | ROWCOL)> =SAS-data-set

names an input SAS data set that contains covariance matrices of the parameter estimates from imputed data sets. If you provide a COVB= data set, you must also provide a PARMS= data set.

The EFFECTVAR= option identifies the variables for parameters displayed in the covariance matrix and is used only when the PARMINFO= option is not specified. The default is EFFECTVAR= STACKING.

See the section “[Input Data Sets](#)” on page 4840 for a detailed description of the COVB= option.

DATA=SAS-data-set

names an input SAS data set.

If the input DATA= data set is not a specially structured SAS data set, the data set contains both the parameter estimates and associated standard errors. The parameter estimates are specified in the MODELEFFECTS statement and the standard errors are specified in the STDERR statement.

If the data set is a specially structured input SAS data set, it must have a TYPE of EST, COV, or CORR that contains estimates from imputed data sets:

- If TYPE=EST, the data set contains the parameter estimates and associated covariance matrices.
- If TYPE=COV, the data set contains the sample means, sample sizes, and covariance matrices. Each covariance matrix for variables is divided by the sample size n to create the covariance matrix for parameter estimates.
- If TYPE=CORR, the data set contains the sample means, sample sizes, standard errors, and correlation matrices. The covariance matrices are computed from the correlation matrices and associated standard errors. Each covariance matrix for variables is divided by the sample size n to create the covariance matrix for parameter estimates.

If you do not specify an input data set with the DATA= or PARMS= option, then the most recently created SAS data set is used as an input DATA= data set. See the section “[Input Data Sets](#)” on page 4840 for a detailed description of the input data sets.

EDF=number

specifies the complete-data degrees of freedom for the parameter estimates. This is used to compute an adjusted degrees of freedom for each parameter estimate. By default, EDF= ∞ and the degrees of freedom for each parameter estimate are not adjusted.

MULT

MULTIVARIATE

requests multivariate inference for the parameters. It is based on Wald tests and is a generalization of the univariate inference. See the section “[Multivariate Inferences](#)” on page 4845 for a detailed description of the multivariate inference.

PARMINFO=SAS-data-set

names an input SAS data set that contains parameter information associated with variables PRM1, PRM2, . . . , and so on. These variables are used as variables for parameters in a COVB= data set. See the section “[Input Data Sets](#)” on page 4840 for a detailed description of the PARMINFO= option.

PARMS <(CLASSVAR= ctype)> =SAS-data-set

names an input SAS data set that contains parameter estimates computed from imputed data sets. When a COVB= data set is not specified, the input PARMS= data set also contains standard errors associated with these parameter estimates. If multivariate inference is requested, you must also provide a COVB= or XPXI= data set.

When the effects contain classification variables, the option CLASSVAR= *ctype* can be used to identify the associated classification variables when reading the classification levels from observations. The available types are FULL, LEVEL, and CLASSVAL. The default is CLASSVAR= FULL. See the section “[Input Data Sets](#)” on page 4840 for a detailed description of the PARMS= option.

TCOV

displays the total covariance matrix derived by assuming that the population between-imputation and within-imputation covariance matrices are proportional to each other.

THETA0=numbers

MU0=numbers

specifies the parameter values θ_0 under the null hypothesis $\theta = \theta_0$ in the t tests for location for the effects. If only one number θ_0 is specified, that number is used for all effects. If more than one number is specified, the specified numbers correspond to effects in the MODELEFFECTS statement in the order in which they appear in the statement. When an effect contains classification variables, the corresponding value is not used and the test is not performed.

WCOV

displays the within-imputation covariance matrices.

XPXI=SAS-data-set

names an input SAS data set that contains the $(X'X)^{-1}$ matrices associated with the parameter estimates computed from imputed data sets. If you provide an XPXI= data set, you must also provide a PARMS= data set. In this case, PROC MIANALYZE reads the standard errors of the estimates from the PARMS= data. The standard errors and $(X'X)^{-1}$ matrices are used to derive the covariance matrices.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC MIANALYZE to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the MIANALYZE procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* ;

The CLASS statement specifies the classification variables in the MODELEFFECTS statement. Classification variables can be either character or numeric. Classification levels are determined from the formatted values of the classification variables. See “The FORMAT Procedure” in the *Base SAS Procedures Guide* for details.

MODELEFFECTS Statement

MODELEFFECTS *effects* ;

The MODELEFFECTS statement lists the effects in the data set to be analyzed. Each effect is a variable or a combination of variables, and is specified with a special notation that uses variable names and operators.

Each variable is either a classification (or CLASS) variable or a continuous variable. If a variable is not declared in the CLASS statement, it is assumed to be continuous. Crossing and nesting operators can be used in an effect to create crossed and nested effects.

One general form of an effect involving several variables is

$$X1 * X2 * A * B * C (D E)$$

where A, B, C, D, and E are classification variables and X1 and X2 are continuous variables.

When the input DATA= data set is not a specially structured SAS data set, you must also specify standard errors of the parameter estimates in an STDERR statement.

STDERR Statement

STDERR *variables* ;

The STDERR statement lists standard errors associated with effects in the MODELEFFECTS statement, when the input DATA= data set contains both parameter estimates and standard errors as variables in the data set.

With the STDERR statement, only continuous effects are allowed in the MODELEFFECTS statement. The specified standard errors correspond to parameter estimates in the order in which they appear in the MODELEFFECTS statement.

For example, you can use the following MODELEFFECTS and STDERR statements to identify both the parameter estimates and associated standard errors in a SAS data set:

```
proc mianalyze;
  modeleffects y1-y3;
  stderr sy1-sy3;
run;
```

TEST Statement

<label> **TEST** *equation1* <, ..., <equationk>> </options> ;

The TEST statement tests linear hypotheses about the parameters β . An F test is used to jointly test the null hypotheses ($H_0 : \mathbf{L}\beta = \mathbf{c}$) specified in a single TEST statement in which the MULT option is specified.

Each *equation* specifies a linear hypothesis (a row of the \mathbf{L} matrix and the corresponding element of the \mathbf{c} vector); multiple *equations* are separated by commas. The label, which must be a valid SAS name, is used to identify the resulting output. You can submit multiple TEST statements. When a label is not included in a TEST statement, a label of “Test j ” is used for the j th TEST statement.

The form of an *equation* is as follows:

term < \pm *term* ... > <= \pm *term* < \pm *term* ... > >

where *term* is a parameter of the model, or a constant, or a constant times a parameter. When no equal sign appears, the expression is set to 0. Only parameters for regressor effects (continuous variables by themselves) are allowed.

For each TEST statement, PROC MIANALYZE displays a “Test Specification” table of the \mathbf{L} matrix and the \mathbf{c} vector. The procedure also displays a “Variance Information” table of the between-imputation, within-imputation, and total variances for combining complete-data inferences, and a “Parameter Estimates” table of a combined estimate and standard error for each linear component. The linear components are labeled TestPrm1, TestPrm2, ... in the tables.

The following statements illustrate possible uses of the TEST statement:

```

proc mianalyze;
  modeleffects intercept a1 a2 a3;
  test1: test intercept + a2 = 0;
  test2: test intercept + a2;
  test3: test a1=a2=a3;
  test4: test a1=a2, a2=a3;
run;

```

The first and second TEST statements are equivalent and correspond to the specification in [Figure 58.5](#).

Figure 58.5 Test Specification for test1 and test2

The MIANALYZE Procedure					
Test: test1					
Test Specification					
-----L Matrix-----					
Parameter	intercept	a1	a2	a3	C
TestPrm1	1.000000	0	1.000000	0	0

The third and fourth TEST statements are also equivalent and correspond to the specification in [Figure 58.6](#).

Figure 58.6 Test Specification for test3 and test4

The MIANALYZE Procedure					
Test: test3					
Test Specification					
-----L Matrix-----					
Parameter	intercept	a1	a2	a3	C
TestPrm1	0	1.000000	-1.000000	0	0
TestPrm2	0	0	1.000000	-1.000000	0

The ALPHA= and EDF options specified in the PROC MIANALYZE statement are also applied to the TEST statement. You can specify the following options in the TEST statement after a slash(/):

BCOV

displays the between-imputation covariance matrix.

MULT

displays the multivariate inference for parameters.

TCOV

displays the total covariance matrix.

WCOV

displays the within-imputation covariance matrix.

For more information, see the section “[Testing Linear Hypotheses about the Parameters](#)” on page 4847.

Details: MIANALYZE Procedure

Input Data Sets

You specify input data sets based on the type of inference you requested. For univariate inference, you can use one of the following options:

- a DATA= data set, which provides both parameter estimates and the associated standard errors
- a DATA=EST, COV, or CORR data set, which provides both parameter estimates and the associated standard errors either explicitly (type CORR) or through the covariance matrix (type EST, COV)
- PARMS= data set, which provides both parameter estimates and the associated standard errors

For multivariate inference, which includes the testing of linear hypotheses about parameters, you can use one of the following option combinations:

- a DATA=EST, COV, or CORR data set, which provides parameter estimates and the associated covariance matrix either explicitly (type EST, COV) or through the correlation matrix and standard errors (type CORR) in a single data set
- PARMS= and COVB= data sets, which provide parameter estimates in a PARMS= data set and the associated covariance matrix in a COVB= data set
- PARMS=, COVB=, and PARMINFO= data sets, which provide parameter estimates in a PARMS= data set, the associated covariance matrix in a COVB= data set with variables named PRM1, PRM2, ..., and the effects associated with these variables in a PARMINFO= data set
- PARMS= and XPXI= data sets, which provide parameter estimates and the associated standard errors in a PARMS= data set and the associated $(\mathbf{X}'\mathbf{X})^{-1}$ matrix in an XPXI= data set

The appropriate combination depends on the type of inference and the SAS procedure you used to create the data sets. For instance, if you used PROC REG to create an OUTEST= data set that contains the parameter estimates and covariance matrix, you would use the DATA= option to read the OUTEST= data set.

When the input DATA= data set is a specially structured SAS data set, the data set must contain the variable `_Imputation_` to identify the imputation by number. Otherwise, each observation corresponds to an imputation and contains both parameter estimates and associated standard errors.

If you do not specify an input data set with the DATA= or PARMS= option, then the most recently created SAS data set is used as an input DATA= data set. Note that with a DATA= data set, each effect represents a continuous variable; only regressor effects (continuous variables by themselves) are allowed in the MODELEFFECTS statement.

DATA= SAS Data Set

The DATA= data set provides both parameter estimates and the associated standard errors computed from imputed data sets. Such data sets are typically created with an OUTPUT statement in procedures such as PROC MEANS and PROC UNIVARIATE.

The MIANALYZE procedure reads parameter estimates from observations with variables in the MODEL-EFFECTS statement, and standard errors for parameter estimates from observations with variables in the STDERR statement. The order of the variables for standard errors must match the order of the variables for parameter estimates.

DATA=EST, COV, or CORR SAS Data Set

The specially structured DATA= data set provides both parameter estimates and the associated covariance matrix computed from imputed data sets. Such data sets are created by procedures such as PROC CORR (type COV, CORR) and PROC REG (type EST).

With TYPE=EST, the MIANALYZE procedure reads parameter estimates from observations with `_TYPE_='PARM'`, `_TYPE_='PARMS'`, `_TYPE_='OLS'`, or `_TYPE_='FINAL'`, and covariance matrices for parameter estimates from observations with `_TYPE_='COV'` or `_TYPE_='COVB'`.

With TYPE=COV, the procedure reads sample means from observations with `_TYPE_='MEAN'`, sample size n from observations with `_TYPE_='N'`, and covariance matrices for variables from observations with `_TYPE_='COV'`.

With TYPE=CORR, the procedure reads sample means from observations with `_TYPE_='MEAN'`, sample size n from observations with `_TYPE_='N'`, correlation matrices for variables from observations with `_TYPE_='CORR'`, and standard errors for variables from observations with `_TYPE_='STD'`. The standard errors and correlation matrix are used to generate a covariance matrix for the variables.

Note that with TYPE=COV or CORR, each covariance matrix for the variables is divided by n to create the covariance matrix for the sample means.

PARMS <(CLASSVAR= ctype)> = Data Set

The PARMS= data set contains both parameter estimates and the associated standard errors computed from imputed data sets. Such data sets are typically created with an ODS OUTPUT statement in procedures such as PROC GENMOD, PROC GLM, PROC LOGISTIC, and PROC MIXED.

The MIANALYZE procedure reads effect names from observations with the variable Parameter, Effect, Variable, or Parm. It then reads parameter estimates from observations with the variable Estimate and standard errors for parameter estimates from observations with the variable StdErr.

When the effects contain classification variables, the option CLASSVAR= *ctype* can be used to identify associated classification variables when reading the classification levels from observations. The available types are FULL, LEVEL, and CLASSVAL. The default is CLASSVAR= FULL.

With CLASSVAR=FULL, the data set contains the classification variables explicitly. PROC MIANALYZE reads the classification levels from observations with their corresponding classification variables. PROC MIXED generates this type of table.

With CLASSVAR=LEVEL, PROC MIANALYZE reads the classification levels for the effect from observations with variables Level1, Level2, and so on, where the variable Level1 contains the classification level

for the first classification variable in the effect, and the variable `Level2` contains the classification level for the second classification variable in the effect. For each effect, the variables in the crossed list are displayed before the variables in the nested list. The variable order in the `CLASS` statement is used for variables inside each list. PROC GENMOD generates this type of table.

For example, with the following statements, the variable `Level1` has the classification level of the variable `c2` for the effect `c2`:

```
proc mianalyze parms(classvar=Level)= dataparm;
  class c1 c2 c3;
  modeleffects c2 c3(c2 c1);
run;
```

For the effect `c3(c2 c1)`, the variable `Level1` has the classification level of the variable `c3`, `Level2` has the level of `c1`, and `Level3` has the level of `c2`.

Similarly, with `CLASSVAR=CLASSVAL`, PROC MIANALYZE reads the classification levels for the effect from observations with variables `ClassVal0`, `ClassVal1`, and so on, where the variable `ClassVal0` contains the classification level for the first classification variable in the effect, and the variable `ClassVal1` contains the classification level for the second classification variable in the effect. For each effect, the variables in the crossed list are displayed before the variables in the nested list. The variable order in the `CLASS` statement is used for variables inside each list. PROC LOGISTIC generates this type of tables.

PARMS <(CLASSVAR= *ctype*)> = and COVB= Data Sets

The `PARMS=` data set contains parameter estimates, and the `COVB=` data set contains associated covariance matrices computed from imputed data sets. Such data sets are typically created with an ODS OUTPUT statement in procedures such as PROC LOGISTIC, PROC MIXED, and PROC REG.

With a `PARMS=` data set, the MIANALYZE procedure reads effect names from observations with the variable `Parameter`, `Effect`, `Variable`, or `Parm`. It then reads parameter estimates from observations with the variable `Estimate`.

When the effects contain classification variables, the option `CLASSVAR= ctype` can be used to identify the associated classification variables when reading the classification levels from observations. The available types are `FULL`, `LEVEL`, and `CLASSVAL`, and they are described in the section “[PARMS <\(CLASSVAR= *ctype*\)> = Data Set](#)” on page 4841. The default is `CLASSVAR= FULL`.

The option `EFFECTVAR= etype` identifies the variables for parameters displayed in the covariance matrix. The available types are `STACKING` and `ROWCOL`. The default is `EFFECTVAR=STACKING`.

With `EFFECTVAR=STACKING`, each parameter is displayed by stacking variables in the effect. Begin with the variables in the crossed list, followed by the continuous list, then followed by the nested list. Each classification variable is displayed with its classification level attached. PROC LOGISTIC generates this type of table.

When each effect is a continuous variable by itself, each stacked parameter name reduces to the effect name. PROC REG generates this type of table.

With `EFFECTVAR=STACKING`, the MIANALYZE procedure reads parameter names from observations with the variable `Parameter`, `Effect`, `Variable`, `Parm`, or `RowName`. It then reads covariance matrices from observations with the stacked variables in a `COVB=` data set.

With `EFFECTVAR=ROWCOL`, parameters are displayed by the variables `Col1`, `Col2`, ... The parameter associated with the variable `Col1` is identified by the observation with value 1 for the variable `Row`. The parameter associated with the variable `Col2` is identified by the observation with value 2 for the variable `Row`. PROC MIXED generates this type of table.

With `EFFECTVAR=ROWCOL`, the MIANALYZE procedure reads the parameter indices from observations with the variable `Row` and the effect names from observations with the variable `Parameter`, `Effect`, `Variable`, `Parm`, or `RowName`. It then reads covariance matrices from observations with the variables `Col1`, `Col2`, and so on in a `COVB=` data set.

When the effects contain classification variables, the data set contains the classification variables explicitly and the MIANALYZE procedure also reads the classification levels from their corresponding classification variables.

PARMS <(CLASSVAR= *ctype*)> =, PARMINFO=, and COVB= Data Sets

The input `PARMS=` data set contains parameter estimates and the input `COVB=` data set contains associated covariance matrices computed from imputed data sets. Such data sets are typically created with an ODS OUTPUT statement using procedure such as PROC GENMOD.

With a `PARMS=` data set, the MIANALYZE procedure reads effect names from observations with the variable `Parameter`, `Effect`, `Variable`, or `Parm`. It then reads parameter estimates from observations with the variable `Estimate`.

When the effects contain classification variables, the option `CLASSVAR= ctype` can be used to identify the associated classification variables when reading the classification levels from observations. The available types are `FULL`, `LEVEL`, and `CLASSVAL`, and they are described in the section “[PARMS <\(CLASSVAR= *ctype*\)> = Data Set](#)” on page 4841. The default is `CLASSVAR= FULL`.

With a `COVB=` data set, the MIANALYZE procedure reads parameter names from observations with the variable `Parameter`, `Effect`, `Variable`, `Parm`, or `RowName`. It then reads covariance matrices from observations with the variables `Prm1`, `Prm2`, and so on.

The parameters associated with the variables `Prm1`, `Prm2`, and so on are identified in the `PARMINFO=` data set. PROC MIANALYZE reads the parameter names from observations with the variable `Parameter` and the corresponding effect from observations with the variable `Effect`. When the effects contain classification variables, the data set contains the classification variables explicitly and the MIANALYZE procedure also reads the classification levels from observations with their corresponding classification variables.

PARMS= and XPXI= Data Sets

The input `PARMS=` data set contains parameter estimates, and the input `XPXI=` data set contains associated $(X'X)^{-1}$ matrices computed from imputed data sets. Such data sets are typically created with an ODS OUTPUT statement in a procedure such as PROC GLM.

With a `PARMS=` data set, the MIANALYZE procedure reads parameter names from observations with the variable `Parameter`, `Effect`, `Variable`, or `Parm`. It then reads parameter estimates from observations with the variable `Estimate` and standard errors for parameter estimates from observations with the variable `StdErr`.

With a `XPXI=` data set, the MIANALYZE procedure reads parameter names from observations with the variable `Parameter` and $(X'X)^{-1}$ matrices from observations with the parameter variables in the data set.

Note that this combination can be used only when each effect is a continuous variable by itself.

Combining Inferences from Imputed Data Sets

With m imputations, m different sets of the point and variance estimates for a parameter Q can be computed. Suppose that \hat{Q}_i and \hat{W}_i are the point and variance estimates, respectively, from the i th imputed data set, $i = 1, 2, \dots, m$. Then the combined point estimate for Q from multiple imputation is the average of the m complete-data estimates:

$$\overline{Q} = \frac{1}{m} \sum_{i=1}^m \hat{Q}_i$$

Suppose that \overline{W} is the within-imputation variance, which is the average of the m complete-data estimates:

$$\overline{W} = \frac{1}{m} \sum_{i=1}^m \hat{W}_i$$

And suppose that B is the between-imputation variance:

$$B = \frac{1}{m-1} \sum_{i=1}^m (\hat{Q}_i - \overline{Q})^2$$

Then the variance estimate associated with \overline{Q} is the total variance (Rubin 1987)

$$T = \overline{W} + (1 + \frac{1}{m})B$$

The statistic $(Q - \overline{Q})T^{-(1/2)}$ is approximately distributed as t with v_m degrees of freedom (Rubin 1987), where

$$v_m = (m-1) \left[1 + \frac{\overline{W}}{(1 + m^{-1})B} \right]^2$$

The degrees of freedom v_m depend on m and the ratio

$$r = \frac{(1 + m^{-1})B}{\overline{W}}$$

The ratio r is called the relative increase in variance due to nonresponse (Rubin 1987). When there is no missing information about Q , the values of r and B are both zero. With a large value of m or a small value of r , the degrees of freedom v_m will be large and the distribution of $(Q - \overline{Q})T^{-(1/2)}$ will be approximately normal.

Another useful statistic is the fraction of missing information about Q :

$$\hat{\lambda} = \frac{r + 2/(v_m + 3)}{r + 1}$$

Both statistics r and λ are helpful diagnostics for assessing how the missing data contribute to the uncertainty about Q .

When the complete-data degrees of freedom v_0 are small, and there is only a modest proportion of missing data, the computed degrees of freedom, v_m , can be much larger than v_0 , which is inappropriate. For example, with $m = 5$ and $r = 10\%$, the computed degrees of freedom $v_m = 484$, which is inappropriate for data sets with complete-data degrees of freedom less than 484.

Barnard and Rubin (1999) recommend the use of adjusted degrees of freedom

$$v_m^* = \left[\frac{1}{v_m} + \frac{1}{\hat{v}_{obs}} \right]^{-1}$$

where $\hat{v}_{obs} = (1 - \gamma) v_0(v_0 + 1)/(v_0 + 3)$ and $\gamma = (1 + m^{-1})B/T$.

If you specify the complete-data degrees of freedom v_0 with the EDF= option, the MIANALYZE procedure uses the adjusted degrees of freedom, v_m^* , for inference. Otherwise, the degrees of freedom v_m are used.

Multiple Imputation Efficiency

The relative efficiency (RE) of using the finite m imputation estimator, rather than using an infinite number for the fully efficient imputation, in units of variance, is approximately a function of m and λ (Rubin 1987, p. 114):

$$RE = \left(1 + \frac{\lambda}{m}\right)^{-1}$$

Table 58.2 shows relative efficiencies with different values of m and λ .

Table 58.2 Relative Efficiencies

m	λ				
	10%	20%	30%	50%	70%
3	0.9677	0.9375	0.9091	0.8571	0.8108
5	0.9804	0.9615	0.9434	0.9091	0.8772
10	0.9901	0.9804	0.9709	0.9524	0.9346
20	0.9950	0.9901	0.9852	0.9756	0.9662

The table shows that for situations with little missing information, only a small number of imputations are necessary. In practice, the number of imputations needed can be informally verified by replicating sets of m imputations and checking whether the estimates are stable between sets (Horton and Lipsitz 2001, p. 246).

Multivariate Inferences

Multivariate inference based on Wald tests can be done with m imputed data sets. The approach is a generalization of the approach taken in the univariate case (Rubin 1987, p. 137; Schafer 1997, p. 113). Suppose that $\hat{\mathbf{Q}}_i$ and $\hat{\mathbf{W}}_i$ are the point and covariance matrix estimates for a p -dimensional parameter \mathbf{Q} (such as a

multivariate mean) from the i th imputed data set, $i = 1, 2, \dots, m$. Then the combined point estimate for \mathbf{Q} from the multiple imputation is the average of the m complete-data estimates:

$$\bar{\mathbf{Q}} = \frac{1}{m} \sum_{i=1}^m \hat{\mathbf{Q}}_i$$

Suppose that $\bar{\mathbf{W}}$ is the within-imputation covariance matrix, which is the average of the m complete-data estimates:

$$\bar{\mathbf{W}} = \frac{1}{m} \sum_{i=1}^m \hat{\mathbf{W}}_i$$

And suppose that \mathbf{B} is the between-imputation covariance matrix:

$$\mathbf{B} = \frac{1}{m-1} \sum_{i=1}^m (\hat{\mathbf{Q}}_i - \bar{\mathbf{Q}})(\hat{\mathbf{Q}}_i - \bar{\mathbf{Q}})'$$

Then the covariance matrix associated with $\bar{\mathbf{Q}}$ is the total covariance matrix

$$\mathbf{T}_0 = \bar{\mathbf{W}} + (1 + \frac{1}{m})\mathbf{B}$$

The natural multivariate extension of the t statistic used in the univariate case is the F statistic

$$F_0 = (\mathbf{Q} - \bar{\mathbf{Q}})' \mathbf{T}_0^{-1} (\mathbf{Q} - \bar{\mathbf{Q}})$$

with degrees of freedom p and

$$v = (m-1)(1 + 1/r)^2$$

where

$$r = (1 + \frac{1}{m}) \text{trace}(\mathbf{B}\bar{\mathbf{W}}^{-1})/p$$

is an average relative increase in variance due to nonresponse (Rubin 1987, p. 137; Schafer 1997, p. 114).

However, the reference distribution of the statistic F_0 is not easily derived. Especially for small m , the between-imputation covariance matrix \mathbf{B} is unstable and does not have full rank for $m \leq p$ (Schafer 1997, p. 113).

One solution is to make an additional assumption that the population between-imputation and within-imputation covariance matrices are proportional to each other (Schafer 1997, p. 113). This assumption implies that the fractions of missing information for all components of \mathbf{Q} are equal. Under this assumption, a more stable estimate of the total covariance matrix is

$$\mathbf{T} = (1 + r)\bar{\mathbf{W}}$$

With the total covariance matrix \mathbf{T} , the F statistic (Rubin 1987, p. 137)

$$F = (\mathbf{Q} - \bar{\mathbf{Q}})' \mathbf{T}^{-1} (\mathbf{Q} - \bar{\mathbf{Q}})/p$$

has an F distribution with degrees of freedom p and v_1 , where

$$v_1 = \frac{1}{2}(p+1)(m-1)\left(1 + \frac{1}{r}\right)^2$$

For $t = p(m-1) \leq 4$, PROC MIANALYZE uses the degrees of freedom v_1 in the analysis. For $t = p(m-1) > 4$, PROC MIANALYZE uses v_2 , a better approximation of the degrees of freedom given by Li, Raghunathan, and Rubin (1991):

$$v_2 = 4 + (t-4) \left[1 + \frac{1}{r} \left(1 - \frac{2}{t} \right) \right]^2$$

Testing Linear Hypotheses about the Parameters

Linear hypotheses for parameters β are expressed in matrix form as

$$H_0 : \mathbf{L}\beta = \mathbf{c}$$

where \mathbf{L} is a matrix of coefficients for the linear hypotheses and \mathbf{c} is a vector of constants.

Suppose that $\hat{\mathbf{Q}}_i$ and $\hat{\mathbf{U}}_i$ are the point and covariance matrix estimates, respectively, for a p -dimensional parameter \mathbf{Q} from the i th imputed data set, $i=1, 2, \dots, m$. Then for a given matrix \mathbf{L} , the point and covariance matrix estimates for the linear functions \mathbf{LQ} in the i th imputed data set are, respectively,

$$\mathbf{L}\hat{\mathbf{Q}}_i$$

$$\mathbf{L}\hat{\mathbf{U}}_i\mathbf{L}'$$

The inferences described in the section “[Combining Inferences from Imputed Data Sets](#)” on page 4844 and the section “[Multivariate Inferences](#)” on page 4845 are applied to these linear estimates for testing the null hypothesis $H_0 : \mathbf{L}\beta = \mathbf{c}$.

For each TEST statement, the “Test Specification” table displays the \mathbf{L} matrix and the \mathbf{c} vector, the “Variance Information” table displays the between-imputation, within-imputation, and total variances for combining complete-data inferences, and the “Parameter Estimates” table displays a combined estimate and standard error for each linear component.

With the WCOV and BCOV options in the TEST statement, the procedure displays the within-imputation and between-imputation covariance matrices, respectively.

With the TCOV option, the procedure displays the total covariance matrix derived under the assumption that the population between-imputation and within-imputation covariance matrices are proportional to each other.

With the MULT option in the TEST statement, the “Multivariate Inference” table displays an F test for the null hypothesis $\mathbf{L}\beta = \mathbf{c}$ of the linear components.

Examples of the Complete-Data Inferences

For a given parameter of interest, it is not always possible to compute the estimate and associated covariance matrix directly from a SAS procedure. This section describes examples of parameters with their estimates and associated covariance matrices, which provide the input to the MIANALYZE procedure. Some are straightforward, and others require special techniques.

Means

For a population mean vector μ , the usual estimate is the sample mean vector

$$\bar{y} = \frac{1}{n} \sum y_i$$

A variance estimate for \bar{y} is $\frac{1}{n}S$, where S is the sample covariance matrix

$$S = \frac{1}{n-1} \sum (y_i - \bar{y})(y_i - \bar{y})'$$

These statistics can be computed from a procedure such as PROC CORR. This approach is illustrated in [Example 58.2](#).

Regression Coefficients

Many SAS procedures are available for regression analysis. Among them, PROC REG provides the most general analysis capabilities, and others like PROC LOGISTIC and PROC MIXED provide more specialized analyses.

Some regression procedures, such as REG and LOGISTIC, create an EST type data set that contains both the parameter estimates for the regression coefficients and their associated covariance matrix. You can read an EST type data set in the MIANALYZE procedure with the DATA= option. This approach is illustrated in [Example 58.3](#).

Other procedures, such as GLM, MIXED, and GENMOD, do not generate EST type data sets for regression coefficients. For PROC MIXED and PROC GENMOD, you can use ODS OUTPUT statement to save parameter estimates in a data set and the associated covariance matrix in a separate data set. These data sets are then read in the MIANALYZE procedure with the PARMS= and COVB= options, respectively. This approach is illustrated in [Example 58.4](#) for PROC MIXED and in [Example 58.5](#) for PROC GENMOD.

PROC GLM does not display tables for covariance matrices. However, you can use the ODS OUTPUT statement to save parameter estimates and associated standard errors in a data set and the associated $(X'X)^{-1}$ matrix in a separate data set. These data sets are then read in the MIANALYZE procedure with the PARMS= and XPXI= options, respectively. This approach is illustrated in [Example 58.6](#).

For univariate inference, only parameter estimates and associated standard errors are needed. You can use the ODS OUTPUT statement to save parameter estimates and associated standard errors in a data set. This data set is then read in the MIANALYZE procedure with the PARMS= option. This approach is illustrated in [Example 58.4](#).

Correlation Coefficients

For the population correlation coefficient ρ , a point estimate is the sample correlation coefficient r . However, for nonzero ρ , the distribution of r is skewed.

The distribution of r can be normalized through Fisher's z transformation

$$z(r) = \frac{1}{2} \log \left(\frac{1+r}{1-r} \right)$$

$z(r)$ is approximately normally distributed with mean $z(\rho)$ and variance $1/(n-3)$.

With a point estimate \hat{z} and an approximate 95% confidence interval (z_1, z_2) for $z(\rho)$, a point estimate \hat{r} and a 95% confidence interval (r_1, r_2) for ρ can be obtained by applying the inverse transformation

$$r = \tanh(z) = \frac{e^{2z} - 1}{e^{2z} + 1}$$

to $z = \hat{z}, z_1$, and z_2 .

This approach is illustrated in [Example 58.10](#).

Ratios of Variable Means

For the ratio μ_1/μ_2 of means for variables Y_1 and Y_2 , the point estimate is \bar{y}_1/\bar{y}_2 , the ratio of the sample means. The Taylor expansion and delta method can be applied to the function y_1/y_2 to obtain the variance estimate (Schafer 1997, p. 196)

$$\frac{1}{n} \left[\left(\frac{\bar{y}_1}{\bar{y}_2^2} \right)^2 s_{22} - 2 \left(\frac{\bar{y}_1}{\bar{y}_2^2} \right) \left(\frac{1}{\bar{y}_2} \right) s_{12} + \left(\frac{1}{\bar{y}_2} \right)^2 s_{11} \right]$$

where s_{11} and s_{22} are the sample variances of Y_1 and Y_2 , respectively, and s_{12} is the sample covariance between Y_1 and Y_2 .

A ratio of sample means will be approximately unbiased and normally distributed if the coefficient of variation of the denominator (the standard error for the mean divided by the estimated mean) is 10% or less (Cochran 1977, p. 166; Schafer 1997, p. 196).

ODS Table Names

PROC MIANALYZE assigns a name to each table it creates. You must use these names to reference tables when using the Output Delivery System (ODS). These names are listed in [Table 58.3](#). For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

Examples: MIANALYZE Procedure

The following statements generate five imputed data sets to be used in this section. The data set Fitness1 was created in the section “[Getting Started: MIANALYZE Procedure](#)” on page 4831. See “The MI Procedure” chapter for details concerning the MI procedure.

```
proc mi data=Fitness1 seed=3237851 noprint out=outmi;
    var Oxygen RunTime RunPulse;
run;
```

The Fish data described in the STEPDISC procedure are measurements of 159 fish of seven species caught in Finland’s lake Laengelmavesi. For each fish, the length, height, and width are measured. See Chapter 89, “[The STEPDISC Procedure](#),” for more information.

The Fish2 data set is constructed from the Fish data set and contains two species of fish. Some values have been set to missing, and the resulting data set has a monotone missing pattern in the variables Length, Height, Width, and Species.

The following statements create the Fish2 data set. It contains two species of fish in the Fish data set.

```
*-----Fish2 Data-----*
| The data set contains two species of the fish (Bream and Pike) |
| and three measurements: Length, Height, Width.                |
| Some values have been set to missing, and the resulting data set |
| has a monotone missing pattern in the variables                |
| Length, Height, Width, and Species.                            |

;

The following statements generate five imputed data sets to be used in this section. The default regression method is used to impute missing values in continuous variables Height and Width, and the discriminant function method is used to impute the variable Species.

```
proc mi data=Fish2 seed=1305417 out=outfish;
  class Species;
  monotone discrim( Species= Length Height Width);
  var Length Height Width Species;
run;
```

Example 58.1 through Example 58.6 use different input option combinations to combine parameter estimates computed from different procedures. Example 58.7 and Example 58.8 combine parameter estimates with classification variables. Example 58.9 shows the use of a TEST statement, and Example 58.10 combines statistics that are not directly derived from procedures.

Example 58.1: Reading Means and Standard Errors from Variables in a DATA= Data Set

This example creates an ordinary SAS data set that contains sample means and standard errors computed from imputed data sets. These estimates are then combined to generate valid univariate inferences about the population means.

The following statements use the UNIVARIATE procedure to generate sample means and standard errors for the variables in each imputed data set:

```
proc univariate data=outmi noprint;
  var Oxygen RunTime RunPulse;
  output out=outuni mean=Oxygen RunTime RunPulse
           stderr=SOxygen SRunTime SRunPulse;
  by _Imputation_;
run;
```

The following statements display the output data set from PROC UNIVARIATE shown in [Output 58.1.1](#):

```
proc print data=outuni;
  title 'UNIVARIATE Means and Standard Errors';
run;
```

Output 58.1.1 UNIVARIATE Output Data Set

UNIVARIATE Means and Standard Errors							
Obs	_Imputation_	Oxygen	RunTime	Run Pulse	SOxygen	SRun Time	SRun Pulse
1	1	47.0120	10.4441	171.216	0.95984	0.28520	1.59910
2	2	47.2407	10.5040	171.244	0.93540	0.26661	1.75638
3	3	47.4995	10.5922	171.909	1.00766	0.26302	1.85795
4	4	47.1485	10.5279	171.146	0.95439	0.26405	1.75011
5	5	47.0042	10.4913	172.072	0.96528	0.27275	1.84807

The following statements combine the means and standard errors from imputed data sets. The EDF= option requests that the adjusted degrees of freedom be used in the analysis. For sample means based on 31 observations, the complete-data error degrees of freedom is 30.

```
proc mianalyze data=outuni edf=30;
  modeleffects Oxygen RunTime RunPulse;
  stderr SOxygen SRunTime SRunPulse;
run;
```

The “Model Information” table in [Output 58.1.2](#) lists the input data set(s) and the number of imputations. The “Variance Information” table in [Output 58.1.2](#) displays the between-imputation variance, within-imputation variance, and total variance for each univariate inference. It also displays the degrees of freedom for the total variance. The relative increase in variance due to missing values, the fraction of missing information, and the relative efficiency for each imputed variable are also displayed. A detailed description of these statistics is provided in the section “[Combining Inferences from Imputed Data Sets](#)” on page 4844 and the section “[Multiple Imputation Efficiency](#)” on page 4845.

Output 58.1.2 Variance Information

Note that the results in this example could also have been obtained with the MI procedure.

Example 58.2: Reading Means and Covariance Matrices from a DATA= COV Data Set

This example creates a COV-type data set that contains sample means and covariance matrices computed from imputed data sets. These estimates are then combined to generate valid statistical inferences about the population means.

The following statements use the CORR procedure to generate sample means and a covariance matrix for the variables in each imputed data set:

```
proc corr data=outmi cov nocorr noprint out=outcov(type=cov);
  var Oxygen RunTime RunPulse;
  by _Imputation_;
run;
```

The following statements display (in [Output 58.2.1](#)) output sample means and covariance matrices from PROC CORR for the first two imputed data sets:

```
proc print data=outcov(obs=12);
  title 'CORR Means and Covariance Matrices'
        ' (First Two Imputations)';
run;
```

Output 58.2.1 COV Data Set

CORR Means and Covariance Matrices (First Two Imputations)						
Obs	_Imputation_	_TYPE_	_NAME_	Oxygen	RunTime	RunPulse
1	1	COV	Oxygen	28.5603	-7.2652	-11.812
2	1	COV	RunTime	-7.2652	2.5214	2.536
3	1	COV	RunPulse	-11.8121	2.5357	79.271
4	1	MEAN		47.0120	10.4441	171.216
5	1	STD		5.3442	1.5879	8.903

11	2	STD		5.2081	1.4844	9.779
12	2	N		31.0000	31.0000	31.000

Note that the covariance matrices in the data set outcov are estimated covariance matrices of variables, $V(y)$. The estimated covariance matrix of the sample means is $V(\bar{y}) = V(y)/n$, where n is the sample size, and is not the same as an estimated covariance matrix for variables.

The following statements combine the results for the imputed data sets, and derive both univariate and multivariate inferences about the means. The EDF= option is specified to request that the adjusted degrees of freedom be used in the analysis. For sample means based on 31 observations, the complete-data error degrees of freedom is 30.

```
proc mianalyze data=outcov edf=30;
  modeleffects Oxygen RunTime RunPulse;
run;
```

The “Variance Information” and “Parameter Estimates” tables display the same results as in [Output 58.1.2](#) and [Output 58.1.3](#), respectively, in [Example 58.1](#).

With the WCOV, BCOV, and TCOV options, as in the following statements, the procedure displays the between-imputation covariance matrix, within-imputation covariance matrix, and total covariance matrix assuming that the between-imputation covariance matrix is proportional to the within-imputation covariance matrix in [Output 58.2.2](#).

```
proc mianalyze data=outcov edf=30 wcov bcov tcov mult;
  modeleffects Oxygen RunTime RunPulse;
run;
```

Output 58.2.2 Covariance Matrices

The MIANALYZE Procedure			
Within-Imputation Covariance Matrix			
	Oxygen	RunTime	RunPulse

RunPulse	-0.595750001	0.103787365	4.024598310

With the MULT option, the procedure assumes that the between-imputation covariance matrix is proportional to the within-imputation covariance matrix and displays a multivariate inference for all the parameters taken jointly.

Output 58.2.3 Multivariate Inference

Multivariate Inference					
Assuming Proportionality of Between/Within Covariance Matrices					
Avg Relative Increase in Variance	Num DF	Den DF	F for H0: Parameter=Theta0	Pr > F	
0.292237	3	122.68	12519.7	<.0001	

The “Multivariate Inference” table in [Output 58.2.3](#) shows a significant p -value for the null hypothesis that the population means are all equal to zero.

Example 58.3: Reading Regression Results from a DATA= EST Data Set

This example creates an EST-type data set that contains regression coefficients and their corresponding covariance matrices computed from imputed data sets. These estimates are then combined to generate valid statistical inferences about the regression model.

The following statements use the REG procedure to generate regression coefficients:

```
proc reg data=outmi outest=outreg covout noprint;
  model Oxygen= RunTime RunPulse;
  by _Imputation_;
run;
```

The following statements display (in [Output 58.3.1](#)) output regression coefficients and their covariance matrices from PROC REG for the first two imputed data sets:

```
proc print data=outreg(obs=8);
  var _Imputation_ _Type_ _Name_
      Intercept RunTime RunPulse;
  title 'REG Model Coefficients and Covariance Matrices'
        ' (First Two Imputations)';
run;
```

Output 58.3.1 EST-Type Data Set

REG Model Coefficients and Covariance Matrices (First Two Imputations)						
Obs	_Imputation_	_TYPE_	_NAME_	Intercept	RunTime	RunPulse
1	1	PARMS		86.544	-2.82231	-0.05873
2	1	COV	Intercept	100.145	-0.53519	-0.55077
3	1	COV	RunTime	-0.535	0.10774	-0.00345
4	1	COV	RunPulse	-0.551	-0.00345	0.00343
5	2	PARMS		83.021	-3.00023	-0.02491
6	2	COV	Intercept	79.032	-0.66765	-0.41918
