generates all possible plots. The CCC and PSEUDO options must be specified to obtain the CCC, PSF and PST2 plots in addition to the dendrogram.

CCC

implicitly specifies the CCC option and, if possible, plots the cubic clustering criterion against the number of clusters.

DENDROGRAM <(*dendrogram-options*)>

requests a dendrogram and specifies *dendrogram-options*. A dendrogram is created by default unless the ONLY *global-plot-option* is requested.

Unlike most graphs, the size of the dendrogram can vary as a function of the number of objects that appear in the dendrogram. You can specify the following *dendrogram-options* to control the size and appearance of the dendrogram:

COMPUTEHEIGHT=*a b***CH=*a b***

specifies the constants for computing the height of the dendrogram. For n points being clustered, intercept a , and slope b , the height is based in part on $a + bn$. For a horizontal dendrogram, the default (given in pixels) is COMPUTEHEIGHT=100 12, the default height in pixels is $\max(100 + 12n, 480)$, the default height in inches is $\max(1.04167 + 0.125n, 5)$, and the default height in centimeters is $\max(2.64583 + 0.3175n, 12.7)$. For a vertical dendrogram, the default height is 480 pixels. The default unit is pixels, and you can use the UNIT= *dendrogram-option* to change the unit to inches or centimeters for this option. Inches equals pixels divided by 96, and centimeters equals inches times 2.54.

COMPUTEWIDTH=*a b***CW=*a b***

specifies the constants for computing the width of the dendrogram. For n points being clustered, intercept a , and slope b , the width is based in part on $a + bn$. For a vertical dendrogram, the default (given in pixels) is COMPUTEWIDTH=100 12, the default width in pixels is $\max(100 + 12n, 640)$, the default width in inches is $\max(1.04167 + 0.125n, 6.66667)$, and the default width in centimeters is $\max(2.64583 + 0.3175n, 16.933)$. For a horizontal dendrogram, the default width is 640 pixels. The default unit is pixels, and you can use the UNIT= *dendrogram-option* to change the unit to inches or centimeters for this option. Inches equals pixels divided by 96, and centimeters equals inches times 2.54.

HEIGHT=HEIGHT | MODE | NCL | RSQ**H=H | M | N | R**

specifies the method for drawing the height of the dendrogram. HEIGHT=HEIGHT is the default.

HEIGHT=HEIGHT specifies the distance or similarity between the last clusters joined, as defined in the section “[Clustering Methods](#)” on page 1926.

HEIGHT=MODE pertains to the modal clusters. With METHOD=DENSITY, the mode indicates the number of modal clusters contained by the current cluster. With METHOD=TWOSTAGE, the mode gives the maximum density in each modal cluster and the fusion density, d^* , for clusters containing two or more modal clusters; for clusters that contain no modal clusters, that value of the _MODE_ variable is missing.

HEIGHT=NCL specifies that the number of clusters is used.

HEIGHT=RSQ specifies that the squared multiple correlation is used.

HORIZONTAL | VERTICAL

specifies either a horizontal dendrogram with the objects on the vertical axis (HORIZONTAL) or a vertical dendrogram with the objects on the horizontal axis (VERTICAL). The default is HORIZONTAL.

SETHEIGHT=*height***SH=*height***

specifies the height of the dendrogram. By default, the height is based on the COMPUTEHEIGHT= option. The default unit is pixels, and you can use the UNIT= *dendrogram-option* to change the unit to inches or centimeters for this *dendrogram-option*.

SETWIDTH=width**SW=width**

specifies the width of the dendrogram. By default, the width is based on the COMPUTEWIDTH= option. The default unit is pixels, and you can use the UNIT= *dendrogram-option* to change the unit to inches or centimeters for this *dendrogram-option*.

UNIT=PX | IN | CM

specifies the unit (pixels, inches, or centimeters) for the SETHEIGHT=, SETWIDTH=, COMPUTEHEIGHT=, and COMPUTEWIDTH= *dendrogram-options*.

NONE

suppresses all plots.

PSEUDO

implicitly specifies the PSEUDO option and, if possible, plots the pseudo F statistic and the pseudo t^2 statistic against the number of clusters.

PSF

implicitly specifies the PSEUDO option and, if possible, plots the pseudo F statistic against the number of clusters.

PST2

implicitly specifies the PSEUDO option and, if possible, plots the pseudo t^2 statistic against the number of clusters.

You can specify one or more of the plot requests in the same PLOT option. For example, all of the following are valid:

```
proc cluster plots=(ccc pst2);
proc cluster plots=(psf);
proc cluster plots=psf;
```

The first statement plots both the cubic clustering criterion and the pseudo t^2 statistic, while the second and third statements plot the pseudo F statistic only. When you specify only one plot request, you can omit the parentheses around the plot request. When you specify more than one plot request, you must specify parentheses. Otherwise the second and subsequent plot requests are options. Since CCC and PSEUDO are both options as well as plot requests, the following three statements are valid, but they are not equivalent:

```
proc cluster plots(only)=ccc pseudo;
proc cluster plots(only)=pseudo ccc;
proc cluster plots(only)=(ccc pseudo);
```

The first two examples have one plot request and one procedure option. The third example has two plot requests.

The names of the graphs that PROC CLUSTER generates are listed in [Table 31.5](#), along with the required statements and options.

PRINT=*n* | P=*n*

specifies the number of generations of the cluster history to display. The PRINT= option displays the latest *n* generations; for example, PRINT=5 displays the cluster history from one cluster through five clusters. The value of PRINT= must be a nonnegative integer. The default is to display all generations. Specify PRINT=0 to suppress the cluster history.

PSEUDO

displays pseudo *F* and t^2 statistics. This option is effective only when the data are coordinates or when METHOD=AVERAGE, METHOD=CENTROID, or METHOD=WARD is specified. See the section “[Miscellaneous Formulas](#)” on page 1933 for more information. The PSEUDO option is not appropriate with METHOD=SINGLE because of the method’s tendency to chop off tails of distributions.

R=*n*

specifies the radius of the sphere of support for uniform-kernel density estimation (Silverman 1986, pp. 11–13 and 75–94).

The value of R= must be greater than zero.

Density estimation is used with the TRIM=, METHOD=DENSITY, and METHOD=TWOSTAGE options.

RMSSTD

displays the root mean square standard deviation of each cluster. This option is effective only when the data are coordinates or when METHOD=AVERAGE, METHOD=CENTROID, or METHOD=WARD is specified.

See the section “[Miscellaneous Formulas](#)” on page 1933 for more information.

RSQUARE | RSQ

displays the R square and semipartial R square. This option is effective only when the data are coordinates or when METHOD=AVERAGE or METHOD=CENTROID is specified. The R square and semipartial R square statistics are always displayed with METHOD=WARD. See the section “[Miscellaneous Formulas](#)” on page 1933 for more information..

SIMPLE | S

displays means, standard deviations, skewness, kurtosis, and a coefficient of bimodality. The SIMPLE option applies only to coordinate data. See the section “[Miscellaneous Formulas](#)” on page 1933 for more information.

STANDARD | STD

standardizes the variables to mean 0 and standard deviation 1. The STANDARD option applies only to coordinate data.

TRIM=*p*

omits points with low estimated probability densities from the analysis. Valid values for the TRIM= option are $0 \leq p < 100$. If $p < 1$, then *p* is the proportion of observations omitted. If $p \geq 1$, then *p* is interpreted as a percentage. A specification of TRIM=10, which trims 10% of the points, is a reasonable value for many data sets. Densities are estimated by the *k*th-nearest-neighbor or uniform-kernel method. Trimmed points are indicated by a negative value of the _FREQ_ variable in the OUTTREE= data set.

You must use either the K= or R= option when you use TRIM=. You cannot use the HYBRID option in combination with TRIM=, so you might want to use the DIM= option instead. If you specify the STANDARD option in combination with TRIM=, the variables are standardized both before and after trimming.

The TRIM= option is useful for removing outliers and reducing chaining. Trimming is highly recommended with METHOD=WARD or METHOD=COMPLETE because clusters from these methods can be severely distorted by outliers. Trimming is also valuable with METHOD=SINGLE since single linkage is the method most susceptible to chaining. Most other methods also benefit from trimming. However, trimming is unnecessary with METHOD=TWOSTAGE or METHOD=DENSITY when *k*th-nearest-neighbor density estimation is used.

Use of the TRIM= option can spuriously inflate the cubic clustering criterion and the pseudo *F* and t^2 statistics. Trimming only outliers improves the accuracy of the statistics, but trimming saddle regions between clusters yields excessively large values.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC CLUSTER to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the CLUSTER procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

COPY Statement

COPY *variables* ;

The variables in the COPY statement are copied from the input data set to the OUTTREE= data set. Observations in the OUTTREE= data set that represent clusters of more than one observation from the input data set have missing values for the COPY variables.

FREQ Statement

FREQ *variable* ;

If one variable in the input data set represents the frequency of occurrence for other values in the observation, specify the variable's name in a FREQ statement. PROC CLUSTER then treats the data set as if each observation appeared n times, where n is the value of the FREQ variable for the observation. Noninteger values of the FREQ variable are truncated to the largest integer less than the FREQ value.

If you omit the FREQ statement but the DATA= data set contains a variable called `_FREQ_`, then frequencies are obtained from the `_FREQ_` variable. If neither a FREQ statement nor an `_FREQ_` variable is present, each observation is assumed to have a frequency of one.

If each observation in the DATA= data set represents a cluster (for example, clusters formed by PROC FASTCLUS), the variable specified in the FREQ statement should give the number of original observations in each cluster.

If you specify the RMSSTD statement, a FREQ statement is required. A FREQ statement or `_FREQ_` variable is required when you specify the HYBRID option.

With most clustering methods, the same clusters are obtained from a data set with a FREQ variable as from a similar data set without a FREQ variable, if each observation is repeated as many times as the value of the FREQ variable in the first data set. The FLEXIBLE method can yield different results due to the nature of the combinatorial formula. The DENSITY and TWOSTAGE methods are also exceptions because two identical observations can be absorbed one at a time by a cluster with a higher density. If you are using a FREQ statement with either the DENSITY or TWOSTAGE method, see the [MODE=option](#) for details.

ID Statement

ID *variable* ;

The values of the ID variable identify observations in the displayed cluster history and in the OUTTREE= data set. If the ID statement is omitted, each observation is denoted by `OB n` , where n is the observation number.

RMSSTD Statement

RMSSTD *variable* ;

If the coordinates in the DATA= data set represent cluster means (for example, formed by the FASTCLUS procedure), you can obtain accurate statistics in the cluster histories for METHOD=AVERAGE, METHOD=CENTROID, or METHOD=WARD if the data set contains both of the following:

- a variable giving the number of original observations in each cluster (see the discussion of the FREQ statement earlier in this chapter)
- a variable giving the root mean squared standard deviation of each cluster

Specify the name of the variable containing root mean squared standard deviations in the RMSSTD statement. If you specify the RMSSTD statement, you must also specify a FREQ statement.

If you omit the RMSSTD statement but the DATA= data set contains a variable called `_RMSSTD_`, then the root mean squared standard deviations are obtained from the `_RMSSTD_` variable.

An RMSSTD statement or `_RMSSTD_` variable is required when you specify the HYBRID option.

A data set created by PROC FASTCLUS, using the MEAN= option, contains `_FREQ_` and `_RMSSTD_` variables, so you do not have to use FREQ and RMSSTD statements when using such a data set as input to the CLUSTER procedure.

VAR Statement

VAR *variables* ;

The VAR statement lists numeric variables to be used in the cluster analysis. If you omit the VAR statement, all numeric variables not listed in other statements are used.

Details: CLUSTER Procedure

Clustering Methods

The following notation is used, with lowercase symbols generally pertaining to observations and uppercase symbols pertaining to clusters:

n	number of observations
v	number of variables if data are coordinates
G	number of clusters at any given level of the hierarchy
x_i or \mathbf{x}_i	i th observation (row vector if coordinate data)
C_K	K th cluster, subset of $\{1, 2, \dots, n\}$
N_K	number of observations in C_K
$\bar{\mathbf{x}}$	sample mean vector
$\bar{\mathbf{x}}_K$	mean vector for cluster C_K
$\ \mathbf{x}\ $	Euclidean length of the vector \mathbf{x} —that is, the square root of the sum of the squares of the elements of \mathbf{x}
T	$\sum_{i=1}^n \ \mathbf{x}_i - \bar{\mathbf{x}}\ ^2$
W_K	$\sum_{i \in C_K} \ \mathbf{x}_i - \bar{\mathbf{x}}_K\ ^2$
P_G	$\sum W_J$, where summation is over the G clusters at the G th level of the hierarchy
B_{KL}	$W_M - W_K - W_L$ if $C_M = C_K \cup C_L$
$d(\mathbf{x}, \mathbf{y})$	any distance or dissimilarity measure between observations or vectors \mathbf{x} and \mathbf{y}
D_{KL}	any distance or dissimilarity measure between clusters C_K and C_L

The distance between two clusters can be defined either directly or combinatorially (Lance and Williams 1967)—that is, by an equation for updating a distance matrix when two clusters are joined. In all of the following combinatorial formulas, it is assumed that clusters C_K and C_L are merged to form C_M , and the formula gives the distance between the new cluster C_M and any other cluster C_J .

For an introduction to most of the methods used in the CLUSTER procedure, see Massart and Kaufman (1983).

Average Linkage

The following method is obtained by specifying METHOD=AVERAGE. The distance between two clusters is defined by

$$D_{KL} = \frac{1}{N_K N_L} \sum_{i \in C_K} \sum_{j \in C_L} d(x_i, x_j)$$

If $d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|^2$, then

$$D_{KL} = \|\bar{\mathbf{x}}_K - \bar{\mathbf{x}}_L\|^2 + \frac{W_K}{N_K} + \frac{W_L}{N_L}$$

The combinatorial formula is

$$D_{JM} = \frac{N_K D_{JK} + N_L D_{JL}}{N_M}$$

In average linkage the distance between two clusters is the average distance between pairs of observations, one in each cluster. Average linkage tends to join clusters with small variances, and it is slightly biased toward producing clusters with the same variance.

Average linkage was originated by Sokal and Michener (1958).

Centroid Method

The following method is obtained by specifying METHOD=CENTROID. The distance between two clusters is defined by

$$D_{KL} = \|\bar{\mathbf{x}}_K - \bar{\mathbf{x}}_L\|^2$$

If $d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|^2$, then the combinatorial formula is

$$D_{JM} = \frac{N_K D_{JK} + N_L D_{JL}}{N_M} - \frac{N_K N_L D_{KL}}{N_M^2}$$

In the centroid method, the distance between two clusters is defined as the (squared) Euclidean distance between their centroids or means. The centroid method is more robust to outliers than most other hierarchical methods but in other respects might not perform as well as Ward's method or average linkage (Milligan 1980).

The centroid method was originated by Sokal and Michener (1958).

Complete Linkage

The following method is obtained by specifying METHOD=COMPLETE. The distance between two clusters is defined by

$$D_{KL} = \max_{i \in C_K} \max_{j \in C_L} d(x_i, x_j)$$

The combinatorial formula is

$$D_{JM} = \max(D_{JK}, D_{JL})$$

In complete linkage, the distance between two clusters is the maximum distance between an observation in one cluster and an observation in the other cluster. Complete linkage is strongly biased toward producing clusters with roughly equal diameters, and it can be severely distorted by moderate outliers (Milligan 1980).

Complete linkage was originated by Sorensen (1948).

Density Linkage

The phrase *density linkage* is used here to refer to a class of clustering methods that use nonparametric probability density estimates (for example, Hartigan 1975, pp. 205–212; Wong 1982; Wong and Lane 1983). Density linkage consists of two steps:

1. A new dissimilarity measure, d^* , based on density estimates and adjacencies is computed. If x_i and x_j are adjacent (the definition of *adjacency* depends on the method of density estimation), then $d^*(x_i, x_j)$ is the reciprocal of an estimate of the density midway between x_i and x_j ; otherwise, $d^*(x_i, x_j)$ is infinite.
2. A single linkage cluster analysis is performed using d^* .

The CLUSTER procedure supports three types of density linkage: the k th-nearest-neighbor method, the uniform-kernel method, and Wong's hybrid method. These are obtained by using METHOD=DENSITY and the K=, R=, and HYBRID options, respectively.

*k*th-Nearest-Neighbor Method

The k th-nearest-neighbor method (Wong and Lane 1983) uses k th-nearest-neighbor density estimates. Let $r_k(x)$ be the distance from point x to the k th-nearest observation, where k is the value specified for the K= option. Consider a closed sphere centered at x with radius $r_k(x)$. The estimated density at x , $f(x)$, is the proportion of observations within the sphere divided by the volume of the sphere. The new dissimilarity measure is computed as

$$d^*(x_i, x_j) = \begin{cases} \frac{1}{2} \left(\frac{1}{f(x_i)} + \frac{1}{f(x_j)} \right) & \text{if } d(x_i, x_j) \leq \max(r_k(x_i), r_k(x_j)) \\ \infty & \text{otherwise} \end{cases}$$

Wong and Lane (1983) show that k th-nearest-neighbor density linkage is strongly set consistent for high-density (density-contour) clusters if k is chosen such that $k/n \rightarrow 0$ and $k/\ln(n) \rightarrow \infty$ as $n \rightarrow \infty$. Wong and Schaack (1982) discuss methods for estimating the number of population clusters by using k th-nearest-neighbor clustering.

Uniform-Kernel Method

The uniform-kernel method uses uniform-kernel density estimates. Let r be the value specified for the R= option. Consider a closed sphere centered at point x with radius r . The estimated density at x , $f(x)$, is the proportion of observations within the sphere divided by the volume of the sphere. The new dissimilarity measure is computed as

$$d^*(x_i, x_j) = \begin{cases} \frac{1}{2} \left(\frac{1}{f(x_i)} + \frac{1}{f(x_j)} \right) & \text{if } d(x_i, x_j) \leq r \\ \infty & \text{otherwise} \end{cases}$$

Wong's Hybrid Method

The Wong (1982) hybrid clustering method uses density estimates based on a preliminary cluster analysis by the k -means method. The preliminary clustering can be done by the FASTCLUS procedure, by using the MEAN= option to create a data set containing cluster means, frequencies, and root mean squared standard deviations. This data set is used as input to the CLUSTER procedure, and the HYBRID option is specified with METHOD=DENSITY to request the hybrid analysis. The hybrid method is appropriate for very large data sets but should not be used with small data sets—say, than those with fewer than 100 observations in the original data. The term *preliminary cluster* refers to an observation in the DATA= data set.

For preliminary cluster C_K , N_K and W_K are obtained from the input data set, as are the cluster means or the distances between the cluster means. Preliminary clusters C_K and C_L are considered adjacent if the midpoint between \bar{x}_K and \bar{x}_L is closer to either \bar{x}_K or \bar{x}_L than to any other preliminary cluster mean or, equivalently, if $d^2(\bar{x}_K, \bar{x}_L) < d^2(\bar{x}_K, \bar{x}_M) + d^2(\bar{x}_L, \bar{x}_M)$ for all other preliminary clusters C_M , $M \neq K$ or L . The new dissimilarity measure is computed as

$$d^*(\bar{x}_K, \bar{x}_L) = \begin{cases} \frac{(W_K + W_L + \frac{1}{4}(N_K + N_L)d^2(\bar{x}_K, \bar{x}_L))^{\frac{v}{2}}}{(N_K + N_L)^{1 + \frac{v}{2}}} & \text{if } C_K \text{ and } C_L \text{ are adjacent} \\ \infty & \text{otherwise} \end{cases}$$

Using the K= and R= Options

The values of the K= and R= options are called *smoothing parameters*. Small values of K= or R= produce jagged density estimates and, as a consequence, many modes. Large values of K= or R= produce smoother density estimates and fewer modes. In the hybrid method, the smoothing parameter is the number of clusters in the preliminary cluster analysis. The number of modes in the final analysis tends to increase as the number of clusters in the preliminary analysis increases. Wong (1982) suggests using $n^{0.3}$ preliminary clusters, where n is the number of observations in the original data set. There is no rule of thumb for selecting K= values. For all types of density linkage, you should repeat the analysis with several different values of the smoothing parameter (Wong and Schaack 1982).

There is no simple answer to the question of which smoothing parameter to use (Silverman 1986, pp. 43–61, 84–88, and 98–99). It is usually necessary to try several different smoothing parameters. A reasonable first guess for the R= option in many coordinate data sets is given by

$$\left[\frac{2^{v+2}(v+2)\Gamma(\frac{v}{2}+1)}{nv^2} \right]^{\frac{1}{v+4}} \sqrt{\sum_{l=1}^v s_l^2}$$

where s_l^2 is the standard deviation of the l th variable. The estimate for R= can be computed in a DATA step by using the GAMMA function for Γ . This formula is derived under the assumption that the data are

sampled from a multivariate normal distribution and tends, therefore, to be too large (oversmooth) if the true distribution is multimodal. Robust estimates of the standard deviations can be preferable if there are outliers. If the data are distances, the factor $\sum s_i^2$ can be replaced by an average (mean, trimmed mean, median, root mean square, and so on) distance divided by $\sqrt{2}$. To prevent outliers from appearing as separate clusters, you can also specify $K=2$, or more generally $K=m$, $m \geq 2$, which in most cases forces clusters to have at least m members.

If the variables all have unit variance (for example, if the STANDARD option is used), Table 31.2 can be used to obtain an initial guess for the R= option.

Since infinite d^* values occur in density linkage, the final number of clusters can exceed one when there are wide gaps between the clusters or when the smoothing parameter results in little smoothing.

Density linkage applies no constraints to the shapes of the clusters and, unlike most other hierarchical clustering methods, is capable of recovering clusters with elongated or irregular shapes. Since density linkage uses less prior knowledge about the shape of the clusters than do methods restricted to compact clusters, density linkage is less effective at recovering compact clusters from small samples than are methods that always recover compact clusters, regardless of the data.

Table 31.2 Reasonable First Guess for the R= Option for Standardized Data

Number of Observations	Number of Variables									
	1	2	3	4	5	6	7	8	9	10
20	1.01	1.36	1.77	2.23	2.73	3.25	3.81	4.38	4.98	5.60
35	0.91	1.24	1.64	2.08	2.56	3.08	3.62	4.18	4.77	5.38
50	0.84	1.17	1.56	1.99	2.46	2.97	3.50	4.06	4.64	5.24
75	0.78	1.09	1.47	1.89	2.35	2.85	3.38	3.93	4.50	5.09
100	0.73	1.04	1.41	1.82	2.28	2.77	3.29	3.83	4.40	4.99
150	0.68	0.97	1.33	1.73	2.18	2.66	3.17	3.71	4.27	4.85
200	0.64	0.93	1.28	1.67	2.11	2.58	3.09	3.62	4.17	4.75
350	0.57	0.85	1.18	1.56	1.98	2.44	2.93	3.45	4.00	4.56
500	0.53	0.80	1.12	1.49	1.91	2.36	2.84	3.35	3.89	4.45
750	0.49	0.74	1.06	1.42	1.82	2.26	2.74	3.24	3.77	4.32
1000	0.46	0.71	1.01	1.37	1.77	2.20	2.67	3.16	3.69	4.23
1500	0.43	0.66	0.96	1.30	1.69	2.11	2.57	3.06	3.57	4.11
2000	0.40	0.63	0.92	1.25	1.63	2.05	2.50	2.99	3.49	4.03

EML

The following method is obtained by specifying METHOD=EML. The distance between two clusters is given by

$$D_{KL} = nv \ln \left(1 + \frac{B_{KL}}{P_G} \right) - 2 (N_M \ln(N_M) - N_K \ln(N_K) - N_L \ln(N_L))$$

The EML method joins clusters to maximize the likelihood at each level of the hierarchy under the following assumptions:

- multivariate normal mixture
- equal spherical covariance matrices
- unequal sampling probabilities

The EML method is similar to Ward's minimum-variance method but removes the bias toward equal-sized clusters. Practical experience has indicated that EML is somewhat biased toward unequal-sized clusters. You can specify the `PENALTY=` option to adjust the degree of bias. If you specify `PENALTY=p`, the formula is modified to

$$D_{KL} = nv \ln \left(1 + \frac{B_{KL}}{P_G} \right) - p (N_M \ln(N_M) - N_K \ln(N_K) - N_L \ln(N_L))$$

The EML method was derived by W. S. Sarle of SAS Institute from the maximum likelihood formula obtained by Symons (1981, p. 37, Equation 8) for disjoint clustering. There are currently no other published references on the EML method.

Flexible-Beta Method

The following method is obtained by specifying `METHOD=FLEXIBLE`. The combinatorial formula is

$$D_{JM} = (D_{JK} + D_{JL}) \frac{1-b}{2} + D_{KL}b$$

where b is the value of the `BETA=` option, or -0.25 by default.

The flexible-beta method was developed by Lance and Williams (1967); see also Milligan (1987).

McQuitty's Similarity Analysis

The following method is obtained by specifying `METHOD=MCQUITTY`. The combinatorial formula is

$$D_{JM} = \frac{D_{JK} + D_{JL}}{2}$$

The method was independently developed by Sokal and Michener (1958) and McQuitty (1966).

Median Method

The following method is obtained by specifying `METHOD=MEDIAN`. If $d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|^2$, then the combinatorial formula is

$$D_{JM} = \frac{D_{JK} + D_{JL}}{2} - \frac{D_{KL}}{4}$$

The median method was developed by Gower (1967).

Single Linkage

The following method is obtained by specifying METHOD=SINGLE. The distance between two clusters is defined by

$$D_{KL} = \min_{i \in C_K} \min_{j \in C_L} d(x_i, x_j)$$

The combinatorial formula is

$$D_{JM} = \min(D_{JK}, D_{JL})$$

In single linkage, the distance between two clusters is the minimum distance between an observation in one cluster and an observation in the other cluster. Single linkage has many desirable theoretical properties (Jardine and Sibson 1971; Fisher and Van Ness 1971; Hartigan 1981) but has fared poorly in Monte Carlo studies (for example, Milligan 1980). By imposing no constraints on the shape of clusters, single linkage sacrifices performance in the recovery of compact clusters in return for the ability to detect elongated and irregular clusters. You must also recognize that single linkage tends to chop off the tails of distributions before separating the main clusters (Hartigan 1981). The notorious chaining tendency of single linkage can be alleviated by specifying the TRIM= option (Wishart 1969, pp. 296–298).

Density linkage and two-stage density linkage retain most of the virtues of single linkage while performing better with compact clusters and possessing better asymptotic properties (Wong and Lane 1983).

Single linkage was originated by Florek et al. (1951b, a) and later reinvented by McQuitty (1957) and Sneath (1957).

Two-Stage Density Linkage

If you specify METHOD=DENSITY, the modal clusters often merge before all the points in the tails have clustered. The option METHOD=TWOSTAGE is a modification of density linkage that ensures that all points are assigned to modal clusters before the modal clusters are permitted to join. The CLUSTER procedure supports the same three varieties of two-stage density linkage as of ordinary density linkage: *k*th-nearest neighbor, uniform kernel, and hybrid.

In the first stage, disjoint modal clusters are formed. The algorithm is the same as the single linkage algorithm ordinarily used with density linkage, with one exception: two clusters are joined only if at least one of the two clusters has fewer members than the number specified by the MODE= option. At the end of the first stage, each point belongs to one modal cluster.

In the second stage, the modal clusters are hierarchically joined by single linkage. The final number of clusters can exceed one when there are wide gaps between the clusters or when the smoothing parameter is small.

Each stage forms a tree that can be plotted by the TREE procedure. By default, the TREE procedure plots the tree from the first stage. To obtain the tree for the second stage, use the option HEIGHT=MODE in the PROC TREE statement. You can also produce a single tree diagram containing both stages, with the number of clusters as the height axis, by using the option HEIGHT=N in the PROC TREE statement. To produce an output data set from PROC TREE containing the modal clusters, use _HEIGHT_ for the HEIGHT variable (the default) and specify LEVEL=0.

Two-stage density linkage was developed by W. S. Sarle of SAS Institute. There are currently no other published references on two-stage density linkage.

Ward's Minimum-Variance Method

The following method is obtained by specifying METHOD=WARD. The distance between two clusters is defined by

$$D_{KL} = B_{KL} = \frac{\|\bar{\mathbf{x}}_K - \bar{\mathbf{x}}_L\|^2}{\frac{1}{N_K} + \frac{1}{N_L}}$$

If $d(\mathbf{x}, \mathbf{y}) = \frac{1}{2}\|\mathbf{x} - \mathbf{y}\|^2$, then the combinatorial formula is

$$D_{JM} = \frac{(N_J + N_K)D_{JK} + (N_J + N_L)D_{JL} - N_J D_{KL}}{N_J + N_M}$$

In Ward's minimum-variance method, the distance between two clusters is the ANOVA sum of squares between the two clusters added up over all the variables. At each generation, the within-cluster sum of squares is minimized over all partitions obtainable by merging two clusters from the previous generation. The sums of squares are easier to interpret when they are divided by the total sum of squares to give proportions of variance (squared semipartial correlations).

Ward's method joins clusters to maximize the likelihood at each level of the hierarchy under the following assumptions:

- multivariate normal mixture
- equal spherical covariance matrices
- equal sampling probabilities

Ward's method tends to join clusters with a small number of observations, and it is strongly biased toward producing clusters with roughly the same number of observations. It is also very sensitive to outliers (Milligan 1980).

Ward (1963) describes a class of hierarchical clustering methods including the minimum variance method.

Miscellaneous Formulas

The root mean squared standard deviation of a cluster C_K is

$$\text{RMSSTD} = \sqrt{\frac{W_K}{v(N_K - 1)}}$$

The R-square statistic for a given level of the hierarchy is

$$R^2 = 1 - \frac{P_G}{T}$$

The squared semipartial correlation for joining clusters C_K and C_L is

$$\text{semipartial } R^2 = \frac{B_{KL}}{T}$$

The bimodality coefficient is

$$b = \frac{m_3^2 + 1}{m_4 + \frac{3(n-1)^2}{(n-2)(n-3)}}$$

where m_3 is skewness and m_4 is kurtosis. Values of b greater than 0.555 (the value for a uniform population) can indicate bimodal or multimodal marginal distributions. The maximum of 1.0 (obtained for the Bernoulli distribution) is obtained for a population with only two distinct values. Very heavy-tailed distributions have small values of b regardless of the number of modes.

Formulas for the cubic-clustering criterion and approximate expected R square are given in Sarle (1983).

The pseudo F statistic for a given level is

$$\text{pseudo } F = \frac{\frac{T - P_G}{G - 1}}{\frac{P_G}{n - G}}$$

The pseudo t^2 statistic for joining C_K and C_L is

$$\text{pseudo } t^2 = \frac{B_{KL}}{\frac{W_K + W_L}{N_K + N_L - 2}}$$

The pseudo F and t^2 statistics can be useful indicators of the number of clusters, but they are *not* distributed as F and t^2 random variables. If the data are independently sampled from a multivariate normal distribution with a scalar covariance matrix and if the clustering method allocates observations to clusters randomly (which no clustering method actually does), then the pseudo F statistic is distributed as an F random variable with $v(G - 1)$ and $v(n - G)$ degrees of freedom. Under the same assumptions, the pseudo t^2 statistic is distributed as an F random variable with v and $v(N_K + N_L - 2)$ degrees of freedom. The pseudo t^2 statistic differs computationally from Hotelling's T^2 in that the latter uses a general symmetric covariance matrix instead of a scalar covariance matrix. The pseudo F statistic was suggested by Calinski and Harabasz (1974). The pseudo t^2 statistic is related to the $J_e(2)/J_e(1)$ statistic of Duda and Hart (1973) by

$$\frac{J_e(2)}{J_e(1)} = \frac{W_K + W_L}{W_M} = \frac{1}{1 + \frac{t^2}{N_K + N_L - 2}}$$

See Milligan and Cooper (1985) and Cooper and Milligan (1988) regarding the performance of these statistics in estimating the number of population clusters. Conservative tests for the number of clusters using the pseudo F and t^2 statistics can be obtained by the Bonferroni approach (Hawkins, Muller, and ten Krooden 1982, pp. 337–340).

Ultrametrics

A dissimilarity measure $d(x, y)$ is called an *ultrametric* if it satisfies the following conditions:

- $d(x, x) = 0$ for all x
- $d(x, y) \geq 0$ for all x, y
- $d(x, y) = d(y, x)$ for all x, y
- $d(x, y) \leq \max(d(x, z), d(y, z))$ for all x, y , and z

Any hierarchical clustering method induces a dissimilarity measure on the observations—say, $h(x_i, x_j)$. Let C_M be the cluster with the fewest members that contains both x_i and x_j . Assume C_M was formed by joining C_K and C_L . Then define $h(x_i, x_j) = D_{KL}$.

If the fusion of C_K and C_L reduces the number of clusters from g to $g - 1$, then define $D_{(g)} = D_{KL}$. Johnson (1967) shows that if

$$0 \leq D_{(n)} \leq D_{(n-1)} \leq \cdots \leq D_{(2)}$$

then $h(\cdot, \cdot)$ is an ultrametric. A method that always satisfies this condition is said to be a *monotonic* or *ultrametric clustering method*. All methods implemented in PROC CLUSTER except CENTROID, EML, and MEDIAN are ultrametric (Milligan 1979; Batagelj 1981).

Algorithms

Anderberg (1973) describes three algorithms for implementing agglomerative hierarchical clustering: stored data, stored distance, and sorted distance. The algorithms used by PROC CLUSTER for each method are indicated in Table 31.3. For METHOD=AVERAGE, METHOD=CENTROID, or METHOD=WARD, either the stored data or the stored distance algorithm can be used. For these methods, if the data are distances or if you specify the NOSQUARE option, the stored distance algorithm is used; otherwise, the stored data algorithm is used.

Table 31.3 Three Algorithms for Implementing Agglomerative Hierarchical Clustering

Clustering Method	Algorithm		
	Stored Data	Stored Distance	Sorted Distance
AVERAGE	x	x	
CENTROID	x	x	
COMPLETE		x	
DENSITY			x
EML	x		
FLEXIBLE		x	
MCQUITTY		x	
MEDIAN		x	
SINGLE		x	
TWOSTAGE			x
WARD	x	x	

Note: All of the hierarchical methods accept coordinate data. Methods that require stored or sorted distances automatically calculate distances from the coordinates.

Computational Resources

The CLUSTER procedure stores the data (including the COPY and ID variables) in memory or, if necessary, on disk. If eigenvalues are computed, the covariance matrix is stored in memory. If the stored distance or sorted distance algorithm is used, the distances are stored in memory or, if necessary, on disk.

With coordinate data, the increase in CPU time is roughly proportional to the number of variables. The VAR statement should list the variables in order of decreasing variance for greatest efficiency.

For both coordinate and distance data, the dominant factor determining CPU time is the number of observations. For density methods with coordinate data, the asymptotic time requirements are somewhere between $n \ln(n)$ and n^2 , depending on how the smoothing parameter increases. For other methods except EML, time is roughly proportional to n^2 . For the EML method, time is roughly proportional to n^3 .

PROC CLUSTER runs much faster if the data can be stored in memory and, when the stored distance algorithm is used, if the distance matrix can be stored in memory as well. To estimate the bytes of memory needed for the data, use the following formula and round up to the nearest multiple of d .

$$\begin{array}{ll}
 n(vd + 8d + i) & \\
 + i & \text{if density estimation or the} \\
 & \text{sorted distance algorithm is used} \\
 + 3d & \text{if stored data algorithm is used} \\
 + 3d & \text{if density estimation is used} \\
 + \max(8, \text{length of ID variable}) & \text{if ID variable is used} \\
 + \text{length of ID variable} & \text{if ID variable is used} \\
 + \text{sum of lengths of COPY variables) & \text{if COPY variables is used}
 \end{array}$$

where

- n is the number of observations
- v is the number of variables
- d is the size of a C variable of type *double*. For most computers, $d = 8$.
- i is the size of a C variable of type *int*. For most computers, $i = 4$.

The number of bytes needed for the distance matrix is $dn(n + 1)/2$.

Missing Values

If the data are coordinates, observations with missing values are excluded from the analysis. If the data are distances, missing values are not permitted in the lower triangle of the distance matrix. The upper triangle is ignored. For more about TYPE=DISTANCE data sets, see Chapter A, “[Special SAS Data Sets](#).”

Ties

At each level of the clustering algorithm, PROC CLUSTER must identify the pair of clusters with the minimum distance. Sometimes, usually when the data are discrete, there can be two or more pairs with the same minimum distance. In such cases the tie must be broken in some arbitrary way. If there are ties, then the results of the cluster analysis depend on the order of the observations in the data set. The presence of ties is reported in the SAS log and in the column of the cluster history labeled “Tie” unless the NOTIE option is specified.

PROC CLUSTER breaks ties as follows. Each cluster is identified by the smallest observation number among its members. For each pair of clusters, there is a smaller identification number and a larger identification number. If two or more pairs of clusters are tied for minimum distance between clusters, the pair that has the minimum larger identification number is merged. If there is a tie for minimum larger identification number, the pair that has the minimum smaller identification number is merged.

A tie means that the level in the cluster history at which the tie occurred and possibly some of the subsequent levels are not uniquely determined. Ties that occur early in the cluster history usually have little effect on the later stages. Ties that occur in the middle part of the cluster history are cause for further investigation. Ties that occur late in the cluster history indicate important indeterminacies.

The importance of ties can be assessed by repeating the cluster analysis for several different random permutations of the observations. The discrepancies at a given level can be examined by crosstabulating the clusters obtained at that level for all of the permutations. See [Example 31.4](#) for details.

Size, Shape, and Correlation

In some biological applications, the organisms that are being clustered can be at different stages of growth. Unless it is the growth process itself that is being studied, differences in size among such organisms are not of interest. Therefore, distances among organisms should be computed in such a way as to control for differences in size while retaining information about differences in shape.

If coordinate data are measured on an interval scale, you can control for size by subtracting a measure of the overall size of each observation from each data item. For example, if no other direct measure of size is available, you could subtract the mean of each row of the data matrix, producing a row-centered coordinate matrix. An easy way to subtract the mean of each row is to use PROC STANDARD on the transposed coordinate matrix:

```
proc transpose data= coordinate-datatype;
run;

proc standard m=0;
run;

proc transpose out=row-centered-coordinate-data;
run;
```

Another way to remove size effects from interval-scale coordinate data is to do a principal component analysis and discard the first component (Blackith and Reyment 1971).

If the data are measured on a ratio scale, you can control for size by dividing each observation by a measure of overall size; in this case, the geometric mean is a more natural measure of size than the arithmetic mean. However, it is often more meaningful to analyze the logarithms of ratio-scaled data, in which case you can subtract the arithmetic mean after taking logarithms. You must also consider the dimensions of measurement. For example, if you have measures of both length and weight, you might need to cube the measures of length or take the cube root of the weights. Various other complications can also arise in real applications, such as different growth rates for different parts of the body (Sneath and Sokal 1973).

Issues of size and shape are pertinent to many areas besides biology (for example, Hamer and Cunningham 1981). Suppose you have data consisting of subjective ratings made by several different raters. Some raters tend to give higher overall ratings than other raters. Some raters also tend to spread out their ratings over more of the scale than other raters. If it is impossible for you to adjust directly for rater differences, then distances should be computed in such a way as to control for differences both in size and variability. For example, if the data are considered to be measured on an interval scale, you can subtract the mean of each observation and divide by the standard deviation, producing a row-standardized coordinate matrix. With some clustering methods, analyzing squared Euclidean distances from a row-standardized coordinate matrix is equivalent to analyzing the matrix of correlations among rows, since squared Euclidean distance is an affine transformation of the correlation (Hartigan 1975, p. 64).

If you do an analysis of row-centered or row-standardized data, you need to consider whether the columns (variables) should be standardized before centering or standardizing the rows, after centering or standardizing the rows, or both before and after. If you standardize the columns after standardizing the rows, then strictly speaking you are not analyzing shape because the profiles are distorted by standardizing the columns; however, this type of double standardization might be necessary in practice to get reasonable results. It is not clear whether iterating the standardization of rows and columns can be of any benefit.

The choice of distance or correlation measure should depend on the meaning of the data and the purpose of the analysis. Simulation studies that compare distance and correlation measures are useless unless the data are generated to mimic data from your field of application. Conclusions drawn from artificial data cannot be generalized, because it is possible to generate data such that distances that include size effects work better or such that correlations work better.

You can standardize the rows of a data set by using a DATA step or by using the TRANSPOSE and STANDARD procedures. You can also use PROC TRANSPOSE and then have PROC CORR create a TYPE=CORR data set containing a correlation matrix. If you want to analyze a TYPE=CORR data set with PROC CLUSTER, you must use a DATA step to perform the following steps:

1. Set the data set TYPE= to DISTANCE.
2. Convert the correlations to dissimilarities by computing $1-r$, $\sqrt{1-r}$, $1-r^2$, or some other decreasing function.
3. Delete observations for which the variable _TYPE_ does not have the value 'CORR'.

Output Data Set

The OUTTREE= data set contains one observation for each observation in the input data set, plus one observation for each cluster of two or more observations (that is, one observation for each node of the

cluster tree). The total number of output observations is usually $2n - 1$, where n is the number of input observations. The density methods can produce fewer output observations when the number of clusters cannot be reduced to one.

The label of the OUTTREE= data set identifies the type of cluster analysis performed and is automatically displayed when the TREE procedure is invoked.

The variables in the OUTTREE= data set are as follows:

- the BY variables, if you use a BY statement
- the ID variable, if you use an ID statement
- the COPY variables, if you use a COPY statement
- `_NAME_`, a character variable giving the name of the node. If the node is a cluster, the name is `CL n` , where n is the number of the cluster. If the node is an observation, the name is `OB n` , where n is the observation number. If the node is an observation and the ID statement is used, the name is the formatted value of the ID variable.
- `_PARENT_`, a character variable giving the value of `_NAME_` of the parent of the node
- `_NCL_`, the number of clusters
- `_FREQ_`, the number of observations in the current cluster
- `_HEIGHT_`, the distance or similarity between the last clusters joined, as defined in the section “[Clustering Methods](#)” on page 1926. The variable `_HEIGHT_` is used by the TREE procedure as the default height axis. The label of the `_HEIGHT_` variable identifies the between-cluster distance measure. For `METHOD=TWOSTAGE`, the `_HEIGHT_` variable contains the densities at which clusters joined in the first stage; for clusters formed in the second stage, `_HEIGHT_` is a very small negative number.

If the input data set contains coordinates, the following variables appear in the output data set:

- the variables containing the coordinates used in the cluster analysis. For output observations that correspond to input observations, the values of the coordinates are the same in both data sets except for some slight numeric error possibly introduced by standardizing and unstandardizing if the `STANDARD` option is used. For output observations that correspond to clusters of more than one input observation, the values of the coordinates are the cluster means.
- `_ERSQ_`, the approximate expected value of R square under the uniform null hypothesis
- `_RATIO_`, equal to $(1 - \text{_ERSQ_}) / (1 - \text{_RSQ_})$
- `_LOGR_`, natural logarithm of `_RATIO_`
- `_CCC_`, the cubic clustering criterion

The variables `_ERSQ_`, `_RATIO_`, `_LOGR_`, and `_CCC_` have missing values when the number of clusters is greater than one-fifth the number of observations.

If the input data set contains coordinates and `METHOD=AVERAGE`, `METHOD=CENTROID`, or `METHOD=WARD`, then the following variables appear in the output data set:

- `_DIST_`, the Euclidean distance between the means of the last clusters joined
- `_AVLINK_`, the average distance between the last clusters joined

If the input data set contains coordinates or `METHOD=AVERAGE`, `METHOD=CENTROID`, or `METHOD=WARD`, then the following variables appear in the output data set:

- `_RMSSTD_`, the root mean squared standard deviation of the current cluster
- `_SPRSQ_`, the semipartial squared multiple correlation or the decrease in the proportion of variance accounted for due to joining two clusters to form the current cluster
- `_RSQ_`, the squared multiple correlation
- `_PSF_`, the pseudo F statistic
- `_PST2_`, the pseudo t^2 statistic

If `METHOD=EML`, then the following variable appears in the output data set:

- `_LNLR_`, the log-likelihood ratio

If `METHOD=TWOSTAGE` or `METHOD=DENSITY`, the following variable appears in the output data set:

- `_MODE_`, pertaining to the modal clusters. With `METHOD=DENSITY`, the `_MODE_` variable indicates the number of modal clusters contained by the current cluster. With `METHOD=TWOSTAGE`, the `_MODE_` variable gives the maximum density in each modal cluster and the fusion density, d^* , for clusters containing two or more modal clusters; for clusters containing no modal clusters, `_MODE_` is missing.

If nonparametric density estimates are requested (when `METHOD=DENSITY` or `METHOD=TWOSTAGE` and the `HYBRID` option is not used; or when any of the `TRIM=`, `K=` or `R=` options are used), the output data set contains the following:

- `_DENS_`, the maximum density in the current cluster

Displayed Output

If you specify the `SIMPLE` option and the data are coordinates, PROC CLUSTER produces simple descriptive statistics for each variable:

- the Mean
- the standard deviation, Std Dev

- the Skewness
- the Kurtosis
- a coefficient of Bimodality

If the data are coordinates and you do not specify the NOEIGEN option, PROC CLUSTER displays the following:

- the Eigenvalues of the Correlation or Covariance Matrix
- the Difference between successive eigenvalues
- the Proportion of variance explained by each eigenvalue
- the Cumulative proportion of variance explained

If the data are coordinates, PROC CLUSTER displays the Root Mean Squared Total-Sample Standard Deviation of the variables

If the distances are normalized, PROC CLUSTER displays one of the following, depending on whether squared or unsquared distances are used:

- the Root Mean Squared Distance Between Observations
- the Mean Distance Between Observations

For the generations in the clustering process specified by the PRINT= option, PROC CLUSTER displays the following:

- the Number of Clusters or NCL
- the names of the Clusters Joined. The observations are identified by the formatted value of the ID variable, if any; otherwise, the observations are identified by OB*n*, where *n* is the observation number. The CLUSTER procedure displays the entire value of the ID variable in the cluster history instead of truncating at 16 characters. Long ID values might be split onto several lines. Clusters of two or more observations are identified as CL*n*, where *n* is the number of clusters existing after the cluster in question is formed.
- the number of observations in the new cluster, Frequency of New Cluster or FREQ

If you specify the RMSSTD option and the data are coordinates, or if you specify METHOD=AVERAGE, METHOD=CENTROID, or METHOD=WARD, then PROC CLUSTER displays the root mean squared standard deviation of the new cluster, RMS Std of New Cluster or RMS Std.

PROC CLUSTER displays the following items if you specify METHOD=WARD. It also displays them if you specify the RSQUARE option and either the data are coordinates or you specify METHOD=AVERAGE or METHOD=CENTROID.

- the decrease in the proportion of variance accounted for resulting from joining the two clusters, Semi-partial R-Square or SPRSQ. This equals the between-cluster sum of squares divided by the corrected total sum of squares.
- the squared multiple correlation, R-Square or RSQ. R square is the proportion of variance accounted for by the clusters.

If you specify the CCC option and the data are coordinates, PROC CLUSTER displays the following:

- Approximate Expected R-Square or ERSQ, the approximate expected value of R square under the uniform null hypothesis
- the Cubic Clustering Criterion or CCC. The cubic clustering criterion and approximate expected R square are given missing values when the number of clusters is greater than one-fifth the number of observations.

If you specify the PSEUDO option and the data are coordinates, or if you specify METHOD=AVERAGE, METHOD=CENTROID, or METHOD=WARD, then PROC CLUSTER displays the following:

- Pseudo F or PSF, the pseudo F statistic measuring the separation among all the clusters at the current level
- Pseudo t^2 or PST2, the pseudo t^2 statistic measuring the separation between the two clusters most recently joined

If you specify the NOSQUARE option and METHOD=AVERAGE, PROC CLUSTER displays the (Normalized) Average Distance or (Norm) Aver Dist, the average distance between pairs of objects in the two clusters joined with one object from each cluster.

If you do not specify the NOSQUARE option and METHOD=AVERAGE, PROC CLUSTER displays the (Normalized) RMS Distance or (Norm) RMS Dist, the root mean squared distance between pairs of objects in the two clusters joined with one object from each cluster.

If METHOD=CENTROID, PROC CLUSTER displays the (Normalized) Centroid Distance or (Norm) Cent Dist, the distance between the two cluster centroids.

If METHOD=COMPLETE, PROC CLUSTER displays the (Normalized) Maximum Distance or (Norm) Max Dist, the maximum distance between the two clusters.

If METHOD=DENSITY or METHOD=TWOSTAGE, PROC CLUSTER displays the following:

- Normalized Fusion Density or Normalized Fusion Dens, the value of d^* as defined in the section “[Clustering Methods](#)” on page 1926
- the Normalized Maximum Density in Each Cluster joined, including the Lesser or Min, and the Greater or Max, of the two maximum density values

If METHOD=EML, PROC CLUSTER displays the following:

- Log Likelihood Ratio or LNLR
- Log Likelihood or LNLIKE

If METHOD=FLEXIBLE, PROC CLUSTER displays the (Normalized) Flexible Distance or (Norm) Flex Dist, the distance between the two clusters based on the Lance-Williams flexible formula.

If METHOD=MEDIAN, PROC CLUSTER displays the (Normalized) Median Distance or (Norm) Med Dist, the distance between the two clusters based on the median method.

If METHOD=MCQUITTY, PROC CLUSTER displays the (Normalized) McQuitty's Similarity or (Norm) MCQ, the distance between the two clusters based on McQuitty's similarity method.

If METHOD=SINGLE, PROC CLUSTER displays the (Normalized) Minimum Distance or (Norm) Min Dist, the minimum distance between the two clusters.

If you specify the NONORM option and METHOD=WARD, PROC CLUSTER displays the Between-Cluster Sum of Squares or BSS, the ANOVA sum of squares between the two clusters joined.

If you specify neither the NOTIE option nor METHOD=TWOSTAGE or METHOD=DENSITY, PROC CLUSTER displays Tie, where a T in the column indicates a tie for minimum distance and a blank indicates the absence of a tie.

After the cluster history, if METHOD=TWOSTAGE or METHOD=DENSITY, PROC CLUSTER displays the number of modal clusters.

ODS Table Names

PROC CLUSTER assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 31.4. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 31.4 ODS Tables Produced by PROC CLUSTER

ODS Table Name	Description	Statement	Option
ClusterHistory	Observation or clusters joined, frequencies and other cluster statistics	PROC	default
SimpleStatistics	Simple statistics, before or after trimming	PROC	SIMPLE
EigenvalueTable	Eigenvalues of the CORR or COV matrix	PROC	default
RMSStd	Root mean square total sample standard deviation	PROC	default
AvDist	Root mean square distance between observations	PROC	default

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

PROC CLUSTER can produce plots of the cubic clustering criterion, pseudo F , and pseudo t^2 statistics, and a dendrogram. To plot a statistic, you must ask for it to be computed via one or more of the CCC, PSEUDO, or PLOT options.

You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC CLUSTER generates are listed in [Table 31.5](#), along with the required statements and options.

Table 31.5 Graphs Produced by PROC CLUSTER

ODS Graph Name	Plot Description	Statement & Option
CubicClusCritPlot	Cubic clustering criterion for the number of clusters	PROC CLUSTER PLOTS=CCC
PseudoFPlot	Pseudo F criterion for the number of clusters	PROC CLUSTER PLOTS=PSF
PseudoTSqPlot	Pseudo t^2 criterion for the number of clusters	PROC CLUSTER PLOTS=PST2
CccAndPsTSqPlot	Cubic clustering criterion and pseudo t^2	PROC CLUSTER PLOTS=(CCC PST2)
CccAndPsfPlot	Cubic clustering criterion and pseudo F	PROC CLUSTER PLOTS=(CCC PSF)
CccPsfAndPsTSqPlot	Cubic clustering criterion, pseudo F , and pseudo t^2	PROC CLUSTER PLOTS=ALL
Dendrogram	Dendrogram (tree diagram)	PROC CLUSTER PLOTS=DENDROGRAM

Examples: CLUSTER Procedure

Example 31.1: Cluster Analysis of Flying Mileages between 10 American Cities

This example clusters 10 American cities based on the flying mileages between them. Six clustering methods are shown with corresponding dendrograms. The EML method cannot be used because it requires coordinate data. The other omitted methods produce the same clusters, although not the same distances between clusters, as one of the illustrated methods: complete linkage and the flexible-beta method yield the same clusters as Ward's method, McQuitty's similarity analysis produces the same clusters as average linkage, and the median method corresponds to the centroid method.

All of the methods suggest a division of the cities into two clusters along the east-west dimension. There is disagreement, however, about which cluster Denver should belong to. Some of the methods indicate a possible third cluster that contains Denver and Houston.

The following step displays the city mileage SAS data set, which is available in the Sashelp library and is designated as a TYPE=DISTANCE data set when it is used by PROC CLUSTER:

```
proc print noobs data=sashelp.mileages;
run;
```

Output 31.1.1 City Mileage Data Set

	Los		New		San		Washington			
Atlanta	Chicago	Denver	Houston	Angeles	Miami	York	Francisco	Seattle	DC	City
0	Atlanta
587	0	Chicago
1212	920	0	Denver
701	940	879	0	Houston
1936	1745	831	1374	0	Los Angeles
604	1188	1726	968	2339	0	Miami
748	713	1631	1420	2451	1092	0	.	.	.	New York
2139	1858	949	1645	347	2594	2571	0	.	.	San Francisco
2182	1737	1021	1891	959	2734	2408	678	0	.	Seattle
543	597	1494	1220	2300	923	205	2442	2329	0	Washington D.C.

A partial listing from the following statements include [Output 31.1.2](#) and [Output 31.1.3](#):

```
title 'Cluster Analysis of Flying Mileages Between 10 American Cities';
ods graphics on;

title2 'Using METHOD=AVERAGE';
proc cluster data=sashelp.mileages (type=distance) method=average pseudo;
  id City;
run;
```

Example 31.2: Crude Birth and Death Rates

This example uses the SAS data set `Poverty` created in the section “Getting Started: CLUSTER Procedure” on page 1907. The data, from Rouncefield (1995), are birth rates, death rates, and infant death rates for 97 countries. Six cluster analyses are performed with eight methods. Scatter plots showing cluster membership at selected levels are produced instead of tree diagrams.

Each cluster analysis is performed by a macro called `ANALYZE`. The macro takes two arguments. The first, `&METHOD`, specifies the value of the `METHOD=` option to be used in the `PROC CLUSTER` statement. The second, `&NCL`, must be specified as a list of integers, separated by blanks, indicating the number of clusters desired in each scatter plot. For example, the first invocation of `ANALYZE` specifies the `AVERAGE` method and requests plots of three and eight clusters. When two-stage density linkage is used, the `K=` and `R=` options are specified as part of the first argument.

The `ANALYZE` macro first invokes the `CLUSTER` procedure with `METHOD=&METHOD`, where `&METHOD` represents the value of the first argument to `ANALYZE`. This part of the macro produces the `PROC CLUSTER` output shown.

The `%DO` loop processes `&NCL`, the list of numbers of clusters to plot. The macro variable `&K` is a counter that indexes the numbers within `&NCL`. The `%SCAN` function picks out the k th number in `&NCL`, which is then assigned to the macro variable `&N`. When `&K` exceeds the number of numbers in `&NCL`, `%SCAN` returns a null string. Thus, the `%DO` loop executes while `&N` is not equal to a null string. In the `%WHILE` condition, a null string is indicated by the absence of any nonblank characters between the comparison operator (`NE`) and the right parenthesis that terminates the condition.

Within the `%DO` loop, the `TREE` procedure creates an output data set containing `&N` clusters. The `SGPLOT` procedure then produces a scatter plot in which each observation is identified by the number of the cluster to which it belongs. The `TITLE2` statement uses double quotes so that `&N` and `&METHOD` can be used within the title. At the end of the loop, `&K` is incremented by 1, and the next number is extracted from `&NCL` by `%SCAN`.

```

title 'Cluster Analysis of Birth and Death Rates';
ods graphics on;

%macro analyze(method,ncl);
  proc cluster data=poverty outtree=tree method=&method print=15 ccc pseudo;
    var birth death;
    title2;
  run;

  %let k=1;
  %let n=%scan(&ncl,&k);
  %do %while(&n NE);

    proc tree data=tree noprint out=out ncl=&n;
      copy birth death;
    run;

```

```

proc sgplot;
  scatter y=death x=death / group=cluster;
  title2 "Plot of &n Clusters from METHOD=&METHOD";
run;

%let k=%eval(&k+1);
%let n=%scan(&ncl,&k);
%end;
%mend;

```

The following statement produces [Output 31.2.1](#), [Output 31.2.3](#), and [Output 31.2.4](#):

```
%analyze(average, 3 8)
```

For average linkage, the CCC has peaks at three, eight, ten, and twelve clusters, but the three-cluster peak is lower than the eight-cluster peak. The pseudo F statistic has peaks at three, eight, and twelve clusters. The pseudo t^2 statistic drops sharply at three clusters, continues to fall at four clusters, and has a particularly low value at twelve clusters. However, there are not enough data to seriously consider as many as twelve clusters. Scatter plots are given for three and eight clusters. The results are shown in [Output 31.2.1](#) through [Output 31.2.4](#). In [Output 31.2.4](#), the eighth cluster consists of the two outlying observations, Mexico and Korea.

Output 31.2.1 Cluster Analysis for Birth and Death Rates: METHOD=AVERAGE

The following statement produces [Output 31.2.8](#) and [Output 31.2.10](#):

```
%analyze(single, 7 10)
```

The CCC and pseudo F statistics are not appropriate for use with single linkage because of the method's tendency to chop off tails of distributions. The pseudo t^2 statistic can be used by looking for *large* values and taking the number of clusters to be one greater than the level at which the large pseudo t^2 value is displayed. For these data, there are large values at levels 6 and 9, suggesting seven or ten clusters.

The scatter plots for seven and ten clusters are shown.

The following statements produce [Output 31.2.11](#) through [Output 31.2.14](#):

```
%analyze(two k=10, 3)
```

```
%analyze(two k=18, 2)
```

For k th-nearest-neighbor density linkage, the number of modes as a function of k is as follows (not all of these analyses are shown):

k	Modes
3	13
4	6
5-7	4
8-15	3
16-21	2
22+	1

Thus, there is strong evidence of three modes and an indication of the possibility of two modes. Uniform-kernel density linkage gives similar results. For K=10 (10th-nearest-neighbor density linkage), the scatter plot for three clusters is shown; and for K=18, the scatter plot for two clusters is shown.

In summary, most of the clustering methods indicate three or eight clusters. Most methods agree at the three-cluster level, but at the other levels, there is considerable disagreement about the composition of the clusters. The presence of numerous ties also complicates the analysis; see [Example 31.4](#).

Example 31.3: Cluster Analysis of Fisher's Iris Data

The iris data published by Fisher (1936) have been widely used for examples in discriminant analysis and cluster analysis. The sepal length, sepal width, petal length, and petal width are measured in millimeters on 50 iris specimens from each of three species, *Iris setosa*, *I. versicolor*, and *I. virginica*. Mezzich and Solomon (1980) discuss a variety of cluster analyses of the iris data.

The following step displays the iris SAS data set, which is available in the Sashelp library:

```
title 'Cluster Analysis of Fisher (1936) Iris Data';

proc print data=sashelp.iris;
run;
```

The results of this step are not shown.

This example analyzes the iris data by using Ward's method and two-stage density linkage and then illustrates how the FASTCLUS procedure can be used in combination with PROC CLUSTER to analyze large data sets.

The following macro, SHOW, is used in the subsequent analyses to display cluster results. It invokes the FREQ procedure to crosstabulate clusters and species. The CANDISC procedure computes canonical variables for discriminating among the clusters, and the first two canonical variables are plotted to show cluster membership. See Chapter 29, “[The CANDISC Procedure](#),” for a canonical discriminant analysis of the iris species.

```
/*--- Define macro show ---*/
%macro show;
  proc freq;
    tables cluster*species / nopercnt norow nocol plot=none;
  run;

  proc candisc noprint out=can;
    class cluster;
    var petal: sepal;;
  run;

  proc sgplot data=can;
    scatter y=can2 x=can1 / group=cluster;
  run;
%mend;
```

The first analysis clusters the iris data by using Ward's method (see [Output 31.3.1](#)) and plots the CCC and pseudo F and t^2 statistics (see [Output 31.3.2](#)). The CCC has a local peak at three clusters but a higher peak at five clusters. The pseudo F statistic indicates three clusters, while the pseudo t^2 statistic suggests three or six clusters.

The TREE procedure creates an output data set containing the three-cluster partition for use by the SHOW macro. The FREQ procedure reveals 16 misclassifications. The results are shown in [Output 31.3.3](#).

```

title2 'By Ward's Method';
ods graphics on;

proc cluster data=sashelp.iris method=ward print=15 ccc pseudo;
  var petal: sepal:;
  copy species;
run;

proc tree noprint ncl=3 out=out;
  copy petal: sepal: species;
run;

%show;

```

The CLUSTER procedure is not practical for very large data sets because, with most methods, the CPU time is roughly proportional to the square or cube of the number of observations. The FASTCLUS procedure requires time proportional to the number of observations and can therefore be used with much larger data sets than PROC CLUSTER. If you want to hierarchically cluster a very large data set, you can use PROC FASTCLUS for a preliminary cluster analysis to produce a large number of clusters and then use PROC CLUSTER to hierarchically cluster the preliminary clusters.

FASTCLUS automatically creates the variables `_FREQ_` and `_RMSSTD_` in the `MEAN=` output data set. These variables are then automatically used by PROC CLUSTER in the computation of various statistics.

The following SAS code uses the iris data to illustrate the process of clustering clusters. In the preliminary analysis, PROC FASTCLUS produces ten clusters, which are then crosstabulated with species. The data set containing the preliminary clusters is sorted in preparation for later merges. The results are shown in [Output 31.3.9](#) and [Output 31.3.10](#).

```

The following macro, CLUS, clusters the preliminary clusters. There is one argument to choose the METHOD= specification to be used by PROC CLUSTER. The TREE procedure creates an output data set containing the three-cluster partition, which is sorted and merged with the OUT= data set from PROC FASTCLUS to determine which cluster each of the original 150 observations belongs to. The SHOW macro is then used to display the results. In this example, the CLUS macro is invoked using Ward's method, which produces 16 misclassifications, and Wong's hybrid method, which produces 22 misclassifications.

```

/*--- Define macro clus ---*/
%macro clus(method);

Output 31.3.17 Scatter Plot for Clustering Clusters using Wong's Hybrid Method

Example 31.4: Evaluating the Effects of Ties

If, at some level of the cluster history, there is a tie for minimum distance between clusters, then one or more levels of the sample cluster tree are not uniquely determined. This example shows how the degree of indeterminacy can be assessed.

Mammals have four kinds of teeth: incisors, canines, premolars, and molars. The following data set gives the number of teeth of each kind on one side of the top and bottom jaws for 32 mammals.

Since all eight variables are measured in the same units, it is not strictly necessary to rescale the data. However, the canines have much less variance than the other kinds of teeth and, therefore, have little effect on the analysis if the variables are not standardized. An average linkage cluster analysis is run with and without standardization to enable comparison of the results.

There are ties at 16 levels for the raw data but at only 10 levels for the standardized data. There are more ties for the raw data because the increments between successive values are the same for all of the raw variables but different for the standardized variables.

One way to assess the importance of the ties in the analysis is to repeat the analysis on several random permutations of the observations and then to see to what extent the results are consistent at the interesting levels of the cluster history. Three macros are presented to facilitate this process, as follows.

```

/* ----- */
/*
/* The macro CLUSPERM randomly permutes observations and
/* does a cluster analysis for each permutation.
/* The arguments are as follows:
/*
/* data      data set name
/* var       list of variables to cluster
/* id        id variable for proc cluster
/* method    clustering method (and possibly other options)
/* nperm     number of random permutations.
/*
/* ----- */
%macro CLUSPERM(data,var,id,method,nperm);

/* -----CREATE TEMPORARY DATA SET WITH RANDOM NUMBERS----- */
data _temp_;
  set &data;
  array _random_ _ran_1-_ran_&nperm;
  do over _random_;
    _random_=ranuni(835297461);
  end;
run;

/* -----PERMUTE AND CLUSTER THE DATA----- */
%do n=1 %to &nperm;
  proc sort data=_temp_ (keep=_ran_&n &var &id) out=_perm_;
    by _ran_&n;
  run;

  proc cluster method=&method noprint outtree=_tree_&n;
    var &var;
    id &id;
  run;
%end;
%mend;

```

```

/* ----- */
/*
/* The macro PLOTPERM plots various cluster statistics
/* against the number of clusters for each permutation.
/* The arguments are as follows:
/*
/*      nclus    maximum number of clusters to be plotted
/*      nperm    number of random permutations.
/*
/* ----- */
%macro PLOTPERM(nclus,nperm);

    /* ---CONCATENATE TREE DATA SETS FOR 20 OR FEWER CLUSTERS--- */
    data _plot_;
        set %do n=1 %to &nperm; _tree_&n(in=_in_&n) %end;;
        if _ncl_<=&nclus;
        %do n=1 %to &nperm;
            if _in_&n then _perm_=&n;
        %end;
        label _perm_='permutation number';
        keep _ncl_ _psf_ _pst2_ _ccc_ _perm_;
    run;

    /* ---PLOT THE REQUESTED STATISTICS BY NUMBER OF CLUSTERS--- */
    proc sgscatter;
        compare y=( _ccc_ _psf_ _pst2_ ) x=_ncl_ /group=_perm_;
        label _ccc_ = 'CCC' _psf_ = 'Pseudo F' _pst2_ = 'Pseudo T-Squared';
    run;
%mend;

/* ----- */
/*
/* The macro TABPERM generates cluster-membership variables
/* for a specified number of clusters for each permutation.
/* PROC TABULATE gives the frequencies and means.
/* The arguments are as follows:
/*
/*      var      list of variables to cluster
/*                (no "-" or ":" allowed)
/*      id       id variable for proc cluster
/*      meanfmt  format for printing means in PROC TABULATE
/*      nclus    number of clusters desired
/*      nperm    number of random permutations.
/*
/* ----- */
%macro TABPERM(var,id,meanfmt,nclus,nperm);

    /* -----CREATE DATA SETS GIVING CLUSTER MEMBERSHIP----- */
    %do n=1 %to &nperm;
        proc tree data=_tree_&n noprint n=&nclus
            out=_out_&n(drop=clusname
                rename=(cluster=_clus_&n));
            copy &var;
            id &id;
        run;

```

```

proc sort;
  by &id &var;
run;
%end;

/* -----MERGE THE CLUSTER VARIABLES----- */
data _merge_;
  merge
    %do n=1 %to &nperm;
      _out_&n
    %end;;
  by &id &var;
  length all_clus $ %eval(3*&nperm);
  %do n=1 %to &nperm;
    substr( all_clus, %eval(1+(&n-1)*3), 3) =
      put( _clus_&n, 3.);
  %end;
run;

/* ----- TABULATE CLUSTER COMBINATIONS----- */
proc sort;
  by _clus_;;
run;
proc tabulate order=data formchar='          ';
  class all_clus;
  var &var;
  table all_clus, n='FREQ'*f=5. mean*f=&meanfmt*(&var) /
    rts=%eval(&nperm*3+1);
run;
%mend;

```

To use these macros, it is first convenient to define a macro variable, `VLIST`, listing the teeth variables, since the forms `V1-V8` or `V:` cannot be used with the `TABULATE` procedure in the `TABPERM` macro:

```

/* -TABULATE does not accept hyphens or colons in VAR lists- */
%let vlist=v1 v2 v3 v4 v5 v6 v7 v8;

```

The `CLUSPERM` macro is then called to analyze 10 random permutations. The `PLOTPERM` macro plots the pseudo F and t^2 statistics and the cubic clustering criterion. Since the data are discrete, the pseudo F statistic and the cubic clustering criterion can be expected to increase as the number of clusters increases, so local maxima or large jumps in these statistics are more relevant than the global maximum in determining the number of clusters. For the raw data, only the pseudo t^2 statistic indicates the possible presence of clusters, with the four-cluster level being suggested. Hence, the macros are used as follows to analyze the results at the four-cluster level:

```

title3 'Raw Data';

/* -----CLUSTER RAW DATA WITH AVERAGE LINKAGE----- */
%clusperm( teeth, &vlist, mammal, average, 10);

```

2	2	2	2	2	2	1	2	1	1	3.6	3.4	1.3	1.8
2	4	2	2	4	2	1	2	1	1	3.0	3.0	3.0	3.0
3	1	3	3	3	1	2	1	3	2	1.2	0.8	3.0	3.0
3	4	3	3	4	1	2	1	3	2	2.5	2.0	3.0	3.0
4	4	4	4	4	4	4	4	4	4	2.0	2.4	3.0	3.0

From the TABULATE output, you can see that two types of clustering are obtained. In one case, the mole is grouped with the carnivores, while the pika and rabbit are grouped with the rodents. In the other case, both the mole and the lagomorphs are grouped with the bats.

Next, the analysis is repeated with the standardized data as shown in the following statements. The pseudo F and t^2 statistics indicate three or four clusters, while the cubic clustering criterion shows a sharp rise up to four clusters and then levels off up to six clusters. So the TABPERM macro is used again at the four-cluster level. In this case, there is no indeterminacy, because the same four clusters are obtained with every permutation, although in different orders. It must be emphasized, however, that lack of indeterminacy in no way indicates validity.

```

Overview: CORRESP Procedure

The CORRESP procedure performs simple correspondence analysis and multiple correspondence analysis (MCA). You can use correspondence analysis to find a low-dimensional graphical representation of the rows and columns of a crosstabulation or contingency table. Each row and column is represented by a point in a plot determined from the cell frequencies. PROC CORRESP can also compute coordinates for supplementary rows and columns.

PROC CORRESP can read two kinds of input: raw categorical responses on two or more classification variables or a two-way contingency table. The correspondence analysis plot is displayed with ODS Graphics. For more information about ODS Graphics, see the section “[ODS Graphics](#)” on page 2038.

Background

Correspondence analysis is a popular data analysis method in France and Japan. In France, correspondence analysis was developed under the influence of Jean-Paul Benzécri; in Japan, it was developed under Chikio Hayashi. The name *correspondence analysis* is a translation of the French *analyse des correspondances*. The technique apparently has many independent beginnings (for example, Richardson and Kuder 1933; Hirshfield 1935; Horst 1935; Fisher 1940; Guttman 1941; Burt 1950; Hayashi 1950). It has had many other names, including optimal scaling, reciprocal averaging, optimal scoring, and appropriate scoring in the United States; quantification method in Japan; homogeneity analysis in the Netherlands; dual scaling in Canada; and scalogram analysis in Israel.

Correspondence analysis is described in more detail in French in Benzécri (1973) and Lebart, Morineau, and Tabard (1977). In Japanese, the subject is described in Komazawa (1982); Nishisato (1982); Kobayashi (1981). In English, correspondence analysis is described in Lebart, Morineau, and Warwick (1984); Greenacre (1984); Nishisato (1980); Tenenhaus and Young (1985); Gifi (1990); Greenacre and Hastie (1987), and many other sources. Hoffman and Franke (1986) offer a short, introductory treatment that uses examples from the field of market research.

Getting Started: CORRESP Procedure

Data are available containing the numbers of Ph.D.’s awarded in the United States during the years 1973 through 1978 (U.S. Bureau of the Census 1979). The table has six rows, one for each of six academic disciplines, and six columns for the six years.

The concept of *inertia* in correspondence analysis is analogous to the concept of variance in principal component analysis, and it is proportional to the chi-square information.

The total chi-square statistic in Figure 32.1, which is a measure of the association between the rows and columns in the full five dimensions of the (centered) table, is 383.856. The maximum number of dimensions (or axes) is the minimum of the number of rows and columns, minus one. More than 96% of the total chi-square and inertia is explained by the first dimension, indicating that the association between the row and column categories is essentially one-dimensional. The plot in Figure 32.2 shows how the number of doctorates in the different disciplines changes over time. The plot shows that the number of doctorates in the behavioral sciences is associated with later years, and the number of doctorates in mathematics and engineering is associated with earlier years. This is consistent with the data that show that the number of doctorates in the behavioral sciences is increasing, the number of doctorates in every other discipline is decreasing, and the rate of decrease is greatest for mathematics and engineering.

Figure 32.2 Correspondence Analysis of Ph.D. Data

Syntax: CORRESP Procedure

The following statements are available in the CORRESP procedure.

```
PROC CORRESP < options > ;
  TABLES < row-variables, > column-variables ;
  VAR variables ;
  BY variables ;
  ID variable ;
  SUPPLEMENTARY variables ;
  WEIGHT variable ;
```

There are two separate forms of input to PROC CORRESP. One form is specified in the TABLES statement, the other in the VAR statement. You must specify either the TABLES or the VAR statement, but not both, each time you run PROC CORRESP.

Specify the TABLES statement if you are using raw, categorical data, the levels of which define the rows and columns of a table.

Specify the VAR statement if your data are already in tabular form. PROC CORRESP is generally more efficient with VAR statement input than with TABLES statement input.

The other statements are optional. All of the statements are explained, in alphabetical order, following the PROC CORRESP statement. All of the options in PROC CORRESP can be abbreviated to their first three letters, except for the OUTF= option. This is a special feature of PROC CORRESP and is not generally true of SAS/STAT procedures.

PROC CORRESP Statement

```
PROC CORRESP < options > ;
```

The PROC CORRESP statement invokes the CORRESP procedure. [Table 32.1](#) summarizes the options available in the PROC CORRESP statement. These options are described following the table.

Table 32.1 Summary of PROC CORRESP Statement Options

Option	Description
Data Set Options	
DATA=	Specifies input SAS data set
OUTC=	Specifies output coordinate SAS data set
OUTF=	Specifies output frequency SAS data set
Row and Column Coordinates	
DIMENS=	Specifies the number of dimensions or axes
MCA	Performs multiple correspondence analysis
PROFILE=	Standardizes the row and column coordinates
Table Construction	
BINARY	Specifies binary table

Table 32.1 *continued*

Option	Description
CROSS=	Specifies cross levels of TABLES variables
FREQOUT	Specifies input data in PROC FREQ output
MISSING	Includes observations with missing values
Control Displayed Output	
ALL	Displays all output
BENZECRI	Displays inertias adjusted by Benzécri's method
CELLCHI2	Displays cell contributions to chi-square
CP	Displays column profile matrix
DEVIATION	Displays observed minus expected values
EXPECTED	Displays chi-square expected values
GREENACRE	Displays inertias adjusted by Greenacre's method
NOCOLUMN=	Suppresses the display of column coordinates
NOPRINT	Suppresses the display of all output
NOROW=	Suppresses the display of row coordinates
OBSERVED	Displays contingency table of observed frequencies
PLOTS=	Specifies ODS Graphics details
PRINT=	Displays percentages or frequencies
RP	Displays row profile matrix
SHORT	Suppresses all point and coordinate statistics
UNADJUSTED	Displays unadjusted inertias
Other Options	
COLUMN=	Specifies esoteric column coordinate standardizations
MININERTIA=	Specifies minimum inertia
NVARS=	Specifies number of classification variables
ROW=	Specifies esoteric row coordinate standardizations
SINGULAR=	Specifies effective zero
SOURCE	Includes level source in the OUTC= data set

The display options control the amount of displayed output. The CELLCHI2, EXPECTED, and DEVIATION options display additional chi-square information. See the “[Details: CORRESP Procedure](#)” section for more information. The unit of the matrices displayed by the CELLCHI2, CP, DEVIATION, EXPECTED, OBSERVED, and RP options depends on the value of the PRINT= option. The table construction options control the construction of the contingency table; these options are valid only when you also specify a TABLES statement.

You can specify the following options in the PROC CORRESP statement. They are given in alphabetical order.

ALL

is equivalent to specifying the OBSERVED, RP, CP, CELLCHI2, EXPECTED, and DEVIATION options. Specifying the ALL option does not affect the PRINT= option. Therefore, only frequencies (not percentages) for these options are displayed unless you specify otherwise with the PRINT= option.

BENZECRI**BEN**

displays adjusted inertias when performing multiple correspondence analysis. By default, unadjusted inertias, the usual inertias from multiple correspondence analysis, are displayed. However, adjusted inertias that use a method proposed by Benzécri (1979) and described by Greenacre (1984, p. 145) can be displayed by specifying the BENZECRI option. Specify the UNADJUSTED option to output the usual table of unadjusted inertias as well. See the section “[MCA Adjusted Inertias](#)” on page 2031 for more information.

BINARY

enables you to create binary tables easily. When you specify the BINARY option, specify only column variables in the TABLES statement. Each input data set observation forms a single row in the constructed table.

CELLCHI2**CEL**

displays the contribution to the total chi-square test statistic for each cell. See also the descriptions of the DEVIATION, EXPECTED, and OBSERVED options.

COLUMN=B | BD | DB | DBD | DBD1/2 | DBID1/2**COL=B | BD | DB | DBD | DBD1/2 | DBID1/2**

provides other standardizations of the column coordinates. The COLUMN= option is rarely needed. Typically, you should use the PROFILE= option instead (see the section “[The PROFILE=, ROW=, and COLUMN= Options](#)” on page 2028). By default, COLUMN=DBD.

CP

displays the column profile matrix. Column profiles contain the observed conditional probabilities of row membership given column membership. See also the RP option.

CROSS=BOTH | COLUMN | NONE | ROW**CRO=BOT | COL | NON | ROW**

specifies the method of crossing (factorially combining) the levels of the TABLES variables. The default is CROSS=NONE.

NONE	causes each level of every row variable to become a row label and each level of every column variable to become a column label.
ROW	causes each combination of levels for all row variables to become a row label, whereas each level of every column variable becomes a column label.
COLUMN	causes each combination of levels for all column variables to become a column label, whereas each level of every row variable becomes a row label.
BOTH	causes each combination of levels for all row variables to become a row label and each combination of levels for all column variables to become a column label.

The section “[TABLES Statement](#)” on page 2008 provides a more detailed description of this option.

DATA=SAS-data-set

specifies the SAS data set to be used by PROC CORRESP. If you do not specify the DATA= option, PROC CORRESP uses the most recently created SAS data set.

DEVIATION**DEV**

displays the matrix of deviations between the observed frequency matrix and the product of its row marginals and column marginals divided by its grand frequency. For ordinary two-way contingency tables, these are the observed minus expected frequencies under the hypothesis of row and column independence and are components of the chi-square test statistic. See also the CELLCHI2, EXPECTED, and OBSERVED options.

DIMENS=*n***DIM=*n***

specifies the number of dimensions or axes to use. The default is DIMENS=2. The maximum value of the DIMENS= option in an $(n_r \times n_c)$ table is $n_r - 1$ or $n_c - 1$, whichever is smaller. For example, in a table with 4 rows and 5 columns, the maximum specification is DIMENS=3. If your table has 2 rows or 2 columns, specify DIMENS=1.

EXPECTED**EXP**

displays the product of the row marginals and the column marginals divided by the grand frequency of the observed frequency table. For ordinary two-way contingency tables, these are the expected frequencies under the hypothesis of row and column independence and are components of the chi-square test statistic. In other situations, this interpretation is not strictly valid. See also the CELLCHI2, DEVIATION, and OBSERVED options.

FREQOUT**FRE**

indicates that the PROC CORRESP input data set has the same form as an output data set from the FREQ procedure, even if it was not directly produced by PROC FREQ. The FREQOUT option enables PROC CORRESP to take shortcuts in constructing the contingency table.

When you specify the FREQOUT option, you must also specify a WEIGHT statement. The cell frequencies in a PROC FREQ output data set are contained in a variable called COUNT, so specify COUNT in a WEIGHT statement with PROC CORRESP. The FREQOUT option might produce unexpected results if the DATA= data set is structured incorrectly. Each of the two variable lists specified in the TABLES statement must consist of a single variable, and observations must be grouped by the levels of the row variable and then by the levels of the column variable. It is not required that the observations be sorted by the row variable and column variable, but they must be grouped consistently. There must be as many observations in the input data set (or BY group) as there are cells in the completed contingency table. Zero cells must be specified with zero weights. When you use PROC FREQ to create the PROC CORRESP input data set, you must specify the SPARSE option in the FREQ procedure's TABLES statement so that the zero cells are written to the output data set.

GREENACRE**GRE**

displays adjusted inertias when you are performing multiple correspondence analysis. By default,

unadjusted inertias, the usual inertias from multiple correspondence analysis, are displayed. However, adjusted inertias that use a method proposed by Greenacre (1984, p. 156) can be displayed by specifying the GREENACRE option. Specify the UNADJUSTED option to output the usual table of unadjusted inertias as well. See the section “[MCA Adjusted Inertias](#)” on page 2031 for more information.

MCA

requests a multiple correspondence analysis. This option requires that the input table be a Burt table, which is a symmetric matrix of crosstabulations among several categorical variables. If you specify the MCA option and a VAR statement, you must also specify the NVAR= option, which gives the number of categorical variables that were used to create the table. With raw categorical data, if you want results for the individuals as well as the categories, use the BINARY option instead.

MININERTIA=*n*

MIN=*n*

specifies the minimum inertia ($0 \leq n \leq 1$) used to create the “best” tables—the indicator of which points best explain the inertia of each dimension. By default, MININERTIA=0.8. See the section “[Algorithm and Notation](#)” on page 2026 for more information.

MISSING

MIS

specifies that observations with missing values for the TABLES statement variables are included in the analysis. Missing values are treated as a distinct level of each categorical variable. By default, observations with missing values are excluded from the analysis.

NOCOLUMN <= BOTH | DATA | PRINT >

NOC <= BOT | DAT | PRI >

suppresses the display of the column coordinates and statistics and omits them from the output coordinate data set.

BOTH suppresses all column information from both the SAS listing and the output data set. The NOCOLUMN option is equivalent to the option NOCOLUMN=BOTH.

DATA suppresses all column information from the output data set.

PRINT suppresses all column information from the SAS listing.

NOPRINT

NOP

suppresses the display of all output. This option is useful when you need only an output data set. This option disables the Output Delivery System (ODS), including ODS Graphics, for the duration of the PROC. For more information, see Chapter 20, “[Using the Output Delivery System](#).”

NOROW <= BOTH | DATA | PRINT >

NOR <= BOT | DAT | PRI >

suppresses the display of the row coordinates and statistics and omits them from the output coordinate data set.

BOTH	suppresses all row information from both the SAS listing and the output data set. The NOROW option is equivalent to the option NOROW=BOTH.
DATA	suppresses all row information from the output data set.
PRINT	suppresses all row information from the SAS listing.

The NOROW option can be useful when the rows of the contingency table are replications.

NVARS=*n*

NVA=*n*

specifies the number of classification variables that were used to create the Burt table. For example, suppose the Burt table was originally created with the following statement:

```
tables a b c;
```

You must specify NVARS=3 to read the table with a VAR statement.

The NVARS= option is required when you specify both the MCA option and a VAR statement. (See the section “[VAR Statement](#)” on page 2008 for an example.)

OBSERVED

OBS

displays the contingency table of observed frequencies and its row, column, and grand totals. If you do not specify the OBSERVED or ALL option, the contingency table is not displayed.

OUTC=*SAS-data-set*

OUT=*SAS-data-set*

creates an output coordinate SAS data set to contain the row, column, supplementary observation, and supplementary variable coordinates. This data set also contains the masses, squared cosines, quality of each point’s representation in the DIMENS=*n* dimensional display, relative inertias, partial contributions to inertia, and best indicators.

OUTF=*SAS-data-set*

creates an output frequency SAS data set to contain the contingency table, row, and column profiles, the expected values, and the observed minus expected values and contributions to the chi-square statistic.

PLOTS<(global-plot-options)> <= plot-request <(options)>>

PLOTS<(global-plot-options)> <= (plot-request <(options)> <... plot-request <(options)>>>

specifies options that control the details of the plots. When you specify only one plot request, you can omit the parentheses around the plot request.

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;

proc corresp;
    tables Marital, Origin;
run;

ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

By default, for simple correspondence analysis, PROC CORRESP prints the configuration of points consisting of the row coordinates and column coordinates. With MCA, only column coordinates are printed. The default plots ($y * x$) are Dim2 * Dim1, Dim3 * Dim1, Dim3 * Dim2, and so on. When you specify PLOTS(FLIP), the plots are Dim1 * Dim2, Dim1 * Dim3, Dim2 * Dim3, and so on.

The global plot option is as follows:

FLIP

FLI

flips or interchanges the X-axis and Y-axis dimensions.

The plot requests include the following:

ALL

produces all appropriate plots.

NONE

NON

suppresses all plots.

PRINT=BOTH | FREQ | PERCENT

PRI=BOT | FRE | PER

affects the OBSERVED, RP, CP, CELLCHI2, EXPECTED, and DEVIATION options. The default is PRINT=FREQ.

- The PRINT=FREQ option displays output in the appropriate raw or natural units. (That is, PROC CORRESP displays raw frequencies for the OBSERVED option, relative frequencies with row marginals of 1.0 for the RP option, and so on.)
- The PRINT=PERCENT option scales results to percentages for the display of the output. (All elements in the OBSERVED matrix sum to 100.0, the row marginals are 100.0 for the RP option, and so on.)
- The PRINT=BOTH option displays both percentages and frequencies.

PROFILE=BOTH | COLUMN | NONE | ROW

PRO=BOT | COL | NON | ROW

specifies the standardization for the row and column coordinates. The default is PROFILE=BOTH.

BOTH specifies a standard correspondence analysis, which jointly displays the principal row and column coordinates. Row coordinates are computed from the row profile matrix, and column coordinates are computed from the column profile matrix.

ROW specifies a correspondence analysis of the row profile matrix. The row coordinates are weighted centroids of the column coordinates.

COLUMN specifies a correspondence analysis of the column profile matrix. The column coordinates are weighted centroids of the row coordinates.

NONE is rarely needed. Row and column coordinates are the generalized singular vectors, without the customary standardizations.

ROW=A | AD | DA | DAD | DAD1/2 | DAID1/2

provides other standardizations of the row coordinates. The ROW= option is rarely needed. Typically, you should use the PROFILE= option instead (see the section “[The PROFILE=, ROW=, and COLUMN= Options](#)” on page 2028). By default, ROW=DAD.

RP

displays the row profile matrix. Row profiles contain the observed conditional probabilities of column membership given row membership. See also the CP option.

SHORT**SHO**

suppresses the display of all point and coordinate statistics except the coordinates. The following information is suppressed: each point’s mass, relative contribution to the total inertia, and quality of representation in the DIMENS=*n* dimensional display; the squared cosines of the angles between each axis and a vector from the origin to the point; the partial contributions of each point to the inertia of each dimension; and the best indicators.

SINGULAR=*n***SIN=*n***

specifies the largest value that is considered to be within rounding error of zero. The default value is 1E–8. This parameter is used in checking for zero rows and columns, in checking Burt table diagonal sums for equality, in checking denominators before dividing, and so on. Typically, you should not assign a value outside the range 1E–6 to 1E–12.

SOURCE**SOU**

adds the variable _VAR_, which contains the name or label of the variable corresponding to the current level, to the OUTC= and OUTF= data sets.

UNADJUSTED**UNA**

displays unadjusted inertias when performing multiple correspondence analysis. By default, unadjusted inertias, the usual inertias from multiple correspondence analysis, are displayed. However, if adjusted inertias are requested by either the GREENACRE option or the BENZECRI option, then the unadjusted inertia table is not displayed unless the UNADJUSTED option is specified. See the section “[MCA Adjusted Inertias](#)” on page 2031 for more information.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC CORRESP to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the CORRESP procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

ID Statement

ID *variable* ;

You specify the ID statement only in conjunction with the VAR statement. You cannot specify the ID statement when you use the TABLES statement or the MCA option. When you specify an ID variable, PROC CORRESP labels the rows of the tables with the ID values and places the ID variable in the output data set.

SUPPLEMENTARY Statement

SUPPLEMENTARY *variables* ;

SUP *variables* ;

The SUPPLEMENTARY statement specifies variables that are to be represented as points in the joint row and column space but that are not used in determining the locations of the other, active row and column points of the contingency table. Supplementary observations on supplementary variables are ignored in simple correspondence analysis but are needed to compute the squared cosines for multiple correspondence analysis. Variables that are specified in the SUPPLEMENTARY statement must also be specified in the TABLES or VAR statement.

When you specify a VAR statement, each SUPPLEMENTARY variable indicates one supplementary column of the table. Supplementary variables must be numeric with VAR statement input.

When you specify a TABLES statement, each SUPPLEMENTARY variable indicates a set of rows or columns of the table that is supplementary. Supplementary variables can be either character or numeric with TABLES statement input.

TABLES Statement

TABLES < row-variables, > column-variables ;

The TABLES statement instructs PROC CORRESP to create a contingency table, Burt table, or binary table from the values of two or more categorical variables. The TABLES statement specifies classification variables that are used to construct the rows and columns of the contingency table. The variables can be either numeric or character. The variable lists in the TABLES statement and the CROSS= option together determine the row and column labels of the contingency table.

You can specify both row variables and column variables separated by a comma, or you can specify only column variables and no comma. If you do not specify row variables (that is, if you list variables but do not use the comma as a delimiter), then you should specify either the MCA or the BINARY option. With the MCA option, PROC CORRESP creates a Burt table, which is a crosstabulation of each variable with itself and every other variable. The Burt table is symmetric. With the BINARY option, PROC CORRESP creates a binary table, which consists of one row for each input data set observation and one column for each category of each TABLES statement variable. If the binary matrix is \mathbf{Z} , then the Burt table is $\mathbf{Z}'\mathbf{Z}$. Specifying the BINARY option with the NOROWS option produces the same results as specifying the MCA option (except for the chi-square statistics).

See [Figure 32.6](#) for an example or see the section “[The MCA Option](#)” on page 2030 for a detailed description of Burt tables.

You can use the WEIGHT statement with the TABLES statement to read category frequencies. Specify the SUPPLEMENTARY statement to name variables with categories that are supplementary rows or columns. You cannot specify the ID or VAR statement with the TABLES statement. See the section “[Using the TABLES Statement](#)” on page 2010 for an example.

VAR Statement

VAR variables ;

You should specify the VAR statement when your data are in tabular form. The VAR variables must be numeric. The VAR statement instructs PROC CORRESP to read an existing contingency table, binary indicator matrix, fuzzy-coded indicator matrix, or Burt table, rather than raw data. See the section “[Algorithm and Notation](#)” on page 2026 for a description of a binary indicator matrix and a fuzzy-coded indicator matrix.

You can specify the WEIGHT statement with the VAR statement to read category frequencies and designate supplementary rows. Specify the SUPPLEMENTARY statement to name supplementary variables. You cannot specify the TABLES statement with the VAR statement.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement specifies weights for each observation and indicates supplementary observations for simple correspondence analyses with VAR statement input. You can include only one WEIGHT statement, and the weight variable must be numeric.

If you omit the WEIGHT statement, each observation contributes a value of 1 to the frequency count for its category. That is, each observation represents one subject. When you specify a WEIGHT statement, each observation contributes the value of the weighting variable for that observation. For example, a weight of 3 means that the observation represents three subjects. Weight values are not required to be integers.

You can specify the WEIGHT statement with a TABLES statement to indicate category frequencies, as in the following example:

```
proc freq;
  tables a*b / out=outfreq sparse;
run;

proc corresp freqout;
  tables a, b;
  weight count;
run;
```

If you specify a VAR statement, you can specify the WEIGHT statement to indicate supplementary observations and to weight some rows of the table more heavily than others. When the value of the WEIGHT variable is negative, the observation is treated as supplementary, and the absolute value of the weight is used as the weighting value.

You cannot specify a WEIGHT statement with a VAR statement and the MCA option, because the table must be symmetric. Supplementary variables are indicated with the SUPPLEMENTARY statement, so differential weighting of rows is inappropriate.

Details: CORRESP Procedure

Input Data Set

PROC CORRESP can read two kinds of input:

- raw category responses on two or more classification variables with the TABLES statement
- a two-way contingency table with the VAR statement

You can use output from PROC FREQ as input for PROC CORRESP.

The classification variables referred to by the TABLES statement can be either numeric or character variables. Normally, all observations for a given variable that have the same formatted value are placed in the same level, and observations with different values are placed in different levels.

The variables in the VAR statement must be numeric. The values of the observations specify the cell frequencies. These values are not required to be integers, but only those observations with all nonnegative, nonmissing values are used in the correspondence analysis. Observations with one or more negative values are removed from the analysis.

The WEIGHT variable must be numeric. Observations with negative weights are treated as supplementary observations. The absolute values of the weights are used to weight the observations.

Using the TABLES Statement

This section explains some of the choices for the correspondence analysis input data table and illustrates some table-construction capabilities of PROC CORRESP. The SAS data set Neighbor, which follows, will be used throughout this section to illustrate various ways in which PROC CORRESP can read and process data. This data set consists of one observation for each resident in a fictitious neighborhood along with some personal information.

```

title 'PROC CORRESP Table Construction';

data Neighbor;
  input Name $ 1-10 Age $ 12-18 Sex $ 19-25
        Height $ 26-30 Hair $ 32-37;

Delafave   Old    Male   Tall  Brown
Singer     Young  Male   Tall  Brown
Igor       Old           Short
;

```

This first step creates a simple contingency table or crosstabulation. In the TABLES statement, each variable list consists of a single variable. The following statements produce the table in [Figure 32.3](#).

```

proc corresp data=Neighbor dims=1 observed short;
  title2 'Simple Crosstabulation';
  ods select observed;
  tables Sex, Age;
run;

```

These statements create a contingency table with two rows (**Female** and **Male**) and two columns (**Old** and **Young**) and show the neighbors categorized by age and sex. The DIMENS=1 option specifies the number of dimensions in the correspondence analysis. Typically, you do not have to specify this option, because typically your tables will be larger than two by two. The default is DIMENS=2, which is too large for a table with a two-level factor. The OBSERVED option displays the contingency table. The SHORT option limits the displayed output. Because it contains missing values, the observation where Name='Igor' is omitted from the analysis. The table is shown in [Figure 32.3](#).

Figure 32.3 Contingency Table for Sex, Age

PROC CORRESP Table Construction

The CORRESP Procedure			
Contingency Table			
	Old	Young	Sum
Female	2	2	4
Male	4	3	7
Sum	6	5	11

The preceding example showed how to make a two-way contingency table based on the levels of two categorical variables, which, if it were larger, would be a very typical form of data for a correspondence analysis. However, many other types of tables, **N**, can be used as input to a correspondence analysis, and all tables can be defined based on a binary matrix, **Z**. The BINARY option enables you to directly compute and display this matrix. The TABLES statement consists of a single list of all the categorical variables. The following statements produce [Figure 32.4](#).

```

proc corresp data=neighbor observed short binary;
  title2 'Binary Coding';
  ods select binary;
  tables Hair Height Sex Age;
run;

```

Figure 32.4 Binary Table Using the BINARY Option

PROC CORRESP Table Construction									
Binary Coding									
The CORRESP Procedure									
Binary Table									
	Blond	Brown	White	Short	Tall	Female	Male	Old	Young
1	0	0	1	1	0	0	1	1	0
2	0	1	0	0	1	1	0	0	1
3	0	1	0	1	0	0	1	1	0
4	0	0	1	0	1	1	0	1	0
5	0	1	0	1	0	1	0	1	0
6	1	0	0	0	1	0	1	0	1
7	0	1	0	0	1	0	1	0	1
8	1	0	0	1	0	0	1	1	0
9	1	0	0	1	0	1	0	0	1
10	0	1	0	0	1	0	1	1	0
11	0	1	0	0	1	0	1	0	1

In this case, $N = Z$ is directly analyzed. The binary matrix has one row for each individual or case and one column for each category. A binary table constructed from m categorical variables has m partitions. This binary table has four partitions, one for each of the four categorical variables. Each partition has a 1 in each row, and each row contains exactly four 1s since there are four categorical variables. More generally, the binary design matrix has exactly m 1s in each row. The 1s indicate the categories to which the observation applies. For example, the categorical variable Sex, with two levels (**Female** and **Male**), is coded using two indicator variables. For the variable Sex, a male would be coded Female=0 and Male=1, and a female would be coded Female=1 and Male=0. This is the same kind of coding that procedures like GLM and TRANSREG use for CLASS variables.

Implicitly, the binary table has an automatic row variable that is equal to the observation number. Alternatively, when there is a row ID variable, as there is in this case, you can use it as a row variable in the TABLES statement, and the resulting ordinary observed frequency table is the binary table. This example uses two variable lists: Name for the row variable, and Hair Height Sex Age for the column variables. Since two lists were provided, the BINARY option was not specified. The following statements produce Figure 32.5.

```
proc corresp data=neighbor observed short;
  title2 'Binary Coding';
  ods select observed;
  tables Name, Hair Height Sex Age;
run;
```

Figure 32.5 Binary Table Using a Row Variable

Sum	3	6	2	5	6	4	7	6	5	44

With the MCA option, the Burt table ($Z'Z$) is analyzed. A Burt table is a partitioned symmetric matrix containing all pairs of crosstabulations among a set of categorical variables. Each diagonal partition is a diagonal matrix containing marginal frequencies (a crosstabulation of a variable with itself). Each off-diagonal partition is an ordinary contingency table. The following statements produce [Figure 32.6](#).

```
proc corresp data=neighbor observed short mca;
  title2 'MCA Burt Table';
  ods select burt;
  tables Hair Height Sex Age;
run;
```

Note that there is a single variable list in the TABLES statement, since the row and column variable lists are the same.

Figure 32.6 MCA Burt Table

PROC CORRESP Table Construction									
MCA Burt Table									
The CORRESP Procedure									
Burt Table									
	Blond	Brown	White	Short	Tall	Female	Male	Old	Young
Blond	3	0	0	2	1	1	2	1	2
Brown	0	6	0	2	4	2	4	3	3
White	0	0	2	1	1	1	1	2	0
Short	2	2	1	5	0	2	3	4	1
Tall	1	4	1	0	6	2	4	2	4
Female	1	2	1	2	2	4	0	2	2
Male	2	4	1	3	4	0	7	4	3
Old	1	3	2	4	2	2	4	6	0
Young	2	3	0	1	4	2	3	0	5

This Burt table is composed of all pairs of crosstabulations among the variables Hair, Height, Sex, and Age. It is composed of sixteen individual subtables—the number of variables squared. Both the rows and the columns have the same nine categories (in this case Blond, Brown, White, Short, Tall, Female, Male, Old, and Young). Below the diagonal (from left to right, top to bottom) are the following crosstabulations: Height * Hair, Sex * Hair, Sex * Height, Age * Hair, Age * Height, and Age * Sex. Each crosstabulation below the diagonal has a transposed counterpart above the diagonal. The diagonal contains the crosstabulations: Hair * Hair, Height * Height, Sex * Sex, and Age * Age. The diagonal elements of the diagonal partitions contain marginal frequencies of the off-diagonal partitions. The table Hair * Height, for example, has three rows for Hair and two columns for Height. The values of the Hair * Height table, summed across rows, sum to the diagonal values of the Height * Height table, as displayed in the following results. The following statements produce [Figure 32.7](#).

```
proc corresp data=neighbor observed short dims=1;
  title2 'Part of the Burt Table';
  ods output observed=o;
  tables Hair Height, Height;
run;

proc print data=o(drop=sum) label noobs;
  where label ne 'Sum';
  label label = '00'x;
run;
```

PROC CORRESP Table Construction Part of the Burt Table		
	Short	Tall
Blond	2	1
Brown	2	4
White	1	1
Short	5	0
Tall	0	6

A simple crosstabulation of Hair \times Height is $N = Z_{\text{Hair}}'Z_{\text{Height}}$. Tables such as $(N = Z_{\text{Hair}}'Z_{\text{Height,Sex}})$, made up of several crosstabulations, can also be analyzed in simple correspondence analysis. The following statements produce Figure 32.8.

```
proc corresp data=neighbor observed short dimens=1;
  title2 'Multiple Crosstabulations';
  ods select observed;
  tables Hair, Height Sex;
run;
```

Figure 32.8 Hair \times (Height Sex) Crosstabulation

PROC CORRESP Table Construction Multiple Crosstabulations

	Short	Tall	Female	Male	Sum
Blond	2	1	1	2	6
Brown	2	4	2	4	12
White	1	1	1	1	4
Sum	5	6	4	7	22

The following statements create a table with six rows (**Blond*Short**, **Blond*Tall**, **Brown*Short**, **Brown*Tall**, **White*Short**, and **White*Tall**) and four columns (**Female**, **Male**, **Old**, and **Young**). The levels of the row variables are crossed by the **CROSS=ROW** option, forming mutually exclusive categories. Hence each individual fits into exactly one row category, but two column categories. The following statements produce Figure 32.9.

```
proc corresp data=Neighbor cross=row observed short;
  title2 'Multiple Crosstabulations with Crossed Rows';
  ods select observed;
  tables Hair Height, Sex Age;
run;
```

White * Short	0	1	1	0	2
White * Tall	1	0	1	0	2
Sum	4	7	6	5	22

You can enter supplementary variables with TABLES input by including a SUPPLEMENTARY statement. Variables named in the SUPPLEMENTARY statement indicate TABLES variables with categories that are supplementary. In other words, the categories of the variable Age are represented in the row and column space, but they are not used in determining the scores of the categories of the variables Hair, Height, and Sex. The variable used in the SUPPLEMENTARY statement must be listed in the TABLES statement as well. For example, the following statements create a Burt table with seven active rows and columns (**Blond**, **Brown**, **White**, **Short**, **Tall**, **Female**, **Male**) and two supplementary rows and columns (**Old** and **Young**). The following statements produce [Figure 32.10](#).

```
proc corresp data=Neighbor observed short mca;
  title2 'MCA with Supplementary Variables';
  ods select burt supcols;
  tables Hair Height Sex Age;
  supplementary Age;
run;
```

Using the VAR Statement

With VAR statement input, the rows of the contingency table correspond to the observations of the input data set, and the columns correspond to the VAR statement variables. The values of the variables typically contain the table frequencies. The table in Figure 32.3 could be created with VAR statement input by using the following statements:

```
data Ages;
  input Sex $ Old Young;
  datalines;
Female  2 2
Male    4 3
;

proc corresp data=Ages dimens=1 observed short;
  var Old Young;
  id Sex;
run;
```

Only nonnegative values are accepted. Negative values are treated as missing, causing the observation to be excluded from the analysis. The values are not required to be integers. Row labels for the table are specified with an ID variable. Column labels are constructed from the variable name or variable label if one is specified. When you specify multiple correspondence analysis (MCA), the row and column labels are the same and are constructed from the variable names or labels, so you cannot include an ID statement. With MCA, the VAR statement must list the variables in the order in which the rows occur. An example is the table in Figure 32.6, which was created with the following TABLES statement.

```
tables Hair Height Sex Age;
```

This table could have been created with a VAR statement as follows:

```
proc corresp data=table nvars=4 mca;
  var Blond Brown White Short Tall Female Male Old Young;
run;
```

You must specify the NVAR= option in order to specify the number of original categorical variables with the MCA option. The option NVAR= n is needed to find boundaries between the subtables of the Burt table. If f is the sum of all elements in the Burt table $\mathbf{Z}'\mathbf{Z}$, then $f n^{-2}$ is the number of rows in the binary matrix \mathbf{Z} . The sum of all elements in each diagonal subtable of the Burt table must be $f n^{-2}$.

To enter supplementary observations, include a WEIGHT statement with negative weights for those observations. Specify the SUPPLEMENTARY statement to include supplementary variables. You must list supplementary variables in both the VAR and SUPPLEMENTARY statements.

Missing and Invalid Data

With VAR statement input, observations with missing or negative frequencies are excluded from the analysis. Supplementary variables and supplementary observations with missing or negative frequencies are also excluded. Negative weights are valid with VAR statement input.

With TABLES statement input, observations with negative weights are excluded from the analysis. With this form of input, missing cell frequencies cannot occur. Observations with missing values on the categorical variables are excluded unless you specify the MISSING option. If you specify the MISSING option, ordinary missing values and special missing values are treated as additional levels of a categorical variable. In all cases, if any row or column of the constructed table contains only zeros, that row or column is excluded from the analysis.

Observations with missing weights are excluded from the analysis.

Coding, Fuzzy Coding, and Doubling

Sometimes, binary data such as Yes/No data are available—for example, 1 means “Yes, I have bought this brand in the last month” and 0 means “No, I have not bought this brand in the last month”. The following statements read a data set with Yes/No purchase data for three hypothetical brands.

```
title 'Doubling Yes/No Data';

proc format;
  value yn 0 = 'No ' 1 = 'Yes';
run;

data BrandChoice;
  input a b c;
  label a = 'Brand A' b = 'Brand B' c = 'Brand B';
```

```

format a b c yn.;
datalines;
0 0 1
1 1 0
0 1 1
0 1 0
1 0 0
;

```

Data such as these cannot be analyzed directly because the raw data do not consist of partitions, each with one column per level and exactly one 1 in each row. (See the section “Using the TABLES Statement” on page 2010.) The data must be *doubled* so that both Yes and No are represented by a column in the data matrix. The TRANSREG procedure provides one way of doubling. In the following statements, the DESIGN option specifies that PROC TRANSREG is being used only for coding, not analysis. The option SEPARATORS=’ : ’ specifies that labels for the coded columns are constructed from input variable labels, followed by a colon and space, followed by the formatted value. The variables are designated in the MODEL statement as CLASS variables, and the ZERO=NONE option creates binary variables for all levels. The OUTPUT statement specifies the output data set and drops the _NAME_, _TYPE_, and Intercept variables. PROC TRANSREG stores a list of coded variable names in a macro variable &_TRGIND, which in this case has the value “aNo aYes bNo bYes cNo cYes”. This macro variable can be used directly in the VAR statement in PROC CORRESP. The following statements produce Figure 32.12. Only the input table is displayed.

```

proc transreg data=BrandChoice design separators=' : ';
  model class(a b c / zero=none);
  output out=Doubled(drop=_: Intercept);
run;

proc print label;
run;

proc corresp data=Doubled norow short;
  var &_trgind;
run;

```

Figure 32.12 Doubling Yes/No Data

Doubling Yes/No Data									
Obs	Brand A: No	Brand A: Yes	Brand B: No	Brand B: Yes	Brand B: No	Brand B: Yes	Brand A	Brand B	Brand B
1	1	0	1	0	0	1	No	No	Yes
2	0	1	0	1	1	0	Yes	Yes	No
3	1	0	0	1	0	1	No	Yes	Yes
4	1	0	0	1	1	0	No	Yes	No
5	0	1	1	0	1	0	Yes	No	No

A fuzzy-coded indicator also sums to 1.0 across levels of the categorical variable, but it is coded with fractions rather than with 0 and 1. The fractions represent the distribution of the attribute across several levels of the categorical variable.

Ordinal variables, such as survey responses of 1 to 3, can be represented as two fuzzy-coded variables, as shown in [Table 32.2](#).

Table 32.2 Coding an Ordinal Variable

Ordinal Values	Coding	
1	0.25	0.75
2	0.50	0.50
3	0.75	0.25

The values of the coding sum to one across the two coded variables.

These next steps illustrate the use of binary and fuzzy-coded indicator variables. Fuzzy-coded indicators are used to represent missing data. Note that the missing values in the observation Igor are coded with equal proportions. The following statements produce [Figure 32.13](#).

```

title 'Fuzzy Coding of Missing Values';

proc transreg data=Neighbor design cprefix=0;
  model class(Age Sex Height Hair / zero=none);
  output out=Neighbor2(drop=_: Intercept);
  id Name;
run;

data Neighbor3;
  set Neighbor2;
  if Sex = ' ' then do;
    Female = 0.5;
    Male   = 0.5;
  end;
  if Hair = ' ' then do;
    White = 1/3;
    Brown = 1/3;
    Blond = 1/3;
  end;
run;

proc print label noobs data=Neighbor3(drop=age--name);
  format _numeric_ best4.;
run;

```

Figure 32.13 Fuzzy Coding of Missing Values

Fuzzy Coding of Missing Values								
Age Old	Age Young	Sex Female	Sex Male	Height Short	Height Tall	Hair Blond	Hair Brown	Hair White
1	0	0	1	1	0	0	0	1
0	1	1	0	0	1	0	1	0
1	0	0	1	1	0	0	1	0
1	0	1	0	0	1	0	0	1
1	0	1	0	1	0	0	1	0
0	1	0	1	0	1	1	0	0
0	1	0	1	0	1	0	1	0
1	0	0	1	1	0	1	0	0
0	1	1	0	1	0	1	0	0
1	0	0	1	0	1	0	1	0
0	1	0	1	0	1	0	1	0
1	0	0.5	0.5	1	0	0.33	0.33	0.33

There is one set of coded variables for each input categorical variable. If observation 12 is excluded, each set is a binary design matrix. Each design matrix has one column for each category and exactly one 1 in each row. Fuzzy coding is shown in the final observation, which corresponds to Igor. The observation for Igor has missing values for the variables Sex and Hair. The design matrix variables are coded with fractions that sum to one within each categorical variable.

An alternative way to represent missing data is to treat missing values as an additional level of the categorical variable. This alternative is available with the MISSING option in the PROC CORRESP statement. This approach yields coordinates for missing responses, allowing the comparison of “missing” along with the other levels of the categorical variables.

Greenacre and Hastie (1987) discuss additional coding schemes, including one for continuous variables. Continuous variables can be coded with PROC TRANSREG by specifying BSPLINE(*variables* / degree=1) in the MODEL statement.

Creating a Data Set Containing the Crosstabulation

The CORRESP procedure can read or create a contingency or Burt table. PROC CORRESP is generally more efficient with VAR statement input than with TABLES statement input. TABLES statement input requires that the table be created from raw categorical variables, whereas the VAR statement is used to read an existing table. For extremely large problems, if PROC CORRESP runs out of memory, it might be possible to use some other method to create the table and then use VAR statement input with PROC CORRESP.

The following example uses the CORRESP, FREQ, and TRANSPOSE procedures to create rectangular tables from a SAS data set WORK.A that contains the categorical variables V1–V5. The Burt table examples assume that no categorical variable has a value found in any of the other categorical variables (that is, that each row and column label is unique).

You can use PROC CORRESP and the ODS OUTPUT statement as follows to create a rectangular two-way contingency table from two categorical variables:

```
proc corresp data=a observed short;
  ods output Observed=Obs (drop=Sum where=(Label ne 'Sum'));
  tables v1, v2;
run;
```

You can use PROC FREQ and PROC TRANSPOSE to create a rectangular two-way contingency table from two categorical variables, as in the following statements:

```
proc freq data=a;
  tables v1 * v2 / sparse noprint out=freqs;
run;

proc transpose data=freqs out=rfreqs(drop=_:);
  id v2;
  var count;
  by v1;
run;
```

You can use PROC CORRESP and the ODS OUTPUT statement as follows to create a Burt table from five categorical variables:

```
proc corresp data=a observed short mca;
  ods output Burt=Obs;
  tables v1-v5;
run;
```

You can use a DATA step, PROC FREQ, and PROC TRANSPOSE to create a Burt table from five categorical variables, as in the following statements:

```
data b;
  set a;
  array v[5] $ v1-v5;
  do i = 1 to 5;
    row = v[i];
    do j = 1 to 5;
      column = v[j];
      output;
    end;
  end;
  keep row column;
run;

proc freq data=b;
  tables row * column / sparse noprint out=freqs;
run;

proc transpose data=freqs out=rfreqs(drop=_:);
  id column;
  var count;
  by row;
run;
```

Output Data Sets

PROC CORRESP has two output data sets. The OUTC= data set contains coordinates and the results of the correspondence analysis. The OUTF= data set contains frequencies and other cross-tabulation results.

The OUTC= Data Set

The OUTC= data set contains two or three character variables and $4n + 4$ numeric variables, where n is the number of axes from DIMENS= n (two by default). The OUTC= data set contains one observation for each row, column, supplementary row, and supplementary column point, and one observation for inertias.

The first variable is named `_TYPE_` and identifies the type of observation. The values of `_TYPE_` are as follows:

- The 'INERTIA' observation contains the total inertia in the INERTIA variable, and each dimension's inertia in the Contr1–Contr n variables.
- The 'OBS' observations contain the coordinates and statistics for the rows of the table.
- The 'SUPOBS' observations contain the coordinates and statistics for the supplementary rows of the table.
- The 'VAR' observations contain the coordinates and statistics for the columns of the table.
- The 'SUPVAR' observations contain the coordinates and statistics for the supplementary columns of the table.

If you specify the SOURCE option, then the data set also contains a variable `_VAR_` containing the name or label of the input variable from which that row originates. The name of the next variable is either `_NAME_` or (if you specify an ID statement) the name of the ID variable.

For observations with a value of 'OBS' or 'SUPOBS' for the `_TYPE_` variable, the values of the second variable are constructed as follows:

- When you use a VAR statement without an ID statement, the values are 'Row1', 'Row2', and so on.
- When you specify a VAR statement with an ID statement, the values are set equal to the values of the ID variable.
- When you specify a TABLES statement, the `_NAME_` variable has values formed from the appropriate row variable values.

For observations with a value of 'VAR' or 'SUPVAR' for the `_TYPE_` variable, the values of the second variable are equal to the names or labels of the VAR (or SUPPLEMENTARY) variables. When you specify a TABLES statement, the values are formed from the appropriate column variable values.

The third and subsequent variables contain the numerical results of the correspondence analysis.

- Quality contains the quality of each point's representation in the DIMENS= n dimensional display, which is the sum of squared cosines over the first n dimensions.
- Mass contains the masses or marginal sums of the relative frequency matrix.
- Inertia contains each point's relative contribution to the total inertia.

- Dim1–Dim n contain the point coordinates.
- Contr1–Contr n contain the partial contributions to inertia.
- SqCos1–SqCos n contain the squared cosines.
- Best1–Best n and Best contain the summaries of the partial contributions to inertia.

The OUTF= Data Set

The OUTF= data set contains frequencies and percentages. It is similar to a PROC FREQ output data set. The OUTF= data set begins with a variable called `_TYPE_`, which contains the observation type. If the SOURCE option is specified, the data set contains two variables, `_ROWVAR_` and `_COLVAR_`, that contain the names or labels of the row and column input variables from which each cell originates. The next two variables are classification variables that contain the row and column levels. If you use TABLES statement input and each variable list consists of a single variable, the names of the first two variables match the names of the input variables; otherwise, these variables are named Row and Column. The next two variables are Count and Percent, which contain frequencies and percentages.

The `_TYPE_` variable can have the following values:

- ‘OBSERVED’ observations contain the contingency table.
- ‘SUPOBS’ observations contain the supplementary rows.
- ‘SUPVAR’ observations contain the supplementary columns.
- ‘EXPECTED’ observations contain the product of the row marginals and the column marginals divided by the grand frequency of the observed frequency table. For ordinary two-way contingency tables, these are the expected frequency matrix under the hypothesis of row and column independence.
- ‘DEVIATION’ observations contain the matrix of deviations between the observed frequency matrix and the product of its row marginals and column marginals divided by its grand frequency. For ordinary two-way contingency tables, these are the observed minus expected frequencies under the hypothesis of row and column independence.
- ‘CELLCHI2’ observations contain contributions to the total chi-square test statistic.
- ‘RP’ observations contain the row profiles.
- ‘SUPRP’ observations contain supplementary row profiles.
- ‘CP’ observations contain the column profiles.
- ‘SUPCP’ observations contain supplementary column profiles.

Computational Resources

Let

n_r = number of rows in the table

n_c = number of columns in the table

n = number of observations

v = number of VAR statement variables

t = number of TABLES statement variables

$c = \max(n_r, n_c)$

$d = \min(n_r, n_c)$

For TABLES statement input, more than

$$32(t + 1) + 8(\max(2tn, (n_r + 3)(n_c + 3)))$$

bytes of array space are required.

For VAR statement input, more than

$$16(v + 2) + 8(n_r + 3)(n_c + 3)$$

bytes of array space are required.

Memory

The computational resources formulas are underestimates of the amounts of memory needed to handle most problems. If you use a utility data set, and if memory could be used with perfect efficiency, then roughly the stated amount of memory would be needed. In reality, most problems require at least two or three times the minimum.

PROC CORRESP tries to store the raw data (TABLES input) and the contingency table in memory. If there is not enough memory, a utility data set is used, potentially resulting in a large increase in execution time.

Time

The time required to perform the generalized singular value decomposition is roughly proportional to $2cd^2 + 5d^3$. Overall computation time increases with table size at a rate roughly proportional to $(n_r n_c)^{\frac{3}{2}}$.

Algorithm and Notation

This section is primarily based on the theory of correspondence analysis found in Greenacre (1984). If you are interested in other references, see the section “[Background](#)” on page 1996.

Let **N** be the contingency table formed from those observations and variables that are not supplementary and from those observations that have no missing values and have a positive weight. This table is an $(n_r \times n_c)$

rank q matrix of nonnegative numbers with nonzero row and column sums. If \mathbf{Z}_a is the binary coding for variable A, and \mathbf{Z}_b is the binary coding for variable B, then $\mathbf{N} = \mathbf{Z}_a' \mathbf{Z}_b$ is a contingency table. Similarly, if $\mathbf{Z}_{b,c}$ contains the binary coding for both variables B and C, then $\mathbf{N} = \mathbf{Z}_a' \mathbf{Z}_{b,c}$ can also be input to a correspondence analysis. With the BINARY option, $\mathbf{N} = \mathbf{Z}$, and the analysis is based on a binary table. In multiple correspondence analysis, the analysis is based on a Burt table, $\mathbf{Z}'\mathbf{Z}$.

Let $\mathbf{1}$ be a vector of 1s of the appropriate order, let \mathbf{I} be an identity matrix, and let $\text{diag}(\cdot)$ be a matrix-valued function that creates a diagonal matrix from a vector. Let

$$\begin{aligned} f &= \mathbf{1}'\mathbf{N}\mathbf{1} \\ \mathbf{P} &= \frac{1}{f}\mathbf{N} \\ \mathbf{r} &= \mathbf{P}\mathbf{1} \\ \mathbf{c} &= \mathbf{P}'\mathbf{1} \\ \mathbf{D}_r &= \text{diag}(\mathbf{r}) \\ \mathbf{D}_c &= \text{diag}(\mathbf{c}) \\ \mathbf{R} &= \mathbf{D}_r^{-1}\mathbf{P} \\ \mathbf{C}' &= \mathbf{D}_c^{-1}\mathbf{P}' \end{aligned}$$

The scalar f is the sum of all elements in \mathbf{N} . The matrix \mathbf{P} is a matrix of relative frequencies. The vector \mathbf{r} contains row marginal proportions or row “masses.” The vector \mathbf{c} contains column marginal proportions or column masses. The matrices \mathbf{D}_r and \mathbf{D}_c are diagonal matrices of marginals.

The rows of \mathbf{R} contain the “row profiles.” The elements of each row of \mathbf{R} sum to one. Each (i, j) element of \mathbf{R} contains the observed probability of being in column j given membership in row i . Similarly, the columns of \mathbf{C} contain the column profiles. The coordinates in correspondence analysis are based on the generalized singular value decomposition of \mathbf{P} ,

$$\mathbf{P} = \mathbf{A}\mathbf{D}_u\mathbf{B}'$$

where

$$\mathbf{A}'\mathbf{D}_r^{-1}\mathbf{A} = \mathbf{B}'\mathbf{D}_c^{-1}\mathbf{B} = \mathbf{I}$$

In multiple correspondence analysis,

$$\mathbf{P} = \mathbf{B}\mathbf{D}_u^2\mathbf{B}'$$

The matrix \mathbf{A} , which is the rectangular matrix of left generalized singular vectors, has n_r rows and q columns; the matrix \mathbf{D}_u , which is a diagonal matrix of singular values, has q rows and columns; and the matrix \mathbf{B} , which is the rectangular matrix of right generalized singular vectors, has n_c rows and q columns. The columns of \mathbf{A} and \mathbf{B} define the principal axes of the column and row point clouds, respectively.

The generalized singular value decomposition of $\mathbf{P} - \mathbf{r}\mathbf{c}'$, discarding the last singular value (which is zero) and the last left and right singular vectors, is exactly the same as a generalized singular value decomposition of \mathbf{P} , discarding the first singular value (which is one), the first left singular vector, \mathbf{r} , and the first right singular vector, \mathbf{c} . The first (trivial) column of \mathbf{A} and \mathbf{B} and the first singular value in \mathbf{D}_u are discarded

before any results are displayed. You can obtain the generalized singular value decomposition of $\mathbf{P} - \mathbf{rc}'$ from the ordinary singular value decomposition of $\mathbf{D}_r^{-1/2}(\mathbf{P} - \mathbf{rc}')\mathbf{D}_c^{-1/2}$:

$$\begin{aligned}\mathbf{D}_r^{-1/2}(\mathbf{P} - \mathbf{rc}')\mathbf{D}_c^{-1/2} &= \mathbf{U}\mathbf{D}_u\mathbf{V}' = (\mathbf{D}_r^{-1/2}\mathbf{A})\mathbf{D}_u(\mathbf{D}_c^{-1/2}\mathbf{B})' \\ \mathbf{P} - \mathbf{rc}' &= \mathbf{D}_r^{1/2}\mathbf{U}\mathbf{D}_u\mathbf{V}'\mathbf{D}_c^{1/2} = (\mathbf{D}_r^{1/2}\mathbf{U})\mathbf{D}_u(\mathbf{D}_c^{1/2}\mathbf{V})' = \mathbf{A}\mathbf{D}_u\mathbf{B}'\end{aligned}$$

Hence, $\mathbf{A} = \mathbf{D}_r^{1/2}\mathbf{U}$ and $\mathbf{B} = \mathbf{D}_c^{1/2}\mathbf{V}$.

The default row coordinates are $\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u$, and the default column coordinates are $\mathbf{D}_c^{-1}\mathbf{B}\mathbf{D}_u$. Typically the first two columns of $\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u$ and $\mathbf{D}_c^{-1}\mathbf{B}\mathbf{D}_u$ are plotted to display graphically associations between the row and column categories. The plot consists of two overlaid plots, one for rows and one for columns. The row points are row profiles, and the column points are column profiles, both rescaled so that distances between profiles can be displayed as ordinary Euclidean distances, then orthogonally rotated to a principal axes orientation. Distances between row points and other row points have meaning, as do distances between column points and other column points. However, distances between column points and row points are not interpretable.

The PROFILE=, ROW=, and COLUMN= Options

The PROFILE=, ROW=, and COLUMN= options standardize the coordinates before they are displayed and placed in the output data set. The options PROFILE=BOTH, PROFILE=ROW, and PROFILE=COLUMN provide the standardizations that are typically used in correspondence analysis. There are six choices each for row and column coordinates (see Table 32.3). However, most of the combinations of the ROW= and COLUMN= options are not useful. The ROW= and COLUMN= options are provided for completeness, but they are not intended for general use.

Table 32.3 Coordinates

ROW=	Matrix Formula
A	\mathbf{A}
AD	$\mathbf{A}\mathbf{D}_u$
DA	$\mathbf{D}_r^{-1}\mathbf{A}$
DAD	$\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u$
DAD1/2	$\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u^{1/2}$
DAID1/2	$\mathbf{D}_r^{-1}\mathbf{A}(\mathbf{I} + \mathbf{D}_u)^{1/2}$
COLUMN=	Matrix Formula
B	\mathbf{B}
BD	$\mathbf{B}\mathbf{D}_u$
DB	$\mathbf{D}_c^{-1}\mathbf{B}$
DBD	$\mathbf{D}_c^{-1}\mathbf{B}\mathbf{D}_u$
DBD1/2	$\mathbf{D}_c^{-1}\mathbf{B}\mathbf{D}_u^{1/2}$
DBID1/2	$\mathbf{D}_c^{-1}\mathbf{B}(\mathbf{I} + \mathbf{D}_u)^{1/2}$

When PROFILE=ROW (ROW=DAD and COLUMN=DB), the row coordinates $\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u$ and column coordinates $\mathbf{D}_c^{-1}\mathbf{B}$ provide a correspondence analysis based on the row profile matrix. The row profile (conditional probability) matrix is defined as $\mathbf{R} = \mathbf{D}_r^{-1}\mathbf{P} = \mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u\mathbf{B}'$. The elements of each row of \mathbf{R} sum to

one. Each (i, j) element of \mathbf{R} contains the observed probability of being in column j given membership in row i . The “principal” row coordinates $\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u$ and “standard” column coordinates $\mathbf{D}_c^{-1}\mathbf{B}$ provide a decomposition of $\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u\mathbf{B}'\mathbf{D}_c^{-1} = \mathbf{D}_r^{-1}\mathbf{P}\mathbf{D}_c^{-1} = \mathbf{R}\mathbf{D}_c^{-1}$. Since $\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u = \mathbf{R}\mathbf{D}_c^{-1}\mathbf{B}$, the row coordinates are weighted centroids of the column coordinates. Each column point, with coordinates scaled to standard coordinates, defines a vertex in $(n_c - 1)$ -dimensional space. All of the principal row coordinates are located in the space defined by the standard column coordinates. Distances among row points have meaning, but distances among column points and distances between row and column points are not interpretable.

The option PROFILE=COLUMN can be described as applying the PROFILE=ROW formulas to the transpose of the contingency table. When PROFILE=COLUMN (ROW=DA and COLUMN=DBD), the principal column coordinates $\mathbf{D}_c^{-1}\mathbf{B}\mathbf{D}_u$ are weighted centroids of the standard row coordinates $\mathbf{D}_r^{-1}\mathbf{A}$. Each row point, with coordinates scaled to standard coordinates, defines a vertex in $(n_r - 1)$ -dimensional space. All of the principal column coordinates are located in the space defined by the standard row coordinates. Distances among column points have meaning, but distances among row points and distances between row and column points are not interpretable.

The usual sets of coordinates are given by the default PROFILE=BOTH (ROW=DAD and COLUMN=DBD). All of the summary statistics, such as the squared cosines and contributions to inertia, apply to these two sets of points. One advantage to using these coordinates is that both sets ($\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u$ and $\mathbf{D}_c^{-1}\mathbf{B}\mathbf{D}_u$) are postmultiplied by the diagonal matrix \mathbf{D}_u , which has diagonal values that are all less than or equal to one. When \mathbf{D}_u is a part of the definition of only one set of coordinates, that set forms a tight cluster near the centroid, whereas the other set of points is more widely dispersed. Including \mathbf{D}_u in both sets makes a better graphical display. However, care must be taken in interpreting such a plot. No correct interpretation of distances between row points and column points can be made.

Another property of this choice of coordinates concerns the geometry of distances between points within each set. The default row coordinates can be decomposed into $\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u = \mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u\mathbf{B}'\mathbf{D}_c^{-1}\mathbf{B} = (\mathbf{D}_r^{-1}\mathbf{P})(\mathbf{D}_c^{-1/2})(\mathbf{D}_c^{-1/2}\mathbf{B})$. The row coordinates are row profiles ($\mathbf{D}_r^{-1}\mathbf{P}$), rescaled by $\mathbf{D}_c^{-1/2}$ (rescaled so that distances between profiles are transformed from a chi-square metric to a Euclidean metric), then orthogonally rotated (with $\mathbf{D}_c^{-1/2}\mathbf{B}$) to a principal axes orientation. Similarly, the column coordinates are column profiles rescaled to a Euclidean metric and orthogonally rotated to a principal axes orientation.

The rationale for computing distances between row profiles by using the non-Euclidean chi-square metric is as follows. Each row of the contingency table can be viewed as a realization of a multinomial distribution conditional on its row marginal frequency. The null hypothesis of row and column independence is equivalent to the hypothesis of homogeneity of the row profiles. A significant chi-square statistic is geometrically interpreted as a significant deviation of the row profiles from their centroid, \mathbf{c}' . The chi-square metric is the Mahalanobis metric between row profiles based on their estimated covariance matrix under the homogeneity assumption (Greenacre and Hastie 1987). A parallel argument can be made for the column profiles.

When ROW=DAD1/2 and COLUMN=DBD1/2 (Gifi 1990; van der Heijden and de Leeuw 1985), the row coordinates $\mathbf{D}_r^{-1}\mathbf{A}\mathbf{D}_u^{1/2}$ and column coordinates $\mathbf{D}_c^{-1}\mathbf{B}\mathbf{D}_u^{1/2}$ are a decomposition of $\mathbf{D}_r^{-1}\mathbf{P}\mathbf{D}_c^{-1}$.

In all of the preceding pairs, distances between row and column points are not meaningful. This prompted Carroll, Green, and Schaffer (1986) to propose that row coordinates $\mathbf{D}_r^{-1}\mathbf{A}(\mathbf{I} + \mathbf{D}_u)^{1/2}$ and column coordinates $\mathbf{D}_c^{-1}\mathbf{B}(\mathbf{I} + \mathbf{D}_u)^{1/2}$ be used. These coordinates are (except for a constant scaling) the coordinates from a multiple correspondence analysis of a Burt table created from two categorical variables. This standardization is available with ROW=DAID1/2 and COLUMN=DBID1/2. However, this approach has been criticized on both theoretical and empirical grounds by Greenacre (1989). The Carroll, Green, and Schaffer standardization relies on the assumption that the chi-square metric is an appropriate metric for measuring the distance between the columns of a bivariate indicator matrix. See the section

“Using the TABLES Statement” on page 2010 for a description of indicator matrices. Greenacre (1989) showed that this assumption cannot be justified.

The MCA Option

The MCA option performs a multiple correspondence analysis (MCA). This option requires a Burt table. You can specify the MCA option with a table created from a design matrix with fuzzy coding schemes as long as every row of every partition of the design matrix has the same marginal sum. For example, each row of each partition could contain the probabilities that the observation is a member of each level. Then the Burt table constructed from this matrix no longer contains all integers, and the diagonal partitions are no longer diagonal matrices, but MCA is still valid.

A TABLES statement with a single variable list creates a Burt table. Thus, you can always specify the MCA option with this type of input. If you use the MCA option when reading an existing table with a VAR statement, you must ensure that the table is a Burt table.

If you perform MCA on a table that is not a Burt table, the results of the analysis are invalid. If the table is not symmetric, or if the sums of all elements in each diagonal partition are not equal, PROC CORRESP displays an error message and quits.

A subset of the columns of a Burt table is not necessarily a Burt table, so in MCA it is not appropriate to designate arbitrary columns as supplementary. You can, however, designate all columns from one or more categorical variables as supplementary.

The results of a multiple correspondence analysis of a Burt table $\mathbf{Z}'\mathbf{Z}$ are the same as the column results from a simple correspondence analysis of the binary (or fuzzy) matrix \mathbf{Z} . Multiple correspondence analysis is not a simple correspondence analysis of the Burt table. It is not appropriate to perform a simple correspondence analysis of a Burt table. The MCA option is based on $\mathbf{P} = \mathbf{BD}_u^2\mathbf{B}'$, whereas a simple correspondence analysis of the Burt table would be based on $\mathbf{P} = \mathbf{BD}_u\mathbf{B}'$.

Since the rows and columns of the Burt table are the same, no row information is displayed or written to the output data sets. The resulting inertias and the default (COLUMN=DBD) column coordinates are the appropriate inertias and coordinates for an MCA. The supplementary column coordinates, cosines, and quality of representation formulas for MCA differ from the simple correspondence analysis formulas because the design matrix column profiles and left singular vectors are not available.

The following statements create a Burt table and perform a multiple correspondence analysis:

```
proc corresp data=Neighbor observed short mca;
  tables Hair Height Sex Age;
run;
```

Both the rows and the columns have the same nine categories (Blond, Brown, White, Short, Tall, Female, Male, Old, and Young).

MCA Adjusted Inertias

The usual principal inertias of a Burt table constructed from m categorical variables in MCA are the eigenvalues u_k from D_u^2 . The problem with these inertias is that they provide a pessimistic indication of fit. Benzécri (1979) proposed the following inertia adjustment, which is also described by Greenacre (1984, p. 145):

$$\left(\frac{m}{m-1}\right)^2 \times \left(u_k - \frac{1}{m}\right)^2 \quad \text{for } u_k > \frac{1}{m}$$

This adjustment computes the percent of adjusted inertia relative to the sum of the adjusted inertias for all inertias greater than $\frac{1}{m}$. The Benzécri adjustment is available with the BENZECRI option.

Greenacre (1994, p. 156) argues that the Benzécri adjustment overestimates the quality of fit. Greenacre proposes instead to compute the percentage of adjusted inertia relative to

$$\frac{m}{m-1} \left(\text{trace}(D_u^4) - \frac{n_c - m}{m^2} \right)$$

for all inertias greater than $\frac{1}{m}$, where $\text{trace}(D_u^4)$ is the sum of squared inertias. The Greenacre adjustment is available with the GREENACRE option.

Ordinary unadjusted inertias are printed by default with MCA when neither the BENZECRI nor the GREENACRE option is specified. However, the unadjusted inertias are not printed by default when either the BENZECRI or the GREENACRE option is specified. To display both adjusted and unadjusted inertias, specify the UNADJUSTED option in addition to the relevant adjusted inertia option (BENZECRI, GREENACRE, or both).

Supplementary Rows and Columns

Supplementary rows and columns are represented as points in the joint row and column space, but they are not used in determining the locations of the other active rows and columns of the table. The formulas that are used to compute coordinates for the supplementary rows and columns depend on the PROFILE= option or the ROW= and COLUMN= options. Let S_o be a matrix with rows that contain the supplementary observations, and let S_v be a matrix with rows that contain the supplementary variables. Note that S_v is defined to be the transpose of the supplementary variable partition of the table. Let $R_s = \text{diag}(S_o \mathbf{1})^{-1} S_o$ be the supplementary observation profile matrix, and let $C_s = \text{diag}(S_v \mathbf{1})^{-1} S_v$ be the supplementary variable profile matrix. Note that the notation $\text{diag}(\cdot)^{-1}$ means to convert the vector to a diagonal matrix, then invert the diagonal matrix. The coordinates for the supplementary observations and variables are shown in Table 32.4.

Table 32.4 Coordinates for Supplementary Observations

ROW=	Matrix Formula
A	$\frac{1}{f} S_o D_c^{-1} B D_u^{-1}$
AD	$\frac{1}{f} S_o D_c^{-1} B$
DA	$R_s D_c^{-1} B D_u^{-1}$
DAD	$R_s D_c^{-1} B$
DAD1/2	$R_s D_c^{-1} B D_u^{-1/2}$
DAID1/2	$R_s D_c^{-1} B D_u^{-1} (I + D_u)^{1/2}$
COLUMN=	Matrix Formula
B	$\frac{1}{f} S_v D_r^{-1} A D_u^{-1}$
BD	$\frac{1}{f} S_v D_r^{-1} A$
DB	$C_s D_r^{-1} A D_u^{-1}$
DBD	$C_s D_r^{-1} A$
DBD1/2	$C_s D_r^{-1} A D_u^{-1/2}$
DBID1/2	$C_s D_r^{-1} A D_u^{-1} (I + D_u)^{1/2}$
MCA COLUMN=	Matrix Formula
B	not allowed
BD	not allowed
DB	$C_s D_r^{-1} B D_u^{-2}$
DBD	$C_s D_r^{-1} B D_u^{-1}$
DBD1/2	$C_s D_r^{-1} B D_u^{-3/2}$
DBID1/2	$C_s D_r^{-1} B D_u^{-2} (I + D_u)^{1/2}$

Statistics That Aid Interpretation

The partial contributions to inertia, squared cosines, quality of representation, inertia, and mass provide additional information about the coordinates. These statistics are displayed by default. Include the SHORT or NOPRINT option in the PROC CORRESP statement to avoid having these statistics displayed.

These statistics pertain to the default PROFILE=BOTH coordinates, no matter what values you specify for the ROW=, COLUMN=, or PROFILE= option. Let $\text{sq}(\cdot)$ be a matrix-valued function denoting element-wise squaring of the argument matrix. Let t be the total inertia (the sum of the elements in D_u^2).

In MCA, let D_s be the Burt table partition containing the intersection of the supplementary columns and the supplementary rows. The matrix D_s is a diagonal matrix of marginal frequencies of the supplemental columns of the binary matrix Z . Let p be the number of rows in this design matrix. The statistics are defined in Table 32.5.

Table 32.5 Statistics That Aid Interpretation

Statistic	Matrix Formula
Row partial contributions to inertia	$\mathbf{D}_r^{-1}\text{sq}(\mathbf{A})$
Column partial contributions to inertia	$\mathbf{D}_c^{-1}\text{sq}(\mathbf{B})$
Row squared cosines	$\text{diag}(\text{sq}(\mathbf{A}\mathbf{D}_u)\mathbf{1})^{-1}\text{sq}(\mathbf{A}\mathbf{D}_u)$
Column squared cosines	$\text{diag}(\text{sq}(\mathbf{B}\mathbf{D}_u)\mathbf{1})^{-1}\text{sq}(\mathbf{B}\mathbf{D}_u)$
Row mass	\mathbf{r}
Column mass	\mathbf{c}
Row inertia	$\frac{1}{t}\mathbf{D}_r^{-1}\text{sq}(\mathbf{A}\mathbf{D}_u)\mathbf{1}$
Column inertia	$\frac{1}{t}\mathbf{D}_c^{-1}\text{sq}(\mathbf{B}\mathbf{D}_u)\mathbf{1}$
Supplementary row squared cosines	$\text{diag}(\text{sq}(\mathbf{R}_s - \mathbf{1}\mathbf{c}')\mathbf{D}_c^{-1}\mathbf{1})^{-1}\text{sq}(\mathbf{R}_s\mathbf{D}_c^{-1}\mathbf{B})$
Supplementary column squared cosines	$\text{diag}(\text{sq}(\mathbf{C}_s - \mathbf{1}\mathbf{r}')\mathbf{D}_r^{-1}\mathbf{1})^{-1}\text{sq}(\mathbf{C}_s\mathbf{D}_r^{-1}\mathbf{A})$
MCA supplementary column squared cosines	$\mathbf{D}_s(p\mathbf{I} - \mathbf{D}_s)^{-1}\text{sq}(\mathbf{C}_s\mathbf{D}_r^{-1}\mathbf{B}\mathbf{D}_u^{-1})$

The quality of representation in the DIMENS= n dimensional display of any point is the sum of its squared cosines over only the n dimensions. Inertia and mass are not defined for supplementary points.

A table that summarizes the partial contributions to inertia table is also computed. The points that best explain the inertia of each dimension and the dimension to which each point contributes the most inertia are indicated. The output data set variable names for this table are Best1–Best n (where DIMENS= n) and Best. The Best column contains the dimension number of the largest partial contribution to inertia for each point (the index of the maximum value in each row of $\mathbf{D}_r^{-1}\text{sq}(\mathbf{A})$ or $\mathbf{D}_c^{-1}\text{sq}(\mathbf{B})$).

For each row, the Best1–Best n columns contain either the corresponding value of Best, if the point is one of the biggest contributors to the dimension's inertia, or 0 if it is not. Specifically, Best1 contains the value of Best for the point with the largest contribution to dimension one's inertia. A cumulative proportion sum is initialized to this point's partial contribution to the inertia of dimension one. If this sum is less than the value for the MININERTIA= option, then Best1 contains the value of Best for the point with the second-largest contribution to dimension one's inertia. Otherwise, this point's Best1 is 0. This point's partial contribution to inertia is added to the sum. This process continues for the point with the third-largest partial contribution, and so on, until adding a point's contribution to the sum increases the sum beyond the value of the MININERTIA= option. This same algorithm is then used for Best2, and so on.

For example, the following table contains contributions to inertia and the corresponding Best variables. The contribution to inertia variables are proportions that sum to 1 within each column. The first point makes its greatest contribution to the inertia of dimension two, so Best for point one is set to 2, and Best1–Best3 for point one must all be 0 or 2. The second point also makes its greatest contribution to the inertia of dimension two, so Best for point two is set to 2, and Best1–Best3 for point two must all be 0 or 2, and so on.

Assume MININERTIA=0.8, the default. Table 32.6 shows some contributions to inertia. In dimension one, the largest contribution is 0.41302 for the fourth point, so Best1 is set to 1, the value of Best for the fourth point. Because this value is less than 0.8, the second-largest value (0.36456 for point five) is found and its Best1 is set to its Best's value of 1. Because $0.41302 + 0.36456 = 0.77758$ is less than 0.8, the third point (0.0882 at point eight) is found and Best1 is set to 3, since the contribution to dimension three for that point is greater than the contribution to dimension one. This increases the sum of the partial contributions to greater than 0.8, so the remaining Best1 values are all 0.

Table 32.6 Best Statistics

Contr1	Contr2	Contr3	Best1	Best2	Best3	Best
0.01593	0.32178	0.07565	0	2	2	2
0.03014	0.24826	0.07715	0	2	2	2
0.00592	0.02892	0.02698	0	0	0	2

Displayed Output

The display options control the amount of displayed output. By default, the following information is displayed:

- an inertia and chi-square decomposition table including the total inertia, the principal inertias of each dimension (eigenvalues), the singular values (square roots of the eigenvalues), each dimension's percentage of inertia, a horizontal bar chart of the percentages, and the total chi-square with its degrees of freedom and decomposition. The chi-square statistics and degrees of freedom are valid only when the constructed table is an ordinary two-way contingency table.
- the coordinates of the rows and columns on the dimensions
- the mass, relative contribution to the total inertia, and quality of representation in the DIMENS= n dimensional display of each row and column
- the squared cosines of the angles between each axis and a vector from the origin to the point
- the partial contributions of each point to each dimension's inertia
- the table of indicators of which points best explain the inertia of each dimension

Specific display options and combinations of options display output as follows.

If you specify the OBSERVED or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays the following:

- the contingency table, including the row and column marginal frequencies; or with BINARY, the binary table; or the Burt table in MCA
- the supplementary rows
- the supplementary columns

If you specify the OBSERVED or ALL option, with the PRINT=PERCENT or PRINT=BOTH option, PROC CORRESP displays the following:

- the contingency table or Burt table in MCA, scaled to percentages, including the row and column marginal percentages
- the supplementary rows, scaled to percentages
- the supplementary columns, scaled to percentages

If you specify the EXPECTED or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays the product of the row marginals and the column marginals divided by the grand frequency of the observed frequency table. For ordinary two-way contingency tables, these are the expected frequencies under the hypothesis of row and column independence.

If you specify the EXPECTED or ALL option with the PRINT=PERCENT or PRINT=BOTH option, PROC CORRESP displays the product of the row marginals and the column marginals divided by the grand frequency of the observed percentages table. For ordinary two-way contingency tables, these are the expected percentages under the hypothesis of row and column independence.

If you specify the DEVIATION or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays the observed minus expected frequencies. For ordinary two-way contingency tables, these are the expected frequencies under the hypothesis of row and column independence.

If you specify the DEVIATION or ALL option with the PRINT=PERCENT or PRINT=BOTH option, PROC CORRESP displays the observed minus expected percentages. For ordinary two-way contingency tables, these are the expected percentages under the hypothesis of row and column independence.

If you specify the CELLCHI2 or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays contributions to the total chi-square test statistic, including the row and column marginals. The intersection of the marginals contains the total chi-square statistic.

If you specify the CELLCHI2 or ALL option with the PRINT=PERCENT or the PRINT=BOTH option, PROC CORRESP displays contributions to the total chi-square, scaled to percentages, including the row and column marginals.

If you specify the RP or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays the row profiles and the supplementary row profiles.

If you specify the RP or ALL option with the PRINT=PERCENT or the PRINT=BOTH option, PROC CORRESP displays the row profiles (scaled to percentages) and the supplementary row profiles (scaled to percentages).

If you specify the CP or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays the column profiles and the supplementary column profiles.

If you specify the CP or ALL option with the PRINT=PERCENT or PRINT=BOTH option, PROC CORRESP displays the column profiles (scaled to percentages) and the supplementary column profiles (scaled to percentages).

If you do not specify the NOPRINT option, PROC CORRESP displays the inertia and chi-square decomposition table. This includes the nonzero singular values of the contingency table (or, in MCA, the binary matrix \mathbf{Z} used to create the Burt table), the nonzero principal inertias (or eigenvalues) for each dimension, the total inertia, the total chi-square, the decomposition of chi-square, the chi-square degrees of freedom (appropriate only when the table is an ordinary two-way contingency table), the percentage of the total chi-square and inertia for each dimension, and a bar chart of the percentages.

If you specify the MCA option and you do not specify the NOPRINT option, PROC CORRESP displays the adjusted inertias. This includes the nonzero adjusted inertias, percentages, cumulative percentages, and a bar chart of the percentages.

If you do not specify the NOROW, NOPRINT, or MCA option, PROC CORRESP displays the row coordinates and the supplementary row coordinates (displayed when there are supplementary row points).

If you do not specify the NOROW, NOPRINT, MCA, or SHORT option, PROC CORRESP displays the following:

- the summary statistics for the row points, including the quality of representation of the row points in the n -dimensional display, the mass, and the relative contributions to inertia
- the quality of representation of the supplementary row points in the n -dimensional display (displayed when there are supplementary row points)
- the partial contributions to inertia for the row points
- the table of indicators of which row points best explain the inertia of each dimension
- the squared cosines for the row points
- the squared cosines for the supplementary row points (displayed when there are supplementary row points)

If you do not specify the NOCOLUMN or NOPRINT option, PROC CORRESP displays the column coordinates and the supplementary column coordinates (displayed when there are supplementary column points).

If you do not specify the NOCOLUMN, NOPRINT, or SHORT option, PROC CORRESP displays the following:

- the summary statistics for the column points, including the quality of representation of the column points in the n -dimensional display, the mass, and the relative contributions to inertia for the supplementary column points
- the quality of representation of the supplementary column points in the n -dimensional display (displayed when there are supplementary column points)
- the partial contributions to inertia for the column points
- the table of indicators of which column points best explain the inertia of each dimension

- the squared cosines for the column points
- the squared cosines for the supplementary column points

ODS Table Names

PROC CORRESP assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 32.7](#) along with the PROC CORRESP statement options needed to produce the table. For more information about ODS, see Chapter 20, “[Using the Output Delivery System.](#)”

Table 32.7 ODS Tables Produced by PROC CORRESP

ODS Table Name	Description	Option
AdjInGreenacre	Greenacre Inertia Adjustment	GREENACRE

SupRowsPct	Supplementary row percentages	OBSERVED*
SupRowSqCos	Supp row squared cosines	default

*Percentages are displayed when you specify the PRINT=PERCENT or PRINT=BOTH option.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

You can reference every graph produced through ODS Graphics with a name. The names of the graph that PROC CORRESP generates is listed in [Table 32.8](#). It is displayed by default when ODS graphics is enabled.

ODS Graph Name	Plot Description
ConfigPlot	Correspondence analysis plot

Examples: CORRESP Procedure

Example 32.1: Simple and Multiple Correspondence Analysis of Automobiles and Their Owners

In this example, PROC CORRESP creates a contingency table from categorical data and performs a simple correspondence analysis. The data are from a sample of individuals who were asked to provide informa-

tion about themselves and their automobiles. The questions included origin of the automobile (American, Japanese, European) and family status (single, married, single and living with children, married living with children).

The first steps read the input data and assign formats. PROC CORRESP is used to perform the simple correspondence analysis. The ALL option displays all tables, including the contingency table, chi-square information, profiles, and all results of the correspondence analysis. The OUTC= option creates an output coordinate data set. The TABLES statement specifies the row and column categorical variables. The results are displayed with ODS Graphics.

The following statements produce [Output 32.1.1](#):

```

run;

```

Correspondence analysis locates all the categories in a Euclidean space. The first two dimensions of this space are plotted to examine the associations among the categories. Since the smallest dimension of this table is three, there is no loss of information when only two dimensions are plotted. The plot should be thought of as two different overlaid plots, one for each categorical variable. Distances between points within a variable have meaning, but distances between points from different variables do not.

Output 32.1.1 *continued*

To interpret the plot, start by interpreting the row points separately from the column points. The European point is near and to the left of the centroid, so it makes a relatively small contribution to the chi-square statistic (because it is near the centroid), it contributes almost nothing to the inertia of dimension one (since its coordinate on dimension one has a small absolute value relative to the other column points), and it makes a relatively large contribution to the inertia of dimension two (since its coordinate on dimension two has a large absolute value relative to the other column points). Its squared cosines for dimension one and two, approximately 0 and 1, respectively, indicate that its position is almost completely determined by its location on dimension two. Its quality of display is 1.0, indicating perfect quality, since the table is two-dimensional after the centering. The American and Japanese points are far from the centroid, and they lie along dimension one. They make relatively large contributions to the chi-square statistic and the inertia of dimension one. The horizontal dimension seems to be largely determined by Japanese versus American automobile ownership.

In the row points, the Married point is near the centroid, and the Single with Kids point has a small coordinate on dimension one that is near zero. The horizontal dimension seems to be largely determined by the Single versus the Married with Kids points. The two interpretations of dimension one show the association with being Married with Kids and owning an American auto, and being single and owning a Japanese auto. The fact that the Married with Kids point is close to the American point and the fact that the Japanese point is near the Single point should be ignored. Distances between row and column points are not defined. The plot shows that more people who are married with kids than you would expect if the rows and columns were independent drive an American auto, and more people who are single than you would expect if the rows and columns were independent drive a Japanese auto.

In the second part of this example, PROC CORRESP creates a Burt table from categorical data and performs a multiple correspondence analysis. The variables used in this example are Origin, Size, Type, Income, Home, Marital, and Sex. MCA specifies multiple correspondence analysis, OBSERVED displays the Burt table, and the OUTC= option creates an output coordinate data set. The TABLES statement with only a single variable list and no comma creates the Burt table.

The following statements produce [Output 32.1.2](#):

```

Multiple correspondence analysis locates all the categories in a Euclidean space. The first two dimensions of this space are plotted to examine the associations among the categories. The top-right quadrant of the plot shows that the categories Single, Single with Kids, 1 Income, and Rent are associated. Proceeding clockwise, the categories Sporty, Small, and Japanese are associated. The bottom-left quadrant shows the association between being married, owning your own home, and having two incomes. Having children is associated with owning a large American family auto. Such information could be used in market research to identify target audiences for advertisements.

This interpretation is based on points found in approximately the same direction from the origin and in approximately the same region of the space. Distances between points do not have a straightforward interpretation in multiple correspondence analysis. The geometry of multiple correspondence analysis is not a simple generalization of the geometry of simple correspondence analysis (Greenacre and Hastie 1987; Greenacre 1988).

If you want to perform a multiple correspondence analysis and get scores for the individuals, you can specify the BINARY option to analyze the binary table, as in the following statements. In the interest of space, only the first 10 rows of coordinates are printed in [Output 32.1.3](#).

Example 32.2: Simple Correspondence Analysis of U.S. Population

In this example, PROC CORRESP reads an existing contingency table with supplementary observations and performs a simple correspondence analysis. The data are populations of the 50 U.S. states, grouped into regions, for each of the census years from 1920 to 1970 (U.S. Bureau of the Census 1979). Alaska and Hawaii are treated as supplementary regions, because they were not states during this entire period and are not physically connected to the other 48 states. Consequently, it is reasonable to expect that population changes in these two states operate differently from population changes in the other states. The correspondence analysis is performed giving the supplementary points negative weight, and then the coordinates for the supplementary points are computed in the solution defined by the other points.

The initial DATA step reads the table, provides labels for the years, flags the supplementary rows with negative weights, and specifies absolute weights of 1000 for all observations since the data were originally reported in units of 1000 people.

In the PROC CORRESP statement, PRINT=PERCENT and the display options display the table of cell percentages (OBSERVED), cell contributions to the total chi-square scaled to sum to 100 (CELLCHI2), row profile rows that sum to 100 (RP), and column profile columns that sum to 100 (CP). The SHORT option specifies that the correspondence analysis summary statistics, contributions to inertia, and squared

cosines should not be displayed. The option OUTC=COOR creates the output coordinate data set. Since the data are already in table form, a VAR statement is used to read the table. Row labels are specified with the ID statement, and column labels come from the variable labels. The WEIGHT statement flags the supplementary observations and restores the table values to populations.

The following statements produce [Output 32.2.1](#):

The contingency table shows that the population of all regions increased over this time period. The row profiles show that population increased at a different rate for the different regions. There was a small increase in population in the Midwest, for example, but the population more than quadrupled in the Pacific region over the same period. The column profiles show that in 1920, the U.S. population was concentrated in the NY, NJ, PA, Great Lakes, Midwest, and South Atlantic regions. With time, the population shifted more to the South Atlantic, Mountain, and Pacific regions. This is also clear from the correspondence analysis. The inertia and chi-square decomposition table shows that there are five nontrivial dimensions in the table, but the association between the rows and columns is almost entirely one-dimensional.

ODS Graphics is used to plot the results. The data are essentially one-dimensional. For data such as these, it is better to plot the first dimension vertically, as opposed to the default, which is horizontally. The vertical orientation has fewer opportunities for label collisions. Specifying PLOTS(FLIP) on the PROC CORRESP statement switches the vertical and horizontal axes to improve the graphical display.

The plot shows that the first dimension correctly orders the years. There is nothing in the correspondence analysis that forces this to happen; the analysis has no information about the inherent ordering of the column categories. The ordering of the regions and the ordering of the years reflect the shift over time of the U.S. population from the Northeast quadrant of the country to the South and to the West. The results show that the West and Southeast grew faster than the rest of the contiguous 48 states during this period.

The plot also shows that the growth pattern for Hawaii was similar to the growth pattern for the mountain states and that Alaska's growth was even more extreme than the Pacific states' growth. The row profiles confirm this interpretation.

The Pacific region is farther from the origin than all other active points. The Midwest is the extreme region in the other direction. The table of contributions to the total chi-square shows that 62% of the total chi-square statistic is contributed by the Pacific region, which is followed by the Midwest at over 14%. Similarly the two extreme years, 1920 and 1970, together contribute over 63% to the total chi-square, whereas the years nearer the origin of the plot contribute less.

Overview: DISCRIM Procedure

For a set of observations containing one or more quantitative variables and a classification variable defining groups of observations, the DISCRIM procedure develops a discriminant criterion to classify each observation into one of the groups. The derived discriminant criterion from this data set can be applied to a second data set during the same execution of PROC DISCRIM. The data set that PROC DISCRIM uses to derive the discriminant criterion is called the *training* or *calibration* data set.

When the distribution within each group is assumed to be multivariate normal, a parametric method can be used to develop a discriminant function. The discriminant function, also known as a classification criterion, is determined by a measure of generalized squared distance (Rao 1973). The classification criterion can be based on either the individual within-group covariance matrices (yielding a quadratic function) or the pooled covariance matrix (yielding a linear function); it also takes into account the prior probabilities of the groups. The calibration information can be stored in a special SAS data set and applied to other data sets.

When no assumptions can be made about the distribution within each group, or when the distribution is assumed not to be multivariate normal, nonparametric methods can be used to estimate the group-specific densities. These methods include the kernel and k -nearest-neighbor methods (Rosenblatt 1956; Parzen 1962). The DISCRIM procedure uses uniform, normal, Epanechnikov, biweight, or triweight kernels for density estimation.

Either Mahalanobis or Euclidean distance can be used to determine proximity. Mahalanobis distance can be based on either the full covariance matrix or the diagonal matrix of variances. With a k -nearest-neighbor method, the pooled covariance matrix is used to calculate the Mahalanobis distances. With a kernel method, either the individual within-group covariance matrices or the pooled covariance matrix can be used to calculate the Mahalanobis distances. With the estimated group-specific densities and their associated prior probabilities, the posterior probability estimates of group membership for each class can be evaluated.

Canonical discriminant analysis is a dimension-reduction technique related to principal component analysis and canonical correlation. Given a classification variable and several quantitative variables, PROC DISCRIM derives canonical variables (linear combinations of the quantitative variables) that summarize between-class variation in much the same way that principal components summarize total variation. (See Chapter 29, “[The CANDISC Procedure](#),” for more information about canonical discriminant analysis.) A discriminant criterion is always derived in PROC DISCRIM. If you want canonical discriminant analysis without the use of a discriminant criterion, you should use the CANDISC procedure.

The DISCRIM procedure can produce an output data set containing various statistics such as means, standard deviations, and correlations. If a parametric method is used, the discriminant function is also stored in the data set to classify future observations. When canonical discriminant analysis is performed, the output data set includes canonical coefficients that can be rotated by the FACTOR procedure. PROC DISCRIM can also create a second type of output data set containing the classification results for each observation. When canonical discriminant analysis is performed, this output data set also includes canonical variable scores. A third type of output data set containing the group-specific density estimates at each observation can also be produced.

PROC DISCRIM evaluates the performance of a discriminant criterion by estimating error rates (probabilities of misclassification) in the classification of future observations. These error-rate estimates include error-count estimates and posterior probability error-rate estimates. When the input data set is an ordinary SAS data set, the error rate can also be estimated by cross validation.

Do not confuse discriminant analysis with cluster analysis. All varieties of discriminant analysis require prior knowledge of the classes, usually in the form of a sample from each class. In cluster analysis, the data do not include information about class membership; the purpose is to construct a classification.

See Chapter 10, “[Introduction to Discriminant Procedures](#),” for a discussion of discriminant analysis.

Getting Started: DISCRIM Procedure

The data in this example are measurements of 159 fish caught in Finland’s lake Laengelmavesi; this data set is available from the Puranen. For each of the seven species (bream, roach, whitefish, parkki, perch, pike, and smelt) the weight, length, height, and width of each fish are tallied. Three different length measurements are recorded: from the nose of the fish to the beginning of its tail, from the nose to the notch of its tail, and from the nose to the end of its tail. The height and width are recorded as percentages of the third length variable. The fish data set is available from the Sashelp library. The goal now is to find a discriminant function based on these six variables that best classifies the fish into species.

First, assume that the data are normally distributed within each group with equal covariances across groups. The following statements use PROC DISCRIM to analyze the Sashelp.Fish data and create [Figure 33.1](#) through [Figure 33.5](#):

```
title 'Fish Measurement Data';

proc discrim data=sashelp.fish;
  class Species;
run;
```

The DISCRIM procedure begins by displaying summary information about the variables in the analysis (see [Figure 33.1](#)). This information includes the number of observations, the number of quantitative variables in the analysis (specified with the VAR statement), and the number of classes in the classification variable (specified with the CLASS statement). The frequency of each class, its weight, the proportion of the total sample, and the prior probability are also displayed. Equal priors are assigned by default.

Figure 33.1 Summary Information

Fish Measurement Data					
The DISCRIM Procedure					
Total Sample Size	158	DF Total	157		
Variables	6	DF Within Classes	151		
Classes	7	DF Between Classes	6		
Number of Observations Read		159			
Number of Observations Used		158			
Class Level Information					
Species	Variable Name	Frequency	Weight	Proportion	Prior Probability
Bream	Bream	34	34.0000	0.215190	0.142857
Parkki	Parkki	11	11.0000	0.069620	0.142857
Perch	Perch	56	56.0000	0.354430	0.142857
Pike	Pike	17	17.0000	0.107595	0.142857
Roach	Roach	20	20.0000	0.126582	0.142857
Smelt	Smelt	14	14.0000	0.088608	0.142857
Whitefish	Whitefish	6	6.0000	0.037975	0.142857

The natural log of the determinant of the pooled covariance matrix is displayed in [Figure 33.2](#).

A summary of how the discriminant function classifies the data used to develop the function is displayed last. In [Figure 33.5](#), you see that only three of the observations are misclassified. The error-count estimates give the proportion of misclassified observations in each group. Since you are classifying the same data that are used to derive the discriminant function, these error-count estimates are biased.

Error Count Estimates for Species								
	Bream	Parkki	Perch	Pike	Roach	Smelt	Whitefish	Total
Rate	0.0000	0.0000	0.0536	0.0000	0.0000	0.0000	0.0000	0.0077
Priors	0.1429	0.1429	0.1429	0.1429	0.1429	0.1429	0.1429	

One way to reduce the bias of the error-count estimates is to split your data into two sets. One set is used to derive the discriminant function, and the other set is used to run validation tests. [Example 33.4](#) shows how to analyze a test data set. Another method of reducing bias is to classify each observation by using a discriminant function computed from all of the other observations; this method is invoked with the CROSSVALIDATE option.

Syntax: DISCRIM Procedure

The following statements are available in the DISCRIM procedure:

```
PROC DISCRIM < options > ;
  CLASS variable ;
  BY variables ;
  FREQ variable ;
  ID variable ;
  PRIORS probabilities ;
  TESTCLASS variable ;
  TESTFREQ variable ;
  TESTID variable ;
  VAR variables ;
  WEIGHT variable ;
```

Only the PROC DISCRIM and CLASS statements are required.

The following sections describe the PROC DISCRIM statement and then describe the other statements in alphabetical order.

PROC DISCRIM Statement

```
PROC DISCRIM < options > ;
```

The PROC DISCRIM statement invokes the DISCRIM procedure. [Table 33.1](#) summarizes the options available in the PROC DISCRIM statement.

Table 33.1 Options Available in the PROC DISCRIM Statement

Option	Description
Input Data Sets	
DATA=	Specifies input SAS data set
TESTDATA=	Specifies input SAS data set to classify
Output Data Sets	
OUTSTAT=	Specifies output statistics data set
OUT=	Specifies output data set with classification results
OUTCROSS=	Specifies output data set with cross validation results
OUTD=	Specifies output data set with densities
SCORES=	Outputs discriminant scores to the OUT= data set
TESTOUT=	Specifies output data set with TEST= results
TESTOUTD=	Specifies output data set with TEST= densities
Method Details	
METHOD=	Specifies parametric or nonparametric method
POOL=	Specifies whether to pool the covariance matrices
SINGULAR=	Specifies the singularity criterion

Table 33.1 *continued*

Option	Description
SLPOOL=	Specifies significance level homogeneity test
THRESHOLD=	Specifies the minimum threshold for classification
Nonparametric Methods	
K=	Specifies k value for k nearest neighbors
KPROP=	Specifies proportion, p , for computing k
R=	Specifies radius for kernel density estimation
KERNEL=	Specifies a kernel density to estimate
METRIC=	Specifies metric in for squared distances
Canonical Discriminant Analysis	
CANONICAL	Performs canonical discriminant analysis
CANPREFIX=	Specifies a prefix for naming the canonical variables
NCAN=	Specifies the number of canonical variables
Resubstitution Classification	
LIST	Displays the classification results
LISTERR	Displays the misclassified observations
NOCLASSIFY	Suppresses the classification
TESTLIST	Displays the classification results of TEST=
TESTLISTERR	Displays the misclassified observations of TEST=
Cross Validation Classification	
CROSSLIST	Displays the cross validation results
CROSSLISTERR	Displays the misclassified cross validation results
CROSSVALIDATE	Specifies cross validation
Control Displayed Output	
ALL	Displays all output
ANOVA	Displays univariate statistics
BCORR	Displays between correlations
BCOV	Displays between covariances
BSSCP	Displays between SSCPs
DISTANCE	Displays squared Mahalanobis distances
FORMULA	Displays formulas in destinations other than LISTING
MANOVA	Displays multivariate ANOVA results
NOPRINT	Suppresses all displayed output
PCORR	Displays pooled correlations
PCOV	Displays pooled covariances
POSTERR	Displays posterior probability error-rate estimates
PSSCP	Displays pooled SSCPs
SHORT	Suppresses some displayed output
SIMPLE	Displays simple descriptive statistics
STDMEAN	Displays standardized class means
TCORR	Displays total correlations
TCOV	Displays total covariances
TSSCP	Displays total SSCPs

Table 33.1 *continued*

Option	Description
WCORR	Displays within correlations
WCOV	Displays within covariances
WSSCP	Displays within SSCP

ALL

activates all options that control displayed output. When the derived classification criterion is used to classify observations, the ALL option also activates the **POSTERR** option.

ANOVA

displays univariate statistics for testing the hypothesis that the class means are equal in the population for each variable.

BCORR

displays between-class correlations.

BCOV

displays between-class covariances. The between-class covariance matrix equals the between-class SSCP matrix divided by $n(c - 1)/c$, where n is the number of observations and c is the number of classes. You should interpret the between-class covariances in comparison with the total-sample and within-class covariances, not as formal estimates of population parameters.

BSSCP

displays the between-class SSCP matrix.

CANONICAL**CAN**

performs canonical discriminant analysis.

CANPREFIX=name

specifies a prefix for naming the canonical variables. By default, the names are Can1, Can2, ..., Can*n*. If you specify CANPREFIX=ABC, the components are named ABC1, ABC2, ABC3, and so on. The number of characters in the prefix, plus the number of digits required to designate the canonical variables, should not exceed 32. The prefix is truncated if the combined length exceeds 32.

The CANONICAL option is activated when you specify either the NCAN= or the CANPREFIX= option. A discriminant criterion is always derived in PROC DISCRIM. If you want canonical discriminant analysis without the use of discriminant criteria, you should use PROC CANDISC.

CROSSLIST

displays the cross validation classification results for each observation.

CROSSLISTERR

displays the cross validation classification results for misclassified observations only.

CROSSVALIDATE

specifies the cross validation classification of the input DATA= data set. When a parametric method is used, PROC DISCRIM classifies each observation in the DATA= data set by using a discriminant function computed from the other observations in the DATA= data set, excluding the observation being classified. When a nonparametric method is used, the covariance matrices used to compute the distances are based on all observations in the data set and do not exclude the observation being classified. However, the observation being classified is excluded from the nonparametric density estimation (if you specify the R= option) or the k nearest neighbors (if you specify the K= or KPROP= option) of that observation. The CROSSVALIDATE option is set when you specify the CROSSLIST, CROSSLISTERR, or OUTCROSS= option. With these options, cross validation information is displayed or output in addition to the usual resubstitution classification results. Cross validation classification results are written to the OUTCROSS= data set, and resubstitution classification results are written to the OUT= data set.

DATA=SAS-data-set

specifies the data set to be analyzed. The data set can be an ordinary SAS data set or one of several specially structured data sets created by SAS/STAT procedures. These specially structured data sets include TYPE=CORR, TYPE=COV, TYPE=CSSCP, TYPE=SSCP, TYPE=LINEAR, TYPE=QUAD, and TYPE=MIXED. The input data set must be an ordinary SAS data set if you specify METHOD=NP. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

DISTANCE**MAHALANOBIS**

displays the squared Mahalanobis distances between the group means, F statistics, and the corresponding probabilities of greater Mahalanobis squared distances between the group means. The squared distances are based on the specification of the POOL= and METRIC= options.

FORMULA

displays formulas in destinations other than LISTING. See the section “Formulas” on page 2097 for more information.

K= k

specifies a k value for the k -nearest-neighbor rule. An observation x is classified into a group based on the information from the k nearest neighbors of x . Do not specify the K= option with the KPROP= or R= option.

KPROP= p

specifies a proportion, p , for computing the k value for the k -nearest-neighbor rule: $k = \max(1, \text{floor}(np))$, where n is the number of valid observations. When there is a FREQ statement, n is the sum of the FREQ variable for the observations used in the analysis (those without missing or invalid values). An observation x is classified into a group based on the information from the k nearest neighbors of x . Do not specify the KPROP= option with the K= or R= option.

KERNEL=BIWEIGHT | BIW

KERNEL=EPANECHNIKOV | EPA

KERNEL=NORMAL | NOR

KERNEL=TRIWEIGHT | TRI

KERNEL=UNIFORM | UNI

specifies a kernel density to estimate the group-specific densities. You can specify the **KERNEL=** option only when the **R=** option is specified. The default is **KERNEL=UNIFORM**.

LIST

displays the resubstitution classification results for each observation. You can specify this option only when the input data set is an ordinary SAS data set.

LISTERR

displays the resubstitution classification results for misclassified observations only. You can specify this option only when the input data set is an ordinary SAS data set.

MANOVA

displays multivariate statistics for testing the hypothesis that the class means are equal in the population.

METHOD=NORMAL | NPAR

determines the method to use in deriving the classification criterion. When you specify **METHOD=NORMAL**, a parametric method based on a multivariate normal distribution within each class is used to derive a linear or quadratic discriminant function. The default is **METHOD=NORMAL**. When you specify **METHOD=NPAR**, a nonparametric method is used and you must also specify either the **K=** or **R=** option.

METRIC=DIAGONAL | FULL | IDENTITY

specifies the metric in which the computations of squared distances are performed. If you specify **METRIC=FULL**, then PROC DISCRIM uses either the pooled covariance matrix (**POOL=YES**) or individual within-group covariance matrices (**POOL=NO**) to compute the squared distances. If you specify **METRIC=DIAGONAL**, then PROC DISCRIM uses either the diagonal matrix of the pooled covariance matrix (**POOL=YES**) or diagonal matrices of individual within-group covariance matrices (**POOL=NO**) to compute the squared distances. If you specify **METRIC=IDENTITY**, then PROC DISCRIM uses Euclidean distance. The default is **METRIC=FULL**. When you specify **METHOD=NORMAL**, the option **METRIC=FULL** is used.

NCAN=number

specifies the number of canonical variables to compute. The value of *number* must be less than or equal to the number of variables. If you specify the option **NCAN=0**, the procedure displays the canonical correlations but not the canonical coefficients, structures, or means. Let v be the number of variables in the VAR statement, and let c be the number of classes. If you omit the **NCAN=** option, only $\min(v, c - 1)$ canonical variables are generated. If you request an output data set (**OUT=**, **OUTCROSS=**, **TESTOUT=**), v canonical variables are generated. In this case, the last $v - (c - 1)$ canonical variables have missing values.

The **CANONICAL** option is activated when you specify either the **NCAN=** or the **CANPREFIX=** option. A discriminant criterion is always derived in PROC DISCRIM. If you want canonical discriminant analysis without the use of discriminant criterion, you should use PROC CANDISC.

NOCLASSIFY

suppresses the resubstitution classification of the input DATA= data set. You can specify this option only when the input data set is an ordinary SAS data set.

NOPRINT

suppresses the normal display of results. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 20, “[Using the Output Delivery System](#),” for more information.

OUT=SAS-data-set

creates an output SAS data set containing all the data from the DATA= data set, plus the posterior probabilities and the class into which each observation is classified by resubstitution. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. See the section “[OUT= Data Set](#)” on page 2089 for more information.

OUTCROSS=SAS-data-set

creates an output SAS data set containing all the data from the DATA= data set, plus the posterior probabilities and the class into which each observation is classified by cross validation. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. See the section “[OUT= Data Set](#)” on page 2089 for more information.

OUTD=SAS-data-set

creates an output SAS data set containing all the data from the DATA= data set, plus the group-specific density estimates for each observation. See the section “[OUT= Data Set](#)” on page 2089 for more information.

OUTSTAT=SAS-data-set

creates an output SAS data set containing various statistics such as means, standard deviations, and correlations. When the input data set is an ordinary SAS data set or when TYPE=CORR, TYPE=COV, TYPE=CSSCP, or TYPE=SSCP, this option can be used to generate discriminant statistics. When you specify the CANONICAL option, canonical correlations, canonical structures, canonical coefficients, and means of canonical variables for each class are included in the data set. If you specify METHOD=NORMAL, the output data set also includes coefficients of the discriminant functions, and the output data set is TYPE=LINEAR (POOL=YES), TYPE=QUAD (POOL=NO), or TYPE=MIXED (POOL=TEST). If you specify METHOD=NPART, this output data set is TYPE=CORR. This data set also holds calibration information that can be used to classify new observations. See the sections “[Saving and Using Calibration Information](#)” on page 2086 and “[OUT= Data Set](#)” on page 2089 for more information.

PCORR

displays pooled within-class correlations.

PCOV

displays pooled within-class covariances.

POOL=NO | TEST | YES

determines whether the pooled or within-group covariance matrix is the basis of the measure of the squared distance. If you specify POOL=YES, then PROC DISCRIM uses the pooled covariance matrix in calculating the (generalized) squared distances. Linear discriminant functions are computed. If you specify POOL=NO, the procedure uses the individual within-group covariance matrices in calculating the distances. Quadratic discriminant functions are computed. The default is POOL=YES.

The k -nearest-neighbor method assumes the default of POOL=YES, and the POOL=TEST option cannot be used with the METHOD=NPART option.

When you specify METHOD=NORMAL, the option POOL=TEST requests Bartlett's modification of the likelihood ratio test (Morrison 1976; Anderson 1984) of the homogeneity of the within-group covariance matrices. The test is unbiased (Perlman 1980). However, it is not robust to nonnormality. If the test statistic is significant at the level specified by the SLPOOL= option, the within-group covariance matrices are used. Otherwise, the pooled covariance matrix is used. The discriminant function coefficients are displayed only when the pooled covariance matrix is used.

POSTERR

displays the posterior probability error-rate estimates of the classification criterion based on the classification results.

PSSCP

displays the pooled within-class corrected SSCP matrix.

R= r

specifies a radius r value for kernel density estimation. With uniform, Epanechnikov, biweight, or triweight kernels, an observation \mathbf{x} is classified into a group based on the information from observations \mathbf{y} in the training set within the radius r of \mathbf{x} —that is, the group t observations \mathbf{y} with squared distance $d_t^2(\mathbf{x}, \mathbf{y}) \leq r^2$. When a normal kernel is used, the classification of an observation \mathbf{x} is based on the information of the estimated group-specific densities from all observations in the training set. The matrix $r^2 \mathbf{V}_t$ is used as the group t covariance matrix in the normal-kernel density, where \mathbf{V}_t is the matrix used in calculating the squared distances. Do not specify the K= or KPROP= option with the R= option. For more information about selecting r , see the section “Nonparametric Methods” on page 2079.

SCORES<= prefix >

computes and outputs discriminant scores to the OUT= and TESTOUT= data sets with the default options METHOD=NORMAL and POOL=YES (or with METHOD=NORMAL, POOL=TEST, and a nonsignificant chi-square test). Otherwise, or if no OUT= or TESTOUT= data set is specified, this option is ignored. The scores are computed by a matrix multiplication of an intercept term and the raw data or test data by the coefficients in the linear discriminant function. One score variable is created for each level of the CLASS variable. By default, the variables are named “Sc_” followed by the formatted class level. You can specify SCORES=prefix to use a prefix other than “Sc_”. The specifications SCORES and SCORES=Sc_ are equivalent.

SHORT

suppresses the display of certain items in the default output. If you specify METHOD=NORMAL, then PROC DISCRIM suppresses the display of determinants, generalized squared distances between-class means, and discriminant function coefficients. When you specify the CANONICAL option, PROC DISCRIM suppresses the display of canonical structures, canonical coefficients, and class means on canonical variables; only tables of canonical correlations are displayed.

SIMPLE

displays simple descriptive statistics for the total sample and within each class.

SINGULAR= p

specifies the criterion for determining the singularity of a matrix, where $0 < p < 1$. The default is SINGULAR=1E-8.

Let S be the total-sample correlation matrix. If the R square for predicting a quantitative variable in the VAR statement from the variables preceding it exceeds $1 - p$, then S is considered singular. If S is singular, the probability levels for the multivariate test statistics and canonical correlations are adjusted for the number of variables with R square exceeding $1 - p$.

Let S_t be the group t covariance matrix, and let S_p be the pooled covariance matrix. In group t , if the R square for predicting a quantitative variable in the VAR statement from the variables preceding it exceeds $1 - p$, then S_t is considered singular. Similarly, if the partial R square for predicting a quantitative variable in the VAR statement from the variables preceding it, after controlling for the effect of the CLASS variable, exceeds $1 - p$, then S_p is considered singular.

If PROC DISCRIM needs to compute either the inverse or the determinant of a matrix that is considered singular, then it uses a quasi inverse or a quasi determinant. For details, see the section “[Quasi-inverse](#)” on page 2083.

SLPOOL= p

specifies the significance level for the test of homogeneity. You can specify the SLPOOL= option only when POOL=TEST is also specified. If you specify POOL= TEST but omit the SLPOOL= option, PROC DISCRIM uses 0.10 as the significance level for the test.

STDMEAN

displays total-sample and pooled within-class standardized class means.

TCORR

displays total-sample correlations.

TCOV

displays total-sample covariances.

TESTDATA=*SAS-data-set*

names an ordinary SAS data set with observations that are to be classified. The quantitative variable names in this data set must match those in the DATA= data set. When you specify the TESTDATA= option, you can also specify the [TESTCLASS](#), [TESTFREQ](#), and [TESTID](#) statements. When you specify the TESTDATA= option, you can use the [TESTOUT=](#) and [TESTOUTD=](#) options to generate classification results and group-specific density estimates for observations in the test data set. Note that if the CLASS variable is not present in the TESTDATA= data set, the output will not include misclassification statistics.

TESTLIST

lists classification results for all observations in the [TESTDATA=](#) data set.

TESTLISTERR

lists only misclassified observations in the [TESTDATA=](#) data set but only if a [TESTCLASS](#) statement is also used.

TESTOUT=SAS-data-set

creates an output SAS data set containing all the data from the **TESTDATA=** data set, plus the posterior probabilities and the class into which each observation is classified. When you specify the **CANONICAL** option, the data set also contains new variables with canonical variable scores. See the section “**OUT= Data Set**” on page 2089 for more information.

TESTOUTD=SAS-data-set

creates an output SAS data set containing all the data from the **TESTDATA=** data set, plus the group-specific density estimates for each observation. See the section “**OUT= Data Set**” on page 2089 for more information.

THRESHOLD= p

specifies the minimum acceptable posterior probability for classification, where $0 \leq p \leq 1$. If the largest posterior probability of group membership is less than the **THRESHOLD** value, the observation is labeled as 'Other'. The default is **THRESHOLD=0**. In some cases, you might want to specify a **THRESHOLD=** value slightly smaller than the desired p so that observations with posterior probabilities within rounding error of p are classified. For example, you can specify **threshold=%sysevalf(0.5 - 1e-8)** instead of **THRESHOLD=0.5** so that observations with posterior probabilities within 1E-8 of 0.5 and larger are classified.

TSSCP

displays the total-sample corrected SSCP matrix.

WCORR

displays within-class correlations for each class level.

WCOV

displays within-class covariances for each class level.

WSSCP

displays the within-class corrected SSCP matrix for each class level.

BY Statement

BY variables ;

You can specify a **BY** statement with **PROC DISCRIM** to obtain separate analyses of observations in groups that are defined by the **BY** variables. When a **BY** statement appears, the procedure expects the input data set to be sorted in order of the **BY** variables. If you specify more than one **BY** statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the **SORT** procedure with a similar **BY** statement.
- Specify the **NOTSORTED** or **DESCENDING** option in the **BY** statement for the **DISCRIM** procedure. The **NOTSORTED** option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the **BY** variables) and that these groups are not necessarily in alphabetical or increasing numeric order.

- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

If you specify the TESTDATA= option and the TESTDATA= data set does not contain any of the BY variables, then the entire TESTDATA= data set is classified according to the discriminant functions computed in each BY group in the DATA= data set.

If the TESTDATA= data set contains some but not all of the BY variables, or if some BY variables do not have the same type or length in the TESTDATA= data set as in the DATA= data set, then PROC DISCRIM displays an error message and stops.

If all BY variables appear in the TESTDATA= data set with the same type and length as in the DATA= data set, then each BY group in the TESTDATA= data set is classified by the discriminant function from the corresponding BY group in the DATA= data set. The BY groups in the TESTDATA= data set must be in the same order as in the DATA= data set. If you specify the NOTSORTED option in the BY statement, there must be exactly the same BY groups in the same order in both data sets. If you omit the NOTSORTED option, some BY groups can appear in one data set but not in the other. If some BY groups appear in the TESTDATA= data set but not in the DATA= data set, and you request an output test data set by using the TESTOUT= or TESTOUTD= option, these BY groups are not included in the output data set.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* ;

The values of the classification variable define the groups for analysis. Class levels are determined by the formatted values of the CLASS variable. The specified variable can be numeric or character. A CLASS statement is required.

FREQ Statement

FREQ *variable* ;

If a variable in the data set represents the frequency of occurrence for the other values in the observation, include the variable's name in a FREQ statement. The procedure then treats the data set as if each observation appears n times, where n is the value of the FREQ variable for the observation. The total number of observations is considered to be equal to the sum of the FREQ variable when the procedure determines degrees of freedom for significance probabilities.

If the value of the FREQ variable is missing or is less than one, the observation is not used in the analysis. If the value is not an integer, it is truncated to an integer.

ID Statement

ID *variable* ;

The ID statement is effective only when you specify the LIST or LISTERR option in the PROC DISCRIM statement. When the DISCRIM procedure displays the classification results, the ID variable (rather than the observation number) is displayed for each observation.

PRIORS Statement

PRIORS EQUAL ;

PRIORS PROPORTIONAL | PROP ;

PRIORS *probabilities* ;

The PRIORS statement specifies the prior probabilities of group membership. To set the prior probabilities equal, use the following statement:

```
priors equal;
```

To set the prior probabilities proportional to the sample sizes, use the following statement:

```
priors proportional;
```

For other than equal or proportional priors, specify the prior probability for each level of the classification variable. Each class level can be written as either a SAS name or a quoted string, and it must be followed by an equal sign and a numeric constant between zero and one. A SAS name begins with a letter or an underscore and can contain digits as well. Lowercase character values and data values with leading blanks must be enclosed in quotes. For example, to define prior probabilities for each level of Grade, where Grade's values are A, B, C, and D, the PRIORS statement can be specified as follows:

```
priors A=0.1 B=0.3 C=0.5 D=0.1;
```

If Grade's values are 'a', 'b', 'c', and 'd', each class level must be written as a quoted string as follows:

```
priors 'a'=0.1 'b'=0.3 'c'=0.5 'd'=0.1;
```

If Grade is numeric, with formatted values of '1', '2', and '3', the PRIORS statement can be written as follows:

```
priors '1'=0.3 '2'=0.6 '3'=0.1;
```

The specified class levels must exactly match the formatted values of the CLASS variable. For example, if a CLASS variable C has the format 4.2 and a value 5, the PRIORS statement must specify '5.00', not '5.0' or '5'. If the prior probabilities do not sum to one, these probabilities are scaled proportionally to have the sum equal to one. The default is PRIORS EQUAL.

TESTCLASS Statement

TESTCLASS *variable* ;

The TESTCLASS statement names the variable in the TESTDATA= data set that is used to determine whether an observation in the TESTDATA= data set is misclassified. The TESTCLASS variable should have the same type (character or numeric) and length as the variable given in the CLASS statement. PROC

DISCRIM considers an observation misclassified when the formatted value of the TESTCLASS variable does not match the group into which the TESTDATA= observation is classified. When the TESTCLASS statement is missing and the TESTDATA= data set contains the variable given in the CLASS statement, the CLASS variable is used as the TESTCLASS variable. Note that if the CLASS variable is not present in the TESTDATA= data set, the output will not include misclassification statistics.

TESTFREQ Statement

TESTFREQ *variable* ;

If a variable in the TESTDATA= data set represents the frequency of occurrence of the other values in the observation, include the variable's name in a TESTFREQ statement. The procedure then treats the data set as if each observation appears n times, where n is the value of the TESTFREQ variable for the observation.

If the value of the TESTFREQ variable is missing or is less than one, the observation is not used in the analysis. If the value is not an integer, it is truncated to an integer.

TESTID Statement

TESTID *variable* ;

The TESTID statement is effective only when you specify the TESTLIST or TESTLISTERR option in the PROC DISCRIM statement. When the DISCRIM procedure displays the classification results for the TESTDATA= data set, the TESTID variable (rather than the observation number) is displayed for each observation. The variable given in the TESTID statement must be in the TESTDATA= data set.

VAR Statement

VAR *variables* ;

The VAR statement specifies the quantitative variables to be included in the analysis. The default is all numeric variables not listed in other statements.

WEIGHT Statement

WEIGHT *variable* ;

To use relative weights for each observation in the input data set, place the weights in a variable in the data set and specify the name in a WEIGHT statement. This is often done when the variance associated with each observation is different and the values of the weight variable are proportional to the reciprocals of the variances. If the value of the WEIGHT variable is missing or is less than zero, then a value of zero for the weight is used.

The WEIGHT and FREQ statements have a similar effect except that the WEIGHT statement does not alter the degrees of freedom.

Details: DISCRIM Procedure

Missing Values

Observations with missing values for variables in the analysis are excluded from the development of the classification criterion. When the values of the classification variable are missing, the observation is excluded from the development of the classification criterion, but if no other variables in the analysis have missing values for that observation, the observation is classified and displayed with the classification results.

Background

The following notation is used to describe the classification methods:

\mathbf{x}	a p -dimensional vector containing the quantitative variables of an observation
\mathbf{S}_p	the pooled covariance matrix
t	a subscript to distinguish the groups
n_t	the number of training set observations in group t
\mathbf{m}_t	the p -dimensional vector containing variable means in group t
\mathbf{S}_t	the covariance matrix within group t
$ \mathbf{S}_t $	the determinant of \mathbf{S}_t
q_t	the prior probability of membership in group t
$p(t \mathbf{x})$	the posterior probability of an observation \mathbf{x} belonging to group t
f_t	the probability density function for group t
$f_t(\mathbf{x})$	the group-specific density estimate at \mathbf{x} from group t
$f(\mathbf{x})$	$\sum_t q_t f_t(\mathbf{x})$, the estimated unconditional density at \mathbf{x}
e_t	the classification error rate for group t

Bayes' Theorem

Assuming that the prior probabilities of group membership are known and that the group-specific densities at \mathbf{x} can be estimated, PROC DISCRIM computes $p(t|\mathbf{x})$, the probability of \mathbf{x} belonging to group t , by applying Bayes' theorem:

$$p(t|\mathbf{x}) = \frac{q_t f_t(\mathbf{x})}{f(\mathbf{x})}$$

PROC DISCRIM partitions a p -dimensional vector space into regions R_t , where the region R_t is the subspace containing all p -dimensional vectors \mathbf{y} such that $p(t|\mathbf{y})$ is the largest among all groups. An observation is classified as coming from group t if it lies in region R_t .

Parametric Methods

Assuming that each group has a multivariate normal distribution, PROC DISCRIM develops a discriminant function or classification criterion by using a measure of generalized squared distance. The classification criterion is based on either the individual within-group covariance matrices or the pooled covariance matrix; it also takes into account the prior probabilities of the classes. Each observation is placed in the class from which it has the smallest generalized squared distance. PROC DISCRIM also computes the posterior probability of an observation belonging to each class.

The squared Mahalanobis distance from \mathbf{x} to group t is

$$d_t^2(\mathbf{x}) = (\mathbf{x} - \mathbf{m}_t)' \mathbf{V}_t^{-1} (\mathbf{x} - \mathbf{m}_t)$$

where $\mathbf{V}_t = \mathbf{S}_t$ if the within-group covariance matrices are used, or $\mathbf{V}_t = \mathbf{S}_p$ if the pooled covariance matrix is used.

The group-specific density estimate at \mathbf{x} from group t is then given by

$$f_t(\mathbf{x}) = (2\pi)^{-\frac{p}{2}} |\mathbf{V}_t|^{-\frac{1}{2}} \exp(-0.5d_t^2(\mathbf{x}))$$

Using Bayes' theorem, the posterior probability of \mathbf{x} belonging to group t is

$$p(t|\mathbf{x}) = \frac{q_t f_t(\mathbf{x})}{\sum_u q_u f_u(\mathbf{x})}$$

where the summation is over all groups.

The generalized squared distance from \mathbf{x} to group t is defined as

$$D_t^2(\mathbf{x}) = d_t^2(\mathbf{x}) + g_1(t) + g_2(t)$$

where

$$g_1(t) = \begin{cases} \ln |\mathbf{S}_t| & \text{if the within-group covariance matrices are used} \\ 0 & \text{if the pooled covariance matrix is used} \end{cases}$$

and

$$g_2(t) = \begin{cases} -2 \ln(q_t) & \text{if the prior probabilities are not all equal} \\ 0 & \text{if the prior probabilities are all equal} \end{cases}$$

The posterior probability of \mathbf{x} belonging to group t is then equal to

$$p(t|\mathbf{x}) = \frac{\exp(-0.5D_t^2(\mathbf{x}))}{\sum_u \exp(-0.5D_u^2(\mathbf{x}))}$$

The discriminant scores are $-0.5D_u^2(\mathbf{x})$. An observation is classified into group u if setting $t = u$ produces the largest value of $p(t|\mathbf{x})$ or the smallest value of $D_t^2(\mathbf{x})$. If this largest posterior probability is less than the threshold specified, \mathbf{x} is labeled as 'Other'.

Nonparametric Methods

Nonparametric discriminant methods are based on nonparametric estimates of group-specific probability densities. Either a kernel method or the k -nearest-neighbor method can be used to generate a nonparametric density estimate in each group and to produce a classification criterion. The kernel method uses uniform, normal, Epanechnikov, biweight, or triweight kernels in the density estimation.

Either Mahalanobis distance or Euclidean distance can be used to determine proximity. When the k -nearest-neighbor method is used, the Mahalanobis distances are based on the pooled covariance matrix. When a kernel method is used, the Mahalanobis distances are based on either the individual within-group covariance matrices or the pooled covariance matrix. Either the full covariance matrix or the diagonal matrix of variances can be used to calculate the Mahalanobis distances.

The squared distance between two observation vectors, \mathbf{x} and \mathbf{y} , in group t is given by

$$d_t^2(\mathbf{x}, \mathbf{y}) = (\mathbf{x} - \mathbf{y})' \mathbf{V}_t^{-1} (\mathbf{x} - \mathbf{y})$$

where \mathbf{V}_t has one of the following forms:

$$\mathbf{V}_t = \begin{cases} \mathbf{S}_p & \text{the pooled covariance matrix} \\ \text{diag}(\mathbf{S}_p) & \text{the diagonal matrix of the pooled covariance matrix} \\ \mathbf{S}_t & \text{the covariance matrix within group } t \\ \text{diag}(\mathbf{S}_t) & \text{the diagonal matrix of the covariance matrix within group } t \\ \mathbf{I} & \text{the identity matrix} \end{cases}$$

The classification of an observation vector \mathbf{x} is based on the estimated group-specific densities from the training set. From these estimated densities, the posterior probabilities of group membership at \mathbf{x} are evaluated. An observation \mathbf{x} is classified into group u if setting $t = u$ produces the largest value of $p(t|\mathbf{x})$. If there is a tie for the largest probability or if this largest probability is less than the threshold specified, \mathbf{x} is labeled as 'Other'.

The kernel method uses a fixed radius, r , and a specified kernel, K_t , to estimate the group t density at each observation vector \mathbf{x} . Let \mathbf{z} be a p -dimensional vector. Then the volume of a p -dimensional unit sphere bounded by $\mathbf{z}'\mathbf{z} = 1$ is

$$v_0 = \frac{\pi^{\frac{p}{2}}}{\Gamma(\frac{p}{2} + 1)}$$

where Γ represents the gamma function (see *SAS Functions and CALL Routines: Reference*).

Thus, in group t , the volume of a p -dimensional ellipsoid bounded by $\{\mathbf{z} \mid \mathbf{z}'\mathbf{V}_t^{-1}\mathbf{z} = r^2\}$ is

$$v_r(t) = r^p |\mathbf{V}_t|^{-\frac{1}{2}} v_0$$

The kernel method uses one of the following densities as the kernel density in group t :

Uniform Kernel

$$K_t(\mathbf{z}) = \begin{cases} \frac{1}{v_r(t)} & \text{if } \mathbf{z}'\mathbf{V}_t^{-1}\mathbf{z} \leq r^2 \\ 0 & \text{elsewhere} \end{cases}$$

Normal Kernel (with mean zero, variance $r^2 \mathbf{V}_t$)

$$K_t(\mathbf{z}) = \frac{1}{c_0(t)} \exp \left(-\frac{1}{2r^2} \mathbf{z}' \mathbf{V}_t^{-1} \mathbf{z} \right)$$

where $c_0(t) = (2\pi)^{\frac{p}{2}} r^p |\mathbf{V}_t|^{\frac{1}{2}}$.

Epanechnikov Kernel

$$K_t(\mathbf{z}) = \begin{cases} c_1(t) \left(1 - \frac{1}{r^2} \mathbf{z}' \mathbf{V}_t^{-1} \mathbf{z} \right) & \text{if } \mathbf{z}' \mathbf{V}_t^{-1} \mathbf{z} \leq r^2 \\ 0 & \text{elsewhere} \end{cases}$$

where $c_1(t) = \frac{1}{v_r(t)} \left(1 + \frac{p}{2} \right)$.

Biweight Kernel

$$K_t(\mathbf{z}) = \begin{cases} c_2(t) \left(1 - \frac{1}{r^2} \mathbf{z}' \mathbf{V}_t^{-1} \mathbf{z} \right)^2 & \text{if } \mathbf{z}' \mathbf{V}_t^{-1} \mathbf{z} \leq r^2 \\ 0 & \text{elsewhere} \end{cases}$$

where $c_2(t) = \left(1 + \frac{p}{4} \right) c_1(t)$.

Triweight Kernel

$$K_t(\mathbf{z}) = \begin{cases} c_3(t) \left(1 - \frac{1}{r^2} \mathbf{z}' \mathbf{V}_t^{-1} \mathbf{z} \right)^3 & \text{if } \mathbf{z}' \mathbf{V}_t^{-1} \mathbf{z} \leq r^2 \\ 0 & \text{elsewhere} \end{cases}$$

where $c_3(t) = \left(1 + \frac{p}{6} \right) c_2(t)$.

The group t density at \mathbf{x} is estimated by

$$f_t(\mathbf{x}) = \frac{1}{n_t} \sum_{\mathbf{y}} K_t(\mathbf{x} - \mathbf{y})$$

where the summation is over all observations \mathbf{y} in group t , and K_t is the specified kernel function. The posterior probability of membership in group t is then given by

$$p(t|\mathbf{x}) = \frac{q_t f_t(\mathbf{x})}{f(\mathbf{x})}$$

where $f(\mathbf{x}) = \sum_u q_u f_u(\mathbf{x})$ is the estimated unconditional density. If $f(\mathbf{x})$ is zero, the observation \mathbf{x} is labeled as 'Other'.

The uniform-kernel method treats $K_t(\mathbf{z})$ as a multivariate uniform function with density uniformly distributed over $\mathbf{z}'\mathbf{V}_t^{-1}\mathbf{z} \leq r^2$. Let k_t be the number of training set observations \mathbf{y} from group t within the closed ellipsoid centered at \mathbf{x} specified by $d_t^2(\mathbf{x}, \mathbf{y}) \leq r^2$. Then the group t density at \mathbf{x} is estimated by

$$f_t(\mathbf{x}) = \frac{k_t}{n_t v_r(t)}$$

When the identity matrix or the pooled within-group covariance matrix is used in calculating the squared distance, $v_r(t)$ is a constant, independent of group membership. The posterior probability of \mathbf{x} belonging to group t is then given by

$$p(t|\mathbf{x}) = \frac{\frac{q_t k_t}{n_t}}{\sum_u \frac{q_u k_u}{n_u}}$$

If the closed ellipsoid centered at \mathbf{x} does not include any training set observations, $f(\mathbf{x})$ is zero and \mathbf{x} is labeled as 'Other'. When the prior probabilities are equal, $p(t|\mathbf{x})$ is proportional to k_t/n_t and \mathbf{x} is classified into the group that has the highest proportion of observations in the closed ellipsoid. When the prior probabilities are proportional to the group sizes, $p(t|\mathbf{x}) = k_t / \sum_u k_u$, \mathbf{x} is classified into the group that has the largest number of observations in the closed ellipsoid.

The nearest-neighbor method fixes the number, k , of training set points for each observation \mathbf{x} . The method finds the radius $r_k(\mathbf{x})$ that is the distance from \mathbf{x} to the k th-nearest training set point in the metric \mathbf{V}_t^{-1} . Consider a closed ellipsoid centered at \mathbf{x} bounded by $\{\mathbf{z} \mid (\mathbf{z} - \mathbf{x})'\mathbf{V}_t^{-1}(\mathbf{z} - \mathbf{x}) = r_k^2(\mathbf{x})\}$; the nearest-neighbor method is equivalent to the uniform-kernel method with a location-dependent radius $r_k(\mathbf{x})$. Note that, with ties, more than k training set points might be in the ellipsoid.

Using the k -nearest-neighbor rule, the k_n (or more with ties) smallest distances are saved. Of these k distances, let k_t represent the number of distances that are associated with group t . Then, as in the uniform-kernel method, the estimated group t density at \mathbf{x} is

$$f_t(\mathbf{x}) = \frac{k_t}{n_t v_k(\mathbf{x})}$$

where $v_k(\mathbf{x})$ is the volume of the ellipsoid bounded by $\{\mathbf{z} \mid (\mathbf{z} - \mathbf{x})'\mathbf{V}_t^{-1}(\mathbf{z} - \mathbf{x}) = r_k^2(\mathbf{x})\}$. Since the pooled within-group covariance matrix is used to calculate the distances used in the nearest-neighbor method, the volume $v_k(\mathbf{x})$ is a constant independent of group membership. When $k = 1$ is used in the nearest-neighbor rule, \mathbf{x} is classified into the group associated with the \mathbf{y} point that yields the smallest squared distance $d_t^2(\mathbf{x}, \mathbf{y})$. Prior probabilities affect nearest-neighbor results in the same way that they affect uniform-kernel results.

With a specified squared distance formula (METRIC=, POOL=), the values of r and k determine the degree of irregularity in the estimate of the density function, and they are called smoothing parameters. Small values of r or k produce jagged density estimates, and large values of r or k produce smoother density estimates. Various methods for choosing the smoothing parameters have been suggested, and there is as yet no simple solution to this problem.

For a fixed kernel shape, one way to choose the smoothing parameter r is to plot estimated densities with different values of r and to choose the estimate that is most in accordance with the prior information about the density. For many applications, this approach is satisfactory.

Another way of selecting the smoothing parameter r is to choose a value that optimizes a given criterion. Different groups might have different sets of optimal values. Assume that the unknown density has bounded

and continuous second derivatives and that the kernel is a symmetric probability density function. One criterion is to minimize an approximate mean integrated square error of the estimated density (Rosenblatt 1956). The resulting optimal value of r depends on the density function and the kernel. A reasonable choice for the smoothing parameter r is to optimize the criterion with the assumption that group t has a normal distribution with covariance matrix \mathbf{V}_t . Then, in group t , the resulting optimal value for r is given by

$$\left(\frac{A(K_t)}{n_t} \right)^{1/(p+4)}$$

where the optimal constant $A(K_t)$ depends on the kernel K_t (Epanechnikov 1969). For some useful kernels, the constants $A(K_t)$ are given by the following:

$$A(K_t) = \frac{1}{p} 2^{p+1} (p+2) \Gamma\left(\frac{p}{2}\right) \quad \text{with a uniform kernel}$$

$$A(K_t) = \frac{4}{2p+1} \quad \text{with a normal kernel}$$

$$A(K_t) = \frac{2^{p+2} p^2 (p+2)(p+4)}{2p+1} \Gamma\left(\frac{p}{2}\right) \quad \text{with an Epanechnikov kernel}$$

These selections of $A(K_t)$ are derived under the assumption that the data in each group are from a multivariate normal distribution with covariance matrix \mathbf{V}_t . However, when the Euclidean distances are used in calculating the squared distance ($\mathbf{V}_t = \mathbf{I}$), the smoothing constant should be multiplied by s , where s is an estimate of standard deviations for all variables. A reasonable choice for s is

$$s = \left(\frac{1}{p} \sum s_{jj} \right)^{\frac{1}{2}}$$

where s_{jj} are group t marginal variances.

The DISCRIM procedure uses only a single smoothing parameter for all groups. However, the selection of the matrix in the distance formula (from the METRIC= or POOL= option), enables individual groups and variables to have different scalings. When \mathbf{V}_t , the matrix used in calculating the squared distances, is an identity matrix, the kernel estimate at each data point is scaled equally for all variables in all groups. When \mathbf{V}_t is the diagonal matrix of a covariance matrix, each variable in group t is scaled separately by its variance in the kernel estimation, where the variance can be the pooled variance ($\mathbf{V}_t = \mathbf{S}_p$) or an individual within-group variance ($\mathbf{V}_t = \mathbf{S}_t$). When \mathbf{V}_t is a full covariance matrix, the variables in group t are scaled simultaneously by \mathbf{V}_t in the kernel estimation.

In nearest-neighbor methods, the choice of k is usually relatively uncritical (Hand 1982). A practical approach is to try several different values of the smoothing parameters within the context of the particular application and to choose the one that gives the best cross validated estimate of the error rate.

Classification Error-Rate Estimates

A classification criterion can be evaluated by its performance in the classification of future observations. PROC DISCRIM uses two types of error-rate estimates to evaluate the derived classification criterion based on parameters estimated by the training sample:

- error-count estimates
- posterior probability error-rate estimates

The error-count estimate is calculated by applying the classification criterion derived from the training sample to a test set and then counting the number of misclassified observations. The group-specific error-count estimate is the proportion of misclassified observations in the group. When the test set is independent of the training sample, the estimate is unbiased. However, the estimate can have a large variance, especially if the test set is small.

When the input data set is an ordinary SAS data set and no independent test sets are available, the same data set can be used both to define and to evaluate the classification criterion. The resulting error-count estimate has an optimistic bias and is called an *apparent error rate*. To reduce the bias, you can split the data into two sets—one set for deriving the discriminant function and the other set for estimating the error rate. Such a split-sample method has the unfortunate effect of reducing the effective sample size.

Another way to reduce bias is cross validation (Lachenbruch and Mickey 1968). Cross validation treats $n - 1$ out of n training observations as a training set. It determines the discriminant functions based on these $n - 1$ observations and then applies them to classify the one observation left out. This is done for each of the n training observations. The misclassification rate for each group is the proportion of sample observations in that group that are misclassified. This method achieves a nearly unbiased estimate but with a relatively large variance.

To reduce the variance in an error-count estimate, smoothed error-rate estimates are suggested (Glick 1978). Instead of summing terms that are either zero or one as in the error-count estimator, the smoothed estimator uses a continuum of values between zero and one in the terms that are summed. The resulting estimator has a smaller variance than the error-count estimate. The posterior probability error-rate estimates provided by the POSTERR option in the PROC DISCRIM statement (see the section “[Posterior Probability Error-Rate Estimates](#)” on page 2085) are smoothed error-rate estimates. The posterior probability estimates for each group are based on the posterior probabilities of the observations classified into that same group. The posterior probability estimates provide good estimates of the error rate when the posterior probabilities are accurate. When a parametric classification criterion (linear or quadratic discriminant function) is derived from a nonnormal population, the resulting posterior probability error-rate estimators might not be appropriate.

The overall error rate is estimated through a weighted average of the individual group-specific error-rate estimates, where the prior probabilities are used as the weights.

To reduce both the bias and the variance of the estimator, Hora and Wilcox (1982) compute the posterior probability estimates based on cross validation. The resulting estimates are intended to have both low variance from using the posterior probability estimate and low bias from cross validation. They use Monte Carlo studies on two-group multivariate normal distributions to compare the cross validation posterior probability estimates with three other estimators: the apparent error rate, cross validation estimator, and posterior probability estimator. They conclude that the cross validation posterior probability estimator has a lower mean squared error in their simulations.

Quasi-inverse

Consider the plot shown in [Figure 33.6](#) with two variables, X1 and X2, and two classes, A and B. The within-class covariance matrix is diagonal, with a positive value for X1 but zero for X2. Using a Moore-Penrose pseudo-inverse would effectively ignore X2 in doing the classification, and the two classes would have a

zero generalized distance and could not be discriminated at all. The quasi inverse used by PROC DISCRIM replaces the zero variance for X2 with a small positive number to remove the singularity. This permits X2 to be used in the discrimination and results correctly in a large generalized distance between the two classes and a zero error rate. It also permits new observations, such as the one indicated by N, to be classified in a reasonable way. PROC CANDISC also uses a quasi inverse when the total-sample covariance matrix is considered to be singular and Mahalanobis distances are requested. This problem with singular within-class covariance matrices is discussed in Ripley (1996, p. 38). The use of the quasi inverse is an innovation introduced by SAS.

Figure 33.6 Plot of Data with Singular Within-Class Covariance Matrix

Let S be a singular covariance matrix. The matrix S can be either a within-group covariance matrix, a pooled covariance matrix, or a total-sample covariance matrix. Let v be the number of variables in the VAR statement, and let the nullity n be the number of variables among them with (partial) R square exceeding $1 - p$. If the determinant of S (Testing of Homogeneity of Within Covariance Matrices) or the inverse of S (Squared Distances and Generalized Squared Distances) is required, a quasi determinant or quasi inverse is used instead. With raw data input, PROC DISCRIM scales each variable to unit total-sample variance before calculating this quasi inverse. The calculation is based on the spectral decomposition $S = \Gamma \Lambda \Gamma'$, where Λ is a diagonal matrix of eigenvalues λ_j , $j = 1, \dots, v$, where $\lambda_i \geq \lambda_j$ when $i < j$, and Γ is a matrix with the corresponding orthonormal eigenvectors of S as columns. When the nullity n is less than v , set $\lambda_j^0 = \lambda_j$ for $j = 1, \dots, v - n$, and $\lambda_j^0 = p\bar{\lambda}$ for $j = v - n + 1, \dots, v$, where

$$\bar{\lambda} = \frac{1}{v - n} \sum_{k=1}^{v-n} \lambda_k$$

When the nullity n is equal to v , set $\lambda_j^0 = p$, for $j = 1, \dots, v$. A quasi determinant is then defined as the product of λ_j^0 , $j = 1, \dots, v$. Similarly, a quasi inverse is then defined as $\mathbf{S}^* = \mathbf{\Gamma} \mathbf{\Lambda}^* \mathbf{\Gamma}'$, where $\mathbf{\Lambda}^*$ is a diagonal matrix of values $1/\lambda_j^0$, $j = 1, \dots, v$.

Posterior Probability Error-Rate Estimates

The posterior probability error-rate estimates (Fukunaga and Kessel 1973; Glick 1978; Hora and Wilcox 1982) for each group are based on the posterior probabilities of the observations classified into that same group.

A sample of observations with classification results can be used to estimate the posterior error rates. The following notation is used to describe the sample:

\mathcal{S}	the set of observations in the (training) sample
n	the number of observations in \mathcal{S}
n_t	the number of observations in \mathcal{S} in group t
\mathcal{R}_t	the set of observations such that the posterior probability belonging to group t is the largest
\mathcal{R}_{ut}	the set of observations from group u such that the posterior probability belonging to group t is the largest

The classification error rate for group t is defined as

$$e_t = 1 - \int_{\mathcal{R}_t} f_t(\mathbf{x}) d\mathbf{x}$$

The posterior probability of \mathbf{x} for group t can be written as

$$p(t|\mathbf{x}) = \frac{q_t f_t(\mathbf{x})}{f(\mathbf{x})}$$

where $f(\mathbf{x}) = \sum_u q_u f_u(\mathbf{x})$ is the unconditional density of \mathbf{x} .

Thus, if you replace $f_t(\mathbf{x})$ with $p(t|\mathbf{x})f(\mathbf{x})/q_t$, the error rate is

$$e_t = 1 - \frac{1}{q_t} \int_{\mathcal{R}_t} p(t|\mathbf{x}) f(\mathbf{x}) d\mathbf{x}$$

An estimator of e_t , unstratified over the groups from which the observations come, is then given by

$$\hat{e}_t \text{ (unstratified)} = 1 - \frac{1}{n q_t} \sum_{\mathcal{R}_t} p(t|\mathbf{x})$$

where $p(t|\mathbf{x})$ is estimated from the classification criterion, and the summation is over all sample observations of \mathcal{S} classified into group t . The true group membership of each observation is not required in the estimation. The term $n q_t$ is the number of observations that are expected to be classified into group t , given the priors. If more observations than expected are classified into group t , then \hat{e}_t can be negative.

Further, if you replace $f(\mathbf{x})$ with $\sum_u q_u f_u(\mathbf{x})$, the error rate can be written as

$$e_t = 1 - \frac{1}{q_t} \sum_u q_u \int_{\mathcal{R}_{ut}} p(t|\mathbf{x}) f_u(\mathbf{x}) d\mathbf{x}$$

and an estimator stratified over the group from which the observations come is given by

$$\hat{e}_t \text{ (stratified)} = 1 - \frac{1}{q_t} \sum_u q_u \frac{1}{n_u} \left(\sum_{\mathcal{R}_{ut}} p(t|\mathbf{x}) \right)$$

The inner summation is over all sample observations of \mathcal{S} coming from group u and classified into group t , and n_u is the number of observations originally from group u . The stratified estimate uses only the observations with known group membership. When the prior probabilities of the group membership are proportional to the group sizes, the stratified estimate is the same as the unstratified estimator.

The estimated group-specific error rates can be less than zero, usually due to a large discrepancy between prior probabilities of group membership and group sizes. To have a reliable estimate for group-specific error rate estimates, you should use group sizes that are at least approximately proportional to the prior probabilities of group membership.

A total error rate is defined as a weighted average of the individual group error rates

$$e = \sum_t q_t e_t$$

and can be estimated from

$$\hat{e} \text{ (unstratified)} = \sum_t q_t \hat{e}_t \text{ (unstratified)}$$

or

$$\hat{e} \text{ (stratified)} = \sum_t q_t \hat{e}_t \text{ (stratified)}$$

The total unstratified error-rate estimate can also be written as

$$\hat{e} \text{ (unstratified)} = 1 - \frac{1}{n} \sum_t \sum_{\mathcal{R}_t} p(t|\mathbf{x})$$

which is one minus the average value of the maximum posterior probabilities for each observation in the sample. The prior probabilities of group membership do not appear explicitly in this overall estimate.

Saving and Using Calibration Information

When you specify METHOD=NORMAL to derive a linear or quadratic discriminant function, you can save the calibration information developed by the DISCRIM procedure in a SAS data set by using the OUTSTAT= option in the procedure. PROC DISCRIM then creates a specially structured SAS data set of TYPE=LINEAR, TYPE=QUAD, or TYPE=MIXED that contains the calibration information. For more information about these data sets, see Appendix A, “[Special SAS Data Sets](#).” Calibration information cannot be saved when METHOD=NPART, but you can classify a TESTDATA= data set in the same step. For an example of this, see [Example 33.1](#).

To use this calibration information to classify observations in another data set, specify both of the following:

- the name of the calibration data set after the DATA= option in the PROC DISCRIM statement

- the name of the data set to be classified after the TESTDATA= option in the PROC DISCRIM statement

Here is an example:

```
data original;
    input position x1 x2;
    datalines;
...[data lines]
;

proc discrim outstat=info;
    class position;
run;

data check;
    input position x1 x2;
    datalines;
...[second set of data lines]
;

proc discrim data=info testdata=check testlist;
    class position;
run;
```

The first DATA step creates the SAS data set Original, which the DISCRIM procedure uses to develop a classification criterion. Specifying OUTSTAT=INFO in the PROC DISCRIM statement causes the DISCRIM procedure to store the calibration information in a new data set called Info. The next DATA step creates the data set Check. The second PROC DISCRIM statement specifies DATA=INFO and TESTDATA=CHECK so that the classification criterion developed earlier is applied to the Check data set. Note that if the CLASS variable is not present in the TESTDATA= data set, the output will not include misclassification statistics.

Input Data Sets

DATA= Data Set

When you specify METHOD=NPART, an ordinary SAS data set is required as the input DATA= data set. When you specify METHOD=NORMAL, the DATA= data set can be an ordinary SAS data set or one of several specially structured data sets created by SAS/STAT procedures. These specially structured data sets include the following:

- TYPE=CORR data sets created by PROC CORR by using a BY statement
- TYPE=COV data sets created by PROC PRINCOMP by using both the COV option and a BY statement
- TYPE=CSSCP data sets created by PROC CORR by using the CSSCP option and a BY statement, where the OUT= data set is assigned TYPE=CSSCP with the TYPE= data set option
- TYPE=SSCP data sets created by PROC REG by using both the OUTSSCP= option and a BY statement

- TYPE=LINEAR, TYPE=QUAD, and TYPE=MIXED data sets produced by previous runs of PROC DISCRIM that used both METHOD=NORMAL and OUTSTAT= options

When the input data set is TYPE=CORR, TYPE=COV, TYPE=CSSCP, or TYPE=SSCP, the BY variable in these data sets becomes the CLASS variable in the DISCRIM procedure.

When the input data set is TYPE=CORR, TYPE=COV, or TYPE=CSSCP, then PROC DISCRIM reads the number of observations for each class from the observations with `_TYPE_='N'` and reads the variable means in each class from the observations with `_TYPE_='MEAN'`. Then PROC DISCRIM reads the within-class correlations from the observations with `_TYPE_='CORR'` and reads the standard deviations from the observations with `_TYPE_='STD'` (data set TYPE=CORR), the within-class covariances from the observations with `_TYPE_='COV'` (data set TYPE=COV), or the within-class corrected sums of squares and crossproducts from the observations with `_TYPE_='CSSCP'` (data set TYPE=CSSCP).

When you specify POOL=YES and the data set does not include any observations with `_TYPE_='CSSCP'` (data set TYPE=CSSCP), `_TYPE_='COV'` (data set TYPE=COV), or `_TYPE_='CORR'` (data set TYPE=CORR) for each class, PROC DISCRIM reads the pooled within-class information from the data set. In this case, PROC DISCRIM reads the pooled within-class covariances from the observations with `_TYPE_='PCOV'` (data set TYPE=COV) or reads the pooled within-class correlations from the observations with `_TYPE_='PCORR'` and the pooled within-class standard deviations from the observations with `_TYPE_='PSTD'` (data set TYPE=CORR) or the pooled within-class corrected SSCP matrix from the observations with `_TYPE_='PSSCP'` (data set TYPE=CSSCP).

When the input data set is TYPE=SSCP, the DISCRIM procedure reads the number of observations for each class from the observations with `_TYPE_='N'`, the sum of weights of observations for each class from the variable INTERCEP in observations with `_TYPE_='SSCP'` and `_NAME_='INTERCEPT'`, the variable sums from the analysis variables in observations with `_TYPE_='SSCP'` and `_NAME_='INTERCEPT'`, and the uncorrected sums of squares and crossproducts from the analysis variables in observations with `_TYPE_='SSCP'` and `_NAME_='variablenames'`.

When the input data set is TYPE=LINEAR, TYPE=QUAD, or TYPE=MIXED, then PROC DISCRIM reads the prior probabilities for each class from the observations with variable `_TYPE_='PRIOR'`.

When the input data set is TYPE=LINEAR, then PROC DISCRIM reads the coefficients of the linear discriminant functions from the observations with variable `_TYPE_='LINEAR'`.

When the input data set is TYPE=QUAD, then PROC DISCRIM reads the coefficients of the quadratic discriminant functions from the observations with variable `_TYPE_='QUAD'`.

When the input data set is TYPE=MIXED, then PROC DISCRIM reads the coefficients of the linear discriminant functions from the observations with variable `_TYPE_='LINEAR'`. If there are no observations with `_TYPE_='LINEAR'`, then PROC DISCRIM reads the coefficients of the quadratic discriminant functions from the observations with variable `_TYPE_='QUAD'`.

TESTDATA= Data Set

The TESTDATA= data set is an ordinary SAS data set with observations that are to be classified. The quantitative variable names in this data set must match those in the DATA= data set. The TESTCLASS statement can be used to specify the variable containing group membership information of the TESTDATA= data set observations. When the TESTCLASS statement is missing and the TESTDATA= data set contains the variable given in the CLASS statement, this variable is used as the TESTCLASS variable. The TESTCLASS

variable should have the same type (character or numeric) and length as the variable given in the CLASS statement. PROC DISCRIM considers an observation misclassified when the value of the TESTCLASS variable does not match the group into which the TESTDATA= observation is classified.

Output Data Sets

When an output data set includes variables containing the posterior probabilities of group membership (OUT=, OUTCROSS=, or TESTOUT= data sets) or group-specific density estimates (OUTD= or TESTOUTD= data sets), the names of these variables are constructed from the formatted values of the class levels converted to valid SAS variable names.

OUT= Data Set

The OUT= data set contains all the variables in the DATA= data set, plus new variables containing the posterior probabilities and the resubstitution classification results. The names of the new variables containing the posterior probabilities are constructed from the formatted values of the class levels converted to SAS names. A new variable, _INTO_, with the same attributes as the CLASS variable, specifies the class to which each observation is assigned. If an observation is labeled as 'Other', the variable _INTO_ has a missing value. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. The NCAN= option determines the number of canonical variables. The names of the canonical variables are constructed as described in the CANPREFIX= option. The canonical variables have means equal to zero and pooled within-class variances equal to one.

An OUT= data set cannot be created if the DATA= data set is not an ordinary SAS data set.

OUTD= Data Set

The OUTD= data set contains all the variables in the DATA= data set, plus new variables containing the group-specific density estimates. The names of the new variables containing the density estimates are constructed from the formatted values of the class levels.

An OUTD= data set cannot be created if the DATA= data set is not an ordinary SAS data set.

OUTCROSS= Data Set

The OUTCROSS= data set contains all the variables in the DATA= data set, plus new variables containing the posterior probabilities and the classification results of cross validation. The names of the new variables containing the posterior probabilities are constructed from the formatted values of the class levels. A new variable, _INTO_, with the same attributes as the CLASS variable, specifies the class to which each observation is assigned. When an observation is labeled as 'Other', the variable _INTO_ has a missing value. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. The NCAN= option determines the number of new variables. The names of the new variables are constructed as described in the CANPREFIX= option. The new variables have mean zero and pooled within-class variance equal to one.

An OUTCROSS= data set cannot be created if the DATA= data set is not an ordinary SAS data set.

TESTOUT= Data Set

The TESTOUT= data set contains all the variables in the TESTDATA= data set, plus new variables containing the posterior probabilities and the classification results. The names of the new variables containing the posterior probabilities are formed from the formatted values of the class levels. A new variable, `_INTO_`, with the same attributes as the CLASS variable, gives the class to which each observation is assigned. If an observation is labeled as 'Other', the variable `_INTO_` has a missing value. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. The NCAN= option determines the number of new variables. The names of the new variables are formed as described in the CANPREFIX= option.

TESTOUTD= Data Set

The TESTOUTD= data set contains all the variables in the TESTDATA= data set, plus new variables containing the group-specific density estimates. The names of the new variables containing the density estimates are formed from the formatted values of the class levels.

OUTSTAT= Data Set

The OUTSTAT= data set is similar to the TYPE=CORR data set produced by the CORR procedure. The data set contains various statistics such as means, standard deviations, and correlations. For an example of an OUTSTAT= data set, see [Example 33.3](#). When you specify the CANONICAL option, canonical correlations, canonical structures, canonical coefficients, and means of canonical variables for each class are included in the data set.

If you specify METHOD=NORMAL, the output data set also includes coefficients of the discriminant functions, and the data set is TYPE=LINEAR (POOL=YES), TYPE=QUAD (POOL=NO), or TYPE=MIXED (POOL=TEST). If you specify METHOD=NPART, this output data set is TYPE=CORR.

The OUTSTAT= data set contains the following variables:

- the BY variables, if any
- the CLASS variable
- `_TYPE_`, a character variable of length 8 that identifies the type of statistic
- `_NAME_`, a character variable of length 32 that identifies the row of the matrix, the name of the canonical variable, or the type of the discriminant function coefficients
- the quantitative variables—that is, those in the VAR statement, or, if there is no VAR statement, all numeric variables not listed in any other statement

The observations, as identified by the variable `_TYPE_`, have the following values:

<code>_TYPE_</code>	Contents
N	number of observations both for the total sample (CLASS variable missing) and within each class (CLASS variable present)
SUMWGT	sum of weights both for the total sample (CLASS variable missing) and within each class (CLASS variable present), if a WEIGHT statement is specified
MEAN	means both for the total sample (CLASS variable missing) and within each class (CLASS variable present)
PRIOR	prior probability for each class
STDMEAN	total-standardized class means
PSTDMEAN	pooled within-class standardized class means
STD	standard deviations both for the total sample (CLASS variable missing) and within each class (CLASS variable present)
PSTD	pooled within-class standard deviations
BSTD	between-class standard deviations
RSQUARED	univariate R squares
LNDETERM	the natural log of the determinant or the natural log of the quasi determinant of the within-class covariance matrix either pooled (CLASS variable missing) or not pooled (CLASS variable present)

The following kinds of observations are identified by the combination of the variables `_TYPE_` and `_NAME_`. When the `_TYPE_` variable has one of the following values, the `_NAME_` variable identifies the row of the matrix:

<code>_TYPE_</code>	Contents
CSSCP	corrected SSCP matrix both for the total sample (CLASS variable missing) and within each class (CLASS variable present)
PSSCP	pooled within-class corrected SSCP matrix
BSSCP	between-class SSCP matrix
COV	covariance matrix both for the total sample (CLASS variable missing) and within each class (CLASS variable present)
PCOV	pooled within-class covariance matrix
BCOV	between-class covariance matrix
CORR	correlation matrix both for the total sample (CLASS variable missing) and within each class (CLASS variable present)
PCORR	pooled within-class correlation matrix
BCORR	between-class correlation matrix

When you request canonical discriminant analysis, the `_NAME_` variable identifies a canonical variable, and `_TYPE_` variable can have one of the following values:

<code>_TYPE_</code>	Contents
CANCORR	canonical correlations
STRUCTUR	canonical structure
BSTRUCT	between canonical structure
PSTRUCT	pooled within-class canonical structure
SCORE	standardized canonical coefficients
RAWSCORE	raw canonical coefficients
CANMEAN	means of the canonical variables for each class

When you specify `METHOD=NORMAL`, the `_NAME_` variable identifies different types of coefficients in the discriminant function, and the `_TYPE_` variable can have one of the following values:

<code>_TYPE_</code>	Contents
LINEAR	coefficients of the linear discriminant functions
QUAD	coefficients of the quadratic discriminant functions

The values of the `_NAME_` variable are as follows:

<code>_NAME_</code>	Contents
<i>variable names</i>	quadratic coefficients of the quadratic discriminant functions (a symmetric matrix for each class)
<code>_LINEAR_</code>	linear coefficients of the discriminant functions
<code>_CONST_</code>	constant coefficients of the discriminant functions

Computational Resources

In the following discussion, let

- n = number of observations in the training data set
- v = number of variables
- c = number of class levels
- k = number of canonical variables
- l = length of the CLASS variable

Memory Requirements

The amount of temporary storage required depends on the discriminant method used and the options specified. The least amount of temporary storage in bytes needed to process the data is approximately

$$c(32v + 3l + 128) + 8v^2 + 104v + 4l$$

A parametric method (METHOD=NORMAL) requires an additional temporary memory of $12v^2 + 100v$ bytes. When you specify the CROSSVALIDATE option, this temporary storage must be increased by $4v^2 + 44v$ bytes. When a nonparametric method (METHOD=NP) is used, an additional temporary storage of $10v^2 + 94v$ bytes is needed if you specify METRIC=FULL to evaluate the distances.

With the MANOVA option, the temporary storage must be increased by $8v^2 + 96v$ bytes. The CANONICAL option requires a temporary storage of $2v^2 + 94v + 8k(v + c)$ bytes. The POSTERR option requires a temporary storage of $8c^2 + 64c + 96$ bytes. Additional temporary storage is also required for classification summary and for each output data set.

Consider the following statements:

```
proc discrim manova;
  class gp;
  var x1 x2 x3;
run;
```

If the CLASS variable gp has a length of 8 and the input data set contains two class levels, the procedure requires a temporary storage of 1992 bytes. This includes 1104 bytes for processing data, 480 bytes for using a parametric method, and 408 bytes for specifying the MANOVA option.

Time Requirements

The following factors determine the time requirements of discriminant analysis:

- The time needed for reading the data and computing covariance matrices is proportional to nv^2 . PROC DISCRIM must also look up each class level in the list. This is faster if the data are sorted by the CLASS variable. The time for looking up class levels is proportional to a value ranging from n to $n \ln(c)$.
- The time for inverting a covariance matrix is proportional to v^3 .
- With a parametric method, the time required to classify each observation is proportional to cv for a linear discriminant function and cv^2 for a quadratic discriminant function. When you specify the CROSSVALIDATE option, the discriminant function is updated for each observation in the classification. A substantial amount of time is required.
- With a nonparametric method, the data are stored in a tree structure (Friedman, Bentley, and Finkel 1977). The time required to organize the observations into the tree structure is proportional to $nv \ln(n)$. The time for performing each tree search is proportional to $\ln(n)$. When you specify the normal KERNEL= option, all observations in the training sample contribute to the density estimation and more computer time is needed.
- The time required for the canonical discriminant analysis is proportional to v^3 .

Each of the preceding factors has a different machine-dependent constant of proportionality.

Displayed Output

The displayed output from PROC DISCRIM includes the class level information table. For each level of the classification variable, the following information is provided: the output data set variable name, frequency sum, weight sum, proportion of the total sample, and prior probability.

The optional output from PROC DISCRIM includes the following:

- Within-class SSCP matrices for each group
- Pooled within-class SSCP matrix
- Between-class SSCP matrix
- Total-sample SSCP matrix
- Within-class covariance matrices, S_i , for each group
- Pooled within-class covariance matrix, S_p
- Between-class covariance matrix, equal to the between-class SSCP matrix divided by $n(c - 1)/c$, where n is the number of observations and c is the number of classes
- Total-sample covariance matrix
- Within-class correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the within-class population correlation coefficients are zero
- Pooled within-class correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the partial population correlation coefficients are zero
- Between-class correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the between-class population correlation coefficients are zero
- Total-sample correlation coefficients and $\text{Pr} > |r|$ to test the hypothesis that the total population correlation coefficients are zero
- Simple statistics, including N (the number of observations), sum, mean, variance, and standard deviation both for the total sample and within each class
- Total-sample standardized class means, obtained by subtracting the grand mean from each class mean and dividing by the total-sample standard deviation
- Pooled within-class standardized class means, obtained by subtracting the grand mean from each class mean and dividing by the pooled within-class standard deviation
- Pairwise squared distances between groups
- Univariate test statistics, including total-sample standard deviations, pooled within-class standard deviations, between-class standard deviations, R square, $R^2/(1 - R^2)$, F , and $\text{Pr} > F$ (univariate F values and probability levels for one-way analyses of variance)

- Multivariate statistics and F approximations, including Wilks' lambda, Pillai's trace, Hotelling-Lawley trace, and Roy's greatest root with F approximations, numerator and denominator degrees of freedom (Num DF and Den DF), and probability values ($\text{Pr} > F$). Each of these four multivariate statistics tests the hypothesis that the class means are equal in the population. See the section "Multivariate Tests" on page 92 in Chapter 4, "Introduction to Regression Procedures," for more information.

If you specify METHOD=NORMAL, the following three statistics are displayed:

- Covariance matrix information, including covariance matrix rank and natural log of determinant of the covariance matrix for each group (POOL=TEST, POOL=NO) and for the pooled within-group (POOL=TEST, POOL=YES)
- Optionally, test of homogeneity of within covariance matrices (the results of a chi-square test of homogeneity of the within-group covariance matrices) (Morrison 1976; Kendall, Stuart, and Ord 1983; Anderson 1984)
- Pairwise generalized squared distances between groups

If the CANONICAL option is specified, the displayed output contains these statistics:

- Canonical correlations
- Adjusted canonical correlations (Lawley 1959). These are asymptotically less biased than the raw correlations and can be negative. The adjusted canonical correlations might not be computable and are displayed as missing values if two canonical correlations are nearly equal or if some are close to zero. A missing value is also displayed if an adjusted canonical correlation is larger than a previous adjusted canonical correlation.
- Approximate standard error of the canonical correlations
- Squared canonical correlations
- Eigenvalues of $\mathbf{E}^{-1}\mathbf{H}$. Each eigenvalue is equal to $\rho^2/(1 - \rho^2)$, where ρ^2 is the corresponding squared canonical correlation and can be interpreted as the ratio of between-class variation to within-class variation for the corresponding canonical variable. The table includes eigenvalues, differences between successive eigenvalues, proportion of the sum of the eigenvalues, and cumulative proportion.
- Likelihood ratio for the hypothesis that the current canonical correlation and all smaller ones are zero in the population. The likelihood ratio for all canonical correlations equals Wilks' lambda.
- Approximate F statistic based on Rao's approximation to the distribution of the likelihood ratio (Rao 1973, p. 556; Kshirsagar 1972, p. 326)
- Numerator degrees of freedom (Num DF), denominator degrees of freedom (Den DF), and $\text{Pr} > F$, the probability level associated with the F statistic

The following statistic concerns the classification criterion:

- the linear discriminant function, but only if you specify METHOD=NORMAL and the pooled covariance matrix is used to calculate the (generalized) squared distances

When the input DATA= data set is an ordinary SAS data set, the displayed output includes the following:

- Optionally, the resubstitution results including the observation number (if an ID statement is included, the values of the ID variable are displayed instead of the observation number), the actual group for the observation, the group into which the developed criterion would classify it, and the posterior probability of membership in each group
- Resubstitution summary, a summary of the performance of the classification criterion based on resubstitution classification results
- Error count estimate of the resubstitution classification results
- Optionally, posterior probability error rate estimates of the resubstitution classification results

If you specify the CROSSVALIDATE option, the displayed output contains these statistics:

- Optionally, the cross validation results including the observation number (if an ID statement is included, the values of the ID variable are displayed instead of the observation number), the actual group for the observation, the group into which the developed criterion would classify it, and the posterior probability of membership in each group
- Cross validation summary, a summary of the performance of the classification criterion based on cross validation classification results
- Error count estimate of the cross validation classification results
- Optionally, posterior probability error rate estimates of the cross validation classification results

If you specify the TESTDATA= option, the displayed output contains these statistics:

- Optionally, the classification results including the observation number (if a TESTID statement is included, the values of the ID variable are displayed instead of the observation number), the actual group for the observation (if a TESTCLASS statement is included), the group into which the developed criterion would classify it, and the posterior probability of membership in each group
- Classification summary, a summary of the performance of the classification criterion
- Error count estimate of the test data classification results
- Optionally, posterior probability error rate estimates of the test data classification results

Formulas

By default, PROC DISCRIM displays formulas such as the following in the LISTING destination:

$$D(i|j) = \sum_i^2 (\bar{X}_i - \bar{X}_j)' \text{DIAG}(\text{COV}_j)^{-1} (\bar{X}_i - \bar{X}_j)$$

$$\text{RHO} = 1.0 - \frac{\left| \sum_i \frac{1}{N(i)} - \frac{1}{N} \right|}{\frac{2P + 3P - 1}{6(P+1)(K-1)}}$$

$$D_j(X) = \sum_j^2 (\bar{X}_j - \bar{X})' \text{COV}_j^{-1} (\bar{X}_j - \bar{X}) + \ln |\text{COV}_j| - 2 \ln \text{PRIOR}_j$$

These formulas are properly displayed only with uniform fonts. Formulas are not displayed by default in destinations such as HTML, RTF, and PDF, because destinations other than LISTING typically use proportional fonts. You can use the FORMULA option to display formulas in destinations other than LISTING.

In the LISTING destination, formulas are displayed as notes. In other destinations, formulas are displayed with batch capture (which provides uniform fonts). Therefore, the names that are used to select and exclude formulas from the LISTING destination are different from the names that are used with other destinations.

By default, batch capture results are displayed in a box. You can remove the box and change the color and font of the formulas as follows:

```
proc template;
  define style styles.batch; parent=styles.htmlblue;
    style fonts from fonts / "BatchFixedFont" =
      ("SAS Monospace, <monospace>, Courier, monospace", 2, bold);
    style batch from batch / frame=void foreground=colors('notefg');
  end;
run;

ods listing;
ods html style=batch body='dis.html';
ods rtf style=batch body='dis.rtf';
ods pdf style=batch body='dis.pdf';

proc discrim data=sashelp.iris formula;
  class Species;
  var Peta;;
run;

ods _all_ close;
```

The results of these steps are not displayed.

ODS Table Names

PROC DISCRIM assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 33.2. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 33.2 ODS Tables Produced by PROC DISCRIM

ODS Table Name	Description	PROC DISCRIM Option
ANOVA	Univariate statistics	ANOVA
AvePostCrossVal	Average posterior probabilities, cross validation	POSTERR & CROSSVALIDATE
AvePostResub	Average posterior probabilities, resubstitution	POSTERR
AvePostTestClass	Average posterior probabilities, test classification	POSTERR & TEST=
AveRSquare	Average R-square	ANOVA
BCorr	Between-class correlations	BCORR
BCov	Between-class covariances	BCOV
BSSCP	Between-class SSCP matrix	BSSCP
BStruc	Between canonical structure	CANONICAL
CanCorr	Canonical correlations	CANONICAL
CanonicalMeans	Class means on canonical variables	CANONICAL
ChiSq	Chi-square information	POOL=TEST

Examples: DISCRIM Procedure

The iris data published by Fisher (1936) are widely used for examples in discriminant analysis and cluster analysis. The sepal length, sepal width, petal length, and petal width are measured in millimeters on 50 iris specimens from each of three species: *Iris setosa*, *I. versicolor*, and *I. virginica*. The iris data set is available from the Sashelp library.

Example 33.1: Univariate Density Estimates and Posterior Probabilities

In this example, several discriminant analyses are run with a single quantitative variable, petal width, so that density estimates and posterior probabilities can be plotted easily. The example produces [Output 33.1.1](#) through [Output 33.1.5](#). ODS Graphics is used to display the sample distribution of petal width in the three species. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS.](#)” Note the overlap between the species *I. versicolor* and *I. virginica* that the bar chart shows. The following statements produce [Output 33.1.1](#):

```
title 'Discriminant Analysis of Fisher (1936) Iris Data';

proc freq data=sashelp.iris noprint;
    tables petalwidth * species / out=freqout;
run;

proc sgplot data=freqout;
    vbar petalwidth / response=count group=species;
    keylegend / location=inside position=ne noborder across=1;
run;
```

Output 33.1.1 Sample Distribution of Petal Width in Three Species

In order to plot the density estimates and posterior probabilities, a data set called `plotdata` is created containing equally spaced values from -5 to 30 , covering the range of petal width with a little to spare on each end. The `plotdata` data set is used with the `TESTDATA=` option in `PROC DISCRIM`. The following statements make the data set:

```
data plotdata;
  do PetalWidth=-5 to 30 by 0.5;
    output;
  end;
run;
```

The same plots are produced after each discriminant analysis, so macros are used to reduce the amount of typing required. The macros use two data sets. The data set `plotd`, containing density estimates, is created by the `TESTOUTD=` option in `PROC DISCRIM`. The data set `plotp`, containing posterior probabilities, is created by the `TESTOUT=` option. For each data set, the macros remove uninteresting values (near zero) and create an overlay plot showing all three species in a single plot.

The following statements create the macros:

```
%macro plotden;
  title3 'Plot of Estimated Densities';

  data plotd2;
    set plotd;
    if setosa      < .002 then setosa      = .;
    if versicolor < .002 then versicolor = .;
    if virginica   < .002 then virginica   = .;
    g = 'Setosa    '; Density = setosa;      output;
    g = 'Versicolor'; Density = versicolor; output;
    g = 'Virginica '; Density = virginica;  output;
    label PetalWidth='Petal Width in mm.';
  run;

  proc sgplot data=plotd2;
    series y=Density x=PetalWidth / group=g;
    discretelegend;
  run;
%mend;

%macro plotprob;
  title3 'Plot of Posterior Probabilities';

  data plotp2;
    set plotp;
    if setosa      < .01 then setosa      = .;
    if versicolor < .01 then versicolor = .;
    if virginica   < .01 then virginica   = .;
    g = 'Setosa    '; Probability = setosa;      output;
    g = 'Versicolor'; Probability = versicolor; output;
    g = 'Virginica '; Probability = virginica;  output;
    label PetalWidth='Petal Width in mm.';
  run;

  proc sgplot data=plotp2;
    series y=Probability x=PetalWidth / group=g;
    discretelegend;
  run;
%mend;
```

The first analysis uses normal-theory methods (METHOD=NORMAL) assuming equal variances (POOL=YES) in the three classes. The NOCLASSIFY option suppresses the resubstitution classification results of the input data set observations. The CROSSLISTERR option lists the observations that are misclassified under cross validation and displays cross validation error-rate estimates. The following statements produce [Output 33.1.2](#):

```

title2 'Using Normal Density Estimates with Equal Variance';

proc discrim data=sashelp.iris method=normal pool=yes
    testdata=plotdata testout=plotp testoutd=plotd
    short noclassify crosslisterr;
    class Species;
    var PetalWidth;
run;

%plotden;
%plotprob;

```

Two more analyses are run with nonparametric methods (METHOD=NPAR), specifically kernel density estimates with normal kernels (KERNEL=NORMAL). The first of these uses equal bandwidths (smoothing parameters) (POOL=YES) in each class. The use of equal bandwidths does not constrain the density estimates to be of equal variance. The value of the radius parameter that, assuming normality, minimizes an approximate mean integrated square error is 0.48 (see the section “Nonparametric Methods” on page 2079). Choosing $r = 0.4$ gives a more detailed look at the irregularities in the data. The following statements produce Output 33.1.4:

```

Example 33.2: Bivariate Density Estimates and Posterior Probabilities

In this example, four more discriminant analyses of iris data are run with two quantitative variables: petal width and petal length. The following statements produce [Output 33.2.1](#) through [Output 33.2.5](#):

```
title 'Discriminant Analysis of Fisher (1936) Iris Data';
proc template;
  define statgraph scatter;
    begingraph;
      entrytitle 'Fisher (1936) Iris Data';
      layout overlayequated / equatetype=fit;
        scatterplot x=petallength y=petalwidth /
          group=species name='iris';
      layout gridded / autoalign=(topleft);
        discretelegend 'iris' / border=false opaque=false;
      endlayout;
    endlayout;
  endgraph;
end;
run;

proc sgrender data=sashelp.iris template=scatter;
run;
```

The scatter plot in [Output 33.2.1](#) shows the joint sample distribution.

Output 33.2.1 Joint Sample Distribution of Petal Width and Petal Length in Three Species

Another data set is created for plotting, containing a grid of points suitable for contour plots. The following statements create the data set:

```
data plotdata;
  do PetalLength = -2 to 72 by 0.5;
    do PetalWidth= - 5 to 32 by 0.5;
      output;
    end;
  end;
end;
run;
```

Three macros are defined as follows to make contour plots of density estimates, posterior probabilities, and classification results:

```
%let close = thresholdmin=0 thresholdmax=0 offsetmin=0 offsetmax=0;
%let close = xaxisopts=(&close) yaxisopts=(&close);

proc template;
  define statgraph contour;
    begingraph;
      layout overlayequated / equatetype=equate &close;
      contourplotparm x=petallength y=petalwidth z=z /
        contourtype=fill nhint=30;
      scatterplot x=pl y=pw / group=species name='iris'
        includemissinggroup=false primary=true;
      layout gridded / autoalign=(topleft);
      discretelegend 'iris' / border=false opaque=false;
    endlayout;
  endgraph;
end;
run;

%macro contden;
  data contour(keep=PetalWidth PetalLength species z pl pw);
    merge plotd(in=d) sashelp.iris(keep=PetalWidth PetalLength species
      rename=(PetalWidth=pw PetalLength=pl));
    if d then z = max(setosa,versicolor,virginica);
  run;

  title3 'Plot of Estimated Densities';

  proc sgrender data=contour template=contour;
  run;
%mend;

%macro contprob;
  data posterior(keep=PetalWidth PetalLength species z pl pw into);
    merge plotp(in=d) sashelp.iris(keep=PetalWidth PetalLength species
      rename=(PetalWidth=pw PetalLength=pl));
    if d then z = max(setosa,versicolor,virginica);
    into = 1 * (_into_ =: 'Set') + 2 * (_into_ =: 'Ver') +
      3 * (_into_ =: 'Vir');
  run;

  title3 'Plot of Posterior Probabilities ';

  proc sgrender data=posterior template=contour;
  run;
%mend;
```

```
%macro contclass;
  title3 'Plot of Classification Results';

  proc sgrender data=posterior(drop=z rename=(into=z)) template=contour;
  run;
%mend;
```

A normal-theory analysis (METHOD=NORMAL) assuming equal covariance matrices (POOL=YES) illustrates the linearity of the classification boundaries. These statements produce [Output 33.2.2](#):

```
title2 'Using Normal Density Estimates with Equal Variance';

proc discrim data=sashelp.iris method=normal pool=yes
  testdata=plotdata testout=plotp testoutd=plotd
  short noclassify crosslisterr;
  class Species;
  var Petal;;
run;

%contden
%contprob
%contclass
```

Example 33.3: Normal-Theory Discriminant Analysis of Iris Data

In this example, PROC DISCRIM uses normal-theory methods to classify the iris data used in [Example 33.1](#). The POOL=TEST option tests the homogeneity of the within-group covariance matrices ([Output 33.3.3](#)). Since the resulting test statistic is significant at the 0.10 level, the within-group covariance matrices are used to derive the quadratic discriminant criterion. The WCOV and PCOV options display the within-group covariance matrices and the pooled covariance matrix ([Output 33.3.2](#)). The DISTANCE option displays squared distances between classes ([Output 33.3.4](#)). The ANOVA and MANOVA options test the hypothesis that the class means are equal, by using univariate statistics and multivariate statistics; all statistics are significant at the 0.0001 level ([Output 33.3.5](#)). The LISTERR option lists the misclassified observations under resubstitution ([Output 33.3.6](#)). The CROSSLISTERR option lists the observations that are misclassified under cross validation and displays cross validation error-rate estimates ([Output 33.3.7](#)). The resubstitution error count estimate, 0.02, is not larger than the cross validation error count estimate, 0.0267, as would be expected because the resubstitution estimate is optimistically biased. The OUTSTAT= option generates a TYPE=MIXED (because POOL=TEST) output data set containing various statistics such as means, covariances, and coefficients of the discriminant function ([Output 33.3.8](#)).

The following statements produce [Output 33.3.1](#) through [Output 33.3.8](#):

```

title 'Discriminant Analysis of Fisher (1936) Iris Data';
title2 'Using Quadratic Discriminant Function';

proc discrim data=sashelp.iris outstat=irisstat
            wcov pcov method=normal pool=test

Example 33.4: Linear Discriminant Analysis of Remote-Sensing Data on Crops

In this example, the remote-sensing data are used. In this data set, the observations are grouped into five crops: clover, corn, cotton, soybeans, and sugar beets. Four measures called x1 through x4 make up the descriptive variables.

In the first PROC DISCRIM statement, the DISCRIM procedure uses normal-theory methods (METHOD=NORMAL) assuming equal variances (POOL=YES) in five crops. The PRIORS statement, PRIORS PROP, sets the prior probabilities proportional to the sample sizes. The LIST option lists the resubstitution classification results for each observation (Output 33.4.2). The CROSSVALIDATE option displays cross validation error-rate estimates (Output 33.4.3). The OUTSTAT= option stores the calibration information in a new data set to classify future observations. A second PROC DISCRIM statement uses this calibration information to classify a test data set. Note that the values of the identification variable, xvalues, are obtained by rereading the x1 through x4 fields in the data lines as a single character variable. The following statements produce Output 33.4.1 through Output 33.4.3:

```

In this next example, PROC DISCRIM uses normal-theory methods (METHOD=NORMAL) assuming unequal variances (POOL=NO) for the remote-sensing data. The PRIORS statement, PRIORS PROP, sets the prior probabilities proportional to the sample sizes. The CROSSVALIDATE option displays cross validation error-rate estimates. Note that the total error count estimate by cross validation (0.5556) is much larger than the total error count estimate by resubstitution (0.1111). The following statements produce [Output 33.4.6](#):

```

Overview: DISTANCE Procedure

The DISTANCE procedure computes various measures of distance, dissimilarity, or similarity between the observations (rows) of an input SAS data set, which can contain numeric or character variables, or both, depending on which proximity measure is used.

The proximity measures are stored as a lower triangular matrix or a square matrix (depending on the SHAPE= option) in an output data set that can then be used as input to the CLUSTER, MDS, and MODULECLUS procedures.

The number of rows and columns in the output data set equals the number of observations in the input data set. If the input data set contains BY groups, an output matrix is computed for each BY group with the size determined by the maximum number of observations in any BY group.

The output data set is of type TYPE=DISTANCE or TYPE=SIMILAR, depending on the value of the METHOD= option. See the METHOD= option for more information about the association between the method and the output data set type.

Data set types do not persist when you copy or modify a data set. You must specify the TYPE= data set option for the new data set, as in the following example:

```
data dist2(type=distance);
    set dist;
run;
```

See the OUT= option for more information about data set type persistence.

PROC DISTANCE also provides various nonparametric and parametric methods for standardizing variables. Different variables can be standardized with different methods.

Distance matrices are used frequently in data mining, genomics, marketing, financial analysis, management science, education, chemistry, psychology, biology, and various other fields.

Levels of Measurement

Measurement of some attribute of a set of objects is the process of assigning numbers or other symbols to the objects in such a way that properties of the numbers or symbols reflect properties of the attribute being measured. There are different *levels* of measurement that involve different properties (relations and operations) of the numbers or symbols. Associated with each level of measurement is a set of transformations of the measurements that preserve the relevant properties; these transformations are called *permissible* transformations. A particular way of assigning numbers or symbols to measure something is called a *scale* of measurement.

The most commonly discussed levels of measurement are as follows:

Nominal	Two objects are assigned the same symbol if they have the same value of the attribute. Permissible transformations are any one-to-one or many-to-one transformation, although a many-to-one transformation loses information.
Ordinal	Objects are assigned numbers such that the order of the numbers reflects an order relation defined on the attribute. Two objects x and y with attribute values $a(x)$ and $a(y)$ are assigned numbers $m(x)$ and $m(y)$ such that if $m(x) > m(y)$, then $a(x) > a(y)$. Permissible transformations are any monotone increasing transformation, although a transformation that is not strictly increasing loses information.
Interval	Objects are assigned numbers such that differences between the numbers reflect differences of the attribute. If $m(x) - m(y) > m(u) - m(v)$, then $a(x) - a(y) > a(u) - a(v)$. Permissible transformations are any affine transformation $t(m) = c * m + d$, where c and d are constants; another way of saying this is that the origin and unit of measurement are arbitrary.

Log-interval	Objects are assigned numbers such that ratios between the numbers reflect ratios of the attribute. If $m(x)/m(y) > m(u)/m(v)$, then $a(x)/a(y) > a(u)/a(v)$. Permissible transformations are any power transformation $t(m) = c * m^d$, where c and d are constants.
Ratio	Objects are assigned numbers such that differences and ratios between the numbers reflect differences and ratios of the attribute. Permissible transformations are any linear (similarity) transformation $t(m) = c * m$, where c is a constant; another way of saying this is that the unit of measurement is arbitrary.
Absolute	Objects are assigned numbers such that all properties of the numbers reflect analogous properties of the attribute. The only permissible transformation is the identity transformation.

Proximity measures provided in the DISTANCE procedure accept four levels of measurement: nominal, ordinal, interval, and ratio. Ordinal variables are transformed to interval variables before processing. This is done by replacing the data with their rank scores, and by assuming that the classes of an ordinal variable are spaced equally along the interval scale. See the RANKSCORE= option in the section “[PROC DISTANCE Statement](#)” on page 2168 for choices on assigning scores to ordinal variables. There are also different approaches for how to transform an ordinal variable to an interval variable. See Anderberg (1973) for alternatives.

Symmetric versus Asymmetric Nominal Variables

A binary variable contains two possible outcomes: 1 (positive/present) or 0 (negative/absent). If there is no preference for which outcome should be coded as 0 and which as 1, the binary variable is called *symmetric*. For example, the binary variable “is evergreen?” for a plant has the possible states “loses leaves in winter” and “does not lose leaves in winter.” Both are equally valuable and carry the same weight when a proximity measure is computed. Commonly used measures that accept symmetric binary variables include the Simple Matching, Hamann, Roger and Tanimoto, Sokal and Sneath 1, and Sokal and Sneath 3 coefficients.

If the outcomes of a binary variable are not equally important, the binary variable is called *asymmetric*. An example of such a variable is the presence or absence of a relatively rare attribute, such as “is color-blind” for a human being. While you say that two people who are color-blind have something in common, you cannot say that people who are not color-blind have something in common. The most important outcome is usually coded as 1 (present) and the other is coded as 0 (absent). The agreement of two 1’s (a present-present match or a positive match) is more significant than the agreement of two 0’s (an absent-absent match or a negative match). Usually, the negative match is treated as irrelevant. Commonly used measures that accept asymmetric binary variables include Jaccard, Dice, Russell and Rao, Binary Lance and Williams nonmetric, and Kulczynski coefficients.

When nominal variables are employed, the comparison of one data unit with another can only be in terms of whether the data units score the same or different on the variables. If a variable is defined as an asymmetric nominal variable and two data units score the same but fall into the absent category, the absent-absent match is excluded from the computation of the proximity measure.

Standardization

Since variables with large variances tend to have more effect on the proximity measure than those with small variances, it is recommended that you standardize the variables before the computation of the proximity measure. The DISTANCE procedure provides a convenient way to standardize each variable with its own method before the proximity measures are computed. You can also perform the standardization by using the STDIZE procedure, with the limitation that all variables must be standardized with the same method.

Mandatory Standardization

Variable standardization is not required if any of the following conditions is true:

- if there is only one level of measurement
- if only asymmetric nominal and nominal levels are specified
- if the NOSTD option is specified in the PROC DISTANCE statement

Otherwise, standardization is mandatory.

When standardization is mandatory and no standardization method is specified, a default method of standardization will be used. This default method is determined by the measurement level. In general, the default method is STD for interval variables and is MAXABS for ratio variables except when METHOD=GOWER or METHOD=DGOWER is specified. See the STD= option in the section “[VAR Statement](#)” on page 2174 for the default methods for GOWER and DGOWER as well as methods available for standardizing variables.

When standardization is mandatory, PROC DISTANCE ignores the REONLY option, if it is specified.

Getting Started: DISTANCE Procedure

Creating a Distance Matrix as Input for a Subsequent Cluster Analysis

The following example demonstrates how you can use the DISTANCE procedure to obtain a distance matrix that will be used as input to a subsequent clustering procedure.

The following data, originated by A. Weber and cited in Hand et al. (1994, p. 297), measure the amount of protein consumed for nine food groups in 25 European countries. The nine food groups are red meat (RedMeat), white meat (WhiteMeat), eggs (Eggs), milk (Milk), fish (Fish), cereal (Cereal), starch (Starch), nuts (Nuts), and fruits and vegetables (FruitVeg). Suppose you want to determine whether national figures in protein consumption can be used to determine certain types or categories of countries; specifically, you want to perform a cluster analysis to determine whether these 25 countries can be formed into groups suggested by the data.

The following DATA step creates the SAS data set Protein:

```
data Protein;
  input Country $14. RedMeat WhiteMeat Eggs Milk
        Fish Cereal Starch Nuts FruitVeg;
  datalines;
Albania      10.1  1.4  0.5   8.9  0.2  42.3  0.6  5.5  1.7
Austria      8.9 14.0  4.3  19.9  2.1  28.0  3.6  1.3  4.3
Belgium     13.5  9.3  4.1  17.5  4.5  26.6  5.7  2.1  4.0
Bulgaria      7.8  6.0  1.6   8.3  1.2  56.7  1.1  3.7  4.2
Czechoslovakia 9.7 11.4  2.8  12.5  2.0  34.3  5.0  1.1  4.0
Denmark     10.6 10.8  3.7  25.0  9.9  21.9  4.8  0.7  2.4
E Germany    8.4 11.6  3.7  11.1  5.4  24.6  6.5  0.8  3.6
Finland      9.5  4.9  2.7  33.7  5.8  26.3  5.1  1.0  1.4
France     18.0  9.9  3.3  19.5  5.7  28.1  4.8  2.4  6.5
Greece     10.2  3.0  2.8  17.6  5.9  41.7  2.2  7.8  6.5
Hungary      5.3 12.4  2.9   9.7  0.3  40.1  4.0  5.4  4.2
Ireland     13.9 10.0  4.7  25.8  2.2  24.0  6.2  1.6  2.9
Italy       9.0  5.1  2.9  13.7  3.4  36.8  2.1  4.3  6.7
Netherlands  9.5 13.6  3.6  23.4  2.5  22.4  4.2  1.8  3.7
Norway      9.4  4.7  2.7  23.3  9.7  23.0  4.6  1.6  2.7
Poland      6.9 10.2  2.7  19.3  3.0  36.1  5.9  2.0  6.6
Portugal     6.2  3.7  1.1   4.9 14.2  27.0  5.9  4.7  7.9
Romania      6.2  6.3  1.5  11.1  1.0  49.6  3.1  5.3  2.8
Spain       7.1  3.4  3.1   8.6  7.0  29.2  5.7  5.9  7.2
Sweden      9.9  7.8  3.5   4.7  7.5  19.5  3.7  1.4  2.0
Switzerland 13.1 10.1  3.1  23.8  2.3  25.6  2.8  2.4  4.9
UK          17.4  5.7  4.7  20.6  4.3  24.3  4.7  3.4  3.3
USSR        9.3  4.6  2.1  16.6  3.0  43.6  6.4  3.4  2.9
W Germany   11.4 12.5  4.1  18.8  3.4  18.6  5.2  1.5  3.8
Yugoslavia   4.4  5.0  1.2   9.5  0.6  55.9  3.0  5.7  3.2
;
```

The data set Protein contains the character variable Country and the nine numeric variables representing the food groups. The \$14. in the INPUT statement specifies that the variable Country has a length of 14.

The following statements create the distance matrix and display part of it:

```

title 'Protein Consumption in Europe';
proc distance data=Protein out=Dist method=Euclid;
    var interval(RedMeat--FruitVeg / std=Std);
    id Country;
run;

proc print data=Dist(obs=10);
    title2 'First 10 Observations in Output Data Set from PROC DISTANCE';
run;
title2;

```

An output SAS data set called `Dist`, which contains the distance matrix, is created through the `OUT=` option. The `METHOD=EUCLID` option requests that Euclidean distances (which is the default) should be computed and produces an output data set of `TYPE=DISTANCE`.¹

The `VAR` statement lists the variables (`RedMeat—FruitVeg`) along with their measurement level to be used in the analysis. An interval level of measurement is assigned to those variables. Since variables with large variances tend to have more effect on the proximity measure than those with small variances, each variable is standardized by the `STD` method to have a mean of 0 and a standard deviation of 1. This is done by adding “/ `STD=STD`” at the end of the variables list.

The `ID` statement specifies that the variable `Country` should be copied to the `OUT=` data set and used to generate names for the distance variables. The distance variables in the output data set are named by the values in the `ID` variable, and the maximum length for the names of these variables is 14.

There are 25 observations in the input data set; therefore, the output data set `Dist` contains a 25-by-25 lower triangular matrix.

The `PROC PRINT` statement displays the first 10 observations in the output data set `Dist` as shown in [Figure 34.1](#).

¹Data set types do not persist when you copy or modify a data set. You must specify the `TYPE=` data set option for the new data set. See the `METHOD=` and `OUT=` options for more information about data set types.

The following statements produce the dendrogram in Figure 34.2:

```
ods graphics on;

proc cluster data=Dist method=Ward plots=dendrogram(height=rsq);
  id Country;
run;
```

The CLUSTER procedure performs a Ward's minimum-variance cluster analysis based on the distance matrix created by PROC DISTANCE. PROC CLUSTER, along with ODS Graphics, produces the dendrogram shown in Figure 34.2. The option PLOTS=DENDROGRAM(HEIGHT=RSQ) specifies the squared multiple correlation as the height variable in the dendrogram.

Figure 34.2 Dendrogram of R Square

After inspecting the dendrogram in [Figure 34.2](#), you will see that when the countries are grouped into six clusters, the proportion of variance accounted for by these clusters is slightly less than 70% (69.3%). The 25 countries are clustered as follows:

- Balkan countries: Albania, Bulgaria, Romania, and Yugoslavia
- Mediterranean countries: Greece and Italy
- Iberian countries: Portugal and Spain
- Western European countries: Austria, Netherlands, Switzerland, Belgium, former West Germany, Ireland, France, and U.K.
- Scandinavian countries: Denmark, Norway, Finland, and Sweden
- Eastern European countries: former Czechoslovakia, former East Germany, Poland, former U.S.S.R., and Hungary

Syntax: **DISTANCE Procedure**

The following statements are available in the DISTANCE procedure:

```
PROC DISTANCE < options > ;  
  BY variables ;  
  COPY variables ;  
  FREQ variable ;  
  ID variable ;  
  VAR level (variables < / options >) ;  
  WEIGHT variable ;
```

Both the PROC DISTANCE statement and the VAR statement are required.

PROC DISTANCE Statement

PROC DISTANCE < options > ;

The PROC DISTANCE statement invokes the DISTANCE procedure. Table 34.1 summarizes the options available in the PROC DISTANCE statement. These options are discussed in the following section.

Table 34.1 Summary of PROC DISTANCE Statement Options

Option	Description
Standardize variables	
ADD=	Specifies the constant to add to each value after standardizing and multiplying by the value specified in the MULT= option
FUZZ=	Specifies the relative fuzz factor for writing the output
INITIAL=	Specifies the method for computing initial estimates for the A-estimates
MULT=	Specifies the constant to multiply each value by after standardizing
NORM	Normalizes the scale estimator to be consistent for the standard deviation of a normal distribution
NOSTD	Suppresses standardization
SNORM	Normalizes the scale estimator to have an expectation of approximately 1 for a standard normal distribution
STDONLY	Standardizes variables only (suppresses computation of the distance matrix)
VARDEF=	Specifies the variances divisor
Generate distance matrix	
ABSENT=	Specifies the value to be used as an absence value for all the asymmetric nominal variables
METHOD=	Specifies the method for computing proximity measures
PREFIX=	Specifies a prefix for naming the distance variables in the OUT= data set
RANKSCORE=	Specifies the method of assigning scores to ordinal variables
SHAPE=	Specifies the shape of the proximity matrix to be stored in the OUT= data set
UNDEF=	Specifies the numeric constant used to replace undefined distances
Replace missing values	
NOMISS	Omits observations with missing values from computation of the location and scale measures, if standardization applies; outputs missing values to the distance matrix for observations with missing values
REPLACE	Replaces missing data with zero in the standardized data
REONLY	Replaces missing data with the location measure (does not standardize the data)
Specify data set details	
DATA=	Specifies the input data set
OUT=	Specifies the output data set
OUTSDZ=	Specifies the output data set for standardized scores

These options and their abbreviations are described (in alphabetical order) in the remainder of this section.

ABSENT=*number* | *qs*

specifies the value to be used as an absence value in an irrelevant absent-absent match for *all* of the asymmetric nominal variables. If you want to specify a different absence value for a particular variable, use the ABSENT= option in the VAR statement. See the ABSENT= option in the section “[VAR Statement](#)” on page 2174 for details.

An absence value for a variable can be either a numeric value or a quoted string consisting of combinations of characters. For instance, ., -999, and “NA” are legal values for the ABSENT= option.

The default absence value for a character variable is “NONE” (notice that a blank value is considered a missing value), and the default absence value for a numeric variable is 0.

ADD=*c*

specifies a constant, *c*, to add to each value after standardizing and multiplying by the value you specify in the MULT= option. The default value is 0.

DATA=*SAS-data-set*

specifies the input data set containing observations from which the proximity is computed. If you omit the DATA= option, the most recently created SAS data set is used.

FUZZ=*c*

specifies the relative fuzz factor for computing the standardized scores. The default value is 1E–14. For the OUTSDZ= data set, the score is computed as follows:

$$\text{if } |\text{standardized scores}| < m \times c, \text{ then standardized scores} = 0$$

where *m* is the numeric constant specified in the MULT= option, or 1 if MULT= option is not specified.

INITIAL=*method*

specifies the method of computing initial estimates for the A-estimates (ABW, AWAVE, and AHUBER). The following methods are not allowed for the INITIAL= option: ABW, AHUBER, AWAVE, and IN.

The default value is INITIAL=MAD.

METHOD=*method*

specifies the method of computing proximity measures.

For use in PROC CLUSTER, distance or dissimilarity measures such as METHOD=EUCLID or METHOD=DGOWER should be chosen.

The following six tables outline the proximity measures available for the METHOD= option. These tables are classified by levels of measurement accepted by each method. Each table contains four or five columns: the Method column shows the proximity measures, one or two Range columns show the upper and lower bounds, and the TYPE= column shows the type of proximity. The TYPE= column contains SIMILAR if a method generates similarity measures or DISTANCE if a method generates distance or dissimilarity measures. The output data set is of the type shown. For more information about the output data set, see the [OUT=](#) option.

For formulas and descriptions of these methods, see the section “[Details: DISTANCE Procedure](#)” on page 2181.

Table 34.2 shows the range and output matrix type of the GOWER and DGOWER methods. These two methods accept all measurement levels including ratio, interval, ordinal, nominal, and asymmetric nominal. METHOD=GOWER or METHOD=DGOWER always implies standardization. Assuming all the numeric (ordinal, interval, and ratio) variables are standardized by their corresponding default methods, the possible range values for both methods are from 0 and 1, inclusive. For more information about the default methods of standardization for METHOD=GOWER or METHOD=DGOWER, see the STD= option in the section “VAR Statement” on page 2174.

Table 34.2 Methods That Accept All Measurement Levels

Method	Description	Range	TYPE=
GOWER	Gower and Legendre (1986) similarity	0 to 1	SIMILAR
DGOWER	1 minus GOWER	0 to 1	DISTANCE

Table 34.3 shows methods that accept ratio, interval, and ordinal variables.

Table 34.3 Methods That Accept Ratio, Interval, and Ordinal Variables

Method	Description	Range	TYPE=
EUCLID	Euclidean distance	≥ 0	DISTANCE
SQEUCLID	Squared Euclidean distance	≥ 0	DISTANCE
SIZE	Size distance	≥ 0	DISTANCE
SHAPE	Shape distance	≥ 0	DISTANCE
COV	Covariance	≥ 0	SIMILAR
CORR	Correlation	-1 to 1	SIMILAR
DCORR	Correlation transformed to Euclidean distance	0 to 2	DISTANCE
SQCORR	Squared correlation	0 to 1	SIMILAR
DSQCORR	One minus squared correlation	0 to 1	DISTANCE
L(p)	Minkowski (L_p) distance, where p is a positive numeric value	≥ 0	DISTANCE
CITYBLOCK	L_1 , city-block, or Manhattan distance	≥ 0	DISTANCE
CHEBYCHEV	L_∞	≥ 0	DISTANCE
POWER(p, r)	Generalized Euclidean distance where p is a positive numeric value and r is a nonnegative numeric value. The distance between two observations is the r th root of sum of the absolute differences to the p th power between the values for the observations.	≥ 0	DISTANCE

Table 34.4 shows methods that accept ratio variables. Notice that all possible range values are non-negative, because ratio variables are assumed to be positive.

Table 34.4 Methods That Accept Ratio Variables

Method	Description	Range	TYPE=
SIMRATIO	Similarity ratio (if variables are binary, this is the Jaccard coefficient)	0 to 1	SIMILAR
DISRATIO	One minus similarity ratio	0 to 1	DISTANCE
NONMETRIC	Lance and Williams nonmetric coefficient	0 to 1	DISTANCE
CANBERRA	Canberra metric distance coefficient	0 to 1	DISTANCE
COSINE	Cosine coefficient	0 to 1	SIMILAR
DOT	Dot (inner) product coefficient	≥ 0	SIMILAR
OVERLAP	Overlap similarity	≥ 0	SIMILAR
DOVERLAP	Overlap dissimilarity	≥ 0	DISTANCE
CHISQ	Chi-square coefficient	≥ 0	DISTANCE
CHI	Square root of chi-square coefficient	≥ 0	DISTANCE
PHISQ	Phi-square coefficient	≥ 0	DISTANCE
PHI	Square root of phi-square coefficient	≥ 0	DISTANCE

Table 34.5 shows methods that accept nominal variables.

Table 34.5 Methods That Accept Nominal Variables

Method	Description	Range	TYPE=
HAMMING	Hamming distance	0 to v	DISTANCE
MATCH	Simple matching coefficient	0 to 1	SIMILAR
DMATCH	Simple matching coefficient transformed to Euclidean distance	0 to 1	DISTANCE
DSQMATCH	Simple matching coefficient transformed to squared Euclidean distance	0 to 1	DISTANCE
HAMANN	Hamann coefficient	-1 to 1	SIMILAR
RT	Roger and Tanimoto	0 to 1	SIMILAR
SS1	Sokal and Sneath 1	0 to 1	SIMILAR
SS3	Sokal and Sneath 3	0 to 1	SIMILAR

Note that v denotes the number of variables (dimensionality).

Table 34.6 shows methods that accept asymmetric nominal variables. Use the ABSENT= option to create a value to be considered absent.

Table 34.6 Methods That Accept Asymmetric Nominal Variables

Method	Description	Range	TYPE=
DICE	Dice coefficient or Czekanowski/Sorensen similarity coefficient	0 to 1	SIMILAR
RR	Russell and Rao	0 to 1	SIMILAR
BLWNM	Binary Lance and Williams nonmetric, or Bray-Curtis coefficient	0 to 1	DISTANCE
K1	Kulczynski 1	≥ 0	SIMILAR

Table 34.7 shows methods that accept asymmetric nominal and ratio variables. Use the ABSENT= option to create a value to be considered absent. The table contains five columns. The third column contains possible range values if only one level of measurement (either ratio or asymmetric nominal but not both) is specified; the fourth column contains possible range values if both levels are specified.

The JACCARD method is equivalent to the SIMRATIO method if there is no asymmetric nominal variable; if both ratio and asymmetric nominal variables are present, the coefficient is computed as the sum of the coefficient from the ratio variables and the coefficient from the asymmetric nominal variables. See “Proximity Measures” in the section “[Details: DISTANCE Procedure](#)” on page 2181 for the formula and descriptions of the JACCARD method.

Table 34.7 Methods That Accept Asymmetric Nominal and Ratio Variables

Method	Description	Range (One Level)	Range (Two Levels)	TYPE=
JACCARD	Jaccard similarity coefficient	0 to 1	0 to 2	SIMILAR
DJACCARD	Jaccard dissimilarity coefficient	0 to 1	0 to 2	DISTANCE

MULT=c

specifies a numeric constant, *c*, by which to multiply each value after standardizing. The default value is 1.

NOMISS

omits observations with missing values from computation of the location and scale measures when standardizing; generates undefined (missing) distances for observations with missing values when computing distances. Use the UNDEF= option to specify the undefined values.

If a distance matrix is created to be used as an input to PROC CLUSTER, the NOMISS option should not be used because PROC CLUSTER does not accept distance matrices with missing values.

NORM

normalizes the scale estimator to be consistent for the standard deviation of a normal distribution when you specify the option STD=AGK, STD=IQR, STD=MAD, or STD=SPACING in the VAR statement.

NOSTD

suppresses standardization of the variables. The NOSTD option should not be specified with the STDONLY option or with the REPLACE option.

OUT=SAS-data-set

specifies the name of the SAS data set created by PROC DISTANCE. The output data set contains the BY variables, the ID variable, computed distance variables, the COPY variables, the FREQ variable, and the WEIGHT variables.

If you omit the OUT= option, PROC DISTANCE creates an output data set named according to the DATA n convention.

The output data set is of type TYPE=DISTANCE or TYPE=SIMILAR. See the [METHOD=](#) option for more information about the association between the method and the output data set type. Data set types do not persist when you copy or modify a data set. You must specify the TYPE= data set option for the new data set, as in the following example:

```
data dist2(type=distance);
    set dist;
run;
```

If you do not specify the TYPE=DISTANCE data set option, the new data set is the default TYPE=DATA. If you use the new data set in a procedure that accepts both TYPE=DATA or TYPE=DISTANCE data sets (such as PROC CLUSTER or PROC MODECLUS), the results will be incorrect.

OUTSDZ=SAS-data-set

specifies the name of the SAS data set containing the standardized scores. The output data set contains a copy of the DATA= data set, except that the analyzed variables have been standardized. Analyzed variables are those listed in the VAR statement.

PREFIX=name

specifies a prefix for naming the distance variables in the OUT= data set. By default, the names are Dist1, Dist2, ..., Dist*n*. If you specify PREFIX=ABC, the variables are named ABC1, ABC2, ..., ABC*n*. If the ID statement is also specified, the variables are named by appending the value of the ID variable to the prefix.

RANKSCORE=MIDRANK | INDEX

specifies the method of assigning scores to ordinal variables. The available methods are listed as follows:

MIDRANK assigns consecutive integers to each category with consideration of the frequency value. This is the default method.

INDEX assigns consecutive integers to each category regardless of frequencies.

The following example explains how each method assigns the rank scores. Suppose the data contain an ordinal variable ABC with values A, B, C. There are two ways to assign numbers. One is to use midranks, which depend on the frequencies of each category. Another is to assign consecutive integers to each category, regardless of frequencies.

Table 34.8 Example of Assigning Rank Scores

ABC	MIDRANK	INDEX
A	1.5	1
A	1.5	1
B	4	2
B	4	2
B	4	2
C	6	3

REPLACE

replaces missing data with zero in the standardized data (to correspond to the location measure before standardizing). To replace missing data with something else, use the MISSING= option in the VAR statement. The REPLACE option implies standardization.

You cannot specify the following options together:

- both the REPLACE and the REONLY options
- both the REPLACE and the NOSTD options

REONLY

measure specified by the MISSING= option or the STD= option (if the MISSING= option is not specified), but does *not* standardize the data. If the MISSING= option is not specified and METHOD=GOWER is specified, missing values are replaced by the location measure from the RANGE method (the minimum value), no matter what the value of the STD= option is.

You cannot specify both the REPLACE and the REONLY options.

SHAPE=TRIANGLE | TRI | SQUARE | SQU | SQR

specifies the shape of the proximity matrix to be stored in the OUT= data set. SHAPE=TRIANGLE requests the matrix to be stored as a lower triangular matrix; SHAPE=SQUARE requests that the matrix be stored as a square matrix. Use SHAPE=SQUARE if the output data set is to be used as input to the MODECLUS procedures. The default is TRIANGLE.

SNORM

normalizes the scale estimator to have an expectation of approximately 1 for a standard normal distribution when the STD=SPACING option is specified.

STDONLY

standardizes variables only and computes no distance matrix. You must use the OUTSDZ= option to save the standardized scores. You cannot specify both the STDONLY option and the NOSTD option.

UNDEF=*n*

specifies the numeric constant used to replace undefined distances, such as when an observation has all missing values, or if a divisor is zero.

VARDEF=DF | N | WDF | WEIGHT | WGT

specifies the divisor to be used in the calculation of distance, dissimilarity, or similarity measures, and for standardizing variables whenever a variance or covariance is computed. By default, VARDEF=DF. The values and associated divisors are as follows:

Value	Divisor	Formula
DF	degrees of freedom	$n - 1$
N	number of observations	n
WDF	sum of weights minus 1	$(\sum_i w_i) - 1$
WEIGHT WGT	sum of weights	$\sum_i w_i$

VAR Statement

VAR *level (variables </ options>)< level (variables </ options>)... >* ;

where the syntax for the *options* is as follows:

ABSENT=*value*

MISSING=*miss-method* | *value*

ORDER=*order-option*

STD=*std-method*

WEIGHTS=*weight-list*

The VAR statement lists variables from which distances are to be computed. The VAR statement is required. The variables can be numeric or character depending on their measurement levels. A variable cannot appear more than once in either the same list or a different list.

level is required. It declares the levels of measurement for those variables specified within the parentheses. Available values for *level* are as follows:

ANOMINAL	variables are asymmetric nominal and can be either numeric or character.
NOMINAL	variables are symmetric nominal and can be either numeric or character.
ORDINAL	variables are ordinal and can be either numeric or character. Values of ordinal variables are replaced by their corresponding rank scores. If standardization is required, the standardized rank scores are output to the data set specified in the OUTSDZ= option. See the RANKSCORE= option in the PROC DISTANCE statement for methods available for assigning rank scores to ordinal variables. After being replaced by scores, ordinal variables are considered interval.
INTERVAL	variables are interval and numeric.
RATIO	variables are ratio and numeric. Ratio variables should always contain positive measurements.

Each variable list can be followed by an option list. Use “/” after the list of variables to start the option list. An option list contains options that are applied to the variables. The following options are available in the option list:

ABSENT=	specifies the value to be used as an absence value in an irrelevant absent-absent match for asymmetric nominal variables.
MISSING=	specifies the method (or numeric value) with which to replace missing data.
ORDER=	selects the order for assigning scores to ordinal variables.
STD=	selects the standardization method.
WEIGHTS=	assigns weights to the variables in the list.

If an option is missing from the current attribute list, PROC DISTANCE provides default values for all the variables in the current list.

For example, in the VAR statement

```
var ratio(x1-x4/std= mad weights= .5 .5 .1 .5 missing= -99)
    interval(x5/std= range)
    ordinal(x6/order= desc);
```

the first option list defines x1–x4 as ratio variables to be standardized by the MAD method. Also, any missing values in x1–x4 should be replaced by –99. x1 is given a weight of 0.5, x2 is given a weight of 0.5, x3 is given a weight of 0.1, and x4 is given a weight of 0.5.

The second option list defines x5 as an interval variable to be standardized by the RANGE method. If the REPLACE option is specified in the PROC DISTANCE statement, missing values in x5 are replaced by the location estimate from the RANGE method. By default, x5 is given a weight of 1.

The last option list defines x6 as an ordinal variable. The scores are assigned from highest to lowest by its unformatted values. Although the STD= option is not specified, x6 is standardized by the default method

(STD) because there is more than one level of measurements (ratio, interval, and ordinal) in the VAR statement. Again, if the REPLACE option is specified, missing values in x_6 are replaced by the location estimate from the STD method. Finally, by default, x_6 is given a weight of 1.

More details for the options are explained as follows.

STD=std-method

specifies the standardization method. Valid values for *std-method* are MEAN, MEDIAN, SUM, EUCLLEN, USTD, STD, RANGE, MIDRANGE, MAXABS, IQR, MAD, ABW, AHUBER, AWAVE, AGK, SPACING, and L. Table 34.9 lists available methods of standardization as well as their corresponding location and scale measures.

Table 34.9 Available Standardization Methods

Method	Scale	Location
MEAN	1	mean
MEDIAN	1	median
SUM	sum	0
EUCLLEN	Euclidean length	0
USTD	standard deviation about origin	0
STD	standard deviation	mean
RANGE	range	minimum
MIDRANGE	range/2	midrange
MAXABS	maximum absolute value	0
IQR	interval quartile range	median
MAD	median absolute deviation from median	median
ABW(<i>c</i>)	biweight A-estimate	biweight 1-step M-estimate
AHUBER(<i>c</i>)	Huber A-estimate	Huber 1-step M-estimate
AWAVE(<i>c</i>)	Wave 1-step M-estimate	Wave A-estimate
AGK(<i>p</i>)	AGK estimate (ACECLUS)	mean
SPACING(<i>p</i>)	minimum spacing	mid minimum-spacing
L(<i>p</i>)	L_p	L_p

These standardization methods are further documented in the section on the METHOD= option in the PROC STDIZE statement of the STDIZE procedure (see the section “Standardization Methods” on page 7468 in Chapter 87, “The STDIZE Procedure”).

Standardization is not required if there is only one level of measurement, or if only asymmetric nominal and nominal levels are specified; otherwise, standardization is mandatory. When standardization is mandatory, a default method is provided when the STD= option is not specified. You can suppress the mandatory standardization by using the NOSTD option in the PROC DISTANCE statement. See the NOSTD option in the section “PROC DISTANCE Statement” on page 2168 and the section “Mandatory Standardization” on page 2162 for details.

The default method is STD for standardizing interval variables and MAXABS for standardizing ratio variables unless METHOD=GOWER or METHOD=DGOWER is specified. If METHOD=GOWER is specified, interval variables are standardized by the RANGE method, and whatever is specified in the STD= option is ignored; if METHOD=DGOWER is specified, the RANGE method is the default

standardization method for interval variables. The MAXABS method is the default standardization method for ratio variables for both the GOWER and DGOWER methods.

Notice that a ratio variable should always be positive.

Table 34.10 lists standardization methods and the levels of measurement that can be accepted by each method. For example, the SUM method can be used to standardize ratio variables but not interval or ordinal variables. Also, the AGK and SPACING methods should not be used to standardize ordinal variables. If you apply AGK and SPACING to ranks, the results are degenerate because all the spacings of a given order are equal.

Table 34.10 Legitimate Levels of Measurements for Each Method

Standardization Method	Legitimate Levels of Measurement
MEAN	ratio, interval, ordinal
MEDIAN	ratio, interval, ordinal
SUM	ratio
EUCLEN	ratio
USTD	ratio
STD	ratio, interval, ordinal
RANGE	ratio, interval, ordinal
MIDRANGE	ratio, interval, ordinal
MAXABS	ratio
IQR	ratio, interval, ordinal
MAD	ratio, interval, ordinal
ABW(<i>c</i>)	ratio, interval, ordinal
AHUBER(<i>c</i>)	ratio, interval, ordinal
AWAVE(<i>c</i>)	ratio, interval, ordinal
AGK(<i>p</i>)	ratio, interval
SPACING(<i>p</i>)	ratio, interval
L(<i>p</i>)	ratio, interval, ordinal

ABSENT=*numner* | *qs*

specifies the value to be used as an absence value in an irrelevant absent-absent match for asymmetric nominal variables. The absence value specified here overwrites the absence value specified through the ABSENT= option in the PROC DISTANCE statement for those variables in the current variable list.

An absence value for a variable can be either a numeric value or a quoted string consisting of combinations of characters. For instance, ., -999, "NA" are legal values for the ABSENT= option.

The default for an absence value for a character variable is "NONE" (notice that a blank value is considered a missing value), and the default for an absence value for a numeric variable is 0.

MISSING=*miss-method* | *value*

specifies the method or a numeric value for replacing missing values. If you omit the MISSING= option, the REPLACE option replaces missing values with the location measure given by the STD= option. Specify the MISSING= option when you want to replace missing values with a different

value. You can specify any method that is valid in the STD= option. The corresponding location measure is used to replace missing values.

If a numeric value is given, the value replaces missing values after standardizing the data. However, when standardization is not mandatory, you can specify the REONLY option with the MISSING= option to suppress standardization for cases in which you want only to replace missing values.

If the NOSTD option is specified, there is no standardization, but missing values are replaced by the corresponding location measures or by the numeric value of the MISSING= option. See the section “[Missing Values](#)” on page 2187 for details about missing values replacement with and without standardization.

ORDER=ASCENDING | DESCENDING | ASCFORMATTED | DESFORMATTED | DSORDER

ORDER=ASC | DESC | ASCFMT | DESFMT | DATA

specifies the order for assigning score to ordinal variables. The value for the ORDER= option can be one of the following:

ASCENDING	scores are assigned in lowest-to-highest order of unformatted values.
DESCENDING	scores are assigned in highest-to-lowest order of unformatted values.
ASCFORMATTED	scores are assigned in ascending order by their formatted values. This option can be applied to character variables only, since unformatted values are always used for numeric variables.
DESFORMATTED	scores are assigned in descending order by their formatted values. This option can be applied to character variables only, since unformatted values are always used for numeric variables.
DSORDER	scores are assigned according to the order of their appearance in the input data set.

The default value is ASCENDING.

WEIGHTS=weight-list

specifies a list of values for weighting individual variables while computing the proximity. Values in this list can be separated by blanks or commas. You can include one or more items of the form *start TO stop BY increment*. This list should contain at least one weight. The maximum number of weights you can list is equal to the number of variables. If the number of weights is less than the number of variables, the last value in the *weight-list* is used for the rest of the variables; conversely, if the number of weights is greater than the number of variables, the trailing weights are discarded.

The default value is 1.

ID Statement

ID variable ;

The ID statement specifies a single variable to be copied to the OUT= data set and used to generate names for the distance variables. The ID variable must be character.

Typically, each ID value occurs only once in the input data set or, if you use a BY statement, only once within a BY group.

If you specify both the ID and BY statements, the ID variable must have the same values in the same order in each BY group.

COPY Statement

COPY *variables* ;

The COPY statement specifies a list of additional variables to be copied to the OUT= data set.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC DISTANCE to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the DISTANCE procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FREQ Statement

FREQ | **FREQUENCY** *variable* ;

The frequency variable is used for either standardizing variables or assigning rank scores to the ordinal variables. It has no direct effect on computing the distances.

For standardizing variables and assigning rank scores, PROC DISTANCE treats the data set as if each observation appeared n times, where n is the value of the FREQ variable for the observation. Nonintegral values of the FREQ variable are truncated to the largest integer less than the FREQ value. If the FREQ variable has a value that is less than 1 or is missing, the observation is not used in the analysis.

WEIGHT Statement

WGT | **WEIGHT** *variable* ;

The WEIGHT statement specifies a numeric variable in the input data set with values that are used to weight each observation. This weight variable is used for standardizing variables rather than computing the distances. Only one variable can be specified.

The WEIGHT variable values can be nonintegers. An observation is used in the analysis only if the value of the WEIGHT variable is greater than zero. The WEIGHT variable applies to variables that are standardized by the following options: STD=MEAN, STD=SUM, STD=EUCLEN, STD=USTD, STD=STD, STD=AGK, or STD=L.

PROC DISTANCE uses the value of the WEIGHT variable w_i to compute the sample mean, uncorrected sample variances, and sample variances as follows:

$$\bar{x}_w = \sum_i w_i x_i / \sum_i w_i$$

$$u_w^2 = \sum_i w_i x_i^2 / d$$

$$s_w^2 = \sum_i w_i (x_i - \bar{x}_w)^2 / d$$

w_i is the weight value of the i th observation, x_i is the value of the i th observation, and d is the divisor controlled by the VARDEF= option (see the VARDEF= option in the PROC DISTANCE statement for details).

PROC DISTANCE uses the value of the WEIGHT variable to calculate the following statistics for standardization:

MEAN	the weighted mean, \bar{x}_w
SUM	the weighted sum, $\sum_i w_i x_i$
USTD	the weighted uncorrected standard deviation, $\sqrt{u_w^2}$
STD	the weighted standard deviation, $\sqrt{s_w^2}$
EUCLEN	the weighted Euclidean length, computed as the square root of the weighted uncorrected sum of squares:

$$\sqrt{\sum_i w_i x_i^2}$$

AGK	the AGK estimate. This estimate is documented further in the ACECLUS procedure as the METHOD=COUNT option. See the discussion of the WEIGHT statement in Chapter 23, “ The ACECLUS Procedure ,” for information about how the WEIGHT variable is applied to the AGK estimate.
-----	---

L the L_p estimate. This estimate is documented further in the FASTCLUS procedure as the LEAST= option. See the discussion of the WEIGHT statement in Chapter 36, “[The FASTCLUS Procedure](#),” for information about how the WEIGHT variable is used to compute weighted cluster means. Note that the number of clusters is always 1.

Details: DISTANCE Procedure

Proximity Measures

The following notation is used in this section:

v	the number of variables or the dimensionality
x_j	data for observation x and the j th variable, where $j = 1$ to v
y_j	data for observation y and the j th variable, where $j = 1$ to v
w_j	weight for the j th variable from the WEIGHTS= option in the VAR statement. $w_j = 0$ when either x_j or y_j is missing.
W	the sum of total weights. No matter if the observation is missing or not, its weight is added to this metric.
\bar{x}	mean for observation x $\bar{x} = \sum_{j=1}^v w_j x_j / \sum_{j=1}^v w_j$
\bar{y}	mean for observation y $\bar{y} = \sum_{j=1}^v w_j y_j / \sum_{j=1}^v w_j$
$d(x, y)$	the distance or dissimilarity between observations x and y
$s(x, y)$	the similarity between observations x and y

The factor $W / \sum_{j=1}^v w_j$ is used to adjust some of the proximity measures for missing values.

Methods That Accept All Measurement Levels

GOWER	<p>Gower's similarity</p> $s_1(x, y) = \sum_{j=1}^v w_j \delta_{x,y}^j d_{x,y}^j / \sum_{j=1}^v w_j \delta_{x,y}^j$ <p>$\delta_{x,y}^j$ is computed as follows:</p> <p>For nominal, ordinal, interval, or ratio variable,</p> $\delta_{x,y}^j = 1$ <p>For asymmetric nominal variable,</p> $\delta_{x,y}^j = 1, \text{ if either } x_j \text{ or } y_j \text{ is present}$ $\delta_{x,y}^j = 0, \text{ if both } x_j \text{ and } y_j \text{ are absent}$
-------	--

For nominal or asymmetric nominal variable,

$$\begin{aligned} d_{x,y}^j &= 1, \text{ if } x_j = y_j \\ d_{x,y}^j &= 0, \text{ if } x_j \neq y_j \end{aligned}$$

For ordinal, interval, or ratio variable,

$$d_{x,y}^j = 1 - |x_j - y_j|$$

DGOWER 1 minus Gower
 $d_2(x, y) = 1 - s_1(x, y)$

Methods That Accept Ratio, Interval, and Ordinal Variables

EUCLID	Euclidean distance $d_3(x, y) = \sqrt{(\sum_{j=1}^v w_j (x_j - y_j)^2)W / (\sum_{j=1}^v w_j)}$
SQEUCID	squared Euclidean distance $d_4(x, y) = (\sum_{j=1}^v w_j (x_j - y_j)^2)W / (\sum_{j=1}^v w_j)$
SIZE	size distance $d_5(x, y) = \sum_{j=1}^v w_j (x_j - y_j) \sqrt{W} / (\sum_{j=1}^v w_j)$
SHAPE	shape distance $d_6(x, y) = \sqrt{(\sum_{j=1}^v w_j [(x_j - \bar{x}) - (y_j - \bar{y})]^2)W / (\sum_{j=1}^v w_j)}$

NOTE: squared shape distance plus squared size distance equals squared Euclidean distance.

COV	covariance similarity coefficient $s_7(x, y) = \sum_{j=1}^v w_j (x_j - \bar{x})(y_j - \bar{y}) / \text{vardiv}, \text{ where}$ $\begin{aligned} \text{vardiv} &= v \text{ if VARDEF} = \text{N} \\ &= v - 1 \text{ if VARDEF} = \text{DF} \\ &= \sum_{j=1}^v w_j \text{ if VARDEF} = \text{WEIGHT} \\ &= \sum_{j=1}^v w_j - 1 \text{ if VARDEF} = \text{WDF} \end{aligned}$
-----	--

CORR	correlation similarity coefficient $s_8(x, y) = \frac{\sum_{j=1}^v w_j (x_j - \bar{x})(y_j - \bar{y})}{\sqrt{\sum_{j=1}^v w_j (x_j - \bar{x})^2 \sum_{j=1}^v w_j (y_j - \bar{y})^2}}$
------	--

DCORR	correlation transformed to Euclidean distance as $\text{sqrt}(1 - \text{CORR})$ $d_9(x, y) = \sqrt{1 - s_8(x, y)}$
-------	---

SQCORR	squared correlation $s_{10}(x, y) = \frac{[\sum_{j=1}^v w_j (x_j - \bar{x})(y_j - \bar{y})]^2}{\sum_{j=1}^v w_j (x_j - \bar{x})^2 \sum_{j=1}^v w_j (y_j - \bar{y})^2}$
--------	---

DSQCORR	squared correlation transformed to squared Euclidean distance as (1–SQCORR)
	$d_{11}(x, y) = 1 - s_{10}(x, y)$
L(<i>p</i>)	Minkowski (L_p) distance, where <i>p</i> is a positive numeric value
	$d_{12}(x, y) = [(\sum_{j=1}^v w_j x_j - y_j ^p)W / (\sum_{j=1}^v w_j)]^{1/p}$
CITYBLOCK	L_1
	$d_{13}(x, y) = (\sum_{j=1}^v w_j x_j - y_j)W / (\sum_{j=1}^v w_j)$
CHEBYCHEV	L_∞
	$d_{14}(x, y) = \max_{j=1}^v w_j x_j - y_j $
POWER(<i>p</i> , <i>r</i>)	generalized Euclidean distance, where <i>p</i> is a nonnegative numeric value and <i>r</i> is a positive numeric value. The distance between two observations is the <i>r</i> th root of sum of the absolute differences to the <i>p</i> th power between the values for the observations:
	$d_{15}(x, y) = [(\sum_{j=1}^v w_j x_j - y_j ^p)W / (\sum_{j=1}^v w_j)]^{1/r}$

Methods That Accept Ratio Variables

SIMRATIO	similarity ratio
	$s_{16}(x, y) = \frac{\sum_{j=1}^v w_j (x_j y_j)}{\sum_{j=1}^v w_j (x_j y_j) + \sum_{j=1}^v w_j (x_j - y_j)^2}$
DISRATIO	one minus similarity ratio
	$d_{17}(x, y) = 1 - s_{16}(x, y)$
NONMETRIC	Lance-Williams nonmetric coefficient
	$d_{18}(x, y) = \frac{\sum_{j=1}^v w_j x_j - y_j }{\sum_{j=1}^v w_j (x_j + y_j)}$
CANBERRA	Canberra metric coefficient. See Sneath and Sokal (1973, pp. 125–126)
	$d_{19}(x, y) = \sum_{j=1}^v \frac{w_j x_j - y_j }{w_j (x_j + y_j)}$
COSINE	cosine coefficient
	$s_{20}(x, y) = \frac{\sum_{j=1}^v w_j (x_j y_j)}{\sqrt{\sum_{j=1}^v w_j x_j^2 \sum_{j=1}^v w_j y_j^2}}$
DOT	dot (inner) product coefficient
	$s_{21}(x, y) = [\sum_{j=1}^v w_j (x_j y_j)] / \sum_{j=1}^v w_j$
OVERLAP	sum of the minimum values
	$s_{22}(x, y) = \sum_{j=1}^v w_j [\min(x_j, y_j)]$

DOVERLAP maximum of the sum of the x and the sum of y minus overlap
 $d_{23}(x, y) = \max(\sum_{j=1}^v w_j x_j, \sum_{j=1}^v w_j y_j) - s_{22}(x, y)$

CHISQ chi-square
 If the data represent the frequency counts, chi-square dissimilarity between two sets of frequencies can be computed. A 2-by- v contingency table is illustrated to explain how the chi-square dissimilarity is computed as follows:

	Variable				Row
Observation	Var 1	Var 2	...	Var v	Sum
X	x_1	x_2	...	x_v	r_x
Y	y_1	y_2	...	y_v	r_y
Column Sum	c_1	c_2	...	c_v	T

where

$$\begin{aligned} r_x &= \sum_{j=1}^v w_j x_j \\ r_y &= \sum_{j=1}^v w_j y_j \\ c_j &= w_j(x_j + y_j) \\ T &= r_x + r_y = \sum_{j=1}^v c_j \end{aligned}$$

The chi-square measure is computed as follows:

$$d_{24}(x, y) = (\sum_{j=1}^v \frac{(w_j x_j - E(x_j))^2}{E(x_j)} + \sum_{j=1}^v \frac{(w_j y_j - E(y_j))^2}{E(y_j)}) / (\sum_{j=1}^v w_j)$$

where for $j = 1, 2, \dots, v$

$$\begin{aligned} E(x_j) &= r_x c_j / T \\ E(y_j) &= r_y c_j / T \end{aligned}$$

CHI square root of chi-square
 $d_{25}(x, y) = \sqrt{d_{24}(x, y)}$

PHISQ phi-square
 This is the CHISQ dissimilarity normalized by the sum of weights
 $d_{26}(x, y) = d_{24}(x, y) / (\sum_{j=1}^v w_j)$

PHI square root of phi-square
 $d_{27}(x, y) = \sqrt{d_{26}(x, y)}$

Methods That Accept Symmetric Nominal Variables

The following notation is used for computing $d_{28}(x, y)$ to $s_{35}(x, y)$. Notice that only the nonmissing pairs are discussed below; all the pairs with at least one missing value will be excluded from any of the computations in the following section because $w_j = 0$, if either x_j or y_j is missing.

M	nonmissing matches $M = \sum_{j=1}^v w_j \delta_{x,y}^j$, where $\delta_{x,y}^j = 1$, if $x_j = y_j$ $\delta_{x,y}^j = 0$, otherwise
X	nonmissing mismatches $X = \sum_{j=1}^v w_j \delta_{x,y}^j$, where $\delta_{x,y}^j = 1$, if $x_j \neq y_j$ $\delta_{x,y}^j = 0$, otherwise
N	total nonmissing pairs $N = \sum_{j=1}^v w_j$
HAMMING	Hamming distance $d_{28}(x, y) = X$
MATCH	simple matching coefficient $s_{29}(x, y) = M/N$
DMATCH	simple matching coefficient transformed to Euclidean distance $d_{30}(x, y) = \sqrt{1 - M/N} = \sqrt{(X/N)}$
DSQMATCH	simple matching coefficient transformed to squared Euclidean distance $d_{31}(x, y) = 1 - M/N = X/N$
HAMANN	Hamann coefficient $s_{32}(x, y) = (M - X)/N$
RT	Roger and Tanimoto $s_{33}(x, y) = M/(M + 2X)$
SS1	Sokal and Sneath 1 $s_{34}(x, y) = 2M/(2M + X)$
SS3	Sokal and Sneath 3. The coefficient between an observation and itself is always indeterminate (missing) since there is no mismatch. $s_{35}(x, y) = M/X$

The following notation is used for computing $s_{36}(x, y)$ to $d_{41}(x, y)$. Notice that only the nonmissing pairs are discussed in the following section; all the pairs with at least one missing value are excluded from any of the computations in the following section because $w_j = 0$, if either x_j or y_j is missing.

Also, the observed nonmissing data of an asymmetric binary variable can have only two possible outcomes: presence or absence. Therefore, the notation, PX (present mismatches), always has a value of zero for an asymmetric binary variable.

The following methods distinguish between the presence and absence of attributes.

X	mismatches with at least one present $X = \sum_{j=1}^v w_j \delta_{x,y}^j, \text{ where}$ $\delta_{x,y}^j = 1, \text{ if } x_j \neq y_j \text{ and not both } x_j \text{ and } y_j \text{ are absent}$ $\delta_{x,y}^j = 0, \text{ otherwise}$
PM	present matches $PM = \sum_{j=1}^v w_j \delta_{x,y}^j, \text{ where}$ $\delta_{x,y}^j = 1, \text{ if } x_j = y_j \text{ and both } x_j \text{ and } y_j \text{ are present}$ $\delta_{x,y}^j = 0, \text{ otherwise}$
PX	present mismatches $PX = \sum_{j=1}^v w_j \delta_{x,y}^j, \text{ where}$ $\delta_{x,y}^j = 1, \text{ if } x_j \neq y_j \text{ and both } x_j \text{ and } y_j \text{ are present}$ $\delta_{x,y}^j = 0, \text{ otherwise}$
PP	both present = $PM + PX$
P	at least one present = $PM + X$
PAX	present-absent mismatches $PAX = \sum_{j=1}^v w_j \delta_{x,y}^j, \text{ where}$ $\delta_{x,y}^j = 1, \text{ if } x_j \neq y_j \text{ and either } x_j \text{ is present and } y_j \text{ is absent or}$ $x_j \text{ is absent and } y_j \text{ is present}$ $\delta_{x,y}^j = 0 \text{ otherwise}$
N	total nonmissing pairs $N = \sum_{j=1}^v w_j$

Methods That Accept Asymmetric Nominal and Ratio Variables

JACCARD Jaccard similarity coefficient

The JACCARD method is equivalent to the SIMRATIO method if there are only ratio variables; if there are both ratio and asymmetric nominal variables, the coefficient is computed as sum of the coefficient from the ratio variables (SIMRATIO) and the coefficient from the asymmetric nominal variables.

$$s_{36}(x, y) = s_{16}(x, y) + PM/P$$

DJACCARD Jaccard dissimilarity coefficient

The DJACCARD method is equivalent to the DISRATIO method if there are only ratio variables; if there are both ratio and asymmetric nominal variables, the coefficient is computed as sum of the coefficient from the ratio variables (DISRATIO) and the coefficient from the asymmetric nominal variables.

$$d_{37}(x, y) = d_{17}(x, y) + X/P$$

Methods That Accept Asymmetric Nominal Variables

DICE Dice coefficient or Czekanowski/Sorensen similarity coefficient

$$s_{38}(x, y) = 2PM/(P + PM)$$

RR Russell and Rao. This is the binary equivalent of the dot product coefficient.

$$s_{39}(x, y) = PM/N$$

BLWNM | BRAYCURTIS Binary Lance and Williams, also known as Bray and Curtis coefficient

$$d_{40}(x, y) = X/(PAX + 2PP)$$

K1 Kulczynski 1. The coefficient between an observation and itself is always indeterminate (missing) since there is no mismatch.

$$d_{41}(x, y) = PM/X$$

Missing Values

Standardization versus No Standardization

You can replace the missing values with or without standardization. Missing values are replaced after standardization by specifying either the REPLACE option in the PROC DISTANCE statement or the MISSING= option in the VAR statement.

To replace missing values without standardization, use the following two options:

- the NOSTD option in the PROC DISTANCE statement. The NOSTD option suppresses standardization but still replaces the missing values with the location of the method or the numeric value specified in the MISSING= option in the VAR statement.
- the REONLY option in the PROC DISTANCE statement. PROC DISTANCE replaces missing values with the location of the standardization method or with the numeric value specified in the MISSING= option in the VAR statement. This approach assumes that standardization is not mandatory (see the section “[Standardization](#)” on page 2162).

Eliminating Observations with Missing Values

If you specify the NOMISS option, PROC DISTANCE omits observations with any missing values in the analyzed variables from computation of the location and scale measures.

Distance Measures

If you specify the NOMISS option, PROC DISTANCE generates missing distance for observations with missing values. If the NOMISS option is not specified, the sum of total weights, no matter if an observation is missing or not, is incorporated into the computation of some of the proximity measures. See the section “[Details: DISTANCE Procedure](#)” on page 2181 for the formulas and descriptions.

Formatted versus Unformatted Values

PROC DISTANCE uses the formatted values from a character variable, if the variable has a format—for example, one assigned by a format statement. PROC DISTANCE uses the unformatted values from a numeric variable, even if it has a format.

Output Data Sets

OUT= Data Set

The DISTANCE procedure always produces an output data set, regardless of whether you specify the OUT= option in the PROC DISTANCE statement. PROC DISTANCE displays no output. Use PROC PRINT to display the output data set.

The output data set contains the following variables:

- the ID variable, if any
- the BY variables, if any
- the COPY variables, if any
- the FREQ variable, if any
- the WEIGHT variable, if any
- the new distance variables, named from PREFIX= options along with the ID values, or from the default values

The output data set is of type TYPE=DISTANCE or TYPE=SIMILAR. See the [METHOD=](#) option for more information about the output data set types. Data set types do not persist when you copy or modify a data set. You must specify the TYPE= data set option for the new data set, as in the following example:

```
data dist2(type=distance);
    set dist;
run;
```

See the [OUT=](#) option for more information about data set type persistence.

OUTSDZ= Data Set

The output data set is a copy of the DATA= data set except that the analyzed variables have been standardized. Analyzed variables are those listed in the VAR statement.

Examples: DISTANCE Procedure

Example 34.1: Divorce Grounds – the Jaccard Coefficient

A wide variety of distance and similarity measures are used in cluster analysis (Anderberg 1973; Sneath and Sokal 1973). If your data are in coordinate form and you want to use a non-Euclidean distance for clustering, you can compute a distance matrix by using the DISTANCE procedure.

Similarity measures must be converted to dissimilarities before being used in PROC CLUSTER. Such conversion can be done in a variety of ways, such as taking reciprocals or subtracting from a large value. The choice of conversion method depends on the application and the similarity measure. If applicable, PROC DISTANCE provides a corresponding dissimilarity measure for each similarity measure.

In the following example, the observations are states. Binary-valued variables correspond to various grounds for divorce and indicate whether the grounds for divorce apply in each of the U.S. states. A value of “1” indicates that the ground for divorce applies, and a value of “0” indicates the opposite. The 0-0 matches are treated as totally irrelevant; therefore, each variable has an asymmetric nominal level of measurement. The absence value is 0.

The DISTANCE procedure is used to compute the Jaccard coefficient (Anderberg 1973, pp. 89, 115, and 117) between each pair of states. The Jaccard coefficient is defined as the number of variables that are coded as 1 for both states divided by the number of variables that are coded as 1 for either or both states. Since dissimilarity measures are required by PROC CLUSTER, the DJACCARD coefficient is selected. [Output 34.1.1](#) displays the distance matrix between the first 10 states.

The CENTROID method is used to perform the cluster analysis, and the resulting tree diagram from PROC CLUSTER is saved into the tree output data set. [Output 34.1.2](#) displays the cluster history.

The TREE procedure generates nine clusters in the output data set out. After being sorted by the state, the out data set is then merged with the input data set divorce. After being sorted by the state, the merged data set is printed to display the cluster membership as shown in [Output 34.1.3](#).

The following statements produce [Output 34.1.1](#) through [Output 34.1.3](#):

```
data divorce;
  input State $15.
        (Incompatibility Cruelty Desertion Non_Support Alcohol
         Felony Impotence Insanity Separation) (1.) @@;

Example 34.2: Financial Data – Stock Dividends

The following data set contains the average dividend yields for 15 utility stocks in the United States. The observations are names of the companies, and the variables correspond to the annual dividend yields for the period 1986–1990. The objective is to group similar stocks into clusters.

Before the cluster analysis is performed, the correlation similarity is chosen for measuring the closeness between each observation. Since distance type of measures are required by PROC CLUSTER, METHOD=DCORR is used in the PROC DISTANCE statement to transform the correlation measures to the distance measures. Notice that in [Output 34.2.1](#), all the values in the distance matrix are between 0 and 2.

PROC CLUSTER performs hierarchical clustering by using agglomerative methods based on the distance data created from the previous PROC DISTANCE statement. Since the cubic clustering criterion is not suitable for distance data, only the pseudo F statistic is requested to identify the number of clusters.

The two clustering methods are Ward's and the average linkage methods. Since the results of the pseudo t^2 statistic from both Ward's and the average linkage methods contain many missing values, only the plot of the pseudo F statistic versus the number of clusters is requested along with the dendrogram by specifying PLOTS(ONLY)=(PSF DENDROGRAM) in the PROC CLUSTER statement.

Both [Output 34.2.2](#) and [Output 34.2.3](#) suggest four clusters. Both methods produce the same clustering result, as shown in [Output 34.2.4](#) and [Output 34.2.5](#). The four clusters are as follows:

- Cincinnati G&E and Detroit Edison
- Texas Utilities and Pennsylvania Power & Light
- Union Electric, Iowa-Ill Gas & Electric, Oklahoma Gas & Electric, and Wisconsin Energy
- Orange & Rockland Utilities, Kentucky Utilities, Kansas Power & Light, Allegheny Power, Green Mountain Power, Dominion Resources, and Minnesota Power & Light

Overview: FACTOR Procedure

The FACTOR procedure performs a variety of common factor and component analyses and rotations. Input can be multivariate data, a correlation matrix, a covariance matrix, a factor pattern, or a matrix of scoring coefficients. The procedure can factor either the correlation or covariance matrix, and you can save most results in an output data set.

PROC FACTOR can process output from other procedures. For example, it can rotate the canonical coefficients from multivariate analyses in the GLM procedure.

The methods for factor extraction are principal component analysis, principal factor analysis, iterated principal factor analysis, unweighted least squares factor analysis, maximum likelihood (canonical) factor analysis, alpha factor analysis, image component analysis, and Harris component analysis. A variety of methods for prior communality estimation is also available.

Specific methods for orthogonal rotation are varimax, quartimax, biquartimax, equamax, parsimax, and factor parsimax. Oblique versions of these methods are also available. In addition, quartimin, biquartimin, and covarimin methods for (direct) oblique rotation are available. General methods for orthogonal rotation are orthomax with user-specified gamma, Crawford-Ferguson family with user-specified weights on variable parsimony and factor parsimony, and generalized Crawford-Ferguson family with user-specified weights. General methods for oblique rotation are direct oblimin with user-specified tau, Crawford-Ferguson family with user-specified weights on variable parsimony and factor parsimony, generalized Crawford-Ferguson family with user-specified weights, promax with user-specified exponent, Harris-Kaiser case II with user-specified exponent, and Procrustes with a user-specified target pattern.

Output includes means, standard deviations, correlations, Kaiser's measure of sampling adequacy, eigenvalues, a scree plot, eigenvectors, prior and final communality estimates, the unrotated factor pattern, residual and partial correlations, the rotated primary factor pattern, the primary factor structure, interfactor correlations, the reference structure, reference axis correlations, the variance explained by each factor both ignoring and eliminating other factors, plots of both rotated and unrotated factors, squared multiple correlation of each factor with the variables, standard error estimates, confidence limits, coverage displays, and scoring coefficients.

The FACTOR procedure uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, [“Statistical Graphics Using ODS.”](#)

Any topics that are not given explicit references are discussed in Mulaik (1972) or Harman (1976).

Background

See Chapter 73, [“The PRINCOMP Procedure,”](#) for a discussion of principal component analysis. See Chapter 27, [“The CALIS Procedure,”](#) for a discussion of confirmatory factor analysis.

Common factor analysis was invented by Spearman (1904). Kim and Mueller (1978a, b) provide a very elementary discussion of the common factor model. Gorsuch (1974) presents a broad survey of factor analysis, and Gorsuch (1974) and Cattell (1978) are useful as guides to practical research methodology. Harman (1976) gives a lucid discussion of many of the more technical aspects of factor analysis, especially oblique rotation. Morrison (1976) and Mardia, Kent, and Bibby (1979) provide excellent statistical treatments of common factor analysis. Mulaik (1972) provides the most thorough and authoritative general reference on

factor analysis and is highly recommended to anyone familiar with matrix algebra. Stewart (1981) gives a nontechnical presentation of some issues to consider when deciding whether or not a factor analysis might be appropriate.

A frequent source of confusion in the field of factor analysis is the term *factor*. It sometimes refers to a hypothetical, unobservable variable, as in the phrase *common factor*. In this sense, *factor analysis* must be distinguished from component analysis since a component is an observable linear combination. *Factor* is also used in the sense of *matrix factor*, in that one matrix is a factor of a second matrix if the first matrix multiplied by its transpose equals the second matrix. In this sense, *factor analysis* refers to all methods of data analysis that use matrix factors, including component analysis and common factor analysis.

A *common factor* is an unobservable, hypothetical variable that contributes to the variance of at least two of the observed variables. The unqualified term “factor” often refers to a common factor. A *unique factor* is an unobservable, hypothetical variable that contributes to the variance of only one of the observed variables. The model for common factor analysis posits one unique factor for each observed variable.

The equation for the common factor model is

$$y_{ij} = x_{i1}b_{1j} + x_{i2}b_{2j} + \cdots + x_{iq}b_{qj} + e_{ij}$$

where

y_{ij}	is the value of the i th observation on the j th variable
x_{ik}	is the value of the i th observation on the k th common factor
b_{kj}	is the regression coefficient of the k th common factor for predicting the j th variable
e_{ij}	is the value of the i th observation on the j th unique factor
q	is the number of common factors

It is assumed, for convenience, that all variables have a mean of 0. In matrix terms, these equations reduce to

$$\mathbf{Y} = \mathbf{XB} + \mathbf{E}$$

In the preceding equation, \mathbf{X} is the matrix of factor scores, and \mathbf{B}' is the factor pattern.

There are two critical assumptions:

- The unique factors are uncorrelated with each other.
- The unique factors are uncorrelated with the common factors.

In principal component analysis, the residuals are generally correlated with each other. In common factor analysis, the unique factors play the role of residuals and are defined to be uncorrelated both with each other and with the common factors. Each common factor is assumed to contribute to at least two variables; otherwise, it would be a unique factor.

When the factors are initially extracted, it is also assumed, for convenience, that the common factors are uncorrelated with each other and have unit variance. In this case, the common factor model implies that the covariance s_{jk} between the j th and k th variables, $j \neq k$, is given by

$$s_{jk} = b_{1j}b_{1k} + b_{2j}b_{2k} + \cdots + b_{qj}b_{qk}$$

or

$$\mathbf{S} = \mathbf{B}'\mathbf{B} + \mathbf{U}^2$$

where \mathbf{S} is the covariance matrix of the observed variables, and \mathbf{U}^2 is the diagonal covariance matrix of the unique factors.

If the original variables are standardized to unit variance, the preceding formula yields correlations instead of covariances. It is in this sense that common factors explain the correlations among the observed variables. When considering the diagonal elements of standardized \mathbf{S} , the variance of the j th variable is expressed as

$$s_{jj} = 1 = b_{1j}^2 + b_{2j}^2 + \cdots + b_{qj}^2 + [\mathbf{U}^2]_{jj}$$

where $b_{1j}^2 + b_{2j}^2 + \cdots + b_{qj}^2$ and $[\mathbf{U}^2]_{jj}$ are the communality and uniqueness, respectively, of the j th variable. The communality represents the extent of the overlap with the common factors. In other words, it is the proportion of variance accounted for by the common factors.

The difference between the correlation predicted by the common factor model and the actual correlation is the *residual correlation*. A good way to assess the goodness of fit of the common factor model is to examine the residual correlations.

The common factor model implies that the partial correlations among the variables, removing the effects of the common factors, must all be zero. When the common factors are removed, only unique factors, which are by definition uncorrelated, remain.

The assumptions of common factor analysis imply that the common factors are, in general, not linear combinations of the observed variables. In fact, even if the data contain measurements on the entire population of observations, you cannot compute the scores of the observations on the common factors. Although the common factor scores cannot be computed directly, they can be estimated in a variety of ways.

The problem of factor score indeterminacy has led several factor analysts to propose methods yielding components that can be considered approximations to common factors. Since these components are defined as linear combinations, they are computable. The methods include Harris component analysis and image component analysis. The advantage of producing determinate component scores is offset by the fact that, even if the data fit the common factor model perfectly, component methods do not generally recover the correct factor solution. You should not use any type of component analysis if you really want a common factor analysis (Dziuban and Harris 1973; Lee and Comrey 1979).

After the factors are estimated, it is necessary to interpret them. Interpretation usually means assigning to each common factor a name that reflects the *salience* of the factor in predicting each of the observed variables—that is, the coefficients in the pattern matrix corresponding to the factor. Factor interpretation is a subjective process. It can sometimes be made less subjective by *rotating* the common factors—that is, by applying a nonsingular linear transformation. A rotated pattern matrix in which all the coefficients are close to 0 or ± 1 is easier to interpret than a pattern with many intermediate elements. Therefore, most rotation methods attempt to optimize a simplicity function of the rotated pattern matrix that measures, in some sense, how close the elements are to 0 or ± 1 . Because the loading estimates are subject to sampling variability, it is useful to obtain the standard error estimates for the loadings for assessing the uncertainty due to random sampling. Notice that the *salience* of a factor loading refers to the magnitude of the loading, while statistical *significance* refers to the statistical evidence against a particular hypothetical value. A loading significantly different from 0 does not automatically mean it must be salient. For example, if salience is defined as a

magnitude larger than 0.4 while the entire 95% confidence interval for a loading lies between 0.1 and 0.3, the loading is statistically significant larger than 0 but it is not salient. Under the maximum likelihood method, you can obtain standard errors and confidence intervals for judging the salience of factor loadings.

After the initial factor extraction, the common factors are uncorrelated with each other. If the factors are rotated by an *orthogonal transformation*, the rotated factors are also uncorrelated. If the factors are rotated by an *oblique transformation*, the rotated factors become correlated. Oblique rotations often produce more useful patterns than do orthogonal rotations. However, a consequence of correlated factors is that there is no single unambiguous measure of the importance of a factor in explaining a variable. Thus, for oblique rotations, the pattern matrix does not provide all the necessary information for interpreting the factors; you must also examine the *factor structure* and the *reference structure*.

Rotating a set of factors does not change the statistical explanatory power of the factors. You cannot say that any rotation is better than any other rotation from a statistical point of view; all rotations, orthogonal or oblique, are equally good statistically. Therefore, the choice among different rotations must be based on nonstatistical grounds. For most applications, the preferred rotation is that which is most easily interpretable, or most compatible with substantive theories.

If two rotations give rise to different interpretations, those two interpretations must not be regarded as conflicting. Rather, they are two different ways of looking at the same thing, two different points of view in the common-factor space. Any conclusion that depends on one and only one rotation being correct is invalid.

Outline of Use

Principal Component Analysis

One important type of analysis performed by the FACTOR procedure is principal component analysis. The following statements result in a principal component analysis:

```
proc factor;
run;
```

The output includes all the eigenvalues and the pattern matrix for eigenvalues greater than one.

Most applications require additional output. For example, you might want to compute principal component scores for use in subsequent analyses or obtain a graphical aid to help decide how many components to keep. You can save the results of the analysis in a permanent SAS data library by using the **OUTSTAT=** option. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*. Assuming that your SAS data library has the libref `save` and that the data are in a SAS data set called `raw`, you could do a principal component analysis as follows:

```
proc factor data=raw method=principal scree mineigen=0 score
      outstat=save.fact_all;
run;
```

The **SCREE** option produces a plot of the eigenvalues that is helpful in deciding how many components to use. Alternatively, you can use the **PLOTS=SCREE** option to produce high-quality scree plots. The **MINEIGEN=0** option causes all components with variance greater than zero to be retained. The **SCORE** option requests that scoring coefficients be computed. The **OUTSTAT=** option saves the results in a specially

structured SAS data set. The name of the data set, in this case `fact_all`, is arbitrary. To compute principal component scores, use the SCORE procedure:

```
proc score data=raw score=save.fact_all out=save.scores;
run;
```

The SCORE procedure uses the data and the scoring coefficients that are saved in `save.fact_all` to compute principal component scores. The component scores are placed in variables named `Factor1`, `Factor2`, ..., `Factor n` and are saved in the data set `save.scores`. If you know ahead of time how many principal components you want to use, you can obtain the scores directly from PROC FACTOR by specifying the `NFACTORS=` and `OUT=` options. To get scores from three principal components, specify the following:

```
proc factor data=raw method=principal
  nfactors=3 out=save.scores;
run;
```

To plot the scores for the first three components, use the SGSCATTER procedure:

```
proc sgscatter;
  matrix factor1-factor3;
run;
```

Principal Factor Analysis

The simplest and computationally most efficient method of common factor analysis is principal factor analysis, which is obtained in the same way as principal component analysis except for the use of the `PRIORS=` option. The usual form of the initial analysis is as follows:

```
proc factor data=raw method=principal scree
  mineigen=0 priors=smc outstat=save.fact_all;
run;
```

The squared multiple correlations (SMC) of each variable with all the other variables are used as the prior communality estimates. If your correlation matrix is singular, you should specify `PRIORS=MAX` instead of `PRIORS=SMC`. The `SCREE` and `MINEIGEN=` options serve the same purpose as in the preceding principal component analysis. Saving the results with the `OUTSTAT=` option enables you to examine the eigenvalues and scree plot before deciding how many factors to rotate and to try several different rotations without re-extracting the factors. The `OUTSTAT=` data set is automatically marked `TYPE=FACTOR`, so the FACTOR procedure realizes that it contains statistics from a previous analysis instead of raw data.

After looking at the eigenvalues to estimate the number of factors, you can try some rotations. Two and three factors can be rotated with the following statements:

```
proc factor data=save.fact_all method=principal n=2
  rotate=promax reorder score outstat=save.fact_2;
run;
proc factor data=save.fact_all method=principal n=3
  rotate=promax reorder score outstat=save.fact_3;
run;
```

The output data set from the previous run is used as input for these analyses. The options `N=2` and `N=3` specify the number of factors to be rotated. The specification `ROTATE=PROMAX` requests a promax rotation, which has the advantage of providing both orthogonal and oblique rotations with only one invocation of

PROC FACTOR. The **REORDER** option causes the variables to be reordered in the output so that variables associated with the same factor appear next to each other.

You can now compute and plot factor scores for the two-factor promax-rotated solution as follows:

```
proc score data=raw score=save.fact_2 out=save.scores;
run;

proc sgplot;
  scatter y=factor2 x=factor1;
run;
```

Maximum Likelihood Factor Analysis

Although principal factor analysis is perhaps the most commonly used method of common factor analysis, most statisticians prefer maximum likelihood (ML) factor analysis (Lawley and Maxwell 1971). The ML method of estimation has desirable asymptotic properties (Bickel and Doksum 1977) and produces better estimates than principal factor analysis in large samples. You can test hypotheses about the number of common factors by using the ML method. You can also obtain standard error and confidence interval estimates for many classes of rotated or unrotated factor loadings, factor correlations, and structure loadings under the ML theory.

The unrotated ML solution is equivalent to Rao's canonical factor solution (Rao 1955) and Howe's solution maximizing the determinant of the partial correlation matrix (Morrison 1976). Thus, as a descriptive method, ML factor analysis does not require a multivariate normal distribution. The validity of Bartlett's χ^2 test for the number of factors does require approximate normality plus additional regularity conditions that are usually satisfied in practice (Geweke and Singleton 1980). Bartlett's test of sphericity in the context of factor analysis is equivalent to Bartlett's χ^2 test for zero common factors. This test is routinely displayed in the maximum likelihood factor analysis output.

Lawley and Maxwell (1971) derive the standard error formulas for unrotated loadings, while Archer and Jennrich (1973) and Jennrich (1973, 1974) derive the standard error formulas for several classes of rotated solutions. Extended formulas for computing standard errors in various situations appear in Browne et al. (2008); Hayashi and Yung (1999); Yung and Hayashi (2001). A combination of these methods is used in PROC FACTOR to compute standard errors in an efficient manner. Confidence intervals are computed by using the asymptotic normality of the estimates. To ensure that the confidence intervals fall within the admissible parameter range, transformation methods due to Browne (1982) are used. The validity of the standard error estimates and confidence limits requires the assumptions of multivariate normality and a fixed number of factors.

The ML method is more computationally demanding than principal factor analysis for two reasons. First, the communalities are estimated iteratively, and each iteration takes about as much computer time as principal factor analysis. The number of iterations typically ranges from about five to twenty. Second, if you want to extract different numbers of factors, as is often the case, you must run the FACTOR procedure once for each number of factors. Therefore, an ML analysis can take 100 times as long as a principal factor analysis. This does not include the time for computing standard error estimates, which is even more computationally demanding. For analyses with fewer than 35 variables, the computing time for the ML method, including the computation of standard errors, usually ranges from a few seconds to well under a minute. This seems to be a reasonable performance.

You can use principal factor analysis to get a rough idea of the number of factors before doing an ML analysis. If you think that there are between one and three factors, you can use the following statements for the ML analysis:

```
proc factor data=raw method=ml n=1
    outstat=save.fact1;
run;
proc factor data=raw method=ml n=2 rotate=promax
    outstat=save.fact2;
run;
proc factor data=raw method=ml n=3 rotate=promax
    outstat=save.fact3;
run;
```

The output data sets can be used for trying different rotations, computing scoring coefficients, or restarting the procedure in case it does not converge within the allotted number of iterations.

If you can determine how many factors should be retained before an analysis, as in the following statements, you can get the standard errors and confidence limits to aid interpretations for the ML analysis:

```
proc factor data=raw method=ml n=3 rotate=quartimin se
    cover=.4;
run;
```

In this analysis, you specify the quartimin rotation in the **ROTATE=** option. The **SE** option requests the computation of standard error estimates. In the **COVER=** option, you require absolute values of 0.4 or greater in order for loadings to be salient. In the output of coverage display, loadings that are salient would have their entire confidence intervals spanning beyond the 0.4 mark (or the -0.4 mark in the opposite direction). Only those salient loadings should be used for interpreting the factors. See the section “[Confidence Intervals and the Salience of Factor Loadings](#)” on page 2243 for more details.

The ML method cannot be used with a singular correlation matrix, and it is especially prone to Heywood cases. See the section “[Heywood Cases and Other Anomalies about Communality Estimates](#)” on page 2248 for a discussion of Heywood cases. If you have problems with ML, the best alternative is to use the **METHOD=ULS** option for unweighted least squares factor analysis.

Factor Rotation

After the initial factor extraction, the factors are uncorrelated with each other. If the factors are rotated by an *orthogonal transformation*, the rotated factors are also uncorrelated. If the factors are rotated by an *oblique transformation*, the rotated factors become correlated. Oblique rotations often produce more useful patterns than orthogonal rotations do. However, a consequence of correlated factors is that there is no single unambiguous measure of the importance of a factor in explaining a variable. Thus, for oblique rotations, the pattern matrix does not provide all the necessary information for interpreting the factors; you must also examine the *factor structure* and the *reference structure*.

Nowadays, most rotations are done analytically. There are many choices for orthogonal and oblique rotations. An excellent summary of a wide class of analytic rotations is in Crawford and Ferguson (1970). The Crawford-Ferguson family of orthogonal rotations includes the orthomax rotation as a subclass and the popular varimax rotation as a special case. To illustrate these relationships, the following four specifications for orthogonal rotations with different **ROTATE=** options will give the same results for a data set with nine observed variables:

```

/* Orthogonal Crawford-Ferguson Family with
   variable parsimony weight =  $nvar - 1 = 8$ , and
   factor parsimony weight = 1 */
proc factor data=raw n=3 rotate=orthcf(8,1);
run;

/* Orthomax without the GAMMA= option */
proc factor data=raw n=3 rotate=orthomax(1);
run;

/* Orthomax with the GAMMA= option */
proc factor data=raw n=3 rotate=orthomax gamma=1;
run;

/* Varimax */
proc factor data=raw n=3 rotate=varimax;
run;

```

You can also get the oblique versions of the varimax in two equivalent ways:

```

/* Oblique Crawford-Ferguson Family with
   variable parsimony weight =  $nvar - 1 = 8$ , and
   factor parsimony weight = 1; */
proc factor data=raw n=3 rotate=oblicf(8,1);
run;

/* Oblique Varimax */
proc factor data=raw n=3 rotate=obvarimax;
run;

```

Jennrich (1973) proposes a generalized Crawford-Ferguson family that includes the Crawford-Ferguson family and the (direct) oblimin family (see Harman 1976) as subclasses. The better-known quartimin rotation is a special case of the oblimin class, and hence a special case of the generalized Crawford-Ferguson family. For example, the following four specifications of oblique rotations are equivalent:

```

/* Oblique generalized Crawford-Ferguson Family
   with weights 0, 1, 0, -1 */
proc factor data=raw n=3 rotate=obligencf(0,1,0,-1);
run;

/* Oblimin family without the TAU= option */
proc factor data=raw n=3 rotate=oblimin(0);
run;

/* Oblimin family with the TAU= option */
proc factor data=raw n=3 rotate=oblimin tau=0;
run;

/* Quartimin */
proc factor data=raw n=3 rotate=quartimin;
run;

```

In addition to the generalized Crawford-Ferguson family, the available oblique rotation methods in PROC FACTOR include Harris-Kaiser, promax, and Procrustes. See the section “[Simplicity Functions for Rotations](#)” on page 2244 for details about the definitions of various rotations. See Harman (1976) and Mulaik (1972) for further information.

Getting Started: FACTOR Procedure

The following example demonstrates how you can use the FACTOR procedure to perform common factor analysis and factor rotation.

In this example, 103 police officers were rated by their supervisors on 14 scales (variables). You conduct a common factor analysis on these variables to see what latent factors are operating behind these ratings. The overall rating variable is excluded from the factor analysis.

The following DATA step creates the SAS data set jobratings:

```
options validvarname=any;
data jobratings;
  input ('Communication Skills'n
        'Problem Solving'n
        'Learning Ability'n
        'Judgment Under Pressure'n
        'Observational Skills'n
        'Willingness to Confront Problems'n
        'Interest in People'n
        'Interpersonal Sensitivity'n
        'Desire for Self-Improvement'n
        'Appearance'n
        'Dependability'n
        'Physical Ability'n
        'Integrity'n
        'Overall Rating'n) (1.);
  datalines;
26838853879867
74758876857667
56757863775875
67869777988997
99997798878888
89897899888799
89999889899798
87794798468886

... more lines ...

99899899899899
76656399567486
;
```

The following statements invoke the FACTOR procedure:

```
proc factor data=jobratings(drop='Overall Rating'n) priors=smc
  rotate=varimax;
run;
```

The **DATA=** option in PROC FACTOR specifies the SAS data set jobratings as the input data set. The **DROP=** option drops the Overall Rating variable from the analysis. To conduct a common factor analysis, you need to set the prior communality estimate to less than one for each variable. Otherwise, the factor solution would simply be a recast of the principal components solution, in which “factors” are linear combinations of observed variables. However, in the common factor model you always assume that observed variables are functions of underlying factors. In this example, the **PRIORS=** option specifies that the squared multiple correlations (SMC) of each variable with all the other variables are used as the prior communality estimates. Note that squared multiple correlations are usually less than one. By default, the principal factor extraction is used if the **METHOD=** option is not specified. To facilitate interpretations, the **ROTATE=** option specifies the VARIMAX orthogonal factor rotation to be used.

The output from the factor analysis is displayed in Figure 35.1 through Figure 35.5.

As displayed in Figure 35.1, the prior communality estimates are set to the squared multiple correlations. Figure 35.1 also displays the table of eigenvalues (the variances of the principal factors) of the reduced correlation matrix. Each row of the table pertains to a single eigenvalue. Following the column of eigenvalues are three measures of each eigenvalue’s relative size and importance. The first of these displays the difference between the eigenvalue and its successor. The last two columns display the individual and cumulative proportions that the corresponding factor contributes to the total variation. The last line displayed in Figure 35.1 states that three factors are retained, as determined by the PROPORTION criterion.

Figure 35.1 Table of Eigenvalues from PROC FACTOR

The FACTOR Procedure				
Initial Factor Method: Principal Factors				
Prior Communality Estimates: SMC				
Communication Skills	Problem Solving	Learning Ability	Judgment Under Pressure	Observational Skills
0.62981394	0.58657431	0.61009871	0.63766021	0.67187583

13	-.20652684		-0.0256	1.0000
3 factors will be retained by the PROPORTION criterion.				

Figure 35.2 displays the initial factor pattern matrix. The factor pattern matrix represents standardized regression coefficients for predicting the variables by using the extracted factors. Because the initial factors are uncorrelated, the pattern matrix is also equal to the correlations between variables and the common factors.

Figure 35.2 Factor Pattern Matrix from PROC FACTOR

Factor Pattern			
	Factor1	Factor2	Factor3
Communication Skills	0.75441	0.07707	-0.25551
Problem Solving	0.68590	0.08026	-0.34788
Learning Ability	0.65904	0.34808	-0.25249
Judgment Under Pressure	0.73391	-0.21405	-0.23513
Observational Skills	0.69039	0.45292	0.10298
Willingness to Confront Problems	0.66458	0.47460	0.09210
Interest in People	0.70770	-0.53427	0.10979
Interpersonal Sensitivity	0.64668	-0.61284	-0.07582
Desire for Self-Improvement	0.73820	0.12506	0.09062
Appearance	0.57188	0.20052	0.16367
Dependability	0.79475	-0.04516	0.16400
Physical Ability	0.51285	0.10251	0.34860
Integrity	0.74906	-0.35091	0.18656

The pattern matrix suggests that Factor1 represents general ability. All loadings for Factor1 in the Factor Pattern are at least 0.5. Factor2 consists of high positive loadings on certain task-related skills (Willingness to Confront Problems, Observational Skills, and Learning Ability) and high negative loadings on some interpersonal skills (Interpersonal Sensitivity, Interest in People, and Integrity). This factor measures individuals' relative strength in these skills. Theoretically, individuals with high positive scores on this factor would exhibit better task-related skills than interpersonal skills. Individuals with high negative scores would exhibit better interpersonal skills than task-related skills. Individuals with scores near zero would have those skills balanced. Factor3 does not have a cluster of very high or very low factor loadings. Therefore, interpreting this factor is difficult.

Figure 35.3 displays the proportion of variance explained by each factor and the final communality estimates, including the total communality. The final communality estimates are the proportion of variance of the variables accounted for by the common factors. When the factors are orthogonal, the final communalities are calculated by taking the sum of squares of each row of the factor pattern matrix.

Figure 35.3 Variance Explained and Final Communality Estimates

Variance Explained by Each Factor				
	Factor1	Factor2	Factor3	
	6.1776055	1.4622860	0.5604525	
Final Communality Estimates: Total = 8.200344				
Communication Skills	Problem Solving	Learning Ability	Judgment Under Pressure	Observational Skills
0.64036292	0.59791844	0.61924167	0.63972863	0.69237485
Willingness to Confront Problems	Interest in People	Interpersonal Sensitivity	Desire for Self-Improvement	
0.67538695	0.79833968	0.79951357	0.56879171	
Appearance	Dependability	Physical Ability	Integrity	
0.39403630	0.66056907	0.39504805	0.71903222	

Figure 35.4 displays the results of the VARIMAX rotation of the three extracted factors and the corresponding orthogonal transformation matrix. The rotated factor pattern matrix is calculated by postmultiplying the original factor pattern matrix (Figure 35.4) by the transformation matrix.

Figure 35.4 Transformation Matrix and Rotated Factor Pattern

Orthogonal Transformation Matrix			
	1	2	3
1	0.59125	0.59249	0.54715
2	-0.80080	0.51170	0.31125
3	0.09557	0.62219	-0.77701

Rotated Factor Pattern			
	Factor1	Factor2	Factor3
Communication Skills	0.35991	0.32744	0.63530
Problem Solving	0.30802	0.23102	0.67058
Learning Ability	0.08679	0.41149	0.66512
Judgment Under Pressure	0.58287	0.17901	0.51764
Observational Skills	0.05533	0.70488	0.43870
Willingness to Confront Problems	0.02168	0.69391	0.43978
Interest in People	0.85677	0.21422	0.13562
Interpersonal Sensitivity	0.86587	0.02239	0.22200
Desire for Self-Improvement	0.34498	0.55775	0.37242
Appearance	0.19319	0.54327	0.24814
Dependability	0.52174	0.54981	0.29337
Physical Ability	0.25445	0.57321	0.04165
Integrity	0.74172	0.38033	0.15567

The rotated factor pattern matrix is somewhat simpler to interpret. If a magnitude of at least 0.5 is required to indicate a salient variable-factor relationship, Factor1 now represents interpersonal skills (Interpersonal Sensitivity, Interest in People, Integrity, Judgment Under Pressure, and Dependability). Factor2 measures physical skills and job enthusiasm (Observational Skills, Willingness to Confront Problems, Physical Ability, Desire for Self-Improvement, Dependability, and Appearance). Factor3 measures cognitive skills (Communication Skills, Problem Solving, Learning Ability, and Judgment Under Pressure).

However, using 0.5 for determining a salient variable-factor relationship does not take sampling variability into account. If the underlying assumptions for the maximum likelihood estimation are approximately satisfied, you can output standard error estimates and the confidence intervals with **METHOD=ML**. You can then determine the salience of the variable-factor relationship by using the coverage displays. See the section “[Confidence Intervals and the Salience of Factor Loadings](#)” on page 2243 for more details.

Figure 35.5 displays the variance explained by each factor and the final communality estimates after the orthogonal rotation. Even though the variances explained by the rotated factors are different from that of the unrotated factor (compare with Figure 35.3), the cumulative variance explained by the common factors remains the same. Note also that the final communalities for variables, as well as the total communality, remain unchanged after rotation. Although rotating a factor solution will not increase or decrease the statistical quality of the factor model, it can simplify the interpretations of the factors and redistribute the variance explained by the factors.

Figure 35.5 Variance Explained and Final Communality Estimates after Rotation

Variance Explained by Each Factor				
	Factor1	Factor2	Factor3	
	3.1024330	2.7684489	2.3294622	
Final Communality Estimates: Total = 8.200344				
Communication Skills	Problem Solving	Learning Ability	Judgment Under Pressure	Observational Skills

0.67538695	0.79833968	0.79951357	0.56879171	
Appearance	Dependability	Physical Ability	Integrity	
0.39403630	0.66056907	0.39504805	0.71903222	

Syntax: **FACTOR Procedure**

The following statements are available in the FACTOR procedure:

```
PROC FACTOR < options > ;
VAR variables ;
PRIORS communalities ;
PARTIAL variables ;
FREQ variable ;
WEIGHT variable ;
BY variables ;
```

Usually only the VAR statement is needed in addition to the PROC FACTOR statement. The descriptions of the BY, FREQ, PARTIAL, PRIORS, VAR, and WEIGHT statements follow the description of the PROC FACTOR statement in alphabetical order.

PROC FACTOR Statement

```
PROC FACTOR < options > ;
```

The PROC FACTOR statement invokes the FACTOR procedure. The options listed in [Table 35.1](#) are available in the PROC FACTOR statement.

Table 35.1 Options Available in the PROC FACTOR Statement

Option	Description
Data Set Options	
DATA=	Specifies input SAS data set
OUT=	Specifies output SAS data set
OUTSTAT=	Specifies output data set containing statistical results
TARGET=	Specifies input data set containing the target pattern for rotation
Factor Extraction and Communalities	
HEYWOOD	Sets to 1 any communality greater than 1
METHOD=	Specifies the estimation method
PRIORS=	Specifies the method for computing prior communality estimates
RANDOM=	Specifies the seed for pseudo-random number generation
ULTRAHEYWOOD	Allows communalities to exceed 1
Number of Factors	
MINEIGEN=	Specifies the smallest eigenvalue for retaining a factor
NFACTORS=	Specifies the number of factors to retain
PROPORTION=	Specifies the proportion of common variance in extracted factors
Data Analysis Options	
ALPHA=	Specifies the confidence level for interval construction
COVARIANCE	Requests factoring of the covariance matrix
COVER=	Computes the confidence interval and specifies the coverage reference point
NOINT	Omits the intercept from computing covariances or correlations
SE	Requests the standard error estimates in ML estimation
VARDEF=	Specifies the divisor used in calculating covariances or correlations
WEIGHT	Factors a weighted correlation or covariance matrix
Rotation Method and Properties	
GAMMA=	Specifies the orthomax weight
HKPOWER=	Specifies the power in Harris-Kaiser rotation
NORM=	Specifies the method for row normalization in rotation
NOPROMAXNORM	Turns off row normalization in promax rotation
POWER=	Specifies the power to be used in promax rotation
PREROTATE=	Specifies the prerotation method in promax rotation
RCONVERGE=	Specifies the convergence criterion for rotation cycles
RITER=	Specifies the maximum number of cycles for rotation
ROTATE=	Specifies the rotation method
TAU=	Specifies the oblimin weight

Table 35.1 *continued*

Option	Description
ODS Graphics	
PLOTS=	Specifies ODS Graphics selection
Control Display Output	
ALL	Displays all optional output except plots
CORR	Displays the (partial) correlation matrix
EIGENVECTORS	Displays the eigenvectors of the reduced correlation matrix
FLAG=	Specifies the minimum absolute value to be flagged in the correlation and loading matrices
FUZZ=	Specifies the maximum absolute value to be displayed as missing in the correlation and loading matrices
MSA	Computes Kaiser's measure of sampling adequacy and the related partial correlations
NOPRINT	Suppresses the display of all output
NPLOT=	Specifies the number of factors to be plotted
PLOT	Plots the rotated factor pattern
PLOTREF	Plots the reference structure
PREPLOT	Plots the factor pattern before rotation
PRINT	Displays the input factor pattern or scoring coefficients and related statistics
REORDER	Reorders the rows (variables) of various factor matrices
RESIDUALS	Displays the residual correlation matrix and the associated partial correlation matrix
ROUND	Prints correlation and loading matrices with rounded values
SCORE	Displays the factor scoring coefficients
SCREE	Displays the scree plot of the eigenvalues
SIMPLE	Displays means, standard deviations, and number of observations
Numerical Properties	
CONVERGE=	Specifies the convergence criterion
MAXITER=	Specifies the maximum number of iterations
SINGULAR=	Specifies the singularity criterion
Miscellaneous	
NOCORR	Excludes the correlation matrix from the OUTSTAT= data set
NOBS=	Specifies the number of observations
PARPREFIX=	Specifies the prefix for the residual variables in the output data sets
PREFIX=	Specifies the prefix for naming factors

ALL

displays all optional output except plots. When the input data set is TYPE=CORR, TYPE=UCORR, TYPE=COV, TYPE=UCOV, or TYPE=FACTOR, simple statistics, correlations, and [MSA](#) are not displayed.

ALPHA= p

specifies the level of confidence $1 - p$ for interval construction. By default, $p = 0.05$, corresponding to $1 - p = 95\%$ confidence intervals. If p is greater than one, it is interpreted as a percentage and divided by 100. With multiple confidence intervals to be constructed, the ALPHA= value is applied to each interval construction one at a time. This will not control the coverage probability of the intervals simultaneously. To control familywise coverage probability, you might consider supplying a nonconventional p by using methods such as Bonferroni adjustment.

CONVERGE= p **CONV= p**

specifies the convergence criterion for the [METHOD=PRINIT](#), [METHOD=ULS](#), [METHOD=ALPHA](#), or [METHOD=ML](#) option. Iteration stops when the maximum change in the communalities is less than the value of the CONVERGE= option. The default value is 0.001. Negative values are not allowed.

CORR**C**

displays the correlation matrix or partial correlation matrix.

COVARIANCE**COV**

requests factoring of the covariance matrix instead of the correlation matrix. The COV option is effective only with the [METHOD=PRINCIPAL](#), [METHOD=PRINIT](#), [METHOD=ULS](#), or [METHOD=IMAGE](#) option. For other methods, PROC FACTOR produces the same results with or without the COV option.

COVER <= p >**CI <= p >**

computes the confidence intervals and optionally specifies the value of factor loading for coverage detection. By default, $p = 0$. The specified value is represented by an asterisk (*) in the coverage display. This is useful for determining the salience of loadings. For example, if COVER=0.4, a display '0*[]' indicates that the entire confidence interval is above 0.4, implying strong evidence for the salience of the loading. See the section "[Confidence Intervals and the Salience of Factor Loadings](#)" on page 2243 for more details.

DATA=SAS-data-set

specifies the input data set, which can be an ordinary SAS data set or a specially structured SAS data set as described in the section "[Input Data Set](#)" on page 2239. If the DATA= option is omitted, the most recently created SAS data set is used.

EIGENVECTORS**EV**

displays the eigenvectors of the reduced correlation matrix, of which the diagonal elements are replaced with the communality estimates. When [METHOD=ML](#), the eigenvectors are for the weighted reduced correlation matrix. PROC FACTOR chooses the solution that makes the sum of the elements of each eigenvector nonnegative. If the sum of the elements is equal to zero, then the sign depends on how the number is rounded off.

FLAG=*p*

flags absolute values larger than *p* with an asterisk in the correlation and loading matrices. Negative values are not allowed for *p*. Values printed in the matrices are multiplied by 100 and rounded to the nearest integer (see the [ROUND](#) option). The FLAG= option has no effect when standard errors or confidence intervals are also printed.

FUZZ=*p*

prints correlations and factor loadings with absolute values less than *p* printed as missing. For partial correlations, the FUZZ= value is divided by 2. For residual correlations, the FUZZ= value is divided by 4. The exact values in any matrix can be obtained from the [OUTSTAT=](#) and ODS output data sets. Negative values are not allowed. The FUZZ= option has no effect when standard errors or confidence intervals are also printed.

GAMMA=*p*

specifies the orthomax weight used with the option [ROTATE=ORTHOMAX](#) or [PRE-ROTATE=ORTHOMAX](#). Alternatively, you can use [ROTATE=ORTHOMAX\(*p*\)](#) with *p* representing the orthomax weight. There is no restriction on valid values for the orthomax weight, although the most common values are between zero and the number of variables. The default GAMMA= value is one, resulting in the varimax rotation. See the section “[Simplicity Functions for Rotations](#)” on page 2244 for more details.

HEYWOOD**HEY**

sets to 1 any communality greater than 1, allowing iterations to proceed. See the section “[Heywood Cases and Other Anomalies about Communality Estimates](#)” on page 2248 for a discussion of Heywood cases.

HKPOWER=*p***HKP=*p***

specifies the power of the square roots of the eigenvalues used to rescale the eigenvectors for Harris-Kaiser ([ROTATE=HK](#)) rotation, assuming that the factors are extracted by the principal factor method. If the principal factor method is not used for factor extraction, the eigenvectors are replaced by the normalized columns of the unrotated factor matrix, and the eigenvalues are replaced by the column normalizing constants. HKPOWER= values between 0.0 and 1.0 are reasonable. The default value is 0.0, yielding the independent cluster solution, in which each variable tends to have a large loading on only one factor. An HKPOWER= value of 1.0 is equivalent to an orthogonal rotation, with the varimax rotation as the default. You can also specify the HKPOWER= option with [ROTATE=QUARTIMAX](#), [ROTATE=BIQUARTIMAX](#), [ROTATE=EQUAMAX](#), or [ROTATE=ORTHOMAX](#), and so on. The only restriction is that the Harris-Kaiser rotation must be associated with an orthogonal rotation.

MAXITER=*n*

specifies the maximum number of iterations for factor extraction. You can use the MAXITER= option with the PRINIT, ULS, ALPHA, or ML method. The default is 30.

METHOD=*name***M=*name***

specifies the method for extracting factors. The default is METHOD=PRINCIPAL unless the DATA= data set is TYPE=FACTOR, in which case the default is METHOD=PATTERN. Valid values for *name* are as follows:

ALPHA A	produces alpha factor analysis.
HARRIS H	yields Harris component analysis of $S^{-1}RS^{-1}$ (Harris 1962), a noniterative approximation to canonical component analysis.
IMAGE I	yields principal component analysis of the image covariance matrix, not the image analysis of Kaiser (1963, 1970) or Kaiser and Rice (1974). A nonsingular correlation matrix is required.
ML M	performs maximum likelihood factor analysis with an algorithm due, except for minor details, to Fuller (1987). The option METHOD=ML requires a nonsingular correlation matrix.
PATTERN	reads a factor pattern from a TYPE=FACTOR, TYPE=CORR, TYPE=UCORR, TYPE=COV, or TYPE=UCOV data set. If you create a TYPE=FACTOR data set in a DATA step, only observations containing the factor pattern (_TYPE_='PATTERN') and, if the factors are correlated, the interfactor correlations (_TYPE_='FCORR') are required.
PRINCIPAL PRIN P	yields principal component analysis if no PRIORS option or statement is used or if you specify PRIORS=ONE; if you specify a PRIORS statement or a PRIORS= value other than PRIORS=ONE, a principal factor analysis is performed.
PRINIT	yields iterated principal factor analysis.
SCORE	reads scoring coefficients (_TYPE_='SCORE') from a TYPE=FACTOR, TYPE=CORR, TYPE=UCORR, TYPE=COV, or TYPE=UCOV data set. The data set must also contain either a correlation or a covariance matrix. Scoring coefficients are also displayed if you specify the OUT= option.
ULS U	produces unweighted least squares factor analysis.

MINEIGEN=*p***MIN=*p***

specifies the smallest eigenvalue for which a factor is retained. If you specify two or more of the MINEIGEN=, NFACTORS=, and PROPORTION= options, the number of factors retained is the minimum number satisfying any of the criteria. The MINEIGEN= option cannot be used with either the METHOD=PATTERN or the METHOD=SCORE option. Negative values are not allowed. The default is 0 unless you omit both the NFACTORS= and the PROPORTION= options and one of the following conditions holds:

- If you specify the METHOD=ALPHA or METHOD=HARRIS option, then MINEIGEN=1.

- If you specify the **METHOD=IMAGE** option, then

$$\text{MINEIGEN} = \frac{\text{total image variance}}{\text{number of variables}}$$

- For any other **METHOD=** specification, if prior communality estimates of 1.0 are used, then

$$\text{MINEIGEN} = \frac{\text{total weighted variance}}{\text{number of variables}}$$

When an unweighted correlation matrix is factored, this value is 1.

MSA

produces the partial correlations between each pair of variables controlling for all other variables (the negative anti-image correlations) and Kaiser's measure of sampling adequacy (Kaiser 1970; Kaiser and Rice 1974; Cerny and Kaiser 1977).

NFACTORS=*n*

NFACT=*n*

N=*n*

specifies the maximum number of factors to be extracted and determines the amount of memory to be allocated for factor matrices. The default is the number of variables. Specifying a number that is small relative to the number of variables can substantially decrease the amount of memory required to run PROC FACTOR, especially with oblique rotations. If you specify two or more of the **NFACTORS=**, **MINEIGEN=**, and **PROPORTION=** options, the number of factors retained is the minimum number satisfying any of the criteria. If you specify the option **NFACTORS=0**, eigenvalues are computed, but no factors are extracted. If you specify the option **NFACTORS=-1**, neither eigenvalues nor factors are computed. You can use the **NFACTORS=** option with the **METHOD=PATTERN** or **METHOD=SCORE** option to specify a smaller number of factors than are present in the data set.

NOBS=*n*

specifies the number of observations. If the **DATA=** input data set is a raw data set, *nobs* is defined by default to be the number of observations in the raw data set. The **NOBS=** option overrides this default definition. If the **DATA=** input data set contains a covariance, correlation, or scalar product matrix, the number of observations can be specified either by using the **NOBS=** option in the PROC FACTOR statement or by including a **_TYPE_='N'** observation in the **DATA=** input data set.

NOCORR

prevents the correlation matrix from being transferred to the **OUTSTAT=** data set when you specify the **METHOD=PATTERN** option. The **NOCORR** option greatly reduces memory requirements when there are many variables but few factors. The **NOCORR** option is not effective if the correlation matrix is required for other requested output; for example, if the scores or the residual correlations are displayed (for example, by using the **SCORE**, **RESIDUALS**, or **ALL** option).

NOINT

omits the intercept from the analysis; covariances or correlations are not corrected for the mean.

NOPRINT

suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, "Using the Output Delivery System."

NOPROMAXNORM | NOPMAXNORM

turns off the default row normalization of the prerotated factor pattern, which is used in computing the promax target matrix.

NORM=COV | KAISER | NONE | RAW | WEIGHT

specifies the method for normalizing the rows of the factor pattern for rotation. If you specify the option **NORM=KAISER**, Kaiser's normalization is used ($\sum_j p_{ij}^2 = 1$). If you specify the option **NORM=WEIGHT**, the rows are weighted by the Cureton-Mulaik technique (Cureton and Mulaik 1975). If you specify the option **NORM=COV**, the rows of the pattern matrix are rescaled to represent covariances instead of correlations. If you specify the option **NORM=NONE** or **NORM=RAW**, normalization is not performed. The default is **NORM=KAISER**.

NPLOTS | NPLOT=*n*

specifies the number of factors to be plotted. The default is to plot all factors. The smallest allowable value is 2. If you specify the option **NPLOTS=*n***, all pairs of the first *n* factors are plotted, producing a total of $n(n - 1)/2$ plots.

OUT=SAS-data-set

creates a data set containing all the data from the **DATA=** data set plus variables called Factor1, Factor2, and so on, containing estimated factor scores. The **DATA=** data set must contain multivariate data, not correlations or covariances. You must also specify the **NFACTORS=** option to determine the number of factor score variables. If you specify partial variables in the **PARTIAL** statement, the **OUT=** data set will also contain the residual variables that are used for factor analysis. The output data set is described in detail in the section “[Output Data Sets](#)” on page 2241. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

OUTSTAT=SAS-data-set

specifies an output data set containing most of the results of the analysis. The output data set is described in detail in the section “[Output Data Sets](#)” on page 2241. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

PARPREFIX=name

specifies the prefix for the residual variables in the **OUT=** and the **OUTSTAT=** data sets when partial variables are specified in the **PARTIAL** statement.

PLOT

plots the factor pattern after rotation. This option produces printer plots. High-quality ODS graphical plots for factor patterns can be requested with the **PLOTS=LOADINGS** or **PLOTS=INITLOADINGS** option.

PLOTREF

plots the reference structure instead of the default factor pattern after oblique rotation.

PLOTS <(global-plot-options)> = plot-request <(options)>**PLOTS <(global-plot-options)> = (plot-request <(options)> <...plot-request <(options)> >)**

specifies one or more ODS graphical plots in PROC FACTOR. When you specify only one *plot-request*, you can omit the parentheses around the *plot-request*. Here are some examples:

```
plots=all
plots(flip)=loadings
plots=(loadings(flip) scree(unpack))
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc factor plots=all;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

For an example containing graphical displays of factor analysis results, see [Example 35.2](#).

The following table shows the available *plot-requests* and their available suboptions:

<i>Plot-Request</i>	Plot Description	Suboptions
ALL	all available plots	all
INITLOADINGS	unrotated factor loadings	CIRCLE=, FLIP, NPLOTS=, PLOTREF, and VECTOR
LOADINGS	rotated factor loadings	CIRCLE=, FLIP, NPLOTS=, PLOTREF, and VECTOR
NONE	no ODS graphical plots	
PRELOADINGS	prerotated factor loadings	CIRCLE=, FLIP, NPLOTS=, PLOTREF, and VECTOR
SCREE	scree and variance explained	UNPACK

The following are the available *global-plot-options* or *options* for plots:

CIRCLE | CIRCLES *< = numbers >* draws circular reference lines in scatter plots or vector plots of factor loadings. You can specify the locations of the circular reference lines in the *numbers* list. Each number indicates the proportion or percentage of area of the unit circle that is enclosed by the specified circle. Each of the *numbers* must lie between 0 and 100, inclusively. When a number is between 0 and 1 (inclusively), it is interpreted as a proportion; otherwise, it is interpreted as a percentage. The maximum number of circles is 5.

The CIRCLE option applies to the scatter or vector plots requested by the INITLOADINGS, LOADINGS, and PRELOADINGS options. By default, a unit-circle, which represents 100% of the total area, is drawn for the vector plots. However, no circle will be drawn for scatter plots unless the CIRCLE option is specified. Two special cases for this option are: (1) With no *numbers* following the CIRCLE option, a 100% circle will be drawn. (2) With CIRCLE=0, no circle will be drawn. This special case is primarily used to turn off the default unit-circle in vector plots.

FLIP switches the X and Y axes. It applies to the INITLOADINGS, LOADINGS, and PRELOADINGS *plot-requests*.

NPLOT | NLOTS=*n* specifies the number of factors *n* ($n \geq 2$) to be plotted. It applies to the INITLOADINGS, LOADINGS, and PRELOADINGS *plot-requests*. Since this option can also be specified in the PROC FACTOR statement, the final value of *n* is determined by the following steps. The NLOTS= value of the PROC FACTOR is read first. If the NLOTS= option is specified as a *global-plot-option*, the value of *n* will be updated. Then, if the NLOTS= option is again specified in an individual *plot-request*, the value will be updated again for that individual *plot-request*. For example, in the following statement, four factors are extracted with the N=4 option:

```
proc factor n=4 nplots=3 plots(nplots=4)=
              (loadings preloadings(nplots=2));
```

Initially, plots of the first three factors are specified with the NLOTS=3 option. When you are producing ODS graphical plots, the *global-plot-option* NLOTS=4 is used. As a result, the LOADINGS *plot-request* will produce plots for all pairs of the first 4 factors. However, because the NLOTS=2 is specified locally for the PRELOADINGS *plot-request*, it will produce a prerotated factor loading plot for the first two factors only.

The default NLOTS= value is 5 or the total number of factors (*m*), whichever is smaller. If you specify an NLOTS= value that is greater than *m*, NLOTS=*m* will be used.

- | | |
|---------|--|
| PLOTREF | plots the reference structures rather than the factor pattern loadings. It applies to the INITLOADINGS, LOADINGS, and PRELOADINGS <i>plot-requests</i> when the factor solution is oblique. This option can also be set globally as an option in the PROC FACTOR statement. |
| UNPACK | plots component graphs separately. It applies to the SCREE <i>plot-request</i> only. |
| VECTOR | plots loadings in vector form. It applies to the INITLOADINGS, LOADINGS, and PRELOADINGS <i>plot-requests</i> when the factor solution is orthogonal. For oblique solutions, the VECTOR option is ignored and the default scatter plots for factor loadings or reference structures are displayed. |

Be aware that the **PLOT** option in the PROC FACTOR statement requests only the printer plots of factor loadings. The current option PLOTS= or PLOT=, however, is for ODS graphical plots.

You can specify options for the requested ODS graphical plots as *global-plot-options* or as local *options*. *Global-plot-options* apply to all appropriate individual *plot-requests* specified. For example, because the SCREE plot is not subject to axes flipping, the following two specifications are equivalent:

```
plots(flip)=(loadings preloadings scree)
plots=(loadings(flip) preloadings(flip) scree)
```

Options specified locally after each *plot-request* apply to that plot-request only. For example, consider the following specification:

```
plots=(scree(unpack) loadings(plotref) preloadings(flip))
```

The FLIP option applies to the PRELOADINGS *plot-request* but not the LOADINGS *plot-request*; the PLOTREF option applies to the LOADINGS *plot-request* but not the PRELOADINGS *plot-request*; and the UNPACK option applies to the SCREE *plot-request* only.

POWER=*n*

specifies the power to be used in computing the target pattern for the option **ROTATE=PROMAX**. Valid values must be integers ≥ 1 . The default value is 3. You can also specify the POWER= value in the **ROTATE=** option—for example, **ROTATE=PROMAX(4)**.

PREFIX=*name*

specifies a prefix for naming the factors. By default, the names are Factor1, Factor2, ..., Factor*n*. If you specify PREFIX=ABC, the factors are named ABC1, ABC2, ABC3, and so on. The number of characters in the prefix plus the number of digits required to designate the variables should not exceed the current name length defined by the VALIDVARNAME= system option.

PREPLOT

plots the factor pattern before rotation. This option produces printer plots. High-quality ODS graphical plots for factor patterns can be requested with the **PLOTS=PRELOADINGS** option.

PREROTATE=*name*

PRE=*name*

specifies the prerotation method for the option **ROTATE=PROMAX**. Any rotation method other than PROMAX or PROCUSTES can be used. The default is PREROTATE=VARIMAX. If a previously rotated pattern is read using the option **METHOD=PATTERN**, you should specify the PREROTATE=NONE option.

PRINT

displays the input factor pattern or scoring coefficients and related statistics. In oblique cases, the reference and factor structures are computed and displayed. The PRINT option is effective only with the option **METHOD=PATTERN** or **METHOD=SCORE**.

PRIORS=*name*

specifies a method for computing prior communality estimates. You can specify numeric values for the prior communality estimates by using the PRIORS statement. Valid values for *name* are as follows:

ASMC A	sets the prior communality estimates proportional to the squared multiple correlations but adjusted so that their sum is equal to that of the maximum absolute correlations (Cureton 1968).
INPUT I	reads the prior communality estimates from the first observation with either <code>_TYPE_='PRIORS'</code> or <code>_TYPE_='COMMUNAL'</code> in the DATA= data set (which cannot be TYPE=DATA).
MAX M	sets the prior communality estimate for each variable to its maximum absolute correlation with any other variable.
ONE O	sets all prior communalities to 1.0.

RANDOM R	sets the prior communality estimates to pseudo-random numbers uniformly distributed between 0 and 1.
SMC S	sets the prior communality estimate for each variable to its squared multiple correlation with all other variables.

The default prior communality estimates are as follows:

METHOD=	PRIORS=
PRINCIPAL	ONE
PRINIT	ONE
ALPHA	SMC
ULS	SMC
ML	SMC
HARRIS	(not applicable)
IMAGE	(not applicable)
PATTERN	(not applicable)
SCORE	(not applicable)

By default, the options **METHOD=PRINIT**, **METHOD=ULS**, **METHOD=ALPHA**, and **METHOD=ML** stop iterating and set the number of factors to 0 if an estimated communality exceeds 1. The options **HEYWOOD** and **ULTRAHEYWOOD** allow processing to continue.

PROPORTION=*p*

PERCENT=*p*

P=*p*

specifies the proportion of common variance to be accounted for by the retained factors. The proportion of common variance is computed using the total prior communality estimates as the basis. If the value is greater than one, it is interpreted as a percentage and divided by 100. The options **PROPORTION=0.75** and **PERCENT=75** are equivalent. The default value is 1.0 or 100%. You cannot specify the **PROPORTION=** option with the **METHOD=PATTERN** or **METHOD=SCORE** option. If you specify two or more of the **PROPORTION=**, **NFACTORS=**, and **MINEIGEN=** options, the number of factors retained is the minimum number satisfying any of the criteria.

RANDOM=*n*

specifies a positive integer as a starting value for the pseudo-random number generator for use with the option **PRIORS=RANDOM**. If you do not specify the **RANDOM=** option, the time of day is used to initialize the pseudo-random number sequence. Valid values must be integers ≥ 1 .

RCONVERGE=*p*

RCONV=*p*

specifies the convergence criterion for rotation cycles. Rotation stops when the scaled change of the simplicity function value is less than the **RCONVERGE=** value. The default convergence criterion is

$$|f_{new} - f_{old}|/K < \epsilon$$

where f_{new} and f_{old} are simplicity function values of the current cycle and the previous cycle, respectively, $K = \max(1, |f_{old}|)$ is a scaling factor, and ϵ is 1E-9 by default and is modified by the RCONVERGE= value.

REORDER

RE

causes the rows (variables) of various factor matrices to be reordered on the output. Variables with their highest absolute loading (reference structure loading for oblique rotations) on the first factor are displayed first, from largest to smallest loading, followed by variables with their highest absolute loading on the second factor, and so on. The order of the variables in the output data set is not affected. The factors are not reordered.

RESIDUALS

RES

displays the residual correlation matrix and the associated partial correlation matrix. The diagonal elements of the residual correlation matrix are the unique variances.

RITER=*n*

specifies the maximum number of cycles *n* for factor rotation. Except for promax and Procrustes, you can use the RITER= option with all rotation methods. The default *n* is the maximum between 10 times the number of variables and 100.

ROTATE=*name*

R=*name*

specifies the rotation method. The default is ROTATE=NONE.

Valid *names* for orthogonal rotations are as follows:

BIQUARTIMAX | BIQMAX specifies orthogonal biquartimax rotation. This corresponds to the specification ROTATE=ORTHOMAX(.5).

EQUAMAX | E specifies orthogonal equamax rotation. This corresponds to the specification ROTATE=ORTHOMAX with **GAMMA=number of factors/2**.

FACTORPARSIMAX | FPA specifies orthogonal factor parsimax rotation. This corresponds to the specification ROTATE=ORTHOMAX with **GAMMA=number of variables**.

NONE | N specifies that no rotation be performed, leaving the original orthogonal solution.

ORTHCF(*p1,p2*) | ORCF(*p1,p2*) specifies the orthogonal Crawford-Ferguson rotation with the weights *p1* and *p2* for variable parsimony and factor parsimony, respectively. See the definitions of weights in the section “[Simplicity Functions for Rotations](#)” on page 2244.

ORTHGENCF(*p1,p2,p3,p4*) | ORGENCF(*p1,p2,p3,p4*) specifies the orthogonal generalized Crawford-Ferguson rotation with the four weights *p1*, *p2*, *p3*, and *p4*. See the definitions of weights in the section “[Simplicity Functions for Rotations](#)” on page 2244.

ORTHOMAX<(p)> | ORMAX<(p)> specifies the orthomax rotation with orthomax weight *p*. If ROTATE=ORTHOMAX is used, the default *p* value is 1 unless specified otherwise in the **GAMMA=** option. Alternatively, ROTATE=ORTHOMAX(*p*) specifies *p* as the orthomax weight or the **GAMMA=** value. See the definition of the orthomax weight in the section “[Simplicity Functions for Rotations](#)” on page 2244.

PARSIMAX | PA specifies orthogonal parsimax rotation. This corresponds to the specification ROTATE=ORTHOMAX with

$$\text{GAMMA} = \frac{nvar \times (nfact - 1)}{nvar + nfact - 2}$$

where *nvar* is the number of variables and *nfact* is the number of factors.

QUARTIMAX | QMAX | Q specifies orthogonal quartimax rotation. This corresponds to the specification ROTATE=ORTHOMAX(0).

VARIMAX | V specifies orthogonal varimax rotation. This corresponds to the specification ROTATE=ORTHOMAX with **GAMMA=1**.

Valid *names* for oblique rotations are as follows:

BIQUARTIMIN | BIQMIN specifies biquartimin rotation. It corresponds to the specification ROTATE=OBLIMIN(.5) or ROTATE=OBLIMIN with **TAU=0.5**.

COVARIMIN | CVMIN specifies covarimin rotation. It corresponds to the specification ROTATE=OBLIMIN(1) or ROTATE=OBLIMIN with **TAU=1**.

HK<(p)> | H<(p)> specifies Harris-Kaiser case II orthoblique rotation. When specifying this option, you can use the **HKPOWER=** option to set the power of the square roots of the eigenvalues by which the eigenvectors are scaled, assuming that the factors are extracted by the principal factor method. For other extraction methods, the unrotated factor pattern is column normalized. The power is then applied to the column normalizing constants, instead of the eigenvalues. You can also use ROTATE=HK(*p*), with *p* representing the **HKPOWER=** value. The default associated orthogonal rotation with ROTATE=HK is the varimax rotation without Kaiser normalization. You might associate the Harris-Kaiser with other orthogonal rotations by using the ROTATE= option together with the **HKPOWER=** option.

OBBIQUARTIMAX | OBIQMAX specifies oblique biquartimax rotation.

OBEQUAMAX | OE specifies oblique equamax rotation.

OBFACORPARSIMAX | OFPA specifies oblique factor parsimax rotation.

OBLICF(*p1,p2*) | OBCF(*p1,p2*) specifies the oblique Crawford-Ferguson rotation with the weights *p1* and *p2* for variable parsimony and factor parsimony, respectively. See the definitions of weights in the section “[Simplicity Functions for Rotations](#)” on page 2244.

OBLIGENCF(*p1,p2,p3,p4*) | OBGENCF(*p1,p2,p3,p4*) specifies the oblique generalized Crawford-Ferguson rotation with the four weights *p1*, *p2*, *p3*, and *p4*. See the definitions of weights in the section “[Simplicity Functions for Rotations](#)” on page 2244.

OBLIMIN<(p)> | OBMIN<(p)> specifies the oblimin rotation with oblimin weight *p*. If ROTATE=OBLIMIN is used, the default *p* value is zero unless specified otherwise in the **TAU=** option. Alternatively, ROTATE=OBLIMIN(*p*) specifies *p* as the oblimin weight or the **TAU=** value. See the definition of the oblimin weight in the section “[Simplicity Functions for Rotations](#)” on page 2244.

OBPARSIMAX | OPA specifies oblique parsimax rotation.

OBQUARTIMAX | **OQMAX** specifies oblique quartimax rotation. This is the same as the **QUARTIMIN** method.

OBVARIMAX | **OV** specifies oblique varimax rotation.

PROCRUSTES specifies oblique Procrustes rotation with the target pattern provided by the **TARGET=** data set. The unrestricted least squares method is used with factors scaled to unit variance after rotation.

PROMAX<(*p*)> | **P**<(*p*)> specifies oblique promax rotation. You can use the **PREROTATE=** option to set the desirable prerotation method, orthogonal or oblique. When used with **ROTATE=PROMAX**, the **POWER=** option lets you specify the power for forming the target. You can also use **ROTATE=PROMAX**(*p*), where *p* represents the **POWER=** value.

QUARTIMIN | **QMIN** specifies quartimin rotation. It is the same as the oblique quartimax method. It also corresponds to the specification **ROTATE=OBLIMIN**(0) or **ROTATE=OBLIMIN** with **TAU=0**.

ROUND

prints correlation and loading matrices with entries multiplied by 100 and rounded to the nearest integer. The exact values can be obtained from the **OUTSTAT=** and ODS output data sets. The **ROUND** option also flags absolute values larger than the **FLAG=** value with an asterisk in correlation and loading matrices (see the **FLAG=** option). If the **FLAG=** option is not specified, the root mean square of all the values in the matrix printed is used as the default **FLAG=** value. The **ROUND** option has no effect when standard errors or confidence intervals are also printed.

SCORE

displays the factor scoring coefficients. The squared multiple correlation of each factor with the variables is also displayed except in the case of unrotated principal components. The **SCORE** option also outputs the factor scoring coefficients in the **_TYPE_=SCORE** or **_TYPE_=USCORE** observations in the **OUTSTAT=** data set. Unless you specify the **NOINT** option in **PROC FACTOR**, the scoring coefficients should be applied to standardized variables—variables that are centered by subtracting the original variable means and then divided by the original variable standard deviations. With the **NOINT** option, the scoring coefficients should be applied to data without centering.

SCREE

displays a scree plot of the eigenvalues (Cattell 1966, 1978; Cattell and Vogelman 1977; Horn and Engstrom 1979). This option produces printer plots. High-quality scree plots can be requested with the **PLOTS=SCREE** option.

SE

STDERR

computes standard errors for various classes of unrotated and rotated solutions under the maximum likelihood estimation.

SIMPLE

S

displays means, standard deviations, and the number of observations.

SINGULAR= p **SING= p**

specifies the singularity criterion, where $0 < p < 1$. The default value is $1E-8$.

TARGET=*SAS-data-set*

specifies an input data set containing the target pattern for Procrustes rotation (see the description of the **ROTATE=** option). The TARGET= data set must contain variables with the same names as those being factored. Each observation in the TARGET= data set becomes one column of the target factor pattern. Missing values are treated as zeros. The **_NAME_** and **_TYPE_** variables are not required and are ignored if present.

TAU= p

specifies the oblimin weight used with the option **ROTATE=OBLIMIN** or **PREROTATE=OBLIMIN**. Alternatively, you can use **ROTATE=OBLIMIN(p)** with p representing the oblimin weight. There is no restriction on valid values for the oblimin weight, although for practical purposes a negative or zero value is recommended. The default TAU= value is 0, resulting in the quartimin rotation. See the section “[Simplicity Functions for Rotations](#)” on page 2244 for more details.

ULTRAHEYWOOD**ULTRA**

allows communalities to exceed 1. The ULTRAHEYWOOD option can cause convergence problems because communalities can become extremely large, and ill-conditioned Hessians might occur. See the section “[Heywood Cases and Other Anomalies about Communality Estimates](#)” on page 2248 for a discussion of Heywood cases.

VARDEF=DF | N | WDF | WEIGHT | WGT

specifies the divisor used in the calculation of variances and covariances. The default value is VARDEF=DF. The values and associated divisors are displayed in the following table where $i=0$ if the **NOINT** option is used and $i=1$ otherwise, and where k is the number of partial variables specified in the PARTIAL statement.

Value	Description	Divisor
DF	degrees of freedom	$n - k - i$
N	number of observations	$n - k$
WDF	sum of weights DF	$\sum_i w_i - k - i$
WEIGHT WGT	sum of weights	$\sum_i w_i - k$

WEIGHT

factors a weighted correlation or covariance matrix. The WEIGHT option can be used only with the **METHOD=PRINCIPAL**, **METHOD=PRINIT**, **METHOD=ULS**, or **METHOD=IMAGE** option. The input data set must be of type CORR, UCORR, COV, UCOV, or FACTOR, and the variable weights are obtained from an observation with **_TYPE_='WEIGHT'**.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC FACTOR to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the FACTOR procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

If you specify the **TARGET=** option and the **TARGET=** data set does not contain any of the BY variables, then the entire **TARGET=** data set is used as a Procrustean target for each BY group in the **DATA=** data set.

If the **TARGET=** data set contains some but not all of the BY variables, or if some BY variables do not have the same type or length in the **TARGET=** data set as in the **DATA=** data set, then PROC FACTOR displays an error message and stops.

If all the BY variables appear in the **TARGET=** data set with the same type and length as in the **DATA=** data set, then each BY group in the **TARGET=** data set is used as a Procrustean target for the corresponding BY group in the **DATA=** data set. The BY groups in the **TARGET=** data set must be in the same order as in the **DATA=** data set. If you specify the NOTSORTED option in the BY statement, there must be identical BY groups in the same order in both data sets. If you do not specify the NOTSORTED option, some BY groups can appear in one data set but not in the other.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FREQ Statement

FREQ *variable* ;

If a variable in the data set represents the frequency of occurrence for the other values in the observation, include the variable's name in a FREQ statement. The procedure then treats the data set as if each observation appears n times, where n is the value of the FREQ variable for the observation. The total number of observations is considered to be equal to the sum of the FREQ variable when the procedure determines degrees of freedom for significance probabilities.

If the value of the FREQ variable is missing or is less than one, the observation is not used in the analysis. If the value is not an integer, the value is truncated to an integer.

The WEIGHT and FREQ statements have a similar effect, except in determining the number of observations for significance tests.

PARTIAL Statement

PARTIAL *variables* ;

If you want the analysis to be based on a partial correlation or covariance matrix, use the PARTIAL statement to list the variables that are used to partial out the variables in the analysis.

PRIORS Statement

PRIORS *communalities* ;

The PRIORS statement specifies numeric values between 0.0 and 1.0 for the prior communality estimates for each variable. The first numeric value corresponds to the first variable in the VAR statement, the second value to the second variable, and so on. The number of numeric values must equal the number of variables. For example:

```
proc factor;  
  var      x  y  z;  
  priors .7 .8 .9;  
run;
```

You can specify various methods for computing prior communality estimates with the **PRIORS=** option in the PROC FACTOR statement. See the description of that option for more information about the default prior communality estimates.

VAR Statement

VAR *variables* ;

The VAR statement specifies the numeric variables to be analyzed. If the VAR statement is omitted, all numeric variables not specified in other statements are analyzed.

WEIGHT Statement

WEIGHT *variable* ;

If you want to use relative weights for each observation in the input data set, specify a variable containing weights in a WEIGHT statement. This is often done when the variance associated with each observation is different and the values of the weight variable are proportional to the reciprocals of the variances. If a variable value is negative or is missing, it is excluded from the analysis.

Details: FACTOR Procedure

Input Data Set

The FACTOR procedure can read an ordinary SAS data set containing raw data or a special data set specified as a TYPE=CORR, TYPE=UCORR, TYPE=SSCP, TYPE=COV, TYPE=UCOV, or TYPE=FACTOR data set containing previously computed statistics. A TYPE=CORR data set can be created by the CORR procedure or various other procedures such as the PRINCOMP procedure. It contains means, standard deviations, the sample size, the correlation matrix, and possibly other statistics if it is created by some procedure other than PROC CORR. A TYPE=COV data set is similar to a TYPE=CORR data set but contains a covariance matrix. A TYPE=UCORR or TYPE=UCOV data set contains a correlation or covariance matrix that is not corrected for the mean. The default VAR variable list does not include Intercept if the DATA= data set is TYPE=SSCP. If the Intercept variable is explicitly specified in the VAR statement with a TYPE=SSCP data set, the NOINT option is activated. A TYPE=FACTOR data set can be created by the FACTOR procedure and is described in the section “Output Data Sets” on page 2241.

If your data set has many observations and you plan to run FACTOR several times, you can save computer time by first creating a TYPE=CORR data set and using it as input to PROC FACTOR, as in the following statements:

```
proc corr data=raw out=correl;      /* create TYPE=CORR data set */
proc factor data=correl method=ml; /* maximum likelihood      */
proc factor data=correl;           /* principal components  */
```

The data set created by the CORR procedure is automatically given the TYPE=CORR data set option, so you do not have to specify TYPE=CORR. However, if you use a DATA step with a SET statement to modify the correlation data set, you must use the TYPE=CORR attribute in the new data set. You can use a VAR statement with PROC FACTOR when reading a TYPE=CORR data set to select a subset of the variables or change the order of the variables.

Problems can arise from using the CORR procedure when there are missing data. By default, PROC CORR computes each correlation from all observations that have values present for the pair of variables involved (pairwise deletion). The resulting correlation matrix might have negative eigenvalues. If you specify the NOMISS option with the CORR procedure, observations with any missing values are completely omitted from the calculations (listwise deletion), and there is no danger of negative eigenvalues.

PROC FACTOR can also create a TYPE=FACTOR data set, which includes all the information in a TYPE=CORR data set, and use it for repeated analyses. For a TYPE=FACTOR data set, the default value of the METHOD= option is PATTERN. The following PROC FACTOR statements produce the same results as the previous example:

```
proc factor data=raw method=ml outstat=fact; /* max. likelihood */
proc factor data=fact method=prin;          /* principal components */
```

You can use a TYPE=FACTOR data set to try several different rotation methods on the same data without repeatedly extracting the factors. In the following example, the second and third PROC FACTOR statements use the data set fact created by the first PROC FACTOR statement:

```
proc factor data=raw outstat=fact; /* principal components */
proc factor rotate=varimax;      /* varimax rotation      */
proc factor rotate=quartimax;    /* quartimax rotation  */
```

You can create a TYPE=CORR, TYPE=UCORR, or TYPE=FACTOR data set in a DATA step for PROC FACTOR to read as input. For example, in the following a TYPE=CORR data set is created and is read as input data set by the subsequent PROC FACTOR statement:

```
data correl(type=corr);
  _TYPE_='CORR';
  input _NAME_ $ x y z;
  datalines;
x  1.0  .  .
y  .7  1.0  .
z  .5  .4  1.0
;
proc factor;
run;
```

Be sure to specify the TYPE= option in parentheses after the data set name in the DATA statement and include the _TYPE_ and _NAME_ variables. In a TYPE=CORR data set, only the correlation matrix (_TYPE_='CORR') is necessary. It can contain missing values as long as every pair of variables has at least one nonmissing value.

You can also create a TYPE=FACTOR data set containing only a factor pattern (_TYPE_='PATTERN') and use the FACTOR procedure to rotate it, as these statements show:

```
data pat(type=factor);
  _TYPE_='PATTERN';
  input _NAME_ $ x y z;
  datalines;
factor1  .5  .7  .3
factor2  .8  .2  .8
;
proc factor rotate=promax prerotate=none;
run;
```

If the input factors are oblique, you must also include the interfactor correlation matrix with _TYPE_='FCORR', as shown here:

```
data pat(type=factor);
  input _TYPE_ $ _NAME_ $ x y z;
  datalines;
pattern factor1  .5  .7  .3
pattern factor2  .8  .2  .8
fcorr  factor1  1.0  .2  .
fcorr  factor2  .2  1.0  .
;
proc factor rotate=promax prerotate=none;
run;
```

Some procedures, such as the PRINCOMP and CANDISC procedures, produce TYPE=CORR or TYPE=UCORR data sets containing scoring coefficients (_TYPE_='SCORE' or _TYPE_='USCORE'). These coefficients can be input to PROC FACTOR and rotated by using the **METHOD=SCORE** option, as in the following statements:

```
proc princomp data=raw n=2 outstat=prin;
run;
proc factor data=prin method=score rotate=varimax;
run;
```

Notice that the input data set `prin` must contain the correlation matrix as well as the scoring coefficients.

Output Data Sets

The OUT= Data Set

The **OUT=** data set contains all the data in the **DATA=** data set plus new variables called `Factor1`, `Factor2`, and so on, containing estimated factor scores. Each estimated factor score is computed as a linear combination of the standardized values of the variables that are factored. The coefficients are always displayed if the **OUT=** option is specified, and they are labeled “Standardized Scoring Coefficients.”

If partial variables are specified in the **PARTIAL** statement, the factor analysis is on the residuals of the variables, which are regressed on the partial variables. In this case, the **OUT=** data set also contains the (unstandardized) residuals, which are prefixed by `R_` by default. For example, the residual of variable `X` is named `R_X` in the **OUT=** data set. You might also assign the prefix by the **PARPREFIX=** option. Because the residuals are factor-analyzed, the estimated factor scores are computed as linear combinations of the standardized values of the residuals, but not the original variables.

The OUTSTAT= Data Set

The **OUTSTAT=** data set is similar to the **TYPE=CORR** or **TYPE=UCORR** data set produced by the **CORR** procedure, but it is a **TYPE=FACTOR** data set and it contains many results in addition to those produced by **PROC CORR**. The **OUTSTAT=** data set contains observations with `_TYPE_='UCORR'` and `_TYPE_='USTD'` if you specify the **NOINT** option.

The output data set contains the following variables:

- the **BY** variables, if any
- two new character variables, `_TYPE_` and `_NAME_`
- the variables analyzed—those in the **VAR** statement, or, if there is no **VAR** statement, all numeric variables not listed in any other statement. If partial variables are specified in the **PARTIAL** statement, the residuals are included instead. By default, the residual variable names are prefixed by `R_`, unless you specify something different in the **PARPREFIX=** option.

Each observation in the output data set contains some type of statistic as indicated by the `_TYPE_` variable. The `_NAME_` variable is blank except where otherwise indicated. The values of the `_TYPE_` variable are as follows:

MEAN	means
STD	standard deviations
USTD	uncorrected standard deviations

N	sample size
CORR	correlations. The <code>_NAME_</code> variable contains the name of the variable corresponding to each row of the correlation matrix.
UCORR	uncorrected correlations. The <code>_NAME_</code> variable contains the name of the variable corresponding to each row of the uncorrected correlation matrix.
IMAGE	image coefficients. The <code>_NAME_</code> variable contains the name of the variable corresponding to each row of the image coefficient matrix.
IMAGECOV	image covariance matrix. The <code>_NAME_</code> variable contains the name of the variable corresponding to each row of the image covariance matrix.
COMMUNAL	final communality estimates
PRIORS	prior communality estimates, or estimates from the last iteration for iterative methods
WEIGHT	variable weights
SUMWGT	sum of the variable weights
EIGENVAL	eigenvalues
UNROTATE	unrotated factor pattern. The <code>_NAME_</code> variable contains the name of the factor.
SE_UNROT	standard error estimates for the unrotated loadings. The <code>_NAME_</code> variable contains the name of the factor.
RESIDUAL	residual correlations. The <code>_NAME_</code> variable contains the name of the variable corresponding to each row of the residual correlation matrix.
PRETRANS	transformation matrix from prerotation. The <code>_NAME_</code> variable contains the name of the factor.
PREFCORR	prerotated interfactor correlations. The <code>_NAME_</code> variable contains the name of the factor.
SE_PREFC	standard error estimates for prerotated interfactor correlations. The <code>_NAME_</code> variable contains the name of the factor.
PREROTAT	prerotated factor pattern. The <code>_NAME_</code> variable contains the name of the factor.
SE_PREPA	standard error estimates for the prerotated loadings. The <code>_NAME_</code> variable contains the name of the factor.
PRERCORR	prerotated reference axis correlations. The <code>_NAME_</code> variable contains the name of the factor.
PREREFER	prerotated reference structure. The <code>_NAME_</code> variable contains the name of the factor.
PRESTRUC	prerotated factor structure. The <code>_NAME_</code> variable contains the name of the factor.
SE_PREST	standard error estimates for prerotated structure loadings. The <code>_NAME_</code> variable contains the name of the factor.
PRESCORE	prerotated scoring coefficients. The <code>_NAME_</code> variable contains the name of the factor.
TRANSFOR	transformation matrix from rotation. The <code>_NAME_</code> variable contains the name of the factor.
FCORR	interfactor correlations. The <code>_NAME_</code> variable contains the name of the factor.
SE_FCORR	standard error estimates for interfactor correlations. The <code>_NAME_</code> variable contains the name of the factor.

PATTERN	factor pattern. The <code>_NAME_</code> variable contains the name of the factor.
SE_PAT	standard error estimates for the rotated loadings. The <code>_NAME_</code> variable contains the name of the factor.
RCORR	reference axis correlations. The <code>_NAME_</code> variable contains the name of the factor.
REFERENC	reference structure. The <code>_NAME_</code> variable contains the name of the factor.
STRUCTUR	factor structure. The <code>_NAME_</code> variable contains the name of the factor.
SE_STRUC	standard error estimates for structure loadings. The <code>_NAME_</code> variable contains the name of the factor.
SCORE	scoring coefficients to be applied to standardized variables if the SCORE option is specified on the PROC FACTOR statement. The <code>_NAME_</code> variable contains the name of the factor.
USCORE	scoring coefficients to be applied without subtracting the mean from the raw variables if the SCORE option is specified on the PROC FACTOR statement. The <code>_NAME_</code> variable contains the name of the factor.

Confidence Intervals and the Saliency of Factor Loadings

The traditional approach to determining salient loadings (loadings that are considered large in absolute values) employs rules of thumb such as 0.3 or 0.4. However, this does not use the statistical evidence efficiently. The asymptotic normality of the distribution of factor loadings enables you to construct confidence intervals to gauge the saliency of factor loadings. To guarantee the range-respecting properties of confidence intervals, a transformation procedure such as in CEFA (Browne et al. 2008) is used. For example, because the orthogonal rotated factor loading θ must be bounded between -1 and $+1$, the Fisher transformation

$$\varphi = \frac{1}{2} \log\left(\frac{1 + \theta}{1 - \theta}\right)$$

is employed so that φ is an unbounded parameter. Assuming the asymptotic normality of $\hat{\varphi}$, a symmetric confidence interval for φ is constructed. Then, a back-transformation on the confidence limits yields an asymmetric confidence interval for θ . Applying the results of Browne (1982), a $(1-\alpha)100\%$ confidence interval for the orthogonal factor loading θ is

$$(\hat{\theta}_l = \frac{a/b - 1}{a/b + 1}, \hat{\theta}_u = \frac{a \times b - 1}{a \times b + 1})$$

where

$$a = \frac{1 + \hat{\theta}}{1 - \hat{\theta}}, \quad b = \exp(z_{\alpha/2} \times \frac{2\hat{\sigma}}{1 - \hat{\theta}^2})$$

and $\hat{\theta}$ is the estimated factor loading, $\hat{\sigma}$ is the standard error estimate of the factor loading, and $z_{\alpha/2}$ is the $(1 - \alpha/2)100$ percentile point of a standard normal distribution.

Once the confidence limits are constructed, you can use the corresponding coverage displays for determining the salience of the variable-factor relationship. In a coverage display, the **COVER=** value is represented by an asterisk (*). The following table summarizes various displays and their interpretations.

Table 35.2 Interpretations of the Coverage Displays

Positive Estimate	Negative Estimate	COVER=0 Specified	Interpretation
[0]*	*[0]		The estimate is not significantly different from zero, and the CI covers a region of values that are smaller in magnitude than the COVER= value. This is strong statistical evidence for the nonsalience of the variable-factor relationship.
0[]*	*[]0		The estimate is significantly different from zero, but the CI covers a region of values that are smaller in magnitude than the COVER= value. This is strong statistical evidence for the nonsalience of the variable-factor relationship.
[0*]	[*0]	[0]	The estimate is not significantly different from zero or the COVER= value. The population value might have been larger or smaller in magnitude than the COVER= value. There is no statistical evidence for the salience of the variable-factor relationship.
0[*]	[*]0		The estimate is significantly different from zero but not from the COVER= value. This is marginal statistical evidence for the salience of the variable-factor relationship.
0*[]	[]*0	0[] or []0	The estimate is significantly different from zero, and the CI covers a region of values that are larger in magnitude than the COVER= value. This is strong statistical evidence for the salience of the variable-factor relationship.

See [Example 35.4](#) for an illustration of the use of confidence intervals for interpreting factors.

Simplicity Functions for Rotations

To rotate a factor pattern is to apply a nonsingular linear transformation to the unrotated factor pattern matrix. An optimal transformation is usually defined as a minimum or maximum point of a simplicity function. Different rotation methods are based on different simplicity functions employed.

For the promax or the Procrustes rotation, the simplicity function used is the sum of squared differences between the rotated factor pattern and the target matrix. The optimal transformation is obtained by minimizing this simplicity function with respect to the choices of all possible transformation.

For the class of the generalized Crawford-Ferguson family Jennrich (1973), the simplicity function being optimized is

$$f = k_1 Z + k_2 H + k_3 V + k_4 Q$$

where

$$Z = \left(\sum_j \sum_i b_{ij}^2 \right)^2, \quad H = \sum_i \left(\sum_j b_{ij}^2 \right)^2$$

$$V = \sum_j \left(\sum_i b_{ij}^2 \right)^2, \quad Q = \sum_j \sum_i b_{ij}^4$$

k_1, k_2, k_3 , and k_4 are constants, and b_{ij} represents an element of the rotated pattern matrix. Except for specialized research purposes, it is uncommon in practice to use this simplicity function directly for rotation. However, this simplicity function reduces to many well-known classes of rotations. One of these is the Crawford-Ferguson family Crawford and Ferguson (1970), which minimizes

$$f_{cf} = c_1(H - Q) + c_2(V - Q)$$

where c_1 and c_2 are constants, $(H - Q)$ represents variable (row) parsimony, and $(V - Q)$ represents factor (column) parsimony. Therefore, the relative importance of both the variable parsimony and of the factor parsimony is adjusted using the constants c_1 and c_2 . The orthomax class (see Harman 1976) maximizes the function

$$f_{or} = pQ - \gamma V$$

where γ is the orthomax weight and is usually between 0 and the number of variables p . The oblimin class minimizes the function

$$f_{ob} = p(H - Q) - \tau(Z - V)$$

where τ is the oblimin weight. For practical purposes, a negative or zero value for τ is recommended.

All of the preceding definitions are for rotations without row normalization. For rotations with Kaiser normalization, the definition of b_{ij} is replaced by b_{ij}/h_i , where h_i is the communality estimate of variable i .

Missing Values

If the **DATA=** data set contains data (rather than a matrix or factor pattern), then observations with missing values for any variables in the analysis are omitted from the computations. If a correlation or covariance matrix is read, it can contain missing values as long as every pair of variables has at least one nonmissing entry. Missing values in a pattern or scoring coefficient matrix are treated as zeros.

Cautions

- The amount of time that FACTOR takes is roughly proportional to the cube of the number of variables. Factoring 100 variables, therefore, takes about 1,000 times as long as factoring 10 variables. Iterative methods (PRINIT, ALPHA, ULS, ML) can also take 100 times as long as noniterative methods (PRINCIPAL, IMAGE, HARRIS).
- No computer program is capable of reliably determining the optimal number of factors, since the decision is ultimately subjective. You should not blindly accept the number of factors obtained by default; instead, use your own judgment to make a decision.
- Singular correlation matrices cause problems with the options **PRIORS=SMC** and **METHOD=ML**. Singularities can result from using a variable that is the sum of other variables, coding too many dummy variables from a classification variable, or having more variables than observations.
- If you use the CORR procedure to compute the correlation matrix and there are missing data and the NOMISS option is not specified, then the correlation matrix might have negative eigenvalues.
- If a TYPE=CORR, TYPE=UCORR, or TYPE=FACTOR data set is copied or modified using a DATA step, the new data set does not automatically have the same TYPE as the old data set. You must specify the TYPE= data set option in the DATA statement. If you try to analyze a data set that has lost its TYPE=CORR attribute, PROC FACTOR displays a warning message saying that the data set contains _NAME_ and _TYPE_ variables but analyzes the data set as an ordinary SAS data set.
- For a TYPE=FACTOR data set, the default is **METHOD=PATTERN**, not **METHOD=PRIN**.

Factor Scores

The FACTOR procedure can compute estimated factor scores directly if you specify the **NFACTORS=** and **OUT=** options, or indirectly using the SCORE procedure. The latter method is preferable if you use the FACTOR procedure interactively to determine the number of factors, the rotation method, or various other aspects of the analysis. To compute factor scores for each observation by using the SCORE procedure, do the following:

- Use the **SCORE** option in the PROC FACTOR statement.
- Create a TYPE=FACTOR output data set with the **OUTSTAT=** option.
- Use the SCORE procedure with both the raw data and the TYPE=FACTOR data set.
- Do not use the TYPE= option in the PROC SCORE statement.

For example, the following statements could be used:

```
proc factor data=raw score outstat=fact;
run;
proc score data=raw score=fact out=scores;
run;
```

or

```
proc corr data=raw out=correl;
run;
proc factor data=correl score outstat=fact;
run;
proc score data=raw score=fact out=scores;
run;
```

For a more detailed example, see [Example 82.1](#) in Chapter 82, “The SCORE Procedure.”

A component analysis (principal, image, or Harris) produces scores with mean zero and variance one. If you have done a common factor analysis, the true factor scores have mean zero and variance one, but the computed factor scores are only estimates of the true factor scores. These estimates have mean zero but variance equal to the squared multiple correlation of the factor with the variables. The estimated factor scores might have small nonzero correlations even if the true factors are uncorrelated.

Variable Weights and Variance Explained

A principal component analysis of a correlation matrix treats all variables as equally important. A principal component analysis of a covariance matrix gives more weight to variables with larger variances. A principal component analysis of a covariance matrix is equivalent to an analysis of a weighted correlation matrix, where the weight of each variable is equal to its variance. Variables with large weights tend to have larger loadings on the first component and smaller residual correlations than variables with small weights.

You might want to give weights to variables by using values other than their variances. Mulaik (1972) explains how to obtain a maximally reliable component by means of a weighted principal component analysis. With the FACTOR procedure, you can indirectly give arbitrary weights to the variables by using the COV option and rescaling the variables to have variance equal to the desired weight, or you can give arbitrary weights directly by using the **WEIGHT** option and including the weights in a TYPE=CORR data set.

Arbitrary variable weights can be used with the **METHOD=PRINCIPAL**, **METHOD=PRINT**, **METHOD=ULS**, or **METHOD=IMAGE** option. Alpha and ML factor analyses compute variable weights based on the communalities (Harman 1976, pp. 217–218). For alpha factor analysis, the weight of a variable is the reciprocal of its communality. In ML factor analysis, the weight is the reciprocal of the uniqueness. Harris component analysis uses weights equal to the reciprocal of one minus the squared multiple correlation of each variable with the other variables.

For uncorrelated factors, the variance explained by a factor can be computed with or without taking the weights into account. The usual method for computing variance accounted for by a factor is to take the sum of squares of the corresponding column of the factor pattern, yielding an unweighted result. If the square of each loading is multiplied by the weight of the variable before the sum is taken, the result is the weighted variance explained, which is equal to the corresponding eigenvalue except in image analysis. Whether the weighted or unweighted result is more important depends on the purpose of the analysis.

In the case of correlated factors, the variance explained by a factor can be computed with or without taking the other factors into account. If you want to ignore the other factors, the variance explained is given by the weighted or unweighted sum of squares of the appropriate column of the factor structure since the factor structure contains simple correlations. If you want to subtract the variance explained by the other factors from the amount explained by the factor in question (the Type II variance explained), you can take the weighted or unweighted sum of squares of the appropriate column of the reference structure because the reference structure contains semipartial correlations. There are other ways of measuring the variance explained. For example, given a prior ordering of the factors, you can eliminate from each factor the variance explained by previous factors and compute a Type I variance explained. Harman (1976, pp. 268–270) provides another method, which is based on direct and joint contributions.

Heywood Cases and Other Anomalies about Communality Estimates

Since communalities are squared correlations, you would expect them always to lie between 0 and 1. It is a mathematical peculiarity of the common factor model, however, that final communality estimates might exceed 1. If a communality equals 1, the situation is referred to as a Heywood case, and if a communality exceeds 1, it is an ultra-Heywood case. An ultra-Heywood case implies that some unique factor has negative variance, a clear indication that something is wrong. Possible causes include the following:

- bad prior communality estimates
- too many common factors
- too few common factors
- not enough data to provide stable estimates
- the common factor model is not an appropriate model for the data

An ultra-Heywood case renders a factor solution invalid. Factor analysts disagree about whether or not a factor solution with a Heywood case can be considered legitimate.

With `METHOD=PRINIT`, `METHOD=ULS`, `METHOD=ALPHA`, or `METHOD=ML`, the FACTOR procedure, by default, stops iterating and sets the number of factors to 0 if an estimated communality exceeds 1. To enable processing to continue with a Heywood or ultra-Heywood case, you can use the `HEYWOOD` or `ULTRAHEYWOOD` option in the PROC FACTOR statement. The `HEYWOOD` option sets the upper bound of any communality to 1, while the `ULTRAHEYWOOD` option allows communalities to exceed 1.

Theoretically, the communality of a variable should not exceed its reliability. Violation of this condition is called a quasi-Heywood case and should be regarded with the same suspicion as an ultra-Heywood case.

Elements of the factor structure and reference structure matrices can exceed 1 only in the presence of an ultra-Heywood case. On the other hand, an element of the factor pattern might exceed 1 in an oblique rotation.

The maximum likelihood method is especially susceptible to quasi- or ultra-Heywood cases. During the iteration process, a variable with high communality is given a high weight; this tends to increase its communality, which increases its weight, and so on.

It is often stated that the squared multiple correlation of a variable with the other variables is a lower bound to its communality. This is true if the common factor model fits the data perfectly, but it is not generally the case with real data. A final communality estimate that is less than the squared multiple correlation can, therefore, indicate poor fit, possibly due to not enough factors. It is by no means as serious a problem as an ultra-Heywood case. Factor methods that use the Newton-Raphson method can actually produce communalities less than 0, a result even more disastrous than an ultra-Heywood case.

The squared multiple correlation of a factor with the variables might exceed 1, even in the absence of ultra-Heywood cases. This situation is also cause for alarm. Alpha factor analysis seems to be especially prone to this problem, but it does not occur with maximum likelihood. If a squared multiple correlation is negative, there are too many factors retained.

With data that do not fit the common factor model perfectly, you can expect some of the eigenvalues to be negative. If an iterative factor method converges properly, the sum of the eigenvalues corresponding to rejected factors should be 0; hence, some eigenvalues are positive and some negative. If a principal factor analysis fails to yield any negative eigenvalues, the prior communality estimates are probably too large. Negative eigenvalues cause the cumulative proportion of variance explained to exceed 1 for a sufficiently large number of factors. The cumulative proportion of variance explained by the retained factors should be approximately 1 for principal factor analysis and should converge to 1 for iterative methods. Occasionally, a single factor can explain more than 100 percent of the common variance in a principal factor analysis, indicating that the prior communality estimates are too low.

If a squared canonical correlation or a coefficient alpha is negative, there are too many factors retained.

Principal component analysis, unlike common factor analysis, has none of these problems if the covariance or correlation matrix is computed correctly from a data set with no missing values. Various methods for missing value correlation or severe rounding of the correlations can produce negative eigenvalues in principal components.

Time Requirements

- n = number of observations
- v = number of variables
- f = number of factors
- i = number of iterations during factor extraction
- r = length of iterations during factor rotation

The time required to compute...	is roughly proportional to
an overall factor analysis	iv^3
the correlation matrix	nv^2
PRIORS=SMC or ASMC	v^3
PRIORS=MAX	v^2
eigenvalues	v^3
final eigenvectors	fv^2
generalized Crawford-Ferguson family of rotations, PROMAX, or HK	rvf^2
ROTATE=PROCRUSTES	vf^2

Each iteration in the PRINIT or ALPHA method requires computation of eigenvalues and f eigenvectors.

Each iteration in the ML or ULS method requires computation of eigenvalues and $v - f$ eigenvectors.

The amount of time that PROC FACTOR takes is roughly proportional to the cube of the number of variables. Factoring 100 variables, therefore, takes about 1000 times as long as factoring 10 variables. Iterative methods (PRINIT, ALPHA, ULS, ML) can also take 100 times as long as noniterative methods (PRINCIPAL, IMAGE, HARRIS).

Displayed Output

PROC FACTOR output includes the following.

- Input data type, numbers of records read and used for raw data input, number of observations (**NOBS=**) set in the PROC FACTOR statements, and the number of observations used in significance tests
- Mean and Std Dev (standard deviation) of each variable and the number of observations, if you specify the **SIMPLE** option
- Correlations, if you specify the **CORR** option
- Inverse Correlation Matrix, if you specify the **ALL** option
- Partial Correlations Controlling all other Variables (negative anti-image correlations), if you specify the **MSA** option. If the data are appropriate for the common factor model, the partial correlations should be small.
- Kaiser's Measure of Sampling Adequacy (Kaiser 1970; Kaiser and Rice 1974; Cerny and Kaiser 1977), both overall and for each variable, if you specify the **MSA** option. The **MSA** is a summary of how small the partial correlations are relative to the ordinary correlations. Values greater than 0.8 can be considered good. Values less than 0.5 require remedial action, either by deleting the offending variables or by including other variables related to the offenders.

- Prior Communality Estimates, unless 1.0s are used or unless you specify the **METHOD=IMAGE**, **METHOD=HARRIS**, **METHOD=PATTERN**, or **METHOD=SCORE** option
- Squared Multiple Correlations of each variable with all the other variables, if you specify the **METHOD=IMAGE** or **METHOD=HARRIS** option
- Image Coefficients, if you specify the **METHOD=IMAGE** option
- Image Covariance Matrix, if you specify the **METHOD=IMAGE** option
- Preliminary Eigenvalues based on the prior communalities, if you specify the **METHOD=PRINIT**, **METHOD=ALPHA**, **METHOD=ML**, or **METHOD=ULS** option. The table produced includes the Total and the Average of the eigenvalues, the Difference between successive eigenvalues, the Proportion of variation represented, and the Cumulative proportion of variation.
- the number of factors that are retained, unless you specify the **METHOD=PATTERN** or **METHOD=SCORE** option
- the Scree Plot of Eigenvalues, if you specify the **SCREE** option. The preliminary eigenvalues are used if you specify the **METHOD=PRINIT**, **METHOD=ALPHA**, **METHOD=ML**, or **METHOD=ULS** option.
- the iteration history, if you specify the **METHOD=PRINIT**, **METHOD=ALPHA**, **METHOD=ML**, or **METHOD=ULS** option. The table produced contains the iteration number (Iter); the Criterion being optimized (Jöreskog 1977); the Ridge value for the iteration if you specify the **METHOD=ML** or **METHOD=ULS** option; the maximum Change in any communality estimate; and the Communalities.
- Significance tests, if you specify the option **METHOD=ML**, including Bartlett's chi-square, df, and Prob > χ^2 for H_0 : No common factors and H_0 : factors retained are sufficient to explain the correlations. The H_0 test for no common factors is equivalent to Bartlett's test of sphericity. The variables should have an approximate multivariate normal distribution for the probability levels to be valid. Lawley and Maxwell (1971) suggest that the number of observations should exceed the number of variables by 50 or more, although Geweke and Singleton (1980) claim that as few as 10 observations are adequate with five variables and one common factor. Certain regularity conditions must also be satisfied for Bartlett's χ^2 test to be valid (Geweke and Singleton 1980), but in practice these conditions usually are satisfied. The notation Prob>chi**2 means "the probability under the null hypothesis of obtaining a greater χ^2 statistic than that observed." The chi-square value is displayed with and without Bartlett's correction.
- Akaike's Information Criterion, if you specify the **METHOD=ML** option. Akaike's information criterion (AIC) (Akaike 1973, 1974, 1987) is a general criterion for estimating the best number of parameters to include in a model when maximum likelihood estimation is used. The number of factors that yields the smallest value of AIC is considered best. Like the chi-square test, AIC tends to include factors that are statistically significant but inconsequential for practical purposes.
- Schwarz's Bayesian Criterion, if you specify the **METHOD=ML** option. Schwarz's Bayesian Criterion (SBC) (Schwarz 1978) is another criterion, similar to AIC, for determining the best number of parameters. The number of factors that yields the smallest value of SBC is considered best; SBC seems to be less inclined to include trivial factors than either AIC or the chi-square test.
- Tucker and Lewis's Reliability Coefficient, if you specify the **METHOD=ML** option (Tucker and Lewis 1973)

- Squared Canonical Correlations, if you specify the **METHOD=ML** option. These are the same as the squared multiple correlations for predicting each factor from the variables.
- Coefficient Alpha for Each Factor, if you specify the **METHOD=ALPHA** option
- Eigenvectors, if you specify the **EIGENVECTORS** or **ALL** option, unless you also specify the **METHOD=PATTERN** or **METHOD=SCORE** option
- Eigenvalues of the (Weighted) (Reduced) (Image) Correlation or Covariance Matrix, unless you specify the **METHOD=PATTERN** or **METHOD=SCORE** option. Included are the Total and the Average of the eigenvalues, the Difference between successive eigenvalues, the Proportion of variation represented, and the Cumulative proportion of variation.
- the Factor Pattern, which is equal to both the matrix of standardized regression coefficients for predicting variables from common factors and the matrix of correlations between variables and common factors since the extracted factors are uncorrelated. Standard error estimates are included if the **SE** option is specified with **METHOD=ML**. Confidence limits and coverage displays are included if **COVER=** option is specified with **METHOD=ML**.
- Variance explained by each factor, both Weighted and Unweighted, if variable weights are used
- Final Community Estimates, including the Total communality; or Final Community Estimates and Variable Weights, including the Total communality, both Weighted and Unweighted, if variable weights are used. Final communality estimates are the squared multiple correlations for predicting the variables from the estimated factors, and they can be obtained by taking the sum of squares of each row of the factor pattern, or a weighted sum of squares if variable weights are used.
- Residual Correlations with Uniqueness on the Diagonal, if you specify the **RESIDUAL** or **ALL** option
- Root Mean Square Off-diagonal Residuals, both Over-all and for each variable, if you specify the **RESIDUAL** or **ALL** option
- Partial Correlations Controlling Factors, if you specify the **RESIDUAL** or **ALL** option
- Root Mean Square Off-diagonal Partials, both Over-all and for each variable, if you specify the **RESIDUAL** or **ALL** option
- Plots of Factor Pattern for unrotated factors, if you specify the **PREPLOT** option. The number of plots is determined by the **NPLOT=** option.
- Variable Weights for Rotation, if you specify the **NORM=WEIGHT** option
- Factor Weights for Rotation, if you specify the **HKPOWER=** option
- Orthogonal Transformation Matrix, if you request an orthogonal rotation
- Rotated Factor Pattern, if you request an orthogonal rotation. Standard error estimates are included if the **SE** option is specified with **METHOD=ML**. Confidence limits and coverage displays are included if **COVER=** option is specified with **METHOD=ML**.
- Variance explained by each factor after rotation. If you request an orthogonal rotation and if variable weights are used, both weighted and unweighted values are produced.

- Target Matrix for Procrustean Transformation, if you specify the **ROTATE=PROMAX** or **ROTATE=PROCRUSTES** option
- the Procrustean Transformation Matrix, if you specify the **ROTATE=PROMAX** or **ROTATE=PROCRUSTES** option
- the Normalized Oblique Transformation Matrix, if you request an oblique rotation, which, for the option **ROTATE=PROMAX**, is the product of the prerotation and the Procrustes rotation
- Inter-factor Correlations, if you specify an oblique rotation. Standard error estimates are included if the **SE** option is specified with **METHOD=ML**. Confidence limits and coverage displays are included if **COVER=** option is specified with **METHOD=ML**.
- Rotated Factor Pattern (Std Reg Coefs), if you specify an oblique rotation, giving standardized regression coefficients for predicting the variables from the factors. Standard error estimates are included if the **SE** option is specified with **METHOD=ML**. Confidence limits and coverage displays are included if **COVER=** option is specified with **METHOD=ML**.
- Reference Axis Correlations if you specify an oblique rotation. These are the partial correlations between the primary factors when all factors other than the two being correlated are partialled out.
- Reference Structure (Semipartial Correlations), if you request an oblique rotation. The reference structure is the matrix of semipartial correlations (Kerlinger and Pedhazur 1973) between variables and common factors, removing from each common factor the effects of other common factors. If the common factors are uncorrelated, the reference structure is equal to the factor pattern.
- Variance explained by each factor eliminating the effects of all other factors, if you specify an oblique rotation. Both Weighted and Unweighted values are produced if variable weights are used. These variances are equal to the (weighted) sum of the squared elements of the reference structure corresponding to each factor.
- Factor Structure (Correlations), if you request an oblique rotation. The (primary) factor structure is the matrix of correlations between variables and common factors. If the common factors are uncorrelated, the factor structure is equal to the factor pattern. Standard error estimates are included if the **SE** option is specified with **METHOD=ML**. Confidence limits and coverage displays are included if **COVER=** option is specified with **METHOD=ML**.
- Variance explained by each factor ignoring the effects of all other factors, if you request an oblique rotation. Both Weighted and Unweighted values are produced if variable weights are used. These variances are equal to the (weighted) sum of the squared elements of the factor structure corresponding to each factor.
- Final Communality Estimates for the rotated factors if you specify the **ROTATE=** option. The estimates should equal the unrotated communalities.
- Squared Multiple Correlations of the Variables with Each Factor, if you specify the **SCORE** or **ALL** option, except for unrotated principal components
- Standardized Scoring Coefficients, if you specify the **SCORE** or **ALL** option
- Plots of the Factor Pattern for rotated factors, if you specify the **PLOT** option and you request an orthogonal rotation. The number of plots is determined by the **NPLOT=** option.

- Plots of the Reference Structure for rotated factors, if you specify the **PLOT** option and you request an oblique rotation. The number of plots is determined by the **NPLOT=** option. Included are the Reference Axis Correlation and the Angle between the Reference Axes for each pair of factors plotted.

If you specify the **ROTATE=PROMAX** option, the output includes results for both the prerotation and the Procrustes rotation.

ODS Table Names

PROC FACTOR assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 35.3](#). For more information about ODS, see Chapter 20, “[Using the Output Delivery System](#).”

Table 35.3 ODS Tables Produced by PROC FACTOR

ODS Table Name	Description	Option
AlphaCoef	Coefficient alpha for each factor	METHOD=ALPHA
CanCorr	Squared canonical correlations	METHOD=ML
CondStdDev	Conditional standard deviations	SIMPLE with PARTIAL
ConvergenceStatus	Convergence status	METHOD=PRINIT, ALPHA, ML, or ULS
Corr	Correlations	CORR
Eigenvalues	Eigenvalues	default, SCREE
Eigenvectors	Eigenvectors	EIGENVECTORS
FactorWeightRotate	Factor weights for rotation	HKPOWER=
FactorPattern	Factor pattern	default
FactorStructure	Factor structure	ROTATE= any oblique rotation
FinalCommun	Final communalities	default
FinalCommunWgt	Final communalities with weights	METHOD=ML or ALPHA
FitMeasures	Measures of fit	METHOD=ML
ImageCoef	Image coefficients	METHOD=IMAGE
ImageCov	Image covariance matrix	METHOD=IMAGE
ImageFactors	Image factor matrix	METHOD=IMAGE
InputFactorPattern	Input factor pattern	METHOD=PATTERN with PRINT or ALL
InputScoreCoef	Standardized input scoring coefficients	METHOD=SCORE with PRINT or ALL
InterFactorCorr	Interfactor correlations	ROTATE= any oblique rotation
InvCorr	Inverse correlation matrix	ALL
IterHistory	Iteration history	METHOD=PRINIT, ALPHA, ML, or ULS
MultipleCorr	Squared multiple correlations	METHOD=IMAGE or METHOD=HARRIS
NObs	Number of records and observations, input data type	default

Table 35.3 *continued*

ODS Table Name	Description	Option
NormObliqueTrans	Normalized oblique transformation matrix	ROTATE= any oblique rotation
ObliqueRotFactPat	Rotated factor pattern	ROTATE= any oblique rotation
ObliqueTrans	Oblique transformation matrix	HKPOWER=
OrthRotFactPat	Rotated factor pattern	ROTATE= any orthogonal rotation
OrthTrans	Orthogonal transformation matrix	ROTATE= any orthogonal rotation
ParCorrControlFactor	Partial correlations controlling factors	RESIDUAL
ParCorrControlVar	Partial correlations controlling other variables	MSA
PartialCorr	Partial correlations	MSA, CORR with PARTIAL
PriorCommunalEst	Prior communality estimates	PRIORS=, METHOD=ML or ALPHA
ProcrustesTarget	Target matrix for Procrustean transformation	ROTATE=PROCRUSTES, ROTATE=PROMAX
ProcrustesTrans	Procrustean transformation matrix	ROTATE=PROCRUSTES, ROTATE=PROMAX
RMSOffDiagPartials	Root mean square off-diagonal partials	RESIDUAL
RMSOffDiagResids	Root mean square off-diagonal residuals	RESIDUAL
ReferenceAxisCorr	Reference axis correlations	ROTATE= any oblique rotation
ReferenceStructure	Reference structure	ROTATE= any oblique rotation
ResCorrUniqueDiag	Residual correlations with uniqueness on the diagonal	RESIDUAL
SamplingAdequacy	Kaiser's measure of sampling adequacy	MSA
SignifTests	Significance tests	METHOD=ML
SimpleStatistics	Simple statistics	SIMPLE
StdScoreCoef	Standardized scoring coefficients	SCORE
VarExplain	Variance explained	default
VarExplainWgt	Variance explained with weights	METHOD=ML, or ALPHA
VarFactorCorr	Squared multiple correlations of the variables with each factor	SCORE
VarWeightRotate	Variable weights for rotation	NORM=WEIGHT, ROTATE=

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The names of the graphs that PROC FACTOR generates are listed in [Table 35.4](#), along with the required statements and options.

Table 35.4 Graphs Produced by PROC FACTOR

ODS Graph Name	Plot Description	Option
PatternPlot	Rotated factor pattern	PLOTS=LOADINGS
InitPatternPlot	Initial factor pattern	PLOTS=INITLOADINGS
InitRefStructurePlot	Initial reference structures	PLOTS=INITLOADINGS and PLOTREF
PrePatternPlot	Prerotated factor pattern	PLOTS=PRELOADINGS
PreRefStructurePlot	Prerotated reference structures	PLOTS=PRELOADINGS and PLOTREF
RefStructurePlot	Rotated reference structures	PLOTS=LOADINGS and PLOTREF
ScreePlot	Scree and variance explained plots	PLOTS=SCREE
VariancePlot	Plot of explained variance	PLOTS=SCREE(UNPACK)

Examples: FACTOR Procedure

Example 35.1: Principal Component Analysis

This example analyzes socioeconomic data provided by Harman (1976). The five variables represent total population (Population), median school years (School), total employment (Employment), miscellaneous professional services (Services), and median house value (HouseValue). Each observation represents one of twelve census tracts in the Los Angeles Standard Metropolitan Statistical Area.

You conduct a principal component analysis by using the following statements:

```

data SocioEconomics;
  input Population School Employment Services HouseValue;
  datalines;
5700      12.8      2500      270      25000
1000      10.9      600       10      10000
3400      8.8       1000      10      9000
3800      13.6      1700      140     25000
4000      12.8      1600      140     25000
8200      8.3       2600      60     12000
1200      11.4      400       10     16000
9100      11.5      3300      60     14000
9900      12.5      3400      180     18000
9600      13.7      3600      390     25000
9600      9.6       3300      80     12000
9400      11.4      4000      100     13000
;

proc factor data=SocioEconomics simple corr;
run;

```

You begin with the specification of the raw data set with 12 observations. Then you use the **DATA=** option in the PROC FACTOR statement to specify the data set in the analysis. You also set the **SIMPLE** and **CORR** options for additional output results, which are shown in [Output 35.1.2](#) and [Output 35.1.3](#), respectively.

By default, PROC FACTOR assumes that all initial communalities are 1, which is the case for the current principal component analysis. If you intend to find common factors instead, use the **PRIORS=** option or the **PRIORS** statement to set initial communalities to values less than 1, which results in extracting the principal factors rather than the principal components. See [Example 35.2](#) for the specification of a principal factor analysis.

For the current principal component analysis, the first output table is displayed in the [Output 35.1.1](#).

Output 35.1.1 Principal Component Analysis: Number of Observations

Five Socioeconomic Variables	
See Page 14 of Harman: Modern Factor Analysis, 3rd Ed	
Principal Component Analysis	
The FACTOR Procedure	
Input Data Type	Raw Data
Number of Records Read	12
Number of Records Used	12
N for Significance Tests	12

In [Output 35.1.1](#), the input data type is shown to be raw data. PROC FACTOR also accepts other data type such as correlations and covariances. See [Example 35.4](#) for the use of correlations as input data. For the current raw data set, PROC FACTOR reads in 12 records and all these 12 records are used. When there are missing values in the data set, these two numbers might not match due to the dropping of the records with missing values. The last row of the table shows that $N = 12$ is used in the significance tests conducted in the analysis.

The **SIMPLE** option specified in the PROC FACTOR statement generates the means and standard deviations of all observed variables in the analysis, as shown in [Output 35.1.2](#).

Output 35.1.2 Principal Component Analysis: Simple Statistics

Means and Standard Deviations from 12 Observations		
Variable	Mean	Std Dev
Population	6241.667	3439.9943
School	11.442	1.7865
Employment	2333.333	1241.2115
Services	120.833	114.9275
HouseValue	17000.000	6367.5313

The ranges of means and standard deviations for the analysis are quite large. Variables are measured on quite different scales. However, this is not an issue because PROC FACTOR basically analyzes the standardized scales (that is, the correlations) of the variables.

The **CORR** option specified in the PROC FACTOR statement generates the output of the observed correlations in [Output 35.1.3](#).

Output 35.1.3 Principal Component Analysis: Correlations

Correlations					
	Population	School	Employment	Services	HouseValue
Population	1.00000	0.00975	0.97245	0.43887	0.02241
School	0.00975	1.00000	0.15428	0.69141	0.86307
Employment	0.97245	0.15428	1.00000	0.51472	0.12193
Services	0.43887	0.69141	0.51472	1.00000	0.77765
HouseValue	0.02241	0.86307	0.12193	0.77765	1.00000

The correlation matrix shown in [Output 35.1.3](#) is analyzed by PROC FACTOR.

The first step of principal component analysis is to look at the eigenvalues of the correlation matrix. The larger eigenvalues are extracted first. Because there are five observed variables, five eigenvalues can be extracted, as shown in [Output 35.1.4](#).

Output 35.1.4 Principal Component Analysis: Eigenvalues

Eigenvalues of the Correlation Matrix: Total = 5 Average = 1				
	Eigenvalue	Difference	Proportion	Cumulative
1	2.87331359	1.07665350	0.5747	0.5747
2	1.79666009	1.58182321	0.3593	0.9340
3	0.21483689	0.11490283	0.0430	0.9770
4	0.09993405	0.08467868	0.0200	0.9969
5	0.01525537		0.0031	1.0000

In [Output 35.1.4](#), the two largest eigenvalues are 2.8733 and 1.7967, which together account for 93.4% of the standardized variance. Thus, the first two principal components provide an adequate summary of the data for most purposes. Three components, which explain 97.7% of the variation, should be sufficient for almost any application. PROC FACTOR retains the first two components on the basis of the eigenvalues-greater-than-one rule since the third eigenvalue is only 0.2148.

To express the observed variables as functions of the components (or factors, in general), you consult the factor loading matrix as shown in [Output 35.1.5](#).

Output 35.1.5 Principal Component Analysis: Factor Pattern

Factor Pattern		
	Factor1	Factor2
Population	0.58096	0.80642
School	0.76704	-0.54476
Employment	0.67243	0.72605
Services	0.93239	-0.10431
HouseValue	0.79116	-0.55818

The factor pattern is often referred to as the factor loading matrix in factor analysis. The elements in the loading matrix are called factor loadings. There are at least two ways you can interpret these factor loadings. First, you can use this table to express the observed variables as functions of the extracted factors (or components, as in the current analysis). Each row of the factor loadings tells you the linear combination of the factor or component scores that would yield the expected value of the associated variable. Second, you can interpret each loading as a correlation between an observed variable and a factor or component, provided that the factor solution is an orthogonal one (that is, factors are uncorrelated), such as the current initial factor solution. Hence, the factor loadings indicate how strongly the variables and the factors or components are related.

In [Output 35.1.5](#), the first component (labeled “Factor1”) has large positive loadings for all five variables. Its correlation with Services (0.9324) is especially high. The second component is basically a contrast of Population (0.8064) and Employment (0.7261) against School (-0.5448) and HouseValue (-0.5582), with a very small loading on Services (-0.1043).

The total variance explained by the two components are shown in [Output 35.1.6](#).

Output 35.1.6 Principal Component Analysis: Total Variance Explained by Factors

Variance Explained by Each Factor	
Factor1	Factor2
2.8733136	1.7966601

The first and second component account for 2.8733 and 1.7967, respectively, of the total variance of 5. In the initial factor solution, the total variance explained by the factors or components are the same as the eigenvalues extracted. (Compare the total variance with the eigenvalues shown in [Output 35.1.4](#).) Due to the dropping of the less important components, the sum of these two numbers is 4.6700, which is only a little bit less than total variance 5 of the original correlation matrix.

You can also look at the variance explained by the two components for each observed variables in [Output 35.1.7](#).

Output 35.1.7 Principal Component Analysis: Final Communality Estimates

Final Communality Estimates: Total = 4.669974				
Population	School	Employment	Services	HouseValue
0.98782629	0.88510555	0.97930583	0.88023562	0.93750041

In [Output 35.1.7](#), the final communality estimates show that all the variables are well accounted for by the two components, with final communality estimates ranging from 0.8802 for Services to 0.9878 for Population. The sum of the communalities is 4.6700, which is the same as the sum of the variance explained by the two components, as shown in [Output 35.1.6](#).

Principal Component Analysis by PROC FACTOR and PROC PRINCOMP

The principal component analysis by PROC FACTOR emphasizes how the principal components explain the observed variables. The factor loadings in the factor pattern as shown in [Output 35.1.5](#) are the coefficients for combining the factor/component scores to yield the observed variable scores when the expected error residuals are zero. For example, the predicted standardized value of Population given the factor/component scores for Factor1 and Factor2 is given by:

$$\text{Population} = 0.58096 \times \text{Factor1} + 0.80642 \times \text{Factor2}$$

If you are primarily interested in getting the component scores as linear combinations of the observed variables, the factor loading matrix table is not the right one for you. However, you might request the standardized scoring coefficients by adding the [SCORE](#) option in the FACTOR statement:

```
proc factor data=SocioEconomics n=5 score;
run;
```

In the preceding PROC FACTOR statement, N=5 is specified for retaining all five components. This is done for comparing the PROC FACTOR results with those of PROC PRINCOMP, which is described later.

The **SCORE** option requests the display of the standardized scoring coefficients, which are shown in [Output 35.1.8](#).

Output 35.1.8 Principal Component Analysis: Scoring Coefficients for Computing Component Scores

Standardized Scoring Coefficients					
	Factor1	Factor2	Factor3	Factor4	Factor5
Population	0.20219065	0.44884459	0.1284067	0.64542101	5.58240225
School	0.26695219	-0.3032049	1.48611655	-1.1184573	1.41573501
Employment	0.23402646	0.40410834	0.53496241	0.07255759	-5.6513542
Services	0.32450082	-0.0580552	-1.432726	-1.5828806	-0.0010006
HouseValue	0.27534803	-0.3106762	-0.3012889	2.41418899	-0.6673445

In [Output 35.1.8](#), each factor/component is expressed as a linear combination of the standardized observed variables. For example, the first principal component or Factor1 is computed as:

$$0.2022 \times \text{Population} + 0.2670 \times \text{School} + 0.2340 \times \text{Employment} + 0.3245 \times \text{Services} + 0.2753 \times \text{HouseValue}$$

Again, when applying this formula you must use the standardized observed variables (with means 0 and standard deviations 1), but not the raw data.

Apart from some scaling differences, the set of scoring coefficients obtained from PROC FACTOR are equivalent to those obtained from PROC PRINCOMP, as specified by the following statement:

```
proc princomp data=SocioEconomics;
run;
```

PROC PRINCOMP displays the scoring coefficients as eigenvectors, which are shown in [Output 35.1.9](#).

Output 35.1.9 Principal Component Analysis by PROC PRINCOMP: Eigenvectors

Eigenvectors					
	Prin1	Prin2	Prin3	Prin4	Prin5
Population	0.342730	0.601629	0.059517	0.204033	0.689497
School	0.452507	-0.406414	0.688822	-0.353571	0.174861
Employment	0.396695	0.541665	0.247958	0.022937	-0.698014
Services	0.550057	-0.077817	-0.664076	-0.500386	-0.000124
HouseValue	0.466738	-0.416429	-0.139649	0.763182	-0.082425

For example, to get the first principal component score, you use the following formula:

$$0.3427 \times \text{Population} + 0.4525 \times \text{School} + 0.3967 \times \text{Employment} + 0.5500 \times \text{Services} + 0.4667 \times \text{HouseValue}$$

This formula is not exactly the same as the one shown by using PROC FACTOR. All scoring coefficients in PROC FACTOR are smaller, approximately a factor of 0.59 to those coefficients obtained from PROC PRINCOMP. The reason for the scalar difference is that PROC FACTOR assumes all factors/components to

have variance of 1, while PROC PRINCOMP creates components that have variances equal to the eigenvalues. You can do a simple rescaling of the standardized scoring coefficients obtained from PROC FACTOR so that they match the associated eigenvectors from the PROC PRINCOMP. Basically, you need to rescale each column of the standardized scoring coefficients obtained from PROC FACTOR to have the sum of squares equaling one, which is a defining characteristic of eigenvectors. This could be accomplished by dividing each coefficient by the square root of the corresponding column sum of squares.

For the present example, you can use PROC STDIZE to do the rescaling, as shown in the following statements:

```
proc factor data=SocioEconomics n=5 score;
    ods output StdScoreCoef=Coef;
run;

proc stdize method=ustd mult=.44721 data=Coef out=eigenvectors;
    Var Factor1-Factor5;
run;

proc print data=eigenvectors;
run;
```

First, you create an output set Coef for the standardized scoring coefficients by the ODS OUTPUT statement. Note that “StdScoreCoef” is the ODS table that contains the standardized scoring coefficients as shown in [Output 35.1.8](#). (See [Table 35.3](#) for all ODS table names for PROC FACTOR.) Next, you use METHOD=USTD in the PROC STDIZE statement to divide the output coefficients by the corresponding uncorrected (for mean) standard deviations. The following formula shows the relationship between the uncorrected standard deviation and the sum of squares:

$$\text{uncorrected standard deviation} = \sqrt{\text{sum of squares}/N}$$

Recall that what you intend to divide from each coefficient is its square root of the corresponding column sum of squares. Therefore, to adjust for what PROC STDIZE does using METHOD=USTD, you have to multiply each variable by a constant term of $1/\sqrt{N}$ in the standardization. For the current example, this constant term is 0.44721 ($= 1/\sqrt{5}$) and is specified through the MULT= option in the PROC STDIZE statement. With the OUT= option, the rescaled scoring coefficients are saved in the SAS data set eigenvectors. The printout of the data set in [Output 35.1.10](#) shows the rescaled standardized scoring coefficients obtained from PROC FACTOR.

Output 35.1.10 Rescaled Standardized Scoring Coefficients

Obs	Variable	Factor1	Factor2	Factor3	Factor4	Factor5
1	Population	0.34272761	0.60162443	0.05951667	0.20403109	0.68949172
2	School	0.45250304	-0.4064112	0.68881691	-0.3535678	0.17485977
3	Employment	0.39669158	0.54166065	0.24795576	0.02293697	-0.6980081
4	Services	0.5500521	-0.0778162	-0.6640703	-0.5003817	-0.0001236
5	HouseValue	0.4667346	-0.4164256	-0.1396478	0.76317568	-0.0824248

As you can see, these standardized scoring coefficients are essentially the same as those obtained from PROC PRINCOMP, as shown in [Output 35.1.9](#). This example shows that principal component analyses by PROC FACTOR and PROC PRINCOMP are indeed equivalent. PROC PRINCOMP emphasizes more the linear combinations of the variables to form the components, while PROC FACTOR expresses variables as linear combinations of the components in the output. If a principal component analysis of the data is all you need in a particular application, there is no reason to use PROC FACTOR instead of PROC PRINCOMP. Therefore, the following examples focus on common factor analysis for which that you can apply only PROC FACTOR, but not PROC PRINCOMP.

Example 35.2: Principal Factor Analysis

This example uses the data presented in [Example 35.1](#) and performs a principal factor analysis with squared multiple correlations for the prior communality estimates. Unlike [Example 35.1](#), which analyzes the principal components (with default `PRIORS=ONE`), the current analysis is based on a common factor model. To use a common factor model, you specify `PRIORS=SMC` in the PROC FACTOR statement, as shown in the following:

```
ods graphics on;

proc factor data=SocioEconomics
  priors=smc msa residual
  rotate=promax reorder
  outstat=fact_all
  plots=(scree initloadings preloadings loadings);
run;

ods graphics off;
```

In the PROC FACTOR statement, you include several other options to help you analyze the results. To help determine whether the common factor model is appropriate, you request the Kaiser's measure of sampling adequacy with the `MSA` option. You specify the `RESIDUALS` option to compute the residual correlations and partial correlations.

The `ROTATE=` and `REORDER` options are specified to enhance factor interpretability. The `ROTATE=PROMAX` option produces an orthogonal varimax prerotation (default) followed by an oblique Procrustes rotation, and the `REORDER` option reorders the variables according to their largest factor loadings. An `OUTSTAT=` data set is created by PROC FACTOR and displayed in [Output 35.2.15](#).

PROC FACTOR can produce high-quality graphs that are very useful for interpreting the factor solutions. To request these graphs, ODS Graphics must be enabled. All ODS graphs in PROC FACTOR are requested with the `PLOTS=` option. In this example, you request a scree plot (`SCREE`) and loading plots for the factor matrix during the following three stages: initial unrotated solution (`INITLOADINGS`), prerotated (varimax) solution (`PRELOADINGS`), and promax-rotated solution (`LOADINGS`). The scree plot helps you determine the number of factors, and the loading plots help you visualize the patterns of factor loadings during various stages of analyses.

Principal Factor Analysis: Kaiser's MSA and Factor Extraction Results

Output 35.2.1 displays the results of the partial correlations and Kaiser's measure of sampling adequacy.

Output 35.2.1 Principal Factor Analysis: Partial Correlations and Kaiser's MSA

Partial Correlations Controlling all other Variables					
	Population	School	Employment	Services	HouseValue
Population	1.00000	-0.54465	0.97083	0.09612	0.15871
School	-0.54465	1.00000	0.54373	0.04996	0.64717
Employment	0.97083	0.54373	1.00000	0.06689	-0.25572
Services	0.09612	0.04996	0.06689	1.00000	0.59415
HouseValue	0.15871	0.64717	-0.25572	0.59415	1.00000
Kaiser's Measure of Sampling Adequacy: Overall MSA = 0.57536759					
	Population	School	Employment	Services	HouseValue
	0.47207897	0.55158839	0.48851137	0.80664365	0.61281377

If the data are appropriate for the common factor model, the partial correlations (controlling all other variables) should be small compared to the original correlations. For example, the partial correlation between the variables School and HouseValue is 0.65, slightly less than the original correlation of 0.86 (see [Output 35.1.3](#)). The partial correlation between Population and School is -0.54, which is much larger in absolute value than the original correlation; this is an indication of trouble. Kaiser's **MSA** is a summary, for each variable and for all variables together, of how much smaller the partial correlations are than the original correlations. Values of 0.8 or 0.9 are considered good, while MSAs below 0.5 are unacceptable. The variables Population, School, and Employment have very poor MSAs. Only the Services variable has a good MSA. The overall MSA of 0.58 is sufficiently poor that additional variables should be included in the analysis to better define the common factors. A commonly used rule is that there should be at least three variables per factor. In the following analysis, you determine that there are two common factors in these data. Therefore, more variables are needed for a reliable analysis.

Output 35.2.2 displays the results of the principal factor extraction.

Output 35.2.2 Principal Factor Analysis: Factor Extraction

Prior Communality Estimates: SMC				
Population	School	Employment	Services	HouseValue
0.96859160	0.82228514	0.96918082	0.78572440	0.84701921

Output 35.2.2 *continued*

Eigenvalues of the Reduced Correlation Matrix:				
Total = 4.39280116 Average = 0.87856023				
	Eigenvalue	Difference	Proportion	Cumulative
1	2.73430084	1.01823217	0.6225	0.6225
2	1.71606867	1.67650586	0.3907	1.0131
3	0.03956281	0.06408626	0.0090	1.0221
4	-.02452345	0.04808427	-0.0056	1.0165
5	-.07260772		-0.0165	1.0000

The square multiple correlations are shown as prior communality estimates in [Output 35.2.2](#). The **PRI-ORS=SMC** option basically replaces the diagonal of the original observed correlation matrix by these square multiple correlations. Because the square multiple correlations are usually less than one, the resulting correlation matrix for factoring is called the reduced correlation matrix. In the current example, the SMCs are all fairly large; hence, you expect the results of the principal factor analysis to be similar to those in the principal component analysis.

The first two largest positive eigenvalues of the reduced correlation matrix account for 101.31% of the common variance. This is possible because the reduced correlation matrix, in general, is not necessarily positive definite, and negative eigenvalues for the matrix are possible. A pattern like this suggests that you might not need more than two common factors. The scree and variance explained plots of [Output 35.2.3](#) clearly support the conclusion that two common factors are present. Showing in the left panel of [Output 35.2.3](#) is the scree plot of the eigenvalues of the reduced correlation matrix. A sharp bend occurs at the third eigenvalue, reinforcing the conclusion that two common factors are present. These cumulative proportions of common variance explained by factors are plotted in the right panel of [Output 35.2.3](#), which shows that the curve essentially flattens out after the second factor.

Output 35.2.3 Scree and Variance Explained Plots

Principal Factor Analysis: Initial Factor Solution

For the current analysis, PROC FACTOR retains two factors by certain default criteria. This decision agrees with the conclusion drawn by inspecting the scree plot. The principal factor pattern with the two factors is displayed in [Output 35.2.4](#). This factor pattern is similar to the principal component pattern seen in [Output 35.1.5](#) of [Example 35.1](#). For example, the variable `Services` has the largest loading on the first factor, and the `Population` variable has the smallest. The variables `Population` and `Employment` have large positive loadings on the second factor, and the `HouseValue` and `School` variables have large negative loadings.

Output 35.2.4 Initial Factor Pattern Matrix and Communalities

Factor Pattern		
	Factor1	Factor2
Services	0.87899	-0.15847
HouseValue	0.74215	-0.57806
Employment	0.71447	0.67936
School	0.71370	-0.55515
Population	0.62533	0.76621
Variance Explained by Each Factor		
	Factor1	Factor2
	2.7343008	1.7160687

Output 35.2.4 *continued*

Final Communality Estimates: Total = 4.450370				
Population	School	Employment	Services	HouseValue
0.97811334	0.81756387	0.97199928	0.79774304	0.88494998

Comparing the current factor loading matrix in [Output 35.2.4](#) with that in [Output 35.1.5](#) in [Example 35.1](#), you notice that the variables are arranged differently in the two output tables. This is due to the use of the **REORDER** option in the current analysis. The advantage of using this option might not be very obvious in [Output 35.2.4](#), but you can see its value when looking at the rotated solutions, as shown in [Output 35.2.7](#) and [Output 35.2.11](#).

The final communality estimates are all fairly close to the priors (shown in [Output 35.2.2](#)). Only the communality for the variable HouseValue increased appreciably, from 0.847 to 0.885. Therefore, you are sure that all the common variance is accounted for.

[Output 35.2.5](#) shows that the residual correlations (off-diagonal elements) are low, the largest being 0.03. The partial correlations are not quite as impressive, since the uniqueness values are also rather small. These results indicate that the squared multiple correlations are good but not quite optimal communality estimates.

Output 35.2.5 Residual and Partial Correlations

Residual Correlations With Uniqueness on the Diagonal					
	Population	School	Employment	Services	HouseValue
Population	0.02189	-0.01118	0.00514	0.01063	0.00124
School	-0.01118	0.18244	0.02151	-0.02390	0.01248
Employment	0.00514	0.02151	0.02800	-0.00565	-0.01561
Services	0.01063	-0.02390	-0.00565	0.20226	0.03370
HouseValue	0.00124	0.01248	-0.01561	0.03370	0.11505
Root Mean Square Off-Diagonal Residuals: Overall = 0.01693282					
	Population	School	Employment	Services	HouseValue
	0.00815307	0.01813027	0.01382764	0.02151737	0.01960158
Partial Correlations Controlling Factors					
	Population	School	Employment	Services	HouseValue

Employment	0.20752	0.30097	1.00000	-0.07504	-0.27509
Services	0.15975	-0.12443	-0.07504	1.00000	0.22093
HouseValue	0.02471	0.08614	-0.27509	0.22093	1.00000

Output 35.2.5 *continued*

Root Mean Square Off-Diagonal Partial: Overall = 0.18550132				
Population	School	Employment	Services	HouseValue
0.15850824	0.19025867	0.23181838	0.15447043	0.18201538

As displayed in [Output 35.2.6](#), the unrotated factor pattern reveals two tight clusters of variables, with the variables HouseValue and School at the negative end of Factor2 axis and the variables Employment and Population at the positive end. The Services variable is in between but closer to the HouseValue and School variables. A good rotation would place the axes so that most variables would have zero loadings on most factors. As a result, the axes would appear as though they are put through the variable clusters.

Output 35.2.6 Unrotated Factor Loading Plot

Principal Factor Analysis: Varimax Prerotation

In [Output 35.2.7](#), the results of the varimax prerotation are shown. To yield the varimax-rotated factor loading (pattern), the initial factor loading matrix is postmultiplied by an orthogonal transformation matrix. This orthogonal transformation matrix is shown in [Output 35.2.7](#), followed by the varimax-rotated factor pattern. This rotation or transformation leads to small loadings of Population and Employment on the first factor and small loadings of HouseValue and School on the second factor. Services appears to have a larger loading on the first factor than it has on the second factor, although both loadings are substantial. Hence, Services appears to be factorially complex.

With the [REORDER](#) option in effect, you can see the variable clusters clearly in the factor pattern. The first factor is associated more with the first three variables (first three rows of variables): HouseValue, School, and Services. The second factor is associated more with the last two variables (last two rows of variables): Population and Employment.

For orthogonal factor solutions such as the current varimax-rotated solution, you can also interpret the values in the factor loading (pattern) matrix as correlations. For example, HouseValue and Factor 1 have a high correlation at 0.94, while Population and Factor 1 have a low correlation at 0.02.

Output 35.2.7 Varimax Rotation: Transform Matrix and Rotated Pattern

Orthogonal Transformation Matrix		
	1	2
1	0.78895	0.61446
2	-0.61446	0.78895

Rotated Factor Pattern		
	Factor1	Factor2
HouseValue	0.94072	-0.00004
School	0.90419	0.00055
Services	0.79085	0.41509
Population	0.02255	0.98874
Employment	0.14625	0.97499

Variance Explained by Each Factor		
	Factor1	Factor2
	2.3498567	2.1005128

Final Communality Estimates: Total = 4.450370

Population	School	Employment	Services	HouseValue
0.97811334	0.81756387	0.97199928	0.79774304	0.88494998

The variance explained by the factors are more evenly distributed in the varimax-rotated solution, as compared with that of the unrotated solution. Indeed, this is a typical fact for any kinds of factor rotation. In the current example, before the varimax rotation the two factors explain 2.73 and 1.72, respectively, of the common variance (see [Output 35.2.4](#)). After the varimax rotation the two rotated factors explain 2.35 and 2.10, respectively, of the common variance. However, the total variance accounted for by the factors remains unchanged after the varimax rotation. This invariance property is also observed for the communalities of the variables after the rotation, as evidenced by comparing the current communality estimates in [Output 35.2.7](#) with those in [Output 35.2.4](#).

[Output 35.2.8](#) shows the graphical plot of the varimax-rotated factor loadings. Clearly, HouseValue and School cluster together on the Factor 1 axis, while Population and Employment cluster together on the Factor 2 axis. Service is closer to the cluster of HouseValue and School.

Output 35.2.8 Varimax-Rotated Factor Loadings

An alternative to the scatter plot of factor loadings is the so-called vector plot of loadings, which is shown in [Output 35.2.9](#). The vector plot is requested with the suboption VECTOR in the **PLOTS=** option. That is:

```
plots=preloadings(vector)
```

This generates the vector plot of loadings in [Output 35.2.9](#).

Output 35.2.9 Varimax-Rotated Factor Loadings: Vector Plot

Principal Factor Analysis: Oblique Promax Rotation

For some researchers, the varimax-rotated factor solution in the preceding section might be good enough to provide them useful and interpretable results. For others who believe that common factors are seldom orthogonal, an obliquely rotated factor solution might be more desirable, or at least should be attempted.

PROC FACTOR provides a very large class of oblique factor rotations. The current example shows a particular one—namely, the promax rotation as requested by the `ROTATE=PROMAX` option.

The results of the promax rotation are shown in [Output 35.2.10](#) and [Output 35.2.11](#). The corresponding plot of factor loadings is shown in [Output 35.2.12](#).

Output 35.2.10 Promax Rotation: Procrustean Target and Transformation

Target Matrix for Procrustean Transformation		
	Factor1	Factor2
HouseValue	1.00000	-0.00000
School	1.00000	0.00000
Services	0.69421	0.10045
Population	0.00001	1.00000
Employment	0.00326	0.96793

Procrustean Transformation Matrix		
	1	2
1	1.04116598	-0.0986534
2	-0.1057226	0.96303019

Normalized Oblique Transformation Matrix		
	1	2
1	0.73803	0.54202
2	-0.70555	0.86528

Output 35.2.10 shows the Procrustean target, to which the varimax factor pattern is rotated, followed by the display of the Procrustean transformation matrix. This is the matrix that transforms the varimax factor pattern so that the rotated pattern is as close as possible to the Procrustean target. However, because the variances of factors have to be fixed at 1 during the oblique transformation, a normalized version of the Procrustean transformation matrix is the one that is actually used in the transformation. This normalized transformation matrix is shown at the bottom of Output 35.2.10. Using this transformation matrix leads to the promax-rotated factor solution, as shown in Output 35.2.11.

Output 35.2.11 Promax Rotation: Factor Correlations and Factor Pattern

Inter-Factor Correlations		
	Factor1	Factor2
Factor1	1.00000	0.20188
Factor2	0.20188	1.00000

Output 35.2.11 *continued*

Rotated Factor Pattern (Standardized Regression Coefficients)		
	Factor1	Factor2
HouseValue	0.95558485	-0.0979201
School	0.91842142	-0.0935214
Services	0.76053238	0.33931804
Population	-0.0790832	1.00192402
Employment	0.04799	0.97509085

After the promax rotation, the factors are no longer uncorrelated. As shown in [Output 35.2.11](#), the correlation of the two factors is now 0.20. In the (initial) unrotated and the varimax solutions, the two factors are not correlated.

In addition to allowing the factors to be correlated, in an oblique factor solution you seek a pattern of factor loadings that is more “differentiated” (referred to as the “simple structures” in the literature). The more differentiated the loadings, the easier the interpretation of the factors.

For example, factor loadings of Services and Population on Factor 2 are 0.415 and 0.989, respectively, in the (orthogonal) varimax-rotated factor pattern (see [Output 35.2.7](#)). With the (oblique) promax rotation (see [Output 35.2.11](#)), these two loadings become even more differentiated with values 0.339 and 1.002, respectively. Overall, however, the factor patterns before and after the promax rotation do not seem to differ too much. This fact is confirmed by comparing the graphical plots of factor loadings. The plots in [Output 35.2.12](#) (promax-rotated factor loadings) and [Output 35.2.8](#) (varimax-rotated factor loadings) show very similar patterns.

Output 35.2.12 Promax Rotation: Factor Loading Plot

Unlike the orthogonal factor solutions where you can interpret the factor loadings as correlations between variables and factors, in oblique factor solutions such as the promax solution, you have to turn to the factor structure matrix for examining the correlations between variables and factors. [Output 35.2.13](#) shows the factor structures of the promax-rotated solution.

Output 35.2.13 Promax Rotation: Factor Structures and Final Communalities

Factor Structure (Correlations)		
	Factor1	Factor2
HouseValue	0.93582	0.09500
School	0.89954	0.09189
Services	0.82903	0.49286
Population	0.12319	0.98596
Employment	0.24484	0.98478

Output 35.2.13 *continued*

Variance Explained by Each Factor Ignoring Other Factors				
	Factor1	Factor2		
	2.4473495	2.2022803		
Final Communality Estimates: Total = 4.450370				
Population	School	Employment	Services	HouseValue
0.97811334	0.81756387	0.97199928	0.79774304	0.88494998

Basically, the factor structure matrix shown in [Output 35.2.13](#) reflects a similar pattern to the factor pattern matrix shown in [Output 35.2.11](#). The critical difference is that you can have the correlation interpretation only by using the factor structure matrix. For example, in the factor structure matrix shown in [Output 35.2.13](#), the correlation between Population and Factor 2 is 0.986. The corresponding value shown in the factor pattern matrix in [Output 35.2.11](#) is 1.002, which certainly cannot be interpreted as a correlation coefficient.

Common variance explained by the promax-rotated factors are 2.447 and 2.202, respectively, for the two factors. Unlike the orthogonal factor solutions (for example, the prerotated varimax solution), variance explained by these promax-rotated factors do not sum up to the total communality estimate 4.45. In oblique factor solutions, variance explained by oblique factors cannot be partitioned for the factors. Variance explained by a common factor is computed while ignoring the contributions from the other factors.

However, the communalities for the variables, as shown in the bottom of [Output 35.2.13](#), do not change from rotation to rotation. They are still the same set of communalities in the initial, varimax-rotated, and promax-rotated solutions. This is a basic fact about factor rotations: they only redistribute the variance explained by the factors; the total variance explained by the factors for any variable (that is, the communality of the variable) remains unchanged.

In the literature of exploratory factor analysis, reference axes had been an important tool in factor rotation. Nowadays, rotations are seldom done through the uses of the reference axes. Despite that, results about reference axes do provide additional information for interpreting factor analysis results. For the current example of the promax rotation, PROC FACTOR shows the relevant results about the reference axes in [Output 35.2.14](#).

Output 35.2.14 Promax Rotation: Reference Axis Correlations and Reference Structures

Reference Axis Correlations		
	Factor1	Factor2
Factor1	1.00000	-0.20188
Factor2	-0.20188	1.00000

Output 35.2.14 *continued*

Reference Structure (Semipartial Correlations)		
	Factor1	Factor2
HouseValue	0.93591	-0.09590
School	0.89951	-0.09160
Services	0.74487	0.33233
Population	-0.07745	0.98129
Employment	0.04700	0.95501
Variance Explained by Each Factor Eliminating Other Factors		
	Factor1	Factor2
	2.2480892	2.0030200

To explain the results in the reference-axis system, some geometric interpretations of the factor axes are needed. Consider a single factor in a system of n common factors in an oblique factor solution. Taking away the factor under consideration, the remaining $n - 1$ factors span a hyperplane in the factor space of $n - 1$ dimensions. The vector that is orthogonal to this hyperplane is the reference axis (reference vector) of the factor under consideration. Using the same definition for the remaining factors, you have n reference vectors for n factors.

A factor in an oblique factor solution can be considered as the sum of two independent components: its associated reference vector and a component that is overlapped with all other factors. In other words, the reference vector of a factor is a unique part of the factor that is not predictable from all other factors. Thus, the loadings on a reference vector are the unique effects of the corresponding factor, partialling out the effects from all other factors. The variances explained by a reference vector are the unique variances explained by the corresponding factor, partialling out the variances explained by all other factors.

Output 35.2.14 shows the reference axis correlations. The correlation between the reference vectors is -0.20 . Next, Output 35.2.14 shows the loadings on the reference vectors in the table entitled “Reference Structure (Semipartial Correlations).” As explained previously, loadings on a reference vector are also the unique effects of the corresponding factor, partialling out the effects from the all other factors. For example, the unique effect of Factor 1 on HouseValue is 0.936. Another important property of the reference vector system is that loadings on a reference vector are also correlations between the variables and the corresponding factor, partialling out the correlations between the variables and other factors. This means that the loading 0.936 in the reference structure table is the unique correlation between HouseValue and Factor 1, partialling out the correlation between HouseValue with Factor 2. Hence, as suggested by the title of table, all loadings reported in the “Reference Structure (Semipartial Correlations)” can be interpreted as semipartial correlations between variables and factors.

The last table shown in [Output 35.2.14](#) are the variances explained by the reference vectors. As explained previously, these are also unique variances explained by the factors, partialling out the variances explained by all other factors (or eliminating all other factors, as suggested by the title of the table). In the current example, Factor 1 explains 2.248 of the variable variances, partialling out all variable variances explained by Factor 2.

Notice that factor pattern (shown in [Output 35.2.11](#)), factor structures (correlations, shown in [Output 35.2.13](#)), and reference structures (semipartial correlations, shown in [Output 35.2.14](#)) give you different information about the oblique factor solutions such as the promax-rotated solution. However, for orthogonal factor solutions such as the varimax-rotated solution, factor structures and reference structures are all the same as the factor pattern.

Principal Factor Analysis: Factor Rotations with Factor Pattern Input

The promax rotation is one of the many rotations that PROC FACTOR provides. You can specify many different rotation algorithms by using the `ROTATE=` options. In this section, you explore different rotated factor solutions from the initial principal factor solution. Specifically, you want to examine the factor patterns yielded by the quartimax transformation (an orthogonal transformation) and the Harris-Kaiser (an oblique transformation), respectively.

Rather than analyzing the entire problem again with new rotations, you can simply use the `OUTSTAT=` data set from the preceding factor analysis results.

First, the `OUTSTAT=` data set is printed using the following statements:

```
proc print data=fact_all;
run;
```

The output data set is displayed in [Output 35.2.15](#).

Output 35.2.15 Output Data Set

Factor Output Data Set						
Obs	_TYPE_	_NAME_	Population	School	Employment	House Value

34	STRUCTUR	Factor2	0.99	0.0919	0.98	0.493

Various results from the previous factor analysis are saved in this data set, including the initial unrotated solution (its factor pattern is saved in observations with `_TYPE_=UNROTATE`), the prerotated varimax solution (its factor pattern is saved in observations with `_TYPE_=PREROTAT`), and the oblique promax solution (its factor pattern is saved in observations with `_TYPE_=PATTERN`).

When PROC FACTOR reads in an input data set with `TYPE=FACTOR`, the observations with `_TYPE_=PATTERN` are treated as the initial factor pattern to be rotated by PROC FACTOR. Hence, it is important that you provide the correct initial factor pattern for PROC FACTOR to read in.

In the current example, you need to provide the unrotated solution from the preceding analysis as the input factor pattern. The following statements create a TYPE=FACTOR data set fact2 from the preceding OUTSTAT= data set fact_all:

```
data fact2(type=factor);
  set fact_all;
  if _TYPE_ in('PATTERN' 'FCORR') then delete;
  if _TYPE_='UNROTATE' then _TYPE_='PATTERN';
run;
```

In these statements, you delete observations with _TYPE_=PATTERN or _TYPE_=FCORR, which are for the promax-rotated factor solution, and change observations with _TYPE_=UNROTATE to _TYPE_=PATTERN in the new data set fact2. In this way, the initial orthogonal factor pattern matrix is saved in the observations with _TYPE_=PATTERN.

You use this new data set and rotate the initial solution to another oblique solution with the ROTATE=QUARTIMAX option, as shown in the following statements:

```
proc factor data=fact2 rotate=quartimax reorder;
run;
```

As shown in [Output 35.2.16](#), the input data set is of the FACTOR type for the new rotation.

Output 35.2.16 Quartimax Rotation With Input Factor Pattern

Quartimax Rotation From a TYPE=FACTOR Data Set	
The FACTOR Procedure	
Input Data Type	FACTOR
N Set/Assumed in Data Set	12
N for Significance Tests	12

The quartimax-rotated factor pattern is displayed in [Output 35.2.17](#).

Output 35.2.17 Quartimax-Rotated Factor Pattern

Orthogonal Transformation Matrix		
	1	2
1	0.80138	0.59815
2	-0.59815	0.80138

Output 35.2.17 *continued*

Rotated Factor Pattern		
	Factor1	Factor2
HouseValue	0.94052	-0.01933
School	0.90401	-0.01799
Services	0.79920	0.39878
Population	0.04282	0.98807
Employment	0.16621	0.97179

Variance Explained by Each Factor		
	Factor1	Factor2
	2.3699941	2.0803754

The quartimax rotation produces an orthogonal transformation matrix shown at the top of [Output 35.2.17](#). After the transformation, the factor pattern is shown next. Compared with the varimax-rotated factor pattern (see [Output 35.2.7](#)), the quartimax-rotated factor pattern shows some differences. The loadings of HouseValue and School on Factor 1 drop only slightly in the quartimax factor pattern, while the loadings of Services, Population, and Employment on Factor 1 gain relatively larger amounts. The total variance explained by Factor 1 in the varimax-rotated solution (see [Output 35.2.7](#)) is 2.350, while it is 2.370 after the quartimax-rotation. In other words, more variable variances are explained by the first factor in the quartimax factor pattern than in the varimax factor pattern. Although not very strongly demonstrated in the current example, this illustrates a well-known property about the quartimax rotation: it tends to produce a general factor for all variables.

Another oblique rotation is now explored. The Harris-Kaiser transformation weighted by the Cureton-Mulaik technique is applied to the initial factor pattern. To achieve this, you use the **ROTATE=HK** and **NORM=WEIGHT** options in the following PROC FACTOR statement:

```
ods graphics on;

proc factor data=fact2 rotate=hk norm=weight reorder
  plots=loadings;
run;

ods graphics off;
```

[Output 35.2.18](#) shows the variable weights in the rotation.

Output 35.2.18 Harris-Kaiser Rotation: Weights

Variable Weights for Rotation				
Population	School	Employment	Services	HouseValue
0.95982747	0.93945424	0.99746396	0.12194766	0.94007263

While all other variables have weights at least as large as 0.93, the weight for **Services** is only 0.12. This means that due to its small weight, **Services** is not as important as the other variables for determining the rotation (transformation). This makes sense when you look at the initial unrotated factor pattern plot in [Output 35.2.6](#). In the plot, there are two main clusters of variables, and **Services** does not seem to fall into either of the clusters. In order to yield a Harris-Kaiser rotation (transformation) that would gear towards to two clusters, the Cureton-Mulaik weighting essentially downweights the contribution from **Services** in the factor rotation.

The results of the Harris-Kaiser factor solution are displayed in [Output 35.2.19](#), with a graphical plot of rotated loadings displayed in [Output 35.2.20](#).

Output 35.2.19 Harris-Kaiser Rotation: Factor Correlations and Factor Pattern

Inter-Factor Correlations		
	Factor1	Factor2
Factor1	1.00000	0.08358
Factor2	0.08358	1.00000
Rotated Factor Pattern (Standardized Regression Coefficients)		
	Factor1	Factor2
HouseValue	0.94048	0.00279
School	0.90391	0.00327
Services	0.75459	0.41892
Population	-0.06335	0.99227
Employment	0.06152	0.97885

Because the Harris-Kaiser produces an oblique factor solution, you compare the current results with that of the promax (see [Output 35.2.11](#)), which also produces an oblique factor solution. The correlation between the factors in the Harris-Kaiser solution is 0.084; this value is much smaller than the same correlation in the promax solution, which is 0.201. However, the Harris-Kaiser rotated factor pattern shown in [Output 35.2.19](#) is more or less the same as that of the promax-rotated factor pattern shown in [Output 35.2.11](#). Which solution would you consider to be more reasonable or interpretable?

From the statistical point of view, the Harris-Kaiser and promax factor solutions are equivalent. They explain the observed variable relationships equally well. From the simplicity point of view, however, you might prefer to interpret the Harris-Kaiser solution because the factor correlation is smaller. In other words, the factors in the Harris-Kaiser solution do not overlap that much conceptually; hence they should be more distinctive to interpret. However, in practice simplicity in factor correlations might not be the only principle to consider. Researchers might actually expect to have some factors to be highly correlated based on theoretical or substantive grounds.

Although the Harris-Kaiser and the promax factor patterns are very similar, the graphical plots of the loadings from the two solutions paint slightly different pictures. The plot of the promax-rotated loadings is shown in [Output 35.2.12](#), while the plot of the loadings for the current Harris-Kaiser solution is shown in [Output 35.2.20](#).

Output 35.2.20 Harris-Kaiser Rotation: Factor Loading Plot

The two factor axes in the Harris-Kaiser rotated pattern ([Output 35.2.20](#)) clearly cut through the centers of the two variable clusters, while the Factor 1 axis in the promax solution lies above a variable cluster ([Output 35.2.12](#)). The reason for this subtle difference is that in the Harris-Kaiser rotation, the *Services* is a “loner” that has been downweighted by the Cureton-Mulaik technique (see its relatively small weight in [Output 35.2.18](#)). As a result, the rotated axes are basically determined by the two variable clusters in the Harris-Kaiser rotation.

As far as the current discussion goes, it is not recommending one rotation method over another. Rather, it simply illustrates how you could control certain types of characteristics of factor rotation through the many options supported by PROC FACTOR. Should you prefer an orthogonal rotation to an oblique rotation? Should you choose the oblique factor solution with the smallest factor correlations? Should you use a weighting scheme that would enable you to find independent variable clusters? While PROC FACTOR enables you to explore all these alternatives, you must consult advanced textbooks and published articles to get satisfactory and complete answers to these questions.

Example 35.3: Maximum Likelihood Factor Analysis

This example uses maximum likelihood factor analyses for one, two, and three factors. It is already apparent from the principal factor analysis that the best number of common factors is almost certainly two. The one- and three-factor ML solutions reinforce this conclusion and illustrate some of the numerical problems that can occur. The following statements produce [Output 35.3.1](#) through [Output 35.3.3](#):

```

title3 'Maximum Likelihood Factor Analysis with One Factor';
proc factor data=SocioEconomics method=ml heywood n=1;
run;

title3 'Maximum Likelihood Factor Analysis with Two Factors';
proc factor data=SocioEconomics method=ml heywood n=2;
run;

title3 'Maximum Likelihood Factor Analysis with Three Factors';
proc factor data=SocioEconomics method=ml heywood n=3;
run;

```

[Output 35.3.1](#) displays the results of the analysis with one factor.

The solution on the second iteration is so close to the optimum that PROC FACTOR cannot find a better solution; hence you receive this message:

Convergence criterion satisfied.

When this message appears, you should try rerunning PROC FACTOR with different prior communality estimates to make sure that the solution is correct. In this case, other prior estimates lead to the same solution or possibly to worse local optima, as indicated by the information criteria or the chi-square values.

The variable Employment has a communality of 1.0 and, therefore, an infinite weight that is displayed next to the final communality estimate as a missing/infinite value. The first eigenvalue is also infinite. Infinite values are ignored in computing the total of the eigenvalues and the total final communality.

In the results, a warning message is displayed:

WARNING: Too many factors for a unique solution.

The number of parameters in the model exceeds the number of elements in the correlation matrix from which they can be estimated, so an infinite number of different perfect solutions can be obtained. The criterion approaches zero at an improper optimum, as indicated by this message:

Converged, but not to a proper optimum.

The degrees of freedom for the chi-square test are -2 , so a probability level cannot be computed for three factors. Note also that the variable Employment is a Heywood case again.

The probability levels for the chi-square test are 0.0001 for the hypothesis of no common factors, 0.0002 for one common factor, and 0.1382 for two common factors. Therefore, the two-factor model seems to be an adequate representation. Akaike's information criterion and Schwarz's Bayesian criterion attain their minimum values at two common factors, so there is little doubt that two factors are appropriate for these data.

Example 35.4: Using Confidence Intervals to Locate Salient Factor Loadings

This example illustrates how you can use the standard errors and confidence intervals to understand the pattern of factor loadings under the maximum likelihood estimation. There are nine tests and you want a three-factor solution ($N=3$) for a correlation matrix based on 200 observations. The following statements define the input data set and specify the desirable analysis by the FACTOR procedure:

```
data test(type=corr);
  title 'Quartimin-Rotated Factor Solution with Standard Errors';
  input _name_ $ test1-test9;
  _type_ = 'corr';
  datalines;
Test1      1  .561  .602  .290  .404  .328  .367  .179 -.268
Test2    .561      1  .743  .414  .526  .442  .523  .289 -.399
Test3    .602  .743      1  .286  .343  .361  .679  .456 -.532
Test4    .290  .414  .286      1  .677  .446  .412  .400 -.491
Test5    .404  .526  .343  .677      1  .584  .408  .299 -.466
Test6    .328  .442  .361  .446  .584      1  .333  .178 -.306
Test7    .367  .523  .679  .412  .408  .333      1  .711 -.760
Test8    .179  .289  .456  .400  .299  .178  .711      1 -.725
Test9   -.268 -.399 -.532 -.491 -.466 -.306 -.760 -.725      1
;

title2 'A nine-variable-three-factor example';
proc factor data=test method=ml reorder rotate=quartimin
  nobs=200 n=3 se cover=.45 alpha=.1;
run;
```

In the PROC FACTOR statement, you apply quartimin rotation with (default) Kaiser normalization. You define loadings with magnitudes greater than 0.45 to be salient (**COVER=0.45**) and use 90% confidence intervals (**ALPHA=0.1**) to judge the salience. The **REORDER** option is specified so that variables that have similar loadings with factors are clustered together.

After the quartimin rotation, the correlation matrix for factors is shown in [Output 35.4.1](#).

Output 35.4.1 Quartimin-Rotated Factor Solution with Standard Errors

Inter-Factor Correlations With 90% confidence limits Estimate/StdErr/LowerCL/UpperCL			
	Factor1	Factor2	Factor3
Factor1	1.00000	0.41283	0.38304
	0.00000	0.06267	0.06060
	.	0.30475	0.27919
	.	0.51041	0.47804
Factor2	0.41283	1.00000	0.47006
	0.06267	0.00000	0.05116
	0.30475	.	0.38177
	0.51041	.	0.54986
Factor3	0.38304	0.47006	1.00000
	0.06060	0.05116	0.00000
	0.27919	0.38177	.
	0.47804	0.54986	.

The factors are medium to highly correlated. The confidence intervals seem to be very wide, suggesting that the estimation of factor correlations might not be very accurate for this sample size. For example, the 90% confidence interval for the correlation between Factor1 and Factor2 is (0.30, 0.51), a range of 0.21. You might need a larger sample to get a narrower interval, or you might need a better estimation.

Next, coverage displays for factor loadings are shown in [Output 35.4.2](#).

Output 35.4.2 Using the Rotated Factor Pattern to Interpret the Factors

The coverage displays in [Output 35.4.2](#) show that Test8, Test7, and Test9 have salient relationships with Factor1. The coverage displays are either '0*[]' or '[]*0', indicating that the entire 90% confidence intervals for the corresponding loadings are beyond the salience value at 0.45. On the other hand, the coverage display for Test3 on Factor1 is '0[]*'. This indicates that even though the loading estimate is significantly larger than zero, it is not large enough to be salient. Similarly, Test3, Test2, and Test1 have salient relationships with Factor2, while Test5 and Test4 have salient relationships with Factor3. For Test6, its relationship with Factor3 is a little bit ambiguous; the 90% confidence interval approximately covers values between 0.40 and 0.64. This means that the population value might have been smaller or larger than 0.45. It is marginal evidence for a salient relationship.

For oblique factor solutions, some researchers prefer to examine the factor structure loadings, which represent correlations, for determining salient relationships. In [Output 35.4.3](#), the factor structure loadings and the associated standard error estimates and coverage displays are shown.

The interpretations based on the factor structure matrix do not change much from that based on the factor loadings except for Test3 and Test9. Test9 now has a salient correlation with Factor3. For Test3, it has salient correlations with both Factor1 and Factor2. Fortunately, there are still tests that have salient correlations only with either Factor1 or Factor2 (but not both). This would make interpretations of factors less problematic.

Overview: FASTCLUS Procedure

The FASTCLUS procedure performs a disjoint cluster analysis on the basis of distances computed from one or more quantitative variables. The observations are divided into clusters such that every observation belongs to one and only one cluster; the clusters do not form a tree structure as they do in the CLUSTER procedure. If you want separate analyses for different numbers of clusters, you can run PROC FASTCLUS once for each analysis. Alternatively, to do hierarchical clustering on a large data set, use PROC FASTCLUS to find initial clusters, and then use those initial clusters as input to PROC CLUSTER.

By default, the FASTCLUS procedure uses Euclidean distances, so the cluster centers are based on least squares estimation. This kind of clustering method is often called a *k-means model*, since the cluster centers

are the means of the observations assigned to each cluster when the algorithm is run to complete convergence. Each iteration reduces the least squares criterion until convergence is achieved.

Often there is no need to run the FASTCLUS procedure to convergence. PROC FASTCLUS is designed to find good clusters (but not necessarily the best possible clusters) with only two or three passes through the data set. The initialization method of PROC FASTCLUS guarantees that, if there exist clusters such that all distances between observations in the same cluster are less than all distances between observations in different clusters, and if you tell PROC FASTCLUS the correct number of clusters to find, it can always find such a clustering without iterating. Even with clusters that are not as well separated, PROC FASTCLUS usually finds initial seeds that are sufficiently good that few iterations are required. Hence, by default, PROC FASTCLUS performs only one iteration.

The initialization method used by the FASTCLUS procedure makes it sensitive to outliers. PROC FASTCLUS can be an effective procedure for detecting outliers because outliers often appear as clusters with only one member.

The FASTCLUS procedure can use an L_p (least p th powers) clustering criterion (Spath 1985, pp. 62–63) instead of the least squares (L_2) criterion used in k -means clustering methods. The `LEAST= p` option specifies the power p to be used. Using the `LEAST= p` option increases execution time since more iterations are usually required, and the default iteration limit is increased when you specify `LEAST= p` . Values of p less than 2 reduce the effect of outliers on the cluster centers compared with least squares methods; values of p greater than 2 increase the effect of outliers.

The FASTCLUS procedure is intended for use with large data sets, with 100 or more observations. With small data sets, the results can be highly sensitive to the order of the observations in the data set.

PROC FASTCLUS uses algorithms that place a larger influence on variables with larger variance, so it might be necessary to standardize the variables before performing the cluster analysis. See the “[Using PROC FASTCLUS](#)” section for standardization details.

PROC FASTCLUS produces brief summaries of the clusters it finds. For more extensive examination of the clusters, you can request an output data set containing a cluster membership variable.

Background

The FASTCLUS procedure combines an effective method for finding initial clusters with a standard iterative algorithm for minimizing the sum of squared distances from the cluster means. The result is an efficient procedure for disjoint clustering of large data sets. PROC FASTCLUS was directly inspired by the Hartigan (1975) *leader algorithm* and the MacQueen (1967) *k-means algorithm*. PROC FASTCLUS uses a method that Anderberg (1973) calls *nearest centroid sorting*. A set of points called *cluster seeds* is selected as a first guess of the means of the clusters. Each observation is assigned to the nearest seed to form temporary clusters. The seeds are then replaced by the means of the temporary clusters, and the process is repeated until no further changes occur in the clusters. Similar techniques are described in most references on clustering (Anderberg 1973; Hartigan 1975; Everitt 1980; Spath 1980).

The FASTCLUS procedure differs from other nearest centroid sorting methods in the way the initial cluster seeds are selected. The importance of initial seed selection is demonstrated by Milligan (1980).

The clustering is done on the basis of Euclidean distances computed from one or more numeric variables. If there are missing values, PROC FASTCLUS computes an adjusted distance by using the nonmissing values. Observations that are very close to each other are usually assigned to the same cluster, while observations that are far apart are in different clusters.

The FASTCLUS procedure operates in four steps:

1. Observations called *cluster seeds* are selected.
2. If you specify the DRIFT option, temporary clusters are formed by assigning each observation to the cluster with the nearest seed. Each time an observation is assigned, the cluster seed is updated as the current mean of the cluster. This method is sometimes called *incremental*, *on-line*, or *adaptive training*.
3. If the maximum number of iterations is greater than zero, clusters are formed by assigning each observation to the nearest seed. After all observations are assigned, the cluster seeds are replaced by either the cluster means or other location estimates (cluster centers) appropriate to the LEAST= p option. This step can be repeated until the changes in the cluster seeds become small or zero (MAXITER= $n \geq 1$).
4. Final clusters are formed by assigning each observation to the nearest seed.

If PROC FASTCLUS runs to complete convergence, the final cluster seeds will equal the cluster means or cluster centers. If PROC FASTCLUS terminates before complete convergence, which often happens with the default settings, the final cluster seeds might not equal the cluster means or cluster centers. If you want complete convergence, specify CONVERGE=0 and a large value for the MAXITER= option.

The initial cluster seeds must be observations with no missing values. You can specify the maximum number of seeds (and, hence, clusters) by using the MAXCLUSTERS= option. You can also specify a minimum distance by which the seeds must be separated by using the RADIUS= option.

PROC FASTCLUS always selects the first complete (no missing values) observation as the first seed. The next complete observation that is separated from the first seed by at least the distance specified in the RADIUS= option becomes the second seed. Later observations are selected as new seeds if they are separated from all previous seeds by at least the radius, as long as the maximum number of seeds is not exceeded.

If an observation is complete but fails to qualify as a new seed, PROC FASTCLUS considers using it to replace one of the old seeds. Two tests are made to see if the observation can qualify as a new seed.

First, an old seed is replaced if the distance between the observation and the closest seed is greater than the minimum distance between seeds. The seed that is replaced is selected from the two seeds that are closest to each other. The seed that is replaced is the one of these two with the shortest distance to the closest of the remaining seeds when the other seed is replaced by the current observation.

If the observation fails the first test for seed replacement, a second test is made. The observation replaces the nearest seed if the smallest distance from the observation to all seeds other than the nearest one is greater than the shortest distance from the nearest seed to all other seeds. If the observation fails this test, PROC FASTCLUS goes on to the next observation.

You can specify the REPLACE= option to limit seed replacement. You can omit the second test for seed replacement (REPLACE=PART), causing PROC FASTCLUS to run faster, but the seeds selected might not be as widely separated as those obtained by the default method. You can also suppress seed replacement entirely by specifying REPLACE=NONE. In this case, PROC FASTCLUS runs much faster, but you must choose a good value for the RADIUS= option in order to get good clusters. This method is similar to the Hartigan (1975, pp. 74–78) leader algorithm and the *simple cluster seeking algorithm* described by Tou and Gonzalez (1974, pp. 90–92).

Getting Started: FASTCLUS Procedure

The following example demonstrates how to use the FASTCLUS procedure to compute disjoint clusters of observations in a SAS data set.

The data in this example are measurements taken on 159 freshwater fish caught from the same lake (Laen-
gelmavesi) near Tampere in Finland. This data set is available from Puranen.

The species (bream, parkki, pike, perch, roach, smelt, and whitefish), weight, three different length measurements (measured from the nose of the fish to the beginning of its tail, the notch of its tail, and the end of its tail), height, and width of each fish are tallied. The height and width are recorded as percentages of the third length variable.

Suppose that you want to group empirically the fish measurements into clusters and that you want to associate the clusters with the species. You can use the FASTCLUS procedure to perform a cluster analysis.

The following DATA step creates the SAS data set Fish:

```
proc format;
  value specfmt
    1='Bream'
    2='Roach'
    3='Whitefish'
    4='Parkki'
    5='Perch'
    6='Pike'
    7='Smelt';
run;

data fish (drop=HtPct WidthPct);
  title 'Fish Measurement Data';
  input Species Weight Length1 Length2 Length3 HtPct WidthPct @@;

  *** transform variables;
  if Weight <= 0 or Weight =. then delete;
  Weight3=Weight**(1/3);
  Height=HtPct*Length3/(Weight3*100);
  Width=WidthPct*Length3/(Weight3*100);
  Length1=Length1/Weight3;
  Length2=Length2/Weight3;
  Length3=Length3/Weight3;
  logLengthRatio=log(Length3/Length1);

  format Species specfmt.;
  symbol = put(Species, specfmt2.);

;
```

The double trailing at sign (@@) in the INPUT statement specifies that observations are input from each line until all values are read. The variables are rescaled in order to adjust for dimensionality. Because the new variables Weight3–logLengthRatio depend on the variable Weight, observations with missing values for Weight are not added to the data set. Consequently, there are 157 observations in the SAS data set Fish.

In the Fish data set, the variables are not measured in the same units and cannot be assumed to have equal variance. Therefore, it is necessary to standardize the variables before performing the cluster analysis.

The following statements standardize the variables and perform a cluster analysis on the standardized data:

```

proc stdize data=Fish out=Stand method=std;
  var Length1 logLengthRatio Height Width Weight3;
run;

proc fastclus data=Stand out=Clust
  maxclusters=7 maxiter=100;
  var Length1 logLengthRatio Height Width Weight3;
run;
```

The STDIZE procedure is first used to standardize all the analytical variables to a mean of 0 and standard deviation of 1. The procedure creates the output data set Stand to contain the transformed variables (for detailed information, see Chapter 87, “[The STDIZE Procedure](#)”).

The FASTCLUS procedure then uses the data set Stand as input and creates the data set Clust. This output data set contains the original variables and two new variables, Cluster and Distance. The variable Cluster contains the cluster number to which each observation has been assigned. The variable Distance gives the distance from the observation to its cluster seed.

It is usually desirable to try several values of the MAXCLUSTERS= option. A reasonable beginning for this example is to use MAXCLUSTERS=7, since there are seven species of fish represented in the data set Fish.

The VAR statement specifies the variables used in the cluster analysis.

The results from this analysis are displayed in the following figures.

Figure 36.1 Initial Seeds Used in the FASTCLUS Procedure

Criterion Based on Final Seeds = 0.3979					

the [Figure 36.1](#) displays the table of initial seeds used for each variable and cluster. The first line in the figure displays the option settings for REPLACE, RADIUS, MAXCLUSTERS, and MAXITER. These options, with the exception of MAXCLUSTERS and MAXITER, are set at their respective default values (REPLACE=FULL, RADIUS=0). Both the MAXCLUSTERS= and MAXITER= options are set in the PROC FASTCLUS statement.

Next, PROC FASTCLUS produces a table of summary statistics for the clusters. [Figure 36.2](#) displays the number of observations in the cluster (frequency) and the root mean squared standard deviation. The next two columns display the largest Euclidean distance from the cluster seed to any observation within the cluster and the number of the nearest cluster.

The last column of the table displays the distance between the centroid of the nearest cluster and the centroid of the current cluster. A centroid is the point having coordinates that are the means of all the observations in the cluster.

Figure 36.2 Cluster Summary Table from the FASTCLUS Procedure

Cluster Summary					
Cluster	Frequency	RMS Std Deviation	Maximum Distance from Seed to Observation	Radius Exceeded	Nearest Cluster
1	17	0.5064	1.7781		4
2	19	0.3696	1.5007		4
3	13	0.3803	1.7135		1
4	13	0.4161	1.3976		7
5	11	0.2466	0.6966		6
6	34	0.3563	1.5443		5
7	50	0.4447	2.3915		4

Cluster Summary		
Cluster	Distance Between Cluster Centroids	
1	2.5106	
2	1.5510	
3	2.6704	
4	1.4266	
5	1.7301	
6	1.7301	
7	1.4266	

Figure 36.3 displays the table of statistics for the variables. The table lists for each variable the total standard deviation, the pooled within-cluster standard deviation and the R-square value for predicting the variable from the cluster. The ratio of between-cluster variance to within-cluster variance (R^2 to $1 - R^2$) appears in the last column.

Figure 36.3 Statistics for Variables Used in the FASTCLUS Procedure

Statistics for Variables				
Variable	Total STD	Within STD	R-Square	RSQ/(1-RSQ)
Length1	1.00000	0.31428	0.905030	9.529606
logLengthRatio	1.00000	0.39276	0.851676	5.741989
Height	1.00000	0.20917	0.957929	22.769295
Width	1.00000	0.55558	0.703200	2.369270
Weight3	1.00000	0.47251	0.785323	3.658162
OVER-ALL	1.00000	0.40712	0.840631	5.274764

Pseudo F Statistic = 131.87

Approximate Expected Over-All R-Squared = 0.57420

Cubic Clustering Criterion = 37.808

The pseudo F statistic, approximate expected overall R square, and cubic clustering criterion (CCC) are listed at the bottom of the figure. You can compare values of these statistics by running PROC FASTCLUS with different values for the MAXCLUSTERS= option. The R square and CCC values are not valid for correlated variables.

Values of the cubic clustering criterion greater than 2 or 3 indicate good clusters. Values between 0 and 2 indicate potential clusters, but they should be taken with caution; large negative values can indicate outliers.

PROC FASTCLUS next produces the within-cluster means and standard deviations of the variables, displayed in Figure 36.4.

Figure 36.4 Cluster Means and Standard Deviations from the FASTCLUS Procedure

Cluster Means

It is useful to study further the clusters calculated by the FASTCLUS procedure. One method is to look at a frequency tabulation of the clusters with other classification variables. The following statements invoke the FREQ procedure to crosstabulate the empirical clusters with the variable Species:

```
proc freq data=Clust;
  tables Species*Cluster;
run;
```

Figure 36.5 displays the marked division between clusters.

For cases in which you have three or more clusters, you can use the CANDISC and SGPLOT procedures to obtain a graphical check on the distribution of the clusters. In the following statements, the CANDISC and SGPLOT procedures are used to compute canonical variables and plot the clusters:

```
proc candisc data=Clust out=Can noprint;
  class Cluster;
  var Length1 logLengthRatio Height Width Weight3;
run;

proc sgplot data=Can;
  scatter y=Can2 x=Can1 / group=Cluster;
run;
```

First, the CANDISC procedure is invoked to perform a canonical discriminant analysis by using the data set Clust and creating the output SAS data set Can. The NOPRINT option suppresses display of the output. The CLASS statement specifies the variable Cluster to define groups for the analysis. The VAR statement specifies the variables used in the analysis.

Next, the SGPLOT procedure plots the two canonical variables from PROC CANDISC, Can1 and Can2. The SCATTER statement specifies the variable Cluster as the group identification variable. The resulting plot (Figure 36.6) illustrates the spatial separation of the clusters calculated in the FASTCLUS procedure.

Figure 36.6 Plot of Canonical Variables and Cluster Value

Syntax: FASTCLUS Procedure

The following statements are available in the FASTCLUS procedure:

```
PROC FASTCLUS < MAXCLUSTERS=n > < RADIUS=t > < options > ;  
  VAR variables ;  
  ID variables ;  
  FREQ variable ;  
  WEIGHT variable ;  
  BY variables ;
```

Usually you need only the VAR statement in addition to the PROC FASTCLUS statement. The BY, FREQ, ID, VAR, and WEIGHT statements are described in alphabetical order after the PROC FASTCLUS statement.

PROC FASTCLUS Statement

```
PROC FASTCLUS < MAXCLUSTERS=n > < RADIUS=t > < options > ;
```

The PROC FASTCLUS statement invokes the FASTCLUS procedure. You must specify the MAXCLUSTERS= option or RADIUS= option or both in the PROC FASTCLUS statement.

MAXCLUSTERS=*n*

MAXC=*n*

specifies the maximum number of clusters permitted. If you omit the MAXCLUSTERS= option, a value of 100 is assumed.

RADIUS=*t*

R=*t*

establishes the minimum distance criterion for selecting new seeds. No observation is considered as a new seed unless its minimum distance to previous seeds exceeds the value given by the RADIUS= option. The default value is 0. If you specify the REPLACE=RANDOM option, the RADIUS= option is ignored.

You can specify the following options in the PROC FASTCLUS statement. [Table 36.1](#) summarizes the options available in the PROC FASTCLUS statement.

Table 36.1 PROC FASTCLUS Statement Options

Option	Description
Specify input and output data sets	
DATA=	Specifies input data set
INSTAT=	Specifies input SAS data set previously created by the OUTSTAT= option
SEED=	Specifies input SAS data set for selecting initial cluster seeds
VARDEF=	Specifies divisor for variances
Output Data Processing	
CLUSTER=	Specifies name for cluster membership variable in OUTSEED= and OUT= data sets
CLUSTERLABEL=	Specifies label for cluster membership variable in OUTSEED= and OUT= data sets
OUT=	Specifies output SAS data set containing original data and cluster assignments
OUTITER	Specifies writing to OUTSEED= data set on every iteration
OUTSEED= or MEAN=	Specifies output SAS data set containing cluster centers
OUTSTAT=	Specifies output SAS data set containing statistics
Initial Clusters	
DRIFT	Permits cluster to seeds to drift during initialization
MAXCLUSTERS=	Specifies maximum number of clusters
RADIUS=	Specifies minimum distance for selecting new seeds
RANDOM=	Specifies seed to initialize pseudo-random number generator
REPLACE=	Specifies seed replacement method
Clustering Methods	
CONVERGE=	Specifies convergence criterion
DELETE=	Deletes cluster seeds with few observations
LEAST=	Optimizes an L_p criterion, where $1 \leq p \leq \infty$
MAXITER=	Specifies maximum number of iterations
STRICT	Prevents an observation from being assigned to a cluster if its distance to the nearest cluster seed is large

Table 36.1 *continued*

Option	Description
Arcane Algorithmic Options	
BINS=	Specifies number of bins used for computing medians for LEAST=1
HC=	Specifies criterion for updating the homotopy parameter
HP=	Specifies initial value of the homotopy parameter
IRLS	Uses an iteratively reweighted least squares method instead of the modified Ekblom-Newton method for $1 < p < 2$
Missing Values	
IMPUTE	Imputes missing values after final cluster assignment
NOMISS	Excludes observations with missing values
Control Displayed Output	
DISTANCE	Displays distances between cluster centers
LIST	Displays cluster assignments for all observations
NOPRINT	Suppresses displayed output
SHORT	Suppresses display of large matrices
SUMMARY	Suppresses display of all results except for the cluster summary
VARIABLESAREUNCORRELATED	Suppresses warning in output

The following list provides details on these options. The list is in alphabetical order.

BINS=*n*

specifies the number of bins used in the bin-sort algorithm for computing medians for LEAST=1. By default, PROC FASTCLUS uses from 10 to 100 bins, depending on the amount of memory available. Larger values use more memory and make each iteration somewhat slower, but they can reduce the number of iterations. Smaller values have the opposite effect. The minimum value of *n* is 5.

CLUSTER=*name*

specifies a name for the variable in the OUTSEED= and OUT= data sets that indicates cluster membership. The default name for this variable is CLUSTER.

CLUSTERLABEL=*name*

specifies a label for the variable CLUSTER in the OUTSEED= and OUT= data sets. By default this variable has no label.

CONVERGE=*c***CONV=*c***

specifies the convergence criterion. Any nonnegative value is permitted. The default value is 0.0001 for all values of *p* if LEAST=*p* is explicitly specified; otherwise, the default value is 0.02. Iterations stop when the maximum relative change in the cluster seeds is less than or equal to the convergence criterion and additional conditions on the homotopy parameter, if any, are satisfied (see the HP= option). The relative change in a cluster seed is the distance between the old seed and the new seed divided by a scaling factor. If you do not specify the LEAST= option, the scaling factor is the minimum distance between the initial seeds. If you specify the LEAST= option, the scaling factor is an L_1 scale estimate and is recomputed on each iteration. Specify the CONVERGE= option only if you specify a MAXITER= value greater than 1.

DATA=SAS-data-set

specifies the input data set containing observations to be clustered. If you omit the DATA= option, the most recently created SAS data set is used. The data must be coordinates, not distances, similarities, or correlations.

DELETE=*n*

deletes cluster seeds to which *n* or fewer observations are assigned. Deletion occurs after processing for the DRIFT option is completed and after each iteration specified by the MAXITER= option. Cluster seeds are not deleted after the final assignment of observations to clusters, so in rare cases a final cluster might not have more than *n* members. The DELETE= option is ineffective if you specify MAXITER=0 and do not specify the DRIFT option. By default, no cluster seeds are deleted.

DISTANCE | DIST

computes distances between the cluster means.

DRIFT

executes the second of the four steps described in the section “[Background](#)” on page 2300. After initial seed selection, each observation is assigned to the cluster with the nearest seed. After an observation is processed, the seed of the cluster to which it is assigned is recalculated as the mean of the observations currently assigned to the cluster. Thus, the cluster seeds drift about rather than remaining fixed for the duration of the pass.

HC=*c***HP=*p*₁ < *p*₂ >**

pertains to the homotopy parameter for LEAST=*p*, where $1 < p < 2$. You should specify these options only if you encounter convergence problems when you use the default values.

For $1 < p < 2$, PROC FASTCLUS tries to optimize a perturbed variant of the L_p clustering criterion (Gonin and Money 1989, pp. 5–6).

When the homotopy parameter is 0, the optimization criterion is equivalent to the clustering criterion. For a large homotopy parameter, the optimization criterion approaches the least squares criterion and is therefore easy to optimize. Beginning with a large homotopy parameter, PROC FASTCLUS gradually decreases it by a factor in the range [0.01,0.5] over the course of the iterations. When both the homotopy parameter and the convergence measure are sufficiently small, the optimization process is declared to have converged.

If the initial homotopy parameter is too large or if it is decreased too slowly, the optimization can require many iterations. If the initial homotopy parameter is too small or if it is decreased too quickly, convergence to a local optimum is likely. The following list gives details on setting the homotopy parameter.

HC=*c* specifies the criterion for updating the homotopy parameter. The homotopy parameter is updated when the maximum relative change in the cluster seeds is less than or equal to *c*. The default is the minimum of 0.01 and 100 times the value of the CONVERGE= option.

HP=*p*₁ specifies *p*₁ as the initial value of the homotopy parameter. The default is 0.05 if the modified Eklblom-Newton method is used; otherwise, it is 0.25.

HP=*p*₁ *p*₂ also specifies *p*₂ as the minimum value for the homotopy parameter, which must be reached for convergence. The default is the minimum of *p*₁ and 0.01 times the value of the CONVERGE= option.

IMPUTE

requests imputation of missing values after the final assignment of observations to clusters. If an observation that is assigned (or would have been assigned) to a cluster has a missing value for variables used in the cluster analysis, the missing value is replaced by the corresponding value in the cluster seed to which the observation is assigned (or would have been assigned). If the observation cannot be assigned to a cluster, missing value replacement depends on whether or not the NOMISS option is specified. If NOMISS is not specified, missing values are replaced by the mean of all observations in the DATA= data set having a value for that variable. If NOMISS is specified, missing values are replaced by the mean of only observations used in the analysis. (A weighted mean is used if a variable is specified in the WEIGHT statement.) For information about cluster assignment see the section “OUT= Data Set” on page 2320. If you specify the IMPUTE option, the imputed values are not used in computing cluster statistics.

If you also request an OUT= data set, it contains the imputed values.

INSTAT=SAS-data-set

reads a SAS data set previously created with the FASTCLUS procedure by using the OUTSTAT= option. If you specify the INSTAT= option, no clustering iterations are performed and no output is displayed. Only cluster assignment and imputation are performed as an OUT= data set is created.

IRLS

causes PROC FASTCLUS to use an iteratively reweighted least squares method instead of the modified Eklblom-Newton method. If you specify the IRLS option, you must also specify LEAST= p , where $1 < p < 2$. Use the IRLS option only if you encounter convergence problems with the default method.

LEAST= p | MAX**L= p | MAX**

causes PROC FASTCLUS to optimize an L_p criterion, where $1 \leq p \leq \infty$ (Spath 1985, pp. 62–63). Infinity is indicated by LEAST=MAX. The value of this clustering criterion is displayed in the iteration history.

If you do not specify the LEAST= option, PROC FASTCLUS uses the least squares (L_2) criterion. However, the default number of iterations is only 1 if you omit the LEAST= option, so the optimization of the criterion is generally not completed. If you specify the LEAST= option, the maximum number of iterations is increased to permit the optimization process a chance to converge. See the MAXITER= n option for details.

Specifying the LEAST= option also changes the default convergence criterion from 0.02 to 0.0001. See the CONVERGE= c for details.

When LEAST=2, PROC FASTCLUS tries to minimize the root mean squared difference between the data and the corresponding cluster means.

When LEAST=1, PROC FASTCLUS tries to minimize the mean absolute difference between the data and the corresponding cluster medians.

When LEAST=MAX, PROC FASTCLUS tries to minimize the maximum absolute difference between the data and the corresponding cluster midranges.

For general values of p , PROC FASTCLUS tries to minimize the p th root of the mean of the p th powers of the absolute differences between the data and the corresponding cluster seeds.

The divisor in the clustering criterion is either the number of nonmissing data used in the analysis or, if there is a WEIGHT statement, the sum of the weights corresponding to all the nonmissing data used in the analysis (that is, an observation with n nonmissing data contributes n times the observation weight to the divisor). The divisor is not adjusted for degrees of freedom.

The method for updating cluster seeds during iteration depends on the LEAST= option, as follows (Gonin and Money 1989).

LEAST= p	Algorithm for Computing Cluster Seeds
$p = 1$	bin sort for median
$1 < p < 2$	modified Merle-Spath if you specify IRLS; otherwise modified Ekblom-Newton
$p = 2$	arithmetic mean
$2 < p < \infty$	Newton
$p = \infty$	midrange

During the final pass, a modified Merle-Spath step is taken to compute the cluster centers for $1 \leq p < 2$ or $2 < p < \infty$.

If you specify the LEAST= p option with a value other than 2, PROC FASTCLUS computes pooled scale estimates analogous to the root mean squared standard deviation but based on p th power deviations instead of squared deviations.

LEAST= p	Scale Estimate
$p = 1$	mean absolute deviation
$1 < p < \infty$	root mean p th-power absolute deviation
$p = \infty$	maximum absolute deviation

The divisors for computing the mean absolute deviation or the root mean p th-power absolute deviation are adjusted for degrees of freedom just like the divisors for computing standard deviations. This adjustment can be suppressed by the VARDEF= option.

LIST

lists all observations, giving the value of the ID variable (if any), the number of the cluster to which the observation is assigned, and the distance between the observation and the final cluster seed.

MAXITER= n

specifies the maximum number of iterations for recomputing cluster seeds. When the value of the MAXITER= option is greater than zero, PROC FASTCLUS executes the third of the four steps described in the section “[Background](#)” on page 2300. In each iteration, each observation is assigned to the nearest seed, and the seeds are recomputed as the means of the clusters.

The default value of the MAXITER= option depends on the LEAST= p option.

LEAST= p	MAXITER=
not specified	1
$p = 1$	20
$1 < p < 1.5$	50
$1.5 \leq p < 2$	20
$p = 2$	10
$2 < p \leq \infty$	20

MEAN=SAS-data-set

creates an output data set to contain the cluster means and other statistics for each cluster. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

NOMISS

excludes observations with missing values from the analysis. However, if you also specify the IMPUTE option, observations with missing values are included in the final cluster assignments.

NOPRINT

suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, “[Using the Output Delivery System](#).”

OUT=SAS-data-set

creates an output data set to contain all the original data, plus the new variables CLUSTER and DISTANCE. If you want to create a SAS data set in a permanent library, you must specify a two-level name. For more information about permanent libraries and SAS data sets, see *SAS Language Reference: Concepts*.

OUTITER

outputs information from the iteration history to the OUTSEED= data set, including the cluster seeds at each iteration.

OUTSEED=SAS-data-set**OUTS=SAS-data-set**

is another name for the MEAN= data set, provided because the data set can contain location estimates other than means. The MEAN= option is still accepted.

OUTSTAT=SAS-data-set

creates an output data set to contain various statistics, especially those not included in the OUTSEED= data set. Unlike the OUTSEED= data set, the OUTSTAT= data set is not suitable for use as a SEED= data set in a subsequent PROC FASTCLUS step.

RANDOM=n

specifies a positive integer as a starting value for the pseudo-random number generator for use with REPLACE=RANDOM. If you do not specify the RANDOM= option, the time of day is used to initialize the pseudo-random number sequence.

REPLACE=FULL | PART | NONE | RANDOM

specifies how seed replacement is performed, as follows:

FULL	requests default seed replacement as described in the section “ Background ” on page 2300.
PART	requests seed replacement only when the distance between the observation and the closest seed is greater than the minimum distance between seeds.
NONE	suppresses seed replacement.
RANDOM	selects a simple pseudo-random sample of complete observations as initial cluster seeds.

SEED=SAS-data-set

specifies an input data set from which initial cluster seeds are to be selected. If you do not specify the SEED= option, initial seeds are selected from the DATA= data set. The SEED= data set must contain the same variables that are used in the data analysis.

SHORT

suppresses the display of the initial cluster seeds, cluster means, and standard deviations.

STRICT**STRICT=s**

prevents an observation from being assigned to a cluster if its distance to the nearest cluster seed exceeds the value of the STRICT= option. If you specify the STRICT option without a numeric value, you must also specify the RADIUS= option, and its value is used instead. In the OUT= data set, observations that are not assigned due to the STRICT= option are given a negative cluster number, the absolute value of which indicates the cluster with the nearest seed.

SUMMARY

suppresses the display of the initial cluster seeds, statistics for variables, cluster means, and standard deviations.

VARDEF=DF | N | WDF | WEIGHT | WGT

specifies the divisor to be used in the calculation of variances and covariances. The default value is VARDEF=DF. The possible values of the VARDEF= option and associated divisors are as follows.

Value	Description	Divisor
DF	error degrees of freedom	$n - c$
N	number of observations	n
WDF	sum of weights DF	$(\sum_i w_i) - c$
WEIGHT WGT	sum of weights	$\sum_i w_i$

In the preceding definitions, c represents the number of clusters.

VARIABLESAREUNCORRELATED

suppresses the warning, displayed in the listing when there are two or more VAR variables, concerning the validity of the Approximate Expected Over-All R-Squared and the Cubic Clustering Criterion when the variables used in clustering are correlated. Note that the FASTCLUS procedure does not compute correlations; the warning is for a potential problem.

BY Statement

BY variables ;

You can specify a BY statement with PROC FASTCLUS to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the FASTCLUS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

If you specify the SEED= option and the SEED= data set does not contain any of the BY variables, then the entire SEED= data set is used to obtain initial cluster seeds for each BY group in the DATA= data set.

If the SEED= data set contains some but not all of the BY variables, or if some BY variables do not have the same type or length in the SEED= data set as in the DATA= data set, then PROC FASTCLUS displays an error message and stops.

If all the BY variables appear in the SEED= data set with the same type and length as in the DATA= data set, then each BY group in the SEED= data set is used to obtain initial cluster seeds for the corresponding BY group in the DATA= data set. All BY groups in the DATA= data set must also appear in the SEED= data set. The BY groups in the SEED= data set must be in the same order as in the DATA= data set. If you specify the NOTSORTED option in the BY statement, both data sets must contain exactly the same BY groups in the same order. If you do not specify NOTSORTED, some BY groups can appear in the SEED= data set but not in the DATA= data set; such BY groups are not used in the analysis.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

FREQ Statement

FREQ *variable* ;

If a variable in the data set represents the frequency of occurrence for the other values in the observation, include the variable's name in a FREQ statement. The procedure then treats the data set as if each observation appears n times, where n is the value of the FREQ variable for the observation.

If the value of the FREQ variable is missing or less than or equal to zero, the observation is not used in the analysis. The exact values of the FREQ variable are used in computations: frequency values are not truncated to integers. The total number of observations is considered to be equal to the sum of the FREQ variable when the procedure determines degrees of freedom for significance probabilities.

The WEIGHT and FREQ statements have a similar effect, except in determining the number of observations for significance tests.

ID Statement

ID *variable* ;

The ID variable, which can be character or numeric, identifies observations on the output when you specify the LIST option.

VAR Statement

VAR *variables* ;

The VAR statement lists the numeric variables to be used in the cluster analysis. If you omit the VAR statement, all numeric variables not listed in other statements are used.

WEIGHT Statement

WEIGHT *variable* ;

The values of the WEIGHT variable are used to compute weighted cluster means. The WEIGHT and FREQ statements have a similar effect, except the WEIGHT statement does not alter the degrees of freedom or the number of observations. The WEIGHT variable can take nonintegral values. An observation is used in the analysis only if the value of the WEIGHT variable is greater than zero.

Details: FASTCLUS Procedure

Updates in the FASTCLUS Procedure

Some FASTCLUS procedure options and statements have changed from previous versions. The differences are as follows:

- Values of the FREQ variable are no longer truncated to integers. Noninteger variables specified in the FREQ statement produce results different from those in previous releases.
- The IMPUTE option produces different cluster standard deviations and related statistics. When you specify the IMPUTE option, imputed values are no longer used in computing cluster statistics. This change causes the cluster standard deviations and other statistics computed from the standard deviations to be different from those in previous releases.
- The INSTAT= option reads a SAS data set previously created with the FASTCLUS procedure by using the OUTSTAT= option. If you specify the INSTAT= option, no clustering iterations are performed and no output is produced. Only cluster assignment and imputation are performed as an OUT= data set is created.
- The OUTSTAT= data set contains additional information used for imputation. `_TYPE_=SEED` corresponds to values that are cluster seeds. Observations previously designated `_TYPE_='SCALE'` are now `_TYPE_='DISPERSION'`.

Missing Values

Observations with all missing values are excluded from the analysis. If you specify the NOMISS option, observations with any missing values are excluded. Observations with missing values cannot be cluster seeds.

The distance between an observation with missing values and a cluster seed is obtained by computing the squared distance based on the nonmissing values, multiplying by the ratio of the number of variables, n , to the number of variables having nonmissing values, m , and taking the square root:

$$\sqrt{\left(\frac{n}{m}\right) \sum (x_i - s_i)^2}$$

where

- n = number of variables
- m = number of variables with nonmissing values
- x_i = value of the i th variable for the observation
- s_i = value of the i th variable for the seed

If you specify the LEAST= p option with a power p other than 2 (the default), the distance is computed using

$$\left(\left(\frac{n}{m}\right) \sum (x_i - s_i)^p\right)^{\frac{1}{p}}$$

The summation is taken over variables with nonmissing values.

The IMPUTE option fills in missing values in the OUT= output data set.

Output Data Sets

OUT= Data Set

The OUT= data set contains the following:

- the original variables
- a new variable indicating the cluster assignment status of each observation. The value will be less than the permitted number of clusters (see the MAXCLUSTERS= option) if the procedure detects fewer clusters than the maximum. A positive value indicates the cluster to which the observation was assigned. A negative value indicates that the observation was not assigned to a cluster (see the STRICT option), and the absolute value indicates the cluster to which the observation would have been assigned. If the value is missing, the observation cannot be assigned to any cluster. You can specify the variable name with the CLUSTER= option. The default name is CLUSTER.
- a new variable, DISTANCE, giving the distance from the observation to its cluster seed

If you specify the IMPUTE option, the OUT= data set also contains a new variable, _IMPUTE_, giving the number of imputed values in each observation.

OUTSEED= Data Set

The OUTSEED= data set contains one observation for each cluster. The variables are as follows:

- the BY variables, if any
- a new variable giving the cluster number. You can specify the variable name with the CLUSTER= option. The default name is CLUSTER.
- either the FREQ variable or a new variable called _FREQ_ giving the number of observations in the cluster
- the WEIGHT variable, if any
- a new variable, _RMSSTD_, giving the root mean squared standard deviation for the cluster. See Chapter 31, “[The CLUSTER Procedure](#),” for details.
- a new variable, _RADIUS_, giving the maximum distance between any observation in the cluster and the cluster seed
- a new variable, _GAP_, containing the distance between the current cluster mean and the nearest other cluster mean. The value is the centroid distance given in the output.
- a new variable, _NEAR_, specifying the cluster number of the nearest cluster
- the VAR variables giving the cluster means

If you specify the LEAST= p option with a value other than 2, the _RMSSTD_ variable is replaced by the _SCALE_ variable, which contains the pooled scale estimate analogous to the root mean squared standard deviation but based on p th-power deviations instead of squared deviations:

LEAST=1	mean absolute deviation
LEAST= p	root mean p -th-power absolute deviation
LEAST=MAX	maximum absolute deviation

If you specify the OUTITER option, there is one set of observations in the OUTSEED= data set for each pass through the data set (that is, one set for initial seeds, one for each iteration, and one for the final clusters). Also, several additional variables appear:

ITER	is the iteration number. For the initial seeds, the value is 0. For the final cluster means or centers, the _ITER_ variable is one greater than the last iteration reported in the iteration history.
CRIT	is the clustering criterion as described under the LEAST= option.
CHANGE	is the maximum over clusters of the relative change in the cluster seed from the previous iteration. The relative change in a cluster seed is the distance between the old seed and the new seed divided by a scaling factor. If you do not specify the LEAST= option, the scaling factor is the minimum distance between the initial seeds. If you specify the LEAST= option, the scaling factor is an L_1 scale estimate and is recomputed on each iteration.

- _HOMPAR_** is the value of the homotopy parameter. This variable appears only for LEAST= p with $1 < p < 2$.
- _BINSIZ_** is the maximum bin size used for estimating medians. This variable appears only for LEAST=1.

If you specify the OUTITER option, the variables **_SCALE_** or **_RMSSTD_**, **_RADIUS_**, **_NEAR_**, and **_GAP_** have missing values except for the last pass.

You can use the OUTSEED= data set as a SEED= input data set for a subsequent analysis.

OUTSTAT= Data Set

The variables in the OUTSTAT= data set are as follows:

- BY variables, if any
- a new character variable, **_TYPE_**, specifying the type of statistic given by other variables (see [Table 36.2](#) and [Table 36.3](#))
- a new numeric variable giving the cluster number. You can specify the variable name with the CLUSTER= option. The default name is CLUSTER.
- a new numeric variable, **OVER_ALL**, containing statistics that apply over all of the VAR variables
- the VAR variables giving statistics for particular variables

The values of **_TYPE_** for all LEAST= options are given in [Table 36.2](#).

Table 36.2 **_TYPE_**

TYPE	Contents of VAR Variables	Contents of OVER_ALL
INITIAL	Initial seeds	Missing
CRITERION	Missing	Optimization criterion (see the LEAST= option); this value is displayed just before the “Cluster Summary” table.
CENTER	Cluster centers (see the LEAST= option)	Missing
SEED	Cluster seeds: additional information used for imputation	
DISPERSION	Dispersion estimates for each cluster (see the LEAST= option); these values are displayed in a separate row with title depending on the LEAST= option	Dispersion estimates pooled over variables (see the LEAST= option); these values are displayed in the “Cluster Summary” table with label depending on the LEAST= option.

Table 36.2 *continued*

TYPE	Contents of VAR variables	Contents of OVER_ALL
FREQ	Frequency of each cluster omitting observations with missing values for the VAR variable; these values are not displayed	Frequency of each cluster based on all observations with any non-missing value; these values are displayed in the “Cluster Summary” table.
WEIGHT	Sum of weights for each cluster omitting observations with missing values for the VAR variable; these values are not displayed	Sum of weights for each cluster based on all observations with any nonmissing value; these values are displayed in the “Cluster Summary” table.

Observations with `_TYPE_='WEIGHT'` are included only if you specify the WEIGHT statement.

The `_TYPE_` values included only for least squares clustering are given [Table 36.3](#). Least squares clustering is obtained by omitting the `LEAST=` option or by specifying `LEAST=2`.

Table 36.3 `_TYPE_`

TYPE	Contents of VAR Variables	Contents of OVER_ALL
MEAN	Mean for the total sample; this is not displayed	Missing
STD	Standard deviation for the total sample; labeled “Total STD” in the output	Standard deviation pooled over all the VAR variables; labeled “Total STD” in the output
WITHIN_STD	Pooled within-cluster standard deviation	Within cluster standard deviation pooled over clusters and all the VAR variables
RSQ	R square for predicting the variable from the clusters; labeled “R-Squared” in the output	R square pooled over all the VAR variables; labeled “R-Squared” in the output
RSQ_RATIO	$\frac{R^2}{1-R^2}$; labeled “RSQ/(1-RSQ)” in the output	$\frac{R^2}{1-R^2}$; labeled “RSQ/(1-RSQ)” in the output
PSEUDO_F	Missing	Pseudo <i>F</i> statistic

Table 36.3 continued

TYPE	Contents of VAR variables	Contents of OVER_ALL
ESRQ	Missing	Approximate expected value of R square under the null hypothesis of a single uniform cluster
CCC	Missing	Cubic clustering criterion

Computational Resources

Let

- n = number of observations
- v = number of variables
- c = number of clusters
- p = number of passes over the data set

Memory

The memory required is approximately $4(19v + 12cv + 10c + 2 \max(c + 1, v))$ bytes.

If you request the DISTANCE option, an additional $4c(c + 1)$ bytes of space is needed.

Time

The overall time required by PROC FASTCLUS is roughly proportional to $nvc p$ if c is small with respect to n .

Initial seed selection requires one pass over the data set. If the observations are in random order, the time required is roughly proportional to

$$nvc + vc^2$$

unless you specify REPLACE=NONE. In that case, a complete pass might not be necessary, and the time is roughly proportional to mvc , where $c \leq m \leq n$.

The DRIFT option, each iteration, and the final assignment of cluster seeds each require one pass, with time for each pass roughly proportional to nvc .

For greatest efficiency, you should list the variables in the VAR statement in order of decreasing variance.

Using PROC FASTCLUS

Before using PROC FASTCLUS, decide whether your variables should be standardized in some way, since variables with large variances tend to have more effect on the resulting clusters than those with small variances. If all variables are measured in the same units, standardization might not be necessary. Otherwise, some form of standardization is strongly recommended. The STDIZE procedure provides a variety of standardization methods, including robust scale estimators (for detailed information, see Chapter 87, “[The STDIZE Procedure](#)”).

The FACTOR or PRINCOMP procedure can compute standardized principal component scores. The ACECLUS procedure can transform the variables according to an estimated within-cluster covariance matrix.

Nonlinear transformations of the variables can change the number of population clusters and should therefore be approached with caution. For most applications, the variables should be transformed so that equal differences are of equal practical importance. An interval scale of measurement is required. Ordinal or ranked data are generally not appropriate.

PROC FASTCLUS produces relatively little output. In most cases you should create an output data set and use another procedure such as PRINT, SGPLOT, MEANS, DISCRIM, or CANDISC to study the clusters. It is usually desirable to try several values of the MAXCLUSTERS= option. Macros are useful for running PROC FASTCLUS repeatedly with other procedures.

A simple application of PROC FASTCLUS with two variables to examine the 2- and 3-cluster solutions can proceed as follows:

```
proc stdize method=std out=stan;
    var v1 v2;
run;

proc fastclus data=stan out=clust maxclusters=2;
    var v1 v2;
run;

proc sgplot;
    scatter y=v2 x=v1 / markerchar=cluster;
run;

proc fastclus data=stan out=clust maxclusters=3;
    var v1 v2;
run;

proc sgplot;
    scatter y=v2 x=v1 / markerchar=cluster;
run;
```

If you have more than two variables, you can use the CANDISC procedure to compute canonical variables for plotting the clusters. For example:

```

proc stdize method=std out=stan;
    var v1-v10;
run;

proc fastclus data=stan out=clust maxclusters=3;
    var v1-v10;
run;

proc candisc out=can;
    var v1-v10;
    class cluster;
run;

proc sgplot;
    scatter y=can2 x=can1 / markerchar=cluster;
run;

```

If the data set is not too large, it might also be helpful to use the following to list the clusters:

```

proc sort;
    by cluster distance;
run;

proc print;
    by cluster;
run;

```

By examining the values of `DISTANCE`, you can determine if any observations are unusually far from their cluster seeds.

It is often advisable, especially if the data set is large or contains outliers, to make a preliminary PROC FASTCLUS run with a large number of clusters, perhaps 20 to 100. Use `MAXITER=0` and `OUTSEED=SAS-data-set`. You can save time on subsequent runs if you select cluster seeds from this output data set by using the `SEED=` option.

You should check the preliminary clusters for outliers, which often appear as clusters with only one member. Use a `DATA` step to delete outliers from the data set created by the `OUTSEED=` option before using it as a `SEED=` data set in later runs. If there are severe outliers, you should specify the `STRICT` option in the subsequent PROC FASTCLUS runs to prevent the outliers from distorting the clusters.

You can use the `OUTSEED=` data set with the `SGPLOT` procedure to plot `_GAP_` by `_FREQ_`. An overlay of `_RADIUS_` by `_FREQ_` provides a baseline against which to compare the values of `_GAP_`. Outliers appear in the upper-left area of the plot, with large `_GAP_` values and small `_FREQ_` values. Good clusters appear in the upper-right area, with large values of both `_GAP_` and `_FREQ_`. Good potential cluster seeds appear in the lower right, as well as in the upper-right, since large `_FREQ_` values indicate high-density regions. Small `_FREQ_` values in the left part of the plot indicate poor cluster seeds because the points are in low-density regions. It often helps to remove all clusters with small frequencies even though the clusters might not be remote enough to be considered outliers. Removing points in low-density regions improves cluster separation and provides visually sharper cluster outlines in scatter plots.

Displayed Output

Unless the SHORT or SUMMARY option is specified, PROC FASTCLUS displays the following:

- Initial Seeds, cluster seeds selected after one pass through the data
- Change in Cluster Seeds for each iteration, if you specify MAXITER= $n > 1$

If you specify the LEAST= p option, with ($1 < p < 2$), and you omit the IRLS option, an additional column is displayed in the Iteration History table. This column contains a character to identify the method used in each iteration. PROC FASTCLUS chooses the most efficient method to cluster the data at each iterative step, given the condition of the data. Thus, the method chosen is data dependent. The possible values are described as follows:

Value	Method
N	Newton's Method
I or L	iteratively weighted least squares (IRLS)
1	IRLS step, halved once
2	IRLS step, halved twice
3	IRLS step, halved three times

PROC FASTCLUS displays a Cluster Summary, giving the following for each cluster:

- Cluster number
- Frequency, the number of observations in the cluster
- Weight, the sum of the weights of the observations in the cluster, if you specify the WEIGHT statement
- RMS Std Deviation, the root mean squared across variables of the cluster standard deviations, which is equal to the root mean square distance between observations in the cluster
- Maximum Distance from Seed to Observation, the maximum distance from the cluster seed to any observation in the cluster
- Nearest Cluster, the number of the cluster with mean closest to the mean of the current cluster
- Centroid Distance, the distance between the centroids (means) of the current cluster and the nearest other cluster

A table of statistics for each variable is displayed unless you specify the SUMMARY option. The table contains the following:

- Total STD, the total standard deviation
- Within STD, the pooled within-cluster standard deviation

- R-Square, the R square for predicting the variable from the cluster
- RSQ/(1 - RSQ), the ratio of between-cluster variance to within-cluster variance ($R^2/(1 - R^2)$)
- OVER-ALL, all of the previous quantities pooled across variables

PROC FASTCLUS also displays the following:

- Pseudo F Statistic,

$$\frac{\frac{R^2}{c-1}}{\frac{1-R^2}{n-c}}$$

where R square is the observed overall R square, c is the number of clusters, and n is the number of observations. The pseudo F statistic was suggested by Calinski and Harabasz (1974). See Milligan and Cooper (1985) and Cooper and Milligan (1988) regarding the use of the pseudo F statistic in estimating the number of clusters. See [Example 31.2](#) in Chapter 31, “The CLUSTER Procedure,” for a comparison of pseudo F statistics.

- Observed Overall R-Square, if you specify the SUMMARY option
- Approximate Expected Overall R-Square, the approximate expected value of the overall R square under the uniform null hypothesis assuming that the variables are uncorrelated. The value is missing if the number of clusters is greater than one-fifth the number of observations.
- Cubic Clustering Criterion, computed under the assumption that the variables are uncorrelated. The value is missing if the number of clusters is greater than one-fifth the number of observations.

If you are interested in the approximate expected R square or the cubic clustering criterion but your variables are correlated, you should cluster principal component scores from the PRINCOMP procedure. Both of these statistics are described by Sarle (1983). The performance of the cubic clustering criterion in estimating the number of clusters is examined by Milligan and Cooper (1985) and Cooper and Milligan (1988).

- Distances Between Cluster Means, if you specify the DISTANCE option

Unless you specify the SHORT or SUMMARY option, PROC FASTCLUS displays the following:

- Cluster Means for each variable
- Cluster Standard Deviations for each variable

ODS Table Names

PROC FASTCLUS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 36.4. For more information on ODS, see Chapter 20, “Using the Output Delivery System.”

Table 36.4 ODS Tables Produced by PROC FASTCLUS

ODS Table Name	Description	Statement	Option
ApproxExpOverAllRSq	Approximate expected overall R-square, single number	PROC	default
CCC	CCC, Cubic Clustering Criterion, single number	PROC	default
ClusterList	Cluster listing, obs, id, and distances	PROC	LIST
ClusterSum	Cluster summary, cluster number, distances	PROC	PRINTALL
ClusterCenters	Cluster centers	PROC	default
ClusterDispersion	Cluster dispersion	PROC	default
ConvergenceStatus	Convergence status	PROC	PRINTALL
Criterion	Criterion based on final seeds, single number	PROC	default

InitialSeeds	Initial seeds	PROC	default
IterHistory	Iteration history, various statistics for each iteration	PROC	PRINTALL
MinDist	Minimum distance between initial seeds, single number	PROC	PRINTALL
NumberOfBins	Number of bins	PROC	default
ObsOverAllRSquare	Observed overall R-square, single number	PROC	SUMMARY
PrelScaleEst	Preliminary L(1) scale estimate, single number	PROC	PRINTALL
PseudoFStat	Pseudo F statistic, single number	PROC	default
SimpleStatistics	Simple statistics for input variables	PROC	default
VariableStat	Statistics for variables within clusters	PROC	default

Examples: FASTCLUS Procedure

Example 36.1: Fisher's Iris Data

The iris data published by Fisher (1936) have been widely used for examples in discriminant analysis and cluster analysis. The sepal length, sepal width, petal length, and petal width are measured in millimeters on 50 iris specimens from each of three species, *Iris setosa*, *I. versicolor*, and *I. virginica*. Mezzich and Solomon (1980) discuss a variety of cluster analyses of the iris data.

In this example, the FASTCLUS procedure is used to find two and then three clusters. In the following code, an output data set is created, and PROC FREQ is invoked to compare the clusters with the species classification. See [Output 36.1.1](#) and [Output 36.1.2](#) for these results.

For three clusters, you can use the CANDISC procedure to compute canonical variables for plotting the clusters. See [Output 36.1.3](#) and [Output 36.1.4](#) for the results.

Output 36.1.4 Plot of Fisher's Iris Data using PROC CANDISC

Example 36.2: Outliers

This example involves data artificially generated to contain two clusters and several severe outliers. A preliminary analysis specifies 20 clusters and outputs an OUTSEED= data set to be used for a diagnostic plot. The exact number of initial clusters is not important; similar results could be obtained with 10 or 50 initial clusters. Examination of the plot suggests that clusters with more than five (again, the exact number is not important) observations can yield good seeds for the main analysis. A DATA step deletes clusters with five or fewer observations, and the remaining cluster means provide seeds for the next PROC FASTCLUS analysis.

Two clusters are requested; the LEAST= option specifies the mean absolute deviation criterion (LEAST=1). Values of the LEAST= option less than 2 reduce the effect of outliers on cluster centers.

The next analysis also requests two clusters; the STRICT= option is specified to prevent outliers from distorting the results. The STRICT= value is chosen to be close to the _GAP_ and _RADIUS_ values of the larger clusters in the diagnostic plot; the exact value is not critical.

A final PROC FASTCLUS run assigns the outliers to clusters.

The following SAS statements implement these steps, and the results are displayed in [Output 36.2.3](#) through [Output 36.2.8](#). First, an artificial data set is created with two clusters and some outliers. Then PROC FASTCLUS is run with many clusters to produce an OUTSEED= data set. A diagnostic plot using the variables `_GAP_` and `_RADIUS_` is then produced using the SGSCATTER procedure. The results from these steps are shown in [Output 36.2.1](#) and [Output 36.2.2](#).

Overview: FMM Procedure

The FMM procedure fits statistical models to data for which the distribution of the response is a finite mixture of univariate distributions—that is, each response comes from one of several random univariate distributions with unknown probabilities. You can use PROC FMM to model the component distributions in addition to the mixing probabilities; see “[A Gentle Introduction to Finite Mixture Models](#)” on page 2423 for more precise definitions and discussion of similar but distinct modeling methodologies.

Classical statistical models are a special case of the finite mixture models in which the distribution of the data has only a single component.

Finite mixture models are useful for the following applications:

- estimating multimodal or heavy-tailed densities
- fitting zero-inflated or hurdle models to count data with excess zeros
- modeling overdispersed data
- fitting regression models with complex error distributions
- classifying observations based on predicted component probabilities
- accounting for unobservable, omitted variables
- estimating switching regressions

The FMM procedure is designed to fit finite mixtures of regression models or finite mixtures of generalized linear models in which the covariates and regression structure can be the same across components or might be different. You can fit finite mixture models by maximum likelihood or Bayesian methods.

For more information about the differences between the FMM procedure and other statistical modeling procedures in SAS/STAT software, see the section “[PROC FMM Contrasted with Other SAS Procedures](#)” on page 2359.

Basic Features

The FMM procedure estimates the parameters in univariate finite mixture models and produces various statistics to evaluate parameters and model fit. The following list summarizes some basic features of the FMM procedure:

- maximum likelihood estimation for all models
- Markov chain Monte Carlo estimation for many models, including zero-inflated Poisson models
- many built-in link and distribution functions for modeling, including the beta, shifted t , Weibull, beta-binomial, and generalized Poisson distributions, in addition to many standard members of the exponential family of distributions
- specialized built-in mixture models such as the binomial cluster model (Morel and Nagaraj 1993; Morel and Neerchal 1997; Neerchal and Morel 1998)
- acceptance of multiple **MODEL** statements to build mixture models in which the model effects, distributions, or link functions vary across mixture components
- model-building syntax using **CLASS** and effect-based **MODEL** statements familiar from many other SAS/STAT procedures (for example, the GLM, GLIMMIX, and MIXED procedures)
- evaluation of sequences of mixture models when you specify ranges for the number of components
- simple syntax to impose linear equality and inequality constraints among parameters
- ability to model regression and classification effects in the mixing probabilities through the **PROB-MODEL** statement
- ability to incorporate full or partially known component membership into the analysis through the **PARTIAL=** option in the **PROC FMM** statement
- **OUTPUT** statement that produces a SAS data set with important statistics for interpreting mixture models, such as component log likelihoods and prior and posterior probabilities
- ability to add zero-inflation to any model
- output data set with posterior parameter values for the Markov chain
- high degree of multithreading for high-performance optimization and Monte Carlo sampling

The FMM procedure uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For specific information about the statistical graphics available with the FMM procedure, see the **PLOTS** options in the **PROC FMM** statement.

Assumptions

The FMM procedure makes the following assumptions in fitting statistical models:

- The number of components k in the finite mixture is known a priori and is not a parameter to be estimated.
- The parameters of the components are distinct a priori.
- The observations are uncorrelated.

Notation for the Finite Mixture Model

The general expression for the finite mixture model fitted with the FMM procedure is as follows:

$$f(y) = \sum_{j=1}^k \pi_j(\mathbf{z}, \boldsymbol{\alpha}_j) p_j(y; \mathbf{x}'_j \boldsymbol{\beta}_j, \phi_j)$$

The number of components in the mixture is denoted as k . The mixture probabilities π_j can depend on regressor variables \mathbf{z} and parameters $\boldsymbol{\alpha}_j$. By default, the FMM procedure models these probabilities using a logit transform if $k = 2$ and as a generalized logit model if $k > 2$. The component distributions p_j can also depend on regressor variables in \mathbf{x}_j , regression parameters $\boldsymbol{\beta}_j$, and possibly scale parameters ϕ_j . Notice that the component distributions p_j are indexed by j since the distributions might belong to different families. For example, in a two-component model, you might model one component as a normal (Gaussian) variable and the second component as a variable with a t distribution with low degrees of freedom to manage overdispersion.

The mixture probabilities π_j satisfy $\pi_j \geq 0$, for all j , and

$$\sum_{j=1}^k \pi_j(\mathbf{z}, \boldsymbol{\alpha}_j) = 1$$

Homogeneous Mixtures

If the component distributions are of the same distributional form, the mixture is called homogeneous. In most applications of homogeneous mixtures, the mixing probabilities do not depend on regression parameters. The general model then simplifies to

$$f(y) = \sum_{j=1}^k \pi_j p(y; \mathbf{x}'_j \boldsymbol{\beta}_j, \phi_j)$$

Since the component distributions depend on regression parameters β_j , this model is known as a homogeneous regression mixture. A homogeneous regression mixture assumes that the regression effects are the same across the components, although the FMM procedure does not impose such a restriction. If the component distributions do not contain regression effects, the model

$$f(y) = \sum_{j=1}^k \pi_j p(y; \mu_j, \phi_j)$$

is *the* homogeneous mixture model. A classical case is the estimation of a continuous density as a k -component mixture of normal distributions.

Special Mixtures

The FMM procedure enables you to fit several special mixture models. The Morel-Neerchal binomial cluster model (Morel and Nagaraj 1993; Morel and Neerchal 1997; Neerchal and Morel 1998) is a mixture of binomial distributions in which the success probabilities depend on the mixing probabilities.

Zero-inflated count models are obtained as two-component mixtures where one component is a classical count model—such as the Poisson or negative binomial model—and the other component is a distribution that is concentrated at zero. If the nondegenerate part of this special mixture is a zero-truncated model, the resulting two-component mixture is known as a hurdle model (Cameron and Trivedi 1998).

PROC FMM Contrasted with Other SAS Procedures

Since the FMM procedure fits finite mixtures of generalized linear models, it can also fit standard forms of these models in which the distribution of the data does not follow a mixture. This enables you to use the FMM procedure to estimate parameters in models that can be fit with the CATMOD, LOGISTIC, GENMOD, or GLIMMIX procedures. However, the FMM procedure does not fit models for multinomial data or models with random effects.

The FMM procedure has limited postprocessing capabilities compared to some other statistical procedures that are based on linear models. Concepts that are well understood and commonplace in linear models, such as (linear) estimable functions, estimability, and least squares means, do not apply to mixture models in the same way. For example, even the computation of a predicted value is not without ambiguity. You can estimate the means in the component distributions in addition to the overall mean of the mixture.

The FMM procedure provides a limited number of built-in distributions and link functions. User-defined distributions or link functions are not supported. Mixture models with component distributions that are not supported by the FMM procedure can be fit with the NLMIXED procedure.

For Bayesian estimation, the FMM procedure implements a small number of highly specialized sampling algorithms. These algorithms are very efficient and specifically designed for generalized linear models and their mixtures. This limits, for example, the allowable specifications for prior distributions of the model parameters. Models that do not fit the targeted algorithms of the FMM procedure can be fit with the MCMC procedure.

Getting Started: FMM Procedure

Mixture Modeling for Binomial Overdispersion: “Student,” Pearson, Beer, and Yeast

The following example demonstrates how you can model a complicated, two-component binomial mixture distribution, either with maximum likelihood or with Bayesian methods, with a few simple PROC FMM statements.

William Sealy Gosset, a chemist at the Arthur Guinness Son and Company brewery in Dublin, joined the statistical laboratory of Karl Pearson in 1906–1907 to study statistics. At first Gosset—who published all but one paper under the pseudonym “Student” because his employer forbade publications by employees after a co-worker had disclosed trade secrets—worked on the Poisson limit to the binomial distribution, using haemocytometer yeast cell counts. Gosset’s interest in studying small-sample (and limit) problems was motivated by the small sample sizes he typically saw in his work at the brewery.

Subsequently, Gosset’s yeast count data have been examined and revisited by many authors. In 1915, Karl Pearson undertook his own examination and realized that the variability in “Student’s” data exceeded that consistent with a Poisson distribution. Pearson (1915) bemoans the fact that if this were so, “it is certainly most unfortunate that such material should have been selected to illustrate Poisson’s limit to the binomial.”

Using a count of Gosset’s yeast cell counts on the 400 squares of a haemocytometer (Table 37.1), Pearson argues that a mixture process would explain the heterogeneity (beyond the Poisson).

Table 37.1 “Student’s” Yeast Cell Counts

Number of Cells	0	1	2	3	4	5
Frequency	213	128	37	18	3	1

Pearson fits various models to these data, chief among them a mixture of two binomial series

$$v_1(p_1 + q_1)^\theta + v_2(p_2 + q_2)^\theta$$

where θ is real-valued and thus the binomial series expands to

$$(p + q)^\theta = \sum_{k=0}^{\infty} \frac{\Gamma(\theta + 1)}{\Gamma(k + 1)\Gamma(\theta - k + 1)} p^k q^{\theta-k}$$

Pearson’s fitted model has $\theta = 4.89997$, $v_1 = 356.986$, $v_2 = 43.014$ (corresponding to a mixing proportion of $356.986/(43.014 + 356.986) = 0.892$), and estimated success probabilities in the binomial components of 0.1017 and 0.4514, respectively. The success probabilities indicate that although the data have about a 90% chance of coming from a distribution with small success probability of about 0.1, there is a 10% chance of coming from a distribution with a much larger success probability of about 0.45.

If θ is an integer, the binomial series is the cumulative mass function of a binomial random variable. The value of θ suggests that a suitable model for these data could also be constructed as a two-component mixture of binomial random variables as follows:

$$f(y) = \pi \text{binomial}(5, \mu_1) + (1 - \pi) \text{binomial}(5, \mu_2)$$

The binomial sample size $n=5$ is suggested by Pearson’s estimate of $\theta = 4.89997$ and the fact that the largest cell count in Table 37.1 is 5.

The following DATA step creates a SAS data set from the data in Table 37.1.

```
data yeast;
  input count f;
  n = 5;
  datalines;
  0      213
  1      128
  2       37
  3       18
  4        3
  5        1
;
```

The two-component binomial model is fit with the FMM procedure with the following statements:

```
proc fmm data=yeast;
  model count/n = / k=2;
  freq f;
run;
```

Because the events/trials syntax is used in the MODEL statement, PROC FMM defaults to the binomial distribution. The $K=2$ option specifies that the number of components is fixed and known to be two. The FREQ statement indicates that the data are grouped; for example, the first observation represents 213 squares on the haemacytometer where no yeast cells were found.

The “Model Information” and “Number of Observations” tables in Figure 37.1 convey that the fitted model is a two-component homogeneous binomial mixture with a logit link function. The mixture is *homogeneous* because there are no model effects in the MODEL statement and because both component distributions belong to the same distributional family. By default, PROC FMM estimates the model parameters by maximum likelihood.

Although only six observations are read from the data set, the data represent 400 observations (squares on the haemacytometer). Since a constant binomial sample size of 5 is assumed, the data represent 273 successes (finding a yeast cell) out of 2,000 Bernoulli trials.

Figure 37.1 Model Information for Yeast Cell Model

The FMM Procedure

Number of Observations Used	6
Sum of Frequencies Read	400
Sum of Frequencies Used	400
Number of Events	273
Number of Trials	2000

The estimated intercepts (on the logit scale) for the two binomial means are -2.2316 and -0.2974 , respectively. These values correspond to binomial success probabilities of 0.09695 and 0.4262 , respectively (Figure 37.2). The two components mix with probabilities 0.8799 and $1 - 0.8799 = 0.1201$. These values are generally close to the values found by Pearson (1915) using infinite binomial series instead of binomial mass functions.

Figure 37.2 Maximum Likelihood Estimates

Parameter Estimates for 'Binomial' Model						
Component	Parameter	Estimate	Standard Error	z Value	Pr > z	Inverse Linked Estimate
1	Intercept	-2.2316	0.1522	-14.66	<.0001	0.09695
2	Intercept	-0.2974	0.3655	-0.81	0.4158	0.4262
Parameter Estimates for Mixing Probabilities						
-----Linked Scale-----						
Parameter	Estimate	Standard Error	z Value	Pr > z	Probability	
Probability	1.9913	0.5725	3.48	0.0005	0.8799	

To obtain fitted values and other observationwise statistics under the stipulated two-component model, you can add the **OUTPUT** statement to the previous PROC FMM run. The following statements request componentwise predicted values and the posterior probabilities:

```
proc fmm data=yeast;
  model count/n = / k=2;
  freq f;
  output out=fmmout pred(components) posterior;
run;
data fmmout;
  set fmmout;
  PredCount_1 = post_1 * f;
  PredCount_2 = post_2 * f;
run;
proc print data=fmmout;
run;
```

The DATA step following the PROC FMM step computes the predicted cell counts in each component (Figure 37.3). The predicted means in the components, 0.48476 and 2.13099, are close to the values determined by Pearson (0.4983 and 2.2118), as are the predicted cell counts.

Figure 37.3 Predicted Cell Counts

Obs	count	f	n	Pred_1	Pred_2	Post_1	Post_2	Pred Count_1	Pred Count_2
1	0	213	5	0.096951	0.42620	0.98606	0.01394	210.030	2.9698
2	1	128	5	0.096951	0.42620	0.91089	0.08911	116.594	11.4058
3	2	37	5	0.096951	0.42620	0.59638	0.40362	22.066	14.9341
4	3	18	5	0.096951	0.42620	0.17598	0.82402	3.168	14.8323
5	4	3	5	0.096951	0.42620	0.02994	0.97006	0.090	2.9102
6	5	1	5	0.096951	0.42620	0.00444	0.99556	0.004	0.9956

Gosset, who was interested in small-sample statistical problems, investigated the use of prior knowledge in mathematical-statistical analysis—for example, deriving the sampling distribution of the correlation coefficient after having assumed a uniform prior distribution for the coefficient in the population (Aldrich 1997). Pearson also was not opposed to using prior information, especially uniform priors that reflect “equal distribution of ignorance.” Fisher, on the other hand, would not have any of it: the best estimator in his opinion is obtained by a criterion that is absolutely independent of prior assumptions about probabilities of particular values. He objected to the insinuation that his derivations in the work on the correlation were deduced from Bayes theorem (Fisher 1921).

The preceding analysis of the yeast cell count data uses maximum likelihood methods that are free of prior assumptions. The following analysis takes instead a Bayesian approach, assuming a beta prior distribution for the binomial success probabilities and a uniform prior distribution for the mixing probabilities. The changes from the previous FMM run are the addition of the ODS GRAPHICS, PERFORMANCE, and BAYES statements and the SEED=12345 option.

```
ods graphics on;
proc fmm data=yeast seed=12345;
  model count/n = / k=2;
  freq f;
  performance cpucount=2;
  bayes;
run;
ods graphics off;
```

With ODS Graphics enabled, PROC FMM produces diagnostic trace plots for the posterior samples. Bayesian analyses are sensitive to the random number seed and thread count; the SEED= and CPUCOUNT= options ensure consistent results for the purposes of this example. The SEED=12345 option in the PROC FMM statement determines the random number seed for the random number generator used in the analysis. The CPUCOUNT=2 option in the PERFORMANCE statement sets the number of available processors to two. The BAYES statement requests a Bayesian analysis.

The “Bayes Information” table in Figure 37.4 provides basic information about the Markov chain Monte Carlo sampler. Because the model is a homogeneous mixture, the FMM procedure applies an efficient conjugate sampling algorithm with a posterior sample size of 10,000 samples after a burn-in size of 2,000

samples. The “Prior Distributions” table displays the prior distribution for each parameter along with its mean and variance and the initial value in the chain. Notice that in this situation all three prior distributions reduce to a uniform distribution on (0, 1).

Figure 37.4 Basic Information about MCMC Sampler

The FMM Procedure					
Bayes Information					
Sampling Algorithm		Conjugate			
Data Augmentation		Latent Variable			
Initial Values of Chain		Data Based			
Burn-In Size		2000			
MC Sample Size		10000			
MC Thinning		1			
Parameters in Sampling		3			
Mean Function Parameters		2			
Scale Parameters		0			
Mixing Prob Parameters		1			
Number of Threads		2			
Prior Distributions					
Component	Parameter	Distribution	Mean	Variance	Initial Value
1	Success Probability	Beta(1, 1)	0.5000	0.08333	0.1365
2	Success Probability	Beta(1, 1)	0.5000	0.08333	0.1365
1	Probability	Dirichlet(1, 1)	0.5000	0.08333	0.6180

The FMM procedure produces a log note for this model, indicating that the sampled quantities are not the linear predictors on the logit scale, but are the actual population parameters (on the data scale):

NOTE: Bayesian results for this model (no regressor variables, non-identity link) are displayed on the data scale, not the linked scale. You can obtain results on the linked (=linear) scale by requesting a Metropolis-Hastings sampling algorithm.

The trace panel for the success probability in the first binomial component is shown in [Figure 37.5](#). Note that the first component in this Bayesian analysis corresponds to the second component in the MLE analysis. The graphics in this panel can be used to diagnose the convergence of the Markov chain. If the chain has not converged, inferences cannot be made based on quantities derived from the chain. You generally look for the following:

- a smooth unimodal distribution of the posterior estimates in the density plot displayed on the lower right
- good mixing of the posterior samples in the trace plot at the top of the panel (good mixing is indicated when the trace traverses the support of the distribution and appears to have reached a stationary distribution)

Figure 37.5 Trace Panel for Success Probability in First Component

The autocorrelation plot in Figure 37.5 shows fairly high and sustained autocorrelation among the posterior estimates. While this is generally not a problem, you can affect the degree of autocorrelation among the posterior estimates by running a longer chain and thinning the posterior estimates; see the `NMC=` and `THIN=` options in the `BAYES` statement.

Both the trace plot and the density plot in Figure 37.5 are indications of successful convergence.

Figure 37.6 reports selected results that summarize the 10,000 posterior samples. The arithmetic means of the success probabilities in the two components are 0.3884 and 0.0905, respectively. The posterior mean of the mixing probability is 0.1771. These values are similar to the maximum likelihood parameter estimates in Figure 37.2 (after swapping components).

Figure 37.6 Summaries for Posterior Estimates

Posterior Summaries						
Component	Parameter	N	Mean	Standard Deviation		
1	Success Probability	10000	0.3884	0.0861		
2	Success Probability	10000	0.0905	0.0162		
1	Probability	10000	0.1771	0.0978		
Posterior Summaries						
Component	Parameter	25%	Percentiles			
			50%	75%		
1	Success Probability	0.3254	0.3835	0.4457		
2	Success Probability	0.0811	0.0923	0.1017		
1	Probability	0.1073	0.1534	0.2227		
Posterior Intervals						
Component	Parameter	Alpha	Equal-Tail		HPD Interval	
			Interval			
1	Success Probability	0.050	0.2355	0.5663	0.2224	0.5494
2	Success Probability	0.050	0.0538	0.1171	0.0572	0.1187
1	Probability	0.050	0.0564	0.4311	0.0424	0.3780

Note that the standard errors in Figure 37.2 are not comparable to those in Figure 37.6, since the standard errors for the MLEs are expressed on the logit scale and the Bayes estimates are expressed on the data scale. You can add the **METROPOLIS** option in the **BAYES** statement to sample the quantities on the logit scale.

The “Posterior Intervals” table in Figure 37.6 displays 95% credible intervals (equal-tail intervals and intervals of highest posterior density). It can be concluded that the component with the higher success probability contributes less than 40% to the process.

Modeling Zero-Inflation: Is it Better to Fish Poorly or Not to Have Fished At All?

The following example shows how you can use PROC FMM to model data with more zero values than expected.

Many count data show an excess of zeros relative to the frequency of zeros expected under a reference model. An excess of zeros leads to overdispersion since the process is more variable than a standard count data model. Different mechanisms can lead to excess zeros. For example, suppose that the data are generated from two processes with different distribution functions—one process generates the zero counts, and the other process generates nonzero counts. In the vernacular of Cameron and Trivedi (1998), such a model is called a *hurdle* model. With a certain probability—the probability of a nonzero count—a hurdle is crossed, and events are being generated. Hurdle models are useful, for example, to model the number of doctor

visits per year. Once the decision to see a doctor has been made—the hurdle has been overcome—a certain number of visits follow.

Hurdle models are closely related to zero-inflated models. Both can be expressed as two-component mixtures in which one component has a degenerate distribution at zero and the other component is a count model. In a hurdle model, the count model follows a zero-truncated distribution. In a zero-inflated model, the count model has a nonzero probability of generating zeros. Formally, a zero-inflated model can be written as

$$\Pr(Y = y) = \pi p_1 + (1 - \pi) p_2(y, \mu)$$

$$p_1 = \begin{cases} 1 & y = 0 \\ 0 & \text{otherwise} \end{cases}$$

where $p_2(y, \mu)$ is a standard count model with mean μ and support $y \in \{0, 1, 2, \dots\}$.

The following data illustrates the use of a zero-inflated model. In a survey of park attendees, randomly selected individuals were asked about the number of fish they caught in the last six months. Along with that count, the gender and age of each sampled individual was recorded. The following DATA step displays the data for the analysis:

```
data catch;
  input gender $ age count @@;
  datalines;
  F 54 18 M 37 0 F 48 12 M 27 0
  M 55 0 M 32 0 F 49 12 F 45 11
  M 39 0 F 34 1 F 50 0 M 52 4
  M 33 0 M 32 0 F 23 1 F 17 0
  F 44 5 M 44 0 F 26 0 F 30 0
  F 38 0 F 38 0 F 52 18 M 23 1
  F 23 0 M 32 0 F 33 3 M 26 0
  F 46 8 M 45 5 M 51 10 F 48 5
  F 31 2 F 25 1 M 22 0 M 41 0
  M 19 0 M 23 0 M 31 1 M 17 0
  F 21 0 F 44 7 M 28 0 M 47 3
  M 23 0 F 29 3 F 24 0 M 34 1
  F 19 0 F 35 2 M 39 0 M 43 6
  ;
```

At first glance, the prevalence of zeros in the DATA set is apparent. Many park attendees did not catch any fish. These zero counts are made up of two populations: attendees who do not fish and attendees who fish poorly. A zero-inflation mechanism thus appears reasonable for this application since a zero count can be produced by two separate distributions.

The following statements fit a standard Poisson regression model to these data. A common intercept is assumed for men and women, and the regression slope varies with gender.

```
proc fmm data=catch;
  class gender;
  model count = gender*age / dist=Poisson;
run;
```

Figure 37.7 displays information about the model and data set. The “Model Information” table conveys that the model is a single-component Poisson model (a Poisson GLM) and that parameters are estimated by maximum likelihood. There are two levels in the **CLASS** variable gender, with females preceding males.

Figure 37.7 Model Information and Class Levels in Poisson Regression

The FMM Procedure		
Model Information		
Data Set	WORK.CATCH	
Response Variable	count	
Type of Model	Generalized Linear (GLM)	
Distribution	Poisson	
Components	1	
Link Function	Log	
Estimation Method	Maximum Likelihood	
Class Level Information		
Class	Levels	Values
gender	2	F M
Number of Observations Read		52
Number of Observations Used		52

The “Fit Statistics” and “Parameter Estimates” tables from the maximum likelihood estimation of the Poisson GLM are shown in Figure 37.8. If the model is not overdispersed, the Pearson statistic should roughly equal the number of observations in the data set minus the number of parameters. With $n=52$, there is evidence of overdispersion in these data.

Figure 37.8 Fit Results in Poisson Regression

Fit Statistics					
		-2 Log Likelihood		182.7	
		AIC (smaller is better)		188.7	
		AICC (smaller is better)		189.2	
		BIC (smaller is better)		194.6	
		Pearson Statistic		85.9573	
Parameter Estimates for 'Poisson' Model					
Effect	gender	Estimate	Standard Error	z Value	Pr > z
Intercept		-3.9811	0.5439	-7.32	<.0001
age*gender	F	0.1278	0.01149	11.12	<.0001
age*gender	M	0.1044	0.01224	8.53	<.0001

Suppose that the cause of overdispersion is zero-inflation of the count data. The following statements fit a zero-inflated Poisson model.

```
proc fmm data=catch;
  class gender;
  model count = gender*age / dist=Poisson ;
  model      +           / dist=Constant;
run;
```

There are two **MODEL** statements, one for each component of the mixture. Because the distributions are different for the components, you cannot specify the mixture model with a single **MODEL** statement. The first **MODEL** statement identifies the response variable for the model (count) and defines a Poisson model with intercept and gender-specific slopes. The second **MODEL** statement uses the continuation operator (“+”) and adds a model with a degenerate distribution by using **DIST=CONSTANT**. Because the mass of the constant is placed by default at zero, the second **MODEL** statement adds a zero-inflation component to the model. It is sufficient to specify the response variable in one of the **MODEL** statements; you use the “=” sign in that statement to separate the response variable from the model effects.

Figure 37.9 displays the “Model Information” and “Optimization Information” tables for this run of the FMM procedure. The model is now identified as a zero-inflated Poisson (ZIP) model with two components, and the parameters continue to be estimated by maximum likelihood. The “Optimization Information” table shows that there are four parameters in the optimization (compared to three parameters in the Poisson GLM model). The four parameters correspond to three parameters in the mean function (intercept and two gender-specific slopes) and the mixing probability.

Figure 37.9 Model and Optimization Information in the ZIP Model

The FMM Procedure	
Model Information

Results from fitting the ZIP model by maximum likelihood are shown in Figure 37.10. The $-2 \log$ likelihood and the information criteria suggest a much-improved fit over the single-component Poisson model (compare Figure 37.10 to Figure 37.8). The Pearson statistic is reduced by factor 2 compared to the Poisson model and suggests a better fit than the standard Poisson model.

Figure 37.10 Maximum Likelihood Results for the ZIP model

		Standard				
Effect	Estimate	Error	z Value	Pr > z	Probability	
Intercept	0.8342	0.4768	1.75	0.0802	0.6972	

The number of effective parameters and components shown in [Figure 37.8](#) equals the values from [Figure 37.9](#). This is not always the case because components can collapse (for example, when the mixing probability approaches zero or when two components have identical parameter estimates). In this example, both components and all four parameters are identifiable. The Poisson regression and the zero process mix, with a probability of approximately 0.6972 attributed to the Poisson component.

The FMM procedure enables you to fit some mixture models by Bayesian techniques. The following statements add the **BAYES** statement to the previous PROC FMM statements:

```
proc fmm data=catch seed=12345;
  class gender;
  model count = gender*age / dist=Poisson;
  model      +           / dist=constant;
  performance cpubcount=2;
  bayes;
run;
```

The “Model Information” table indicates that the model parameters are estimated by Markov chain Monte Carlo techniques, and it displays the random number seed ([Figure 37.11](#)). This is useful if you did not specify a seed to identify the seed value that reproduces the current analysis. The “Bayes Information” table provides basic information about the Monte Carlo sampling scheme. The sampling method uses a data augmentation scheme to impute component membership and then the Gamerman (1997) algorithm to

sample the component-specific parameters. The 2,000 burn-in samples are followed by 10,000 Monte Carlo samples without thinning.

Prior Distributions						
Component	Effect	gender	Distribution	Mean	Variance	Initial Value
1	Intercept		Normal(0, 1000)	0	1000.00	-3.5215
1	age*gender	F	Normal(0, 1000)	0	1000.00	0.1216
1	age*gender	M	Normal(0, 1000)	0	1000.00	0.1056
1	Probability		Dirichlet(1, 1)	0.5000	0.08333	0.6972

The “Prior Distributions” table identifies the prior distributions, their parameters for the sampled quantities, and their initial values. The prior distribution of parameters associated with model effects is a normal distribution with mean 0 and variance 1,000. The prior distribution for the mixing probability is a Dirichlet(1,1), which is identical to a uniform distribution (Figure 37.11). Since the second mixture component is a degeneracy at zero with no associated parameters, it does not appear in the “Prior Distributions” table in Figure 37.11.

Figure 37.12 displays descriptive statistics about the 10,000 posterior samples. Recall from Figure 37.10 that the maximum likelihood estimates were -3.5215, 0.1216, 0.1056, and 0.6972, respectively. With this choice of prior, the means of the posterior samples are generally close to the MLEs in this example. The “Posterior Intervals” table displays 95% intervals of equal-tail probability and 95% intervals of highest posterior density (HPD) intervals.

Figure 37.12 Posterior Summaries and Intervals in the ZIP Model

Posterior Summaries							
Component	Effect	gender	N	Mean	Standard Deviation		
1	Intercept		10000	-3.5524	0.6509		
1	age*gender	F	10000	0.1220	0.0136		
1	age*gender	M	10000	0.1058	0.0140		
1	Probability		10000	0.6938	0.0945		
Posterior Summaries							
Component	Effect	gender	25%	Percentiles			
				50%	75%		
1	Intercept		-3.9922	-3.5359	-3.0875		
1	age*gender	F	0.1124	0.1218	0.1314		
1	age*gender	M	0.0961	0.1055	0.1153		
1	Probability		0.6293	0.6978	0.7605		
Posterior Intervals							
Component	Effect	gender	Alpha	Equal-Tail		HPD Interval	
				Interval			
1	Intercept		0.050	-4.8693	-2.3222	-4.8927	-2.3464
1	age*gender	F	0.050	0.0960	0.1494	0.0961	0.1494
1	age*gender	M	0.050	0.0792	0.1339	0.0796	0.1341
1	Probability		0.050	0.5041	0.8688	0.5025	0.8666

You can generate trace plots for the posterior parameter estimates by enabling ODS Graphics:

```
ods graphics on;
ods select TADPanel;
proc fmm data=catch seed=12345;
  class gender;
  model count = gender*age / dist=Poisson;
  model      +           / dist=constant;
  performance cpubcount=2;
  bayes;
run;
ods graphics off;
```

A separate trace panel is produced for each sampled parameter, and the panels for the gender-specific slopes are shown in Figure 37.13. There is good mixing in the chains: the modest autocorrelation that diminishes after about 10 successive samples. By default, the FMM procedure transfers the credible intervals for each parameter from the “Posterior Intervals” table to the trace plot and the density plot in the trace panel.

Figure 37.13 Trace Panels for Gender-Specific Slopes

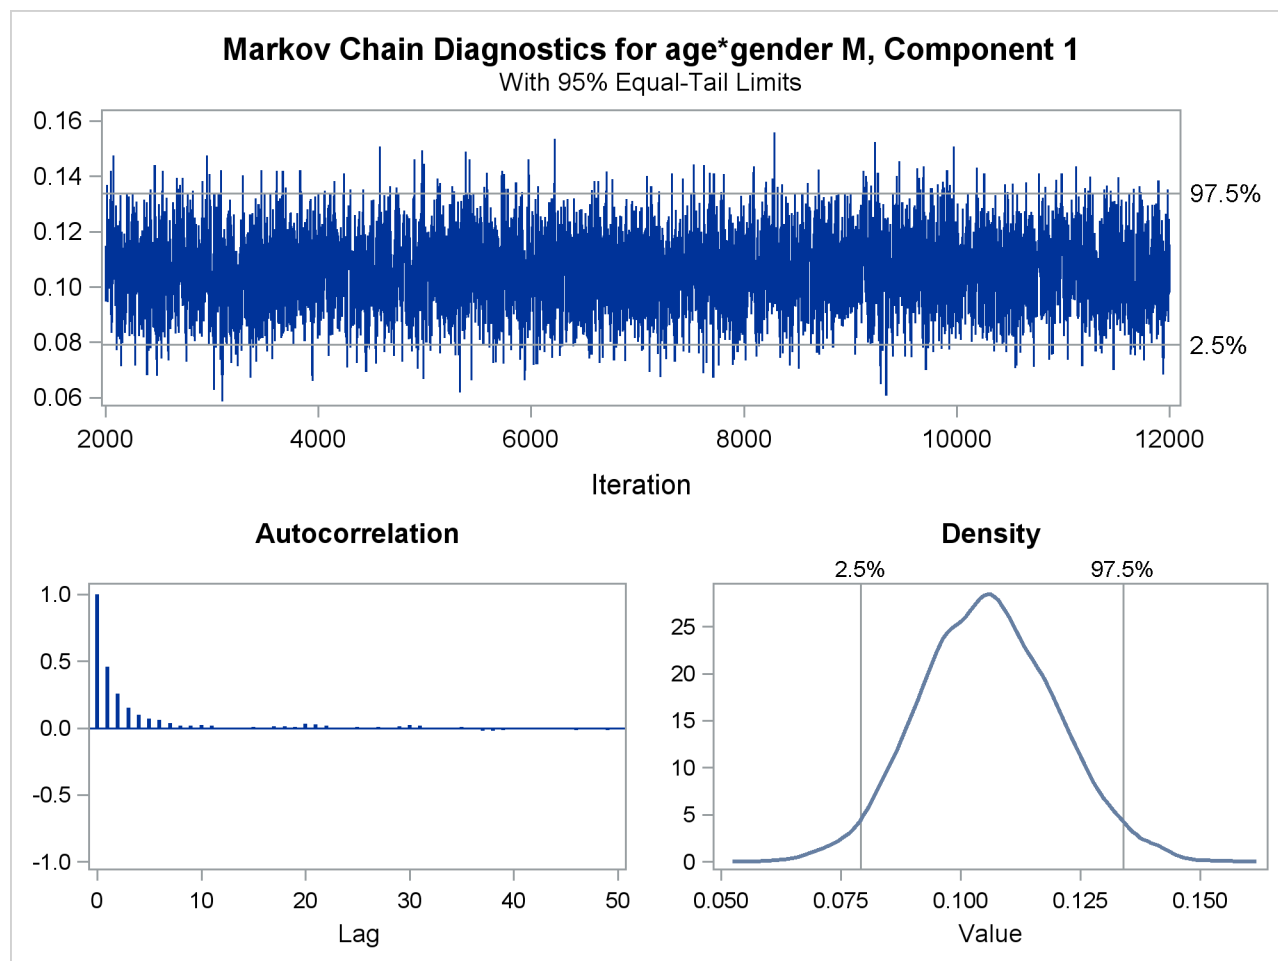

Figure 37.13 continued

Looking for Multiple Modes: Are Galaxies Clustered?

Mixture modeling is essentially a generalized form of one-dimensional cluster analysis. The following example shows how you can use PROC FMM to explore the number and nature of Gaussian clusters in univariate data.

Roeder (1990) presents data from the Corona Borealis sky survey with the velocities of 82 galaxies in a narrow slice of the sky. Cosmological theory suggests that the observed velocity of each galaxy is proportional to its distance from the observer. Thus, the presence of multiple modes in the density of these velocities could indicate a clustering of the galaxies at different distances.

The following DATA step recreates the data set in Roeder (1990). The computed variable *v* represents the measured velocity in thousands of kilometers per second.

```

;

```

Analysis of potentially multimodal data is a natural application of finite mixture models. In this case, the modeling is complicated by the question of the variance for each of the components. Using identical variances for each component could obscure underlying structure, but the additional flexibility granted by component-specific variances might introduce spurious features.

You can use PROC FMM to prepare analyses for equal and unequal variances and use one of the available fit statistics to compare the resulting models. You can use the model selection facility to explore models with varying numbers of mixture components—say, from three to seven as investigated in Roeder (1990). The following statements select the best unequal-variance model using Akaike's information criterion (AIC), which has a built-in penalty for model complexity:

```

title2 "Three to Seven Components, Unequal Variances";
ods graphics on;
ods select DensityPlot;
proc fmm data=galaxies criterion=AIC;
    model v = / kmin=3 kmax=7;
    ods exclude IterHistory OptInfo ComponentInfo;
run;

```

The **KMIN=** and **KMAX=** options indicate the smallest and largest number of components to consider. The ODS GRAPHICS and ODS SELECT statements request a density plot. The output for unequal variances is shown in Figure 37.14 and Figure 37.15.

Figure 37.17 Density Plot for Best (Six-Component) Model Assuming Equal Variances

Not surprisingly, the two variance specifications produce different optimal models. The unequal variance specification favors a three-component model while the equal variance specification favors a four-component model. Comparison of the AIC fit statistics, 423.0 and 432.5, indicates that the three-component, unequal variance model provides the best overall fit.

Comparison with Roeder's Method

It is important to note that Roeder's original analysis proceeds in a different manner than the finite mixture modeling presented here. The technique presented by Roeder first develops a "best" range of scale parameters based on a specific criterion. Roeder then uses fixed scale parameters taken from this range to develop optimal equal-scale Gaussian mixture models.

You can reproduce Roeder's point estimate for the density by specifying a five-component Gaussian mixture. In addition, use the **EQUATE=SCALE** option in the **MODEL** statement and a **RESTRICT** statement fixing the first component's scale parameter at 0.9025 (Roeder's $h = 0.95$, $\text{scale} = h^2$). The combination of these options produces a mixture of five Gaussian components, each with variance 0.9025. The following statements conduct this analysis:

```

title2 "Five Components, Equal Variances = 0.9025";
ods select DensityPlot;
proc fmm data=galaxies;
  model v = / K=5 equate=scale;
  restrict int 0 (scale 1) = 0.9025;
  ods exclude IterHistory OptInfo ComponentInfo;
run;
ods graphics off;

```

The output is shown in [Figure 37.18](#) and [Figure 37.19](#).

Syntax: FMM Procedure

The following statements are available in the FMM procedure:

```
PROC FMM < options > ;
  BAYES bayes-options ;
  BY variables ;
  CLASS variables < / TRUNCATE > ;
  FREQ variable ;
  ID variables ;
  MODEL response< (response-options) > = < effects > < / model-options > ;
  MODEL events/trials = < effects > < / model-options > ;
  MODEL          + < effects > < / model-options > ;
  OUTPUT < OUT=SAS-data-set >
    < keyword< (keyword-options) > < =name > > ...
    < keyword< (keyword-options) > < =name > > < / options > ;
  PERFORMANCE performance-options ;
  PROBMODEL < effects > < / probmodel-options > ;
  RESTRICT < 'label' > constraint-specification < , ... , constraint-specification >
    < operator < value > > < / option > ;
  WEIGHT variable ;
```

The **PROC FMM** statement and at least one **MODEL** statement is required. The **CLASS**, **RESTRICT** and **MODEL** statements can appear multiple times. If a **CLASS** statement is specified, it must precede the **MODEL** statements. The **RESTRICT** statements must appear after the **MODEL** statements.

PROC FMM Statement

```
PROC FMM < options > ;
```

The **PROC FMM** statement invokes the FMM procedure. [Table 37.2](#) summarizes the options available in the **PROC FMM** statement. These and other options in the **PROC FMM** statement are then described fully in alphabetical order.

Table 37.2 PROC FMM Statement Options

Option	Description
Basic Options	
DATA=	Specifies the input data set
EXCLUSION=	Specifies how the procedure responds to support violations in the data
NAMELEN=	Specifies the length of effect names
ORDER=	Determines the sort order of CLASS variables
SEED=	Specifies the random number seed for analyses that require random number draws

Table 37.2 *continued*

Option	Description
Displayed Output	
COMPONENTINFO	Displays information about the mixture components
CORR	Displays the asymptotic correlation matrix of the maximum likelihood parameter estimates or the empirical correlation matrix of the Bayesian posterior estimates
COV	Displays the asymptotic covariance matrix of the maximum likelihood parameter estimates or the empirical covariance matrix of the Bayesian posterior estimates
COVI	Displays the inverse of the covariance matrix of the parameter estimates
FITDETAILS	Displays fit information for all examined models
ITDETAILS	Adds estimates and gradients to the “Iteration History” table
NOCLPRINT	Suppresses the “Class Level Information” table completely or partially
NOITPRINT	Suppresses the “Iteration History Information” table
NOPRINT	Suppresses tabular and graphical output
PARMSTYLE=	Specifies how parameters are displayed in ODS tables
PLOTS	Produces ODS statistical graphics
Computational Options	
CRITERION=	Specifies the criterion used in model selection
NOCENTER	Prevents centering and scaling of the regressor variables
PARTIAL=	Specifies a variable that defines a partial classification
Options Related to Optimization	
ABSCONV=	Tunes an absolute function convergence criterion
ABSFCNV=	Tunes an absolute function difference convergence criterion
ABSGCONV=	Tunes the absolute gradient convergence criterion
FCONV=	Specifies a relative function convergence criterion that is based on a relative change of the function value
FCONV2=	Specifies a relative function convergence criterion that is based on a predicted reduction of the objective function
GCONV=	Tunes the relative gradient convergence criterion
MAXITER=	Specifies the maximum number of iterations in any optimization
MAXFUNC=	Specifies the maximum number of function evaluations in any optimization
MAXTIME=	Specifies the upper limit of CPU time in seconds for any optimization
MINITER=	Specifies the minimum number of iterations in any optimization
TECHNIQUE=	Selects the optimization technique
Singularity Tolerances	
INVALIDLOGL=	Tunes the value assigned to an invalid component log likelihood
SINGCHOL=	Tunes singularity for Cholesky decompositions

Table 37.2 *continued*

Option	Description
SINGRES=	Tunes singularity for the residual variance
SINGULAR=	Tunes general singularity criterion

You can specify the following *options* in the PROC FMM statement.

ABSCONV=*r***ABSTOL=*r***

specifies an absolute function convergence criterion. For minimization, the termination criterion is $f(\boldsymbol{\psi}^{(k)}) \leq r$, where $\boldsymbol{\psi}$ is the vector of parameters in the optimization and $f(\cdot)$ is the objective function. The default value of r is the negative square root of the largest double-precision value, which serves only as a protection against overflows.

ABSFCNV=*r* <*n*>**ABSFTOL=*r* <*n*>**

specifies an absolute function difference convergence criterion. For all techniques except NMSIMP, the termination criterion is a small change of the function value in successive iterations:

$$|f(\boldsymbol{\psi}^{(k-1)}) - f(\boldsymbol{\psi}^{(k)})| \leq r$$

Here, $\boldsymbol{\psi}$ denotes the vector of parameters that participate in the optimization, and $f(\cdot)$ is the objective function. The same formula is used for the NMSIMP technique, but $\boldsymbol{\psi}^{(k)}$ is defined as the vertex with the lowest function value, and $\boldsymbol{\psi}^{(k-1)}$ is defined as the vertex with the highest function value in the simplex. The default value is $r=0$. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

ABSGCONV=*r* <*n*>**ABSGTOL=*r* <*n*>**

specifies an absolute gradient convergence criterion. The termination criterion is a small maximum absolute gradient element:

$$\max_j |g_j(\boldsymbol{\psi}^{(k)})| \leq r$$

Here, $\boldsymbol{\psi}$ denotes the vector of parameters that participate in the optimization, and $g_j(\cdot)$ is the gradient of the objective function with respect to the j th parameter. This criterion is not used by the NMSIMP technique. The default value is $r=1\text{E}-5$. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

COMPONENTINFO**COMPINFO****CINFO**

produces a table with additional details about the fitted model components.

COV

produces the covariance matrix of the parameter estimates. For maximum likelihood estimation, this matrix is based on the inverse (projected) Hessian matrix. For Bayesian estimation, it is the empirical covariance matrix of the posterior estimates. The covariance matrix is shown for all parameters, even if they did not participate in the optimization or sampling.

COVI

produces the inverse of the covariance matrix of the parameter estimates. For maximum likelihood estimation, the covariance matrix is based on the inverse (projected) Hessian matrix. For Bayesian estimation, it is the empirical covariance matrix of the posterior estimates. This matrix is then inverted by sweeping, and rows and columns that correspond to linear dependencies or singularities are zeroed.

CORR

produces the correlation matrix of the parameter estimates. For maximum likelihood estimation this matrix is based on the inverse (projected) Hessian matrix. For Bayesian estimation, it is based on the empirical covariance matrix of the posterior estimates.

CRITERION=keyword**CRIT=keyword**

specifies the criterion by which the FMM procedure ranks models when multiple models are evaluated during maximum likelihood estimation. You can choose from the following *keywords* to rank models:

AIC	based on Akaike's information criterion
AICC	based on the bias-corrected AIC criterion
BIC	based on the Bayesian information criterion
GRADIENT	based on the largest element of the gradient (in absolute value)
LOGL LL	based on the mixture log likelihood
PEARSON	based on the Pearson statistic

The default is CRITERION=BIC.

DATA=SAS-data-set

names the SAS data set to be used by PROC FMM. The default is the most recently created data set.

EXCLUSION=NONE | ANY | ALL**EXCLUDE=NONE | ANY | ALL**

specifies how the FMM procedure handles support violations of observations. For example, in a mixture of two Poisson variables, negative response values are not possible. However, in a mixture of a Poisson and a normal variable, negative values are possible, and their likelihood contribution to the Poisson component is zero. An observation that violates the support of one component distribution of the model might be a valid response with respect to one or more other component distributions. This requires some nuanced handling of support violations in mixture models.

The default exclusion technique, EXCLUSION=ALL, removes an observation from the analysis only if it violates the support of all component distributions. The other extreme, EXCLUSION=NONE, permits an observation into the analysis regardless of support violations. EXCLUSION=ANY removes observations from the analysis if the response violates the support of any component distributions. In the single-component case, EXCLUSION=ALL and EXCLUSION=ANY are identical.

FCONV= $r < n$ **FTOL**= $r < n$

specifies a relative function convergence criterion that is based on the relative change of the function value. For all techniques except NMSIMP, PROC FMM terminates when there is a small relative change of the function value in successive iterations:

$$\frac{|f(\boldsymbol{\psi}^{(k)}) - f(\boldsymbol{\psi}^{(k-1)})|}{|f(\boldsymbol{\psi}^{(k-1)})|} \leq r$$

Here, $\boldsymbol{\psi}$ denotes the vector of parameters that participate in the optimization, and $f(\cdot)$ is the objective function. The same formula is used for the NMSIMP technique, but $\boldsymbol{\psi}^{(k)}$ is defined as the vertex with the lowest function value, and $\boldsymbol{\psi}^{(k-1)}$ is defined as the vertex with the highest function value in the simplex.

The default is $r = 10^{-\text{FDIGITS}}$, where FDIGITS is by default $-\log_{10}\{\epsilon\}$, and ϵ is the machine precision. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process terminates.

FCONV2= $r < n$ **FTOL2**= $r < n$

specifies a relative function convergence criterion that is based on the predicted reduction of the objective function. For all techniques except NMSIMP, the termination criterion is a small predicted reduction

$$df^{(k)} \approx f(\boldsymbol{\theta}^{(k)}) - f(\boldsymbol{\theta}^{(k)} + \mathbf{s}^{(k)})$$

of the objective function. The predicted reduction

$$\begin{aligned} df^{(k)} &= -\mathbf{g}^{(k)'} \mathbf{s}^{(k)} - \frac{1}{2} \mathbf{s}^{(k)'} \mathbf{H}^{(k)} \mathbf{s}^{(k)} \\ &= -\frac{1}{2} \mathbf{s}^{(k)'} \mathbf{g}^{(k)} \\ &\leq r \end{aligned}$$

is computed by approximating the objective function f by the first two terms of the Taylor series and substituting the Newton step:

$$\mathbf{s}^{(k)} = -[\mathbf{H}^{(k)}]^{-1} \mathbf{g}^{(k)}$$

For the NMSIMP technique, the termination criterion is a small standard deviation of the function values of the $n + 1$ simplex vertices $\boldsymbol{\theta}_l^{(k)}$, $l = 0, \dots, n$,

$$\sqrt{\frac{1}{n+1} \sum_l \left[f(\boldsymbol{\theta}_l^{(k)}) - \bar{f}(\boldsymbol{\theta}^{(k)}) \right]^2} \leq r$$

where $\bar{f}(\boldsymbol{\theta}^{(k)}) = \frac{1}{n+1} \sum_l f(\boldsymbol{\theta}_l^{(k)})$. If there are n_{act} boundary constraints active at $\boldsymbol{\theta}^{(k)}$, the mean and standard deviation are computed only for the $n + 1 - n_{act}$ unconstrained vertices.

The default value is $r = 1\text{E-}6$ for the NMSIMP technique and $r = 0$ otherwise. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process terminates.

FITDETAILS

requests that the “Optimization Information,” “Iteration History,” and “Fit Statistics” tables be produced for all optimizations when models with different number of components are evaluated. For example, the following statements fit a binomial regression model with up to three components and produces fit and optimization information for all three:

```
proc fmm fitdetails;
  model y/n = x / kmax=3;
run;
```

Without the FITDETAILS option, only the “Fit Statistics” table for the selected model is displayed.

GCONV= $r < n$ >**GTOL= $r < n$ >**

specifies a relative gradient convergence criterion. For all techniques except CONGRA and NMSIMP, the termination criterion is a small normalized predicted function reduction:

$$\frac{\mathbf{g}(\boldsymbol{\psi}^{(k)})' [\mathbf{H}^{(k)}]^{-1} \mathbf{g}(\boldsymbol{\psi}^{(k)})}{|f(\boldsymbol{\psi}^{(k)})|} \leq r$$

Here, $\boldsymbol{\psi}$ denotes the vector of parameters that participate in the optimization, $f(\cdot)$ is the objective function, and $\mathbf{g}(\cdot)$ is the gradient. For the CONGRA technique (where a reliable Hessian estimate \mathbf{H} is not available), the following criterion is used:

$$\frac{\|\mathbf{g}(\boldsymbol{\psi}^{(k)})\|_2^2 \|\mathbf{s}(\boldsymbol{\psi}^{(k)})\|_2}{\|\mathbf{g}(\boldsymbol{\psi}^{(k)}) - \mathbf{g}(\boldsymbol{\psi}^{(k-1)})\|_2 |f(\boldsymbol{\psi}^{(k)})|} \leq r$$

This criterion is not used by the NMSIMP technique. The default value is $r=1\text{E}-8$. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

HESSIAN

displays the Hessian matrix of the model. This option is not available for Bayesian estimation.

INVALIDLOGL= r

specifies the value assumed by the FMM procedure if a log likelihood cannot be computed (for example, because the value of the response variable falls outside of the response distribution’s support). The default value is $-1\text{E}20$.

ITDETAILS

adds parameter estimates and gradients to the “Iteration History” table. If the FMM procedure centers or scales the model variables (or both), the parameter estimates and gradients reported during the iteration refer to that scale. You can suppress centering and scaling with the [NOCENTER](#) option.

MAXFUNC= n **MAXFU= n**

specifies the maximum number of function calls in the optimization process. The default values are as follows, depending on the optimization technique:

- TRUREG, NRRIDG, and NEWRAP: 125
- QUANEW and DBLDOG: 500
- CONGRA: 1000
- NMSIMP: 3000

The optimization can terminate only after completing a full iteration. Therefore, the number of function calls that are actually performed can exceed the number that is specified by the MAXFUNC= option. You can choose the optimization technique with the [TECHNIQUE=](#) option.

MAXITER=*n*

MAXIT=*n*

specifies the maximum number of iterations in the optimization process. The default values are as follows, depending on the optimization technique:

- TRUREG, NRRIDG, and NEWRAP: 50
- QUANEW and DBLDOG: 200
- CONGRA: 400
- NMSIMP: 1000

These default values also apply when *n* is specified as a missing value. You can choose the optimization technique with the [TECHNIQUE=](#) option.

MAXTIME=*r*

specifies an upper limit of *r* seconds of CPU time for the optimization process. The default value is the largest floating-point double representation of your computer. The time specified by the MAXTIME= option is checked only once at the end of each iteration. Therefore, the actual running time can be longer than that specified by the MAXTIME= option.

MINITER=*n*

MINIT=*n*

specifies the minimum number of iterations. The default value is 0. If you request more iterations than are actually needed for convergence to a stationary point, the optimization algorithms can behave strangely. For example, the effect of rounding errors can prevent the algorithm from continuing for the required number of iterations.

NAMELEN=*number*

specifies the length to which long effect names are shortened. The default and minimum value is 20.

NOCENTER

requests that regressor variables not be centered or scaled. By default the FMM procedure centers and scales columns of the **X** matrix if the models contain intercepts. If [NOINT](#) options in [MODEL](#) statements are in effect, the columns of **X** are scaled but not centered. Centering and scaling can help with the stability of estimation and sampling algorithms. The FMM procedure does not produce a table of the centered and scaled coefficients and provides no user control over the type of centering and scaling that is applied. The NOCENTER option turns any centering and scaling off and processes the raw values of the continuous variables.

NOCLPRINT*<=number>*

suppresses the display of the “Class Level Information” table if you do not specify *number*. If you specify *number*, the values of the classification variables are displayed for only those variables whose number of levels is less than *number*. Specifying a *number* helps to reduce the size of the “Class Level Information” table if some classification variables have a large number of levels.

NOITPRINT

suppresses the display of the “Iteration History Information” table.

NOPRINT

suppresses the normal display of tabular and graphical results. The NOPRINT option is useful when you want to create only one or more output data sets with the procedure. This option temporarily disables the Output Delivery System (ODS); see Chapter 20, “[Using the Output Delivery System](#),” for more information.

ORDER*=order-type*

specifies the sort order for the levels of **CLASS** variables. This ordering determines which parameters in the model correspond to each level in the data.

You can specify the following values for *order-type*:

DATA

sorts the levels by order of appearance in the input data set.

FORMATTED

sorts the levels by external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value.

FREQ

sorts the levels by descending frequency count; levels with the most observations come first in the order.

INTERNAL

sorts the levels by unformatted value.

FREQDATA

sorts the levels by order of descending frequency count, and within counts by order of appearance in the input data set when counts are tied.

FREQFORMATTED

sorts the levels by order of descending frequency count, and within counts by formatted value (as above) when counts are tied.

FREQINTERNAL

sorts the levels by order of descending frequency count, and within counts by unformatted value when counts are tied.

When the default ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. To order numeric class levels with no explicit format by their BEST12. formatted values, you can specify this format explicitly for the **CLASS** variables.

When FORMATTED and INTERNAL values are involved, the sort order is machine-dependent.

When the response variable appears in a **CLASS** statement, the ORDER= option in the PROC FMM statement applies to its sort order. For example, in the following statements the sort order of the wheeze variable is determined by the order of appearance in the input data set because the response variable appears in the **CLASS** statement:

```
proc fmm order=data;
  class city wheeze;
  model wheeze = city age / dist=binary s;
run;
```

However, in the following statements the sort order of the wheeze variable is determined by the formatted value (the default *response-option* in the **MODEL** statement):

```
proc fmm order=data;
  class city;
  model wheeze = city age / dist=binary s;
run;
```

The ORDER= option in the PROC FMM statement has no effect on the sort order of the wheeze variable because it does not appear in the **CLASS** statement.

When you specify a *response-option* in the **MODEL** statement, it overrides the ORDER= option in the PROC FMM statement.

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PARMSTYLE=EFFECT | LABEL

specifies the display style for parameters and effects. The FMM procedure can display parameters in two styles:

- The EFFECT style (which is used by the MIXED and GLIMMIX procedure, for example) identifies a parameter with an “Effect” column and adds separate columns for the **CLASS** variables in the model.
- The LABEL style creates one column, named Parameter, that combines the relevant information about a parameter into a single column. If your model contains multiple **CLASS** variables, the LABEL style might use space more economically.

The EFFECT style is the default for models that contain effects; otherwise the LABEL style is used (for example, in homogeneous mixtures). You can change the display style with the PARMSTYLE= option. Regardless of the display style, ODS output data sets that contain information about parameter estimates contain columns for both styles.

PARTIAL=variable

MEMBERSHIP=variable

specifies a variable in the input data set that identifies component membership. You can specify missing values for observations whose component membership is undetermined; this is known as a partial classification (McLachlan and Peel 2000, p. 75). For observations with known membership,

the likelihood contribution is no longer a mixture. If observation i is known to be a member of component m , then its log likelihood contribution is

$$\log \{ \pi_m(\mathbf{z}, \boldsymbol{\alpha}_m) p_m(y; \mathbf{x}'_m \boldsymbol{\beta}_m, \phi_m) \}$$

Otherwise, if membership is undetermined, it is

$$\log \left\{ \sum_{j=1}^k \pi_j(\mathbf{z}, \boldsymbol{\alpha}_j) p_j(y; \mathbf{x}'_j \boldsymbol{\beta}_j, \phi_j) \right\}$$

The variable specified in the PARTIAL= option can be numeric or character. In case of a character variable, the variable must appear in the CLASS statement. If the PARTIAL= variable appears in the CLASS statement, the membership assignment is made based on the levelized values of the variable, as shown in the “Class Level Information” table. Invalid values of the PARTIAL= variable are ignored.

In a model in which label switching is a problem, the switching can sometimes be avoided by assigning just a few observations to categories. For example, in a three-component model, switches might be prevented by assigning the observation with the smallest response value to the first component and the observation with the largest response value to the last component.

PLOTS <(global-plot-options)> <= plot-request <(options)>>

PLOTS <(global-plot-options)> <= (plot-request <(options)> <... plot-request <(options)>>>

controls the plots produced through ODS Graphics.

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc fmm data=yeast seed=12345;
  model count/n = / k=2;
  freq f;
  performance cpucount=2;
  bayes;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

Global Plot Options

The *global-plot-options* apply to all relevant plots generated by the FMM procedure. The *global-plot-options* supported by the FMM procedure are as follows:

UNPACKPANEL**UNPACK**

displays each graph separately. (By default, some graphs can appear together in a single panel.)

ONLY

produces only the specified plots. This option is useful if you do not want the procedure to generate all default graphics, but only the ones specified.

Specific Plot Options

The following listing describes the specific plots and their options.

ALL

requests that all plots appropriate for the analysis be produced.

NONE

requests that no ODS graphics be produced.

DENSITY <(density-options)>

requests a plot of the data histogram and mixture density function. This graphic is a default graphic in models without effects in the **MODEL** statements and is available only in these models. Furthermore, all distributions involved in the mixture must be continuous. You can specify the following *density-options* to modify the plot:

CUMULATIVE**CDF**

displays the histogram and densities in cumulative form.

NBINS=*n***BINS**=*n*

specifies the number of bins in the histogram; *n* is greater than or equal to 0. By default, the FMM procedure computes a suitable bin width and number of bins, based on the range of the response and the number of usable observations. The option has no effect for binary data.

NOCOMPONENTS**NOCOMP**

suppresses the component densities from the plot. If the component densities are displayed, they are scaled so that their sum equals the mixture density at any point on the graph. In single-component models, this option has no effect.

NODENSITY**NODENS**

suppresses the computation of the mixture density (and the component densities if the **COMPONENTS** suboption is specified). If you specify the **NOHISTOGRAM** and the **NODENSITY** option, no graphic is produced.

NOLABEL

suppresses the component identification with labels. By default, the FMM procedure labels component densities in the legend of the plot. If you do not specify a model label with the **LABEL=** option in the **MODEL** statement, an identifying label is constructed from the parameter estimates that are associated with the component. In this case the parameter values are not necessarily the mean and variance of the distribution; the values used to identify the densities on the plot are chosen to simplify linking between graphical and tabular results.

NOHISTOGRAM**NOHIST**

suppresses the computation of the histogram of the raw values. If you specify the **NOHISTOGRAM** and the **NODENSITY** option, no graphic is produced.

NPOINTS=*n***N=*n***

specifies the number of values used to compute the density functions; *n* is greater than or equal to 0. The default is **N=200**.

WIDTH=*value***BINWIDTH=*value***

specifies the bin width for the histogram. The *value* is specified in units of the response variable and must be positive. The option has no effect for binary data.

TRACE <(tadpanel-options)>

requests a trace panel with posterior diagnostics for a Bayesian analysis. If a **BAYES** statement is present, the trace panel plots are generated by default, one for each sampled parameter. You can specify the following *tadpanel-options* to modify the graphic:

BOX**BOXPLOT**

replaces the autocorrelation plot with a box plot of the posterior sample.

SMOOTH=NONE | MEAN | SPLINE

adds a reference estimate to the trace plot. By default, **SMOOTH=NONE**. **SMOOTH=MEAN** uses the arithmetic mean of the trace as the reference. **SMOOTH=SPLINE** adds a penalized B-spline.

REFERENCE= *reference-style*

adds vertical reference lines to the density plot, trace plot, and box plot. The available options for the *reference-style* are:

NONE	suppresses the reference lines
EQT	requests equal-tail intervals
HPD	requests intervals of highest posterior density. The level for the credible or HPD intervals is chosen based on the “Posterior Interval Statistics” table.
PERCENTILES	(or PERC) for percentiles. Up to three percentiles can be displayed, as based on the “Posterior Summary Statistics” table.

The default is **REFERENCE=CREDIBLE**.

UNPACK

unpacks the panel graphic and displays its elements as separate plots.

SEED=*n*

determines the random number seed for analyses that depend on a random number stream. If you do not specify a seed or if you specify a value less than or equal to zero, the seed is generated from reading the time of day from the computer clock. The largest possible value for the seed is $2^{31} - 1$. The seed value is reported in the “Model Information” table.

You can use the SYSRANDOM and SYSRANEND macro variables after a PROC FMM run to query the initial and final seed values. However, using the final seed value as the starting seed for a subsequent analysis does not continue the random number stream where the previous analysis left off. The SYSRANEND macro variable provides a mechanism to pass on seed values to ensure that the sequence of random numbers is the same every time you run an entire program.

Analyses that use the same (nonzero) seed are not completely reproducible if they are executed with a different number of threads since the random number streams in separate threads are independent. You can control the number of threads used by the FMM procedure with system options or through the **PERFORMANCE** statement in the FMM procedure.

SINGCHOL=*number*

tunes the singularity criterion in Cholesky decompositions. The default is 1E4 times the machine epsilon; this product is approximately 1E–12 on most computers.

SINGRES=*number*

sets the tolerance for which the residual variance or scale parameter is considered to be zero. The default is 1E4 times the machine epsilon; this product is approximately 1E–12 on most computers.

SINGULAR=*number*

tunes the general singularity criterion applied by the FMM procedure in sweeps and inversions. The default is 1E4 times the machine epsilon; this product is approximately 1E–12 on most computers.

TECHNIQUE=*keyword***TECH=*keyword***

specifies the optimization technique to obtain maximum likelihood estimates. You can choose from the following techniques by specifying the appropriate *keyword*:

CONGRA	performs a conjugate-gradient optimization.
DBLDOG	performs a version of double-dogleg optimization.
NEWRAP	performs a Newton-Raphson optimization combining a line-search algorithm with ridging.
NMSIMP	performs a Nelder-Mead simplex optimization.
NONE	performs no optimization.
NRRIDG	performs a Newton-Raphson optimization with ridging.
QUANEW	performs a dual quasi-Newton optimization.
TRUREG	performs a trust-region optimization.

The default is TECH=QUANEW.

For more details about these optimization methods, see the section “Choosing an Optimization Algorithm” on page 494 of Chapter 19, “Shared Concepts and Topics.”

BAYES Statement

BAYES *bayes-options* ;

The BAYES statement requests that the parameters of the model be estimated by Markov chain Monte Carlo sampling techniques. The FMM procedure can estimate by maximum likelihood the parameters of all models supported by the procedure. Bayes estimation, on the other hand, is available for only a subset of these models.

In Bayesian analysis, it is essential to examine the convergence of the Markov chains before you proceed with posterior inference. With ODS Graphics turned on, the FMM procedure produces graphs at the end of the procedure output; these graphs enable you to visually examine the convergence of the chain. Inferences cannot be made if the Markov chain has not converged.

The output produced for a Bayesian analysis is markedly different from that for a frequentist (maximum likelihood) analysis for the following reasons:

- Parameter estimates do not have the same interpretation in the two analyses. Parameters are fixed unknown constants in the frequentist context and random variables in a Bayesian analysis.
- The results of a Bayesian analysis are summarized through chain diagnostics and posterior summary statistics and intervals.
- The FMM procedure samples the mixing probabilities in Bayesian models directly, rather than mapping them onto a logistic (or other) scale.

The FMM procedure applies highly specialized sampling algorithms in Bayesian models. For single-component models without effects, a conjugate sampling algorithm is used where possible. For models in the exponential family that contain effects, the sampling algorithm is based on Gamerman (1997). For the normal and t distributions, a conjugate sampler is the default sampling algorithm for models with and without effects. In multi-component models, the sampling algorithm is based on latent variable sampling through data augmentation (Frühwirth-Schnatter 2006) and the Gamerman or conjugate sampler. Because of this specialization, the options for controlling the prior distributions of the parameters are limited.

Table 37.3 summarizes the *bayes-options* available in the BAYES statement. The full assortment of options is then described in alphabetical order.

Table 37.3 BAYES Statement Options

Option	Description
Options Related to Sampling	
INITIAL=	Specifies how to construct initial values
NBI=	Specifies the number of burn-in samples
NMC=	Specifies the number of samples after burn-in

Table 37.3 continued

Option	Description
METROPOLIS	Forces a Metropolis-Hastings sampling algorithm even if conjugate sampling is possible
OUTPOST=	Generates a data set that contains the posterior estimates
THIN=	Controls the thinning of the Markov chain
Specification of Prior Information	
MIXPRIORPARMS	Specifies the prior parameters for the Dirichlet distribution of the mixing probabilities
BETAPRIORPARMS=	Specifies the parameters of the normal prior distribution for individual parameters in the β vector
MUPRIORPARMS=	Specifies the parameters of the prior distribution for the means in homogeneous mixtures without effects
PHIPRIORPARMS=	Specifies the parameters of the inverse gamma prior distribution for the scale parameters in homogeneous mixtures
PRIOROPTIONS	Specifies additional options used in the determination of the prior distribution
Posterior Summary Statistics and Convergence Diagnostics	
DIAGNOSTICS=	Displays convergence diagnostics for the Markov chain
STATISTICS	Displays posterior summary information for the Markov chain
Other Options	
ESTIMATE=	Specifies which estimate is used for the computation of OUTPUT statistics and graphics
TIMEINC=	Specifies the time interval to report on sampling progress (in seconds)

You can specify the following *bayes-options* in the BAYES statement.

BETAPRIORPARMS=*pair-specification*

BETAPRIORPARMS(*pair-specification* ... *pair-specification*)

specifies the parameters for the normal prior distribution of the parameters that are associated with model effects (β s). The *pair-specification* is of the form (a, b), and the values a and b are the mean and variance of the normal distribution, respectively. This option overrides the **PRIOROPTIONS** option.

The form of the BETAPRIORPARMS with an equal sign and a single pair is used to specify one pair of prior parameters that applies to all components in the mixture. In the following example, the two intercepts and the two regression coefficients all have a $N(0, 100)$ prior distribution:

```
proc fmm;
  model y = x / k=2;
  bayes betapriorparms=(0,100);
run;
```

You can also provide a list of pairs to specify different sets of prior parameters for the various regression parameters and components. For example:

```
proc fmm;
  model y = x/ k=2;
  bayes betapriorparms( (0,10) (0,20) (.,.) (3,100) );
run;
```

The simple linear regression in the first component has a $N(0, 10)$ prior for the intercept and a $N(0, 20)$ prior for the slope. The prior for the intercept in the second component uses the FMM default, whereas the prior for the slope is $N(3, 100)$.

DIAGNOSTICS=ALL | NONE | (keyword-list)

DIAG=ALL | NONE | (keyword-list)

controls the computation of diagnostics for the posterior chain. You can request all posterior diagnostics by specifying **DIAGNOSTICS=ALL** or suppress the computation of posterior diagnostics by specifying **DIAGNOSTICS=NONE**. The following *keywords* enable you to select subsets of posterior diagnostics; the default is **DIAGNOSTICS=(AUTOCORR)**.

AUTOCORR <(LAGS= numeric-list)>

computes for each sampled parameter the autocorrelations of lags specified in the **LAGS=** list. Elements in the list are truncated to integers, and repeated values are removed. If the **LAGS=** option is not specified, autocorrelations are computed by default for lags 1, 5, 10, and 50. See the section “[Autocorrelations](#)” on page 152 for details.

ESS

computes an estimate of the effective sample size (Kass et al. 1998), the correlation time, and the efficiency of the chain for each parameter. See the section “[Effective Sample Size](#)” on page 152 for details.

GEWEKE <(geweke-options)>

computes the Geweke spectral density diagnostics (Geweke 1992), which are essentially a two-sample t test between the first f_1 portion and the last f_2 portion of the chain. The default is $f_1 = 0.1$ and $f_2 = 0.5$, but you can choose other fractions by using the following *geweke-options*:

FRAC1=value

specifies the fraction f_1 for the first window.

FRAC2=value

specifies the fraction f_2 for the second window.

See the section “[Geweke Diagnostics](#)” on page 146 for details.

HEIDELBERGER <(Heidel-options)>

HEIDEL <(Heidel-options)>

computes the Heidelberg and Welch diagnostic (which consists of a stationarity test and a half-width test) for each variable. The stationary diagnostic test tests the null hypothesis that the posterior samples are generated from a stationary process. If the stationarity test is passed, a half-width test is then carried out. See the section “[Heidelberg and Welch Diagnostics](#)” on page 148 for more details.

These diagnostics are not performed by default. You can specify the `DIAGNOSTICS=HEIDELBERGER` option to request these diagnostics, and you can also specify suboptions, such as `DIAGNOSTICS=HEIDELBERGER(EPS=0.05)`, as follows:

SALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the stationarity test. By default, `SALPHA=0.05`.

HALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the half-width test. By default, `HALPHA=0.05`.

EPS=*value*

specifies a small positive number ϵ such that if the half-width is less than ϵ times the sample mean of the retaining iterates, the half-width test is passed. By default, `EPS=0.1`.

MCERROR

MCSE

computes an estimate of the Monte Carlo standard error for each sampled parameter. See the section “[Standard Error of the Mean Estimate](#)” on page 153 for details.

MAXLAG=*n*

specifies the largest lag used in computing the effective sample size and the Monte Carlo standard error. Specifying this option implies the `ESS` and `MCERROR` options. The default is `MAXLAG=250`.

RAFTERY <(Raftery-options)>

RL <(Raftery-options)>

computes the Raftery and Lewis diagnostics, which evaluate the accuracy of the estimated quantile ($\hat{\theta}_Q$ for a given $Q \in (0, 1)$) of a chain. $\hat{\theta}_Q$ can achieve any degree of accuracy when the chain is allowed to run for a long time. The algorithm stops when the estimated probability $\hat{P}_Q = \Pr(\theta \leq \hat{\theta}_Q)$ reaches within $\pm R$ of the value Q with probability S ; that is, $\Pr(Q - R \leq \hat{P}_Q \leq Q + R) = S$. See the section “[Raftery and Lewis Diagnostics](#)” on page 149 for more details. The *Raftery-options* enable you to specify Q , R , S , and a precision level ϵ for a stationary test.

These diagnostics are not performed by default. You can specify the `DIAGNOSTICS=RAFERTY` option to request these diagnostics, and you can also specify suboptions, such as `DIAGNOSTICS=RAFERTY(QUANTILE=0.05)`, as follows:

QUANTILE=*value*

Q=*value*

specifies the order (a value between 0 and 1) of the quantile of interest. By default, `QUANTILE=0.025`.

ACCURACY=*value***R=***value*

specifies a small positive number as the margin of error for measuring the accuracy of estimation of the quantile. By default, ACCURACY=0.005.

PROB=*value***S=***value*

specifies the probability of attaining the accuracy of the estimation of the quantile. By default, PROB=0.95.

EPS=*value*

specifies the tolerance level (a small positive number between 0 and 1) for the stationary test. By default, EPS=0.001.

MIXPRIORPARMS=*K***MIXPRIORPARMS**(*value-list*)

specifies the parameters used in constructing the Dirichlet prior distribution for the mixing parameters. If you specify MIXPRIORPARMS=*K*, the parameters of the *k*-dimensional Dirichlet distribution are a vector that contains the number of components in the model (*k*), whatever that might be. You can specify an explicit list of parameters in *value-list*. If the MIXPRIORPARMS option is not specified, the default Dirichlet parameter vector is a vector of length *k* of ones. This results in a uniform prior over the unit simplex; for *k*=2, this is the uniform distribution. See the section “[Prior Distributions](#)” on page 2435 for the distribution function of the Dirichlet as used by the FMM procedure.

ESTIMATE=MEAN | MAP

determines which overall estimate is used, based on the posterior sample, in the computation of [OUTPUT](#) statistics and certain ODS graphics. By default, the arithmetic average of the (thinned) posterior sample is used. If you specify ESTIMATE=MAP, the parameter vector is used that corresponds to the maximum log posterior density in the posterior sample. In any event, a message is written to the SAS log if postprocessing results depend on a summary estimate of the posterior sample.

INITIAL=DATA | MLE | MODE | RANDOM

determines how initial values for the Markov chain are obtained. The default when a conjugate sampler is used is INITIAL=DATA, in which case the FMM procedure uses the same algorithm to obtain data-dependent starting values as it uses for maximum likelihood estimation. If no conjugate sampler is available or if you use the METROPOLIS option to explicitly request that it not be used, then the default is INITIAL=MLE, in which case the maximum likelihood estimates are used as the initial values. If the maximum likelihood optimization fails, the FMM procedure switches to the default INITIAL=DATA.

The options INITIAL=MODE and INITIAL=RANDOM use the mode and random draws from the prior distribution, respectively, to obtain initial values. If the mode does not exist or if it falls on the boundary of the parameter space, the prior mean is used instead.

METROPOLIS

requests that the FMM procedure use the Metropolis-Hastings sampling algorithm based on Gamerman (1997), even in situations where a conjugate sampler is available.

MUPRIORPARMS=*pair-specification*

MUPRIORPARMS(*pair-specification* ... *pair-specification*)

specifies the parameters for the means in homogeneous mixtures without regression coefficients. The *pair-specification* is of the form (a, b) , where a and b are the two parameters of the prior distribution, optionally delimited with a comma. The actual distribution of the parameter is implied by the distribution selected in the **MODEL** statement. For example, it is a normal distribution for a mixture of normals, a gamma distribution for a mixture of Poisson variables, a beta distribution for a mixture of binary variables, and an inverse gamma distribution for a mixture of exponential variables. This option overrides the **PRIOROPTIONS** option.

The parameters correspond as follows:

Beta:	The parameters correspond to the α and β parameters of the beta prior distribution such that its mean is $\mu = \alpha/(\alpha + \beta)$ and its variance is $\mu(1 - \mu)/(\alpha + \beta + 1)$.
Normal:	The parameters correspond to the mean and variance of the normal prior distribution.
Gamma:	The parameters correspond to the α and β parameters of the gamma prior distribution such that its mean is α/β and its variance is α/β^2 .
Inverse gamma:	The parameters correspond to the α and β parameters of the inverse gamma prior distribution such that its mean is $\mu = \beta/(\alpha - 1)$ and its variance is $\mu^2/(\alpha - 2)$.

The two techniques for specifying the prior parameters with the **MUPRIORPARMS** option are as follows:

- Specify an equal sign and a single pair of values:

```
proc fmm seed=12345;
  model y = / k=2;
  bayes mupriorparms=(0,50);
run;
```

- Specify a list of parameter pairs within parentheses:

```
proc fmm seed=12345;
  model y = / k=2;
  bayes mupriorparms( (.,.) (1.4,10.5) );
run;
```

If you specify an invalid value (outside of the parameter space for the prior distribution), the FMM procedure chooses the default value and writes a message to the SAS log. If you want to use the default values for a particular parameter, you can also specify missing values in the *pair-specification*. For example, the preceding list specification assigns default values for the first component and uses the values 1.4 and 10.5 for the mean and variance of the normal prior distribution in the second component. The first example assigns a $N(0, 50)$ prior distribution to the means in both components.

NBI=*n*

specifies the number of burn-in samples. During the burn-in phase, chains are not saved. The default is NBI=2000.

NMC=*n***SAMPLE=*n***

specifies the number of Monte Carlo samples after the burn-in. Samples after the burn-in phase are saved unless they are thinned with the THIN= option. The default is NMC=10000.

OUTPOST<(outpost-options)>=*data-set*

requests that the posterior sample be saved to a SAS data set. In addition to variables that contain log likelihood and log posterior values, the OUTPOST data set contains variables for the parameters. The variable names for the parameters are generic (Parm_1, Parm_2, ..., Parm_p). The labels of the parameters are descriptive and correspond to the “Parameter Mapping” table that is produced when the OUTPOST= option is in effect.

You can specify the following *outpost-options* in parentheses:

LOGPRIOR

adds the value of the log prior distribution to the data set.

NONSINGULAR | NONSING | COMPRESS

eliminates parameters that correspond to singular columns in the design matrix (and were not sampled) from the posterior data set. This is the default.

SINGULAR | SING

adds columns of zeros to the data set in positions that correspond to singularities in the model or to parameters that were not sampled for other reasons. By default, these columns of zeros are not written to the posterior data set.

PHIPRIORPARMS=*pair-specification***PHIPRIORPARMS(*pair-specification* ... *pair-specification*)**

specifies the parameters for the inverse gamma prior distribution of the scale parameters (ϕ 's) in the model. The *pair-specification* is of the form (*a*, *b*), and the values are chosen such that the prior distribution has mean $\mu = b/(a - 1)$ and variance $\mu^2/(a - 2)$.

The form of the PHIPRIORPARMS with an equal sign and a single pair is used to specify one pair of prior parameters that applies to all components in the mixture. For example:

```
proc fmm seed=12345;
  model y = / k=2;
  bayes phipriorparms=(2.001,1.001);
run;
```

The form with a list of pairs is used to specify different prior parameters for the scale parameters in different components. For example:

```
proc fmm seed=12345;
  model y = / k=2;
  bayes phipriorparms( (.,1.001) (3.001,2.001) );
run;
```

If you specify an invalid value (outside of the parameter space for the prior distribution), the FMM procedure chooses the default value and writes a message to the SAS log. If you want to use the default values for a particular parameter, you can also specify missing values in the *pair-specification*. For example, the preceding list specification assigns default values for the first component a prior parameter and uses the value 1.001 for the b prior parameter. The second pair assigns 3.001 and 2.001 for the a and b prior parameters, respectively.

PRIOROPTIONS $\leq \geq$ (*prior-options*)

PRIOROPTS $\leq \geq$ (*prior-options*)

specifies options related to the construction of the prior distribution and the choice of their parameters. Some *prior-options* apply only in particular models. The **BETAPRIORPARMS=** and **MUPRIORPARMS=** options override this option.

You can specify the following *prior-options*:

CONDITIONAL | COND

chooses a conditional prior specification for the homogeneous normal and t distribution response components. The default prior specification in these models is an independence prior where the mean of the h th component has prior $\mu_h \sim N(a, b)$. The conditional prior is characterized by $\mu_h \sim N(a, \sigma_h^2/b)$.

DEPENDENT | DEP

chooses a data-dependent prior for the homogeneous models without effects. The prior parameters a and b are chosen as follows, based on the distribution in the **MODEL** statement:

Binary and binomial: $a = \bar{y}/(1-\bar{y})$, $b=1$, and the prior distribution for the success probability is $\text{beta}(a, b)$.

Poisson: $a = 1$, $b = 1/\bar{y}$, and the prior distribution for μ is $\text{gamma}(a, b)$. See Frühwirth-Schnatter (2006, p. 280) and Viallefont, Richardson, and Greene (2002).

Exponential: $a = 3$, $b = 2\bar{y}$, and the prior distribution for μ is inverse gamma with parameters a and b .

Normal and t : Under the default independence prior, the prior distribution for μ is $N(\bar{y}, fs^2)$ where f is the variance factor from the **VAR=** option and

$$s^2 = \frac{1}{n} \sum_{i=1}^n (y_i - \bar{y})^2$$

Under the default conditional prior specification, the prior for μ_h is $N(a, \sigma_h^2/b)$ where $a = \bar{y}$ and $b = 2.6/(\max\{y\} - \min\{y\})$. The prior for the scale parameter is inverse gamma with parameters 1.28 and $0.36s^2$. For further details, see Raftery (1996) and Frühwirth-Schnatter (2006, p. 179).

VAR=f

specifies the variance for normal prior distributions. The default is **VAR=1000**. This factor is used, for example, in determining the prior variance of regression coefficients or in determining the prior variance of means in homogeneous mixtures of t or normal distributions (unless a data-dependent prior is used).

MLE=<=r>

specifies that the prior distribution for regression variables be based on a multivariate normal distribution centered at the MLEs and whose dispersion is a multiple r of the asymptotic MLE covariance matrix. The default is MLE=10. In other words, if you specify PRIOROPTIONS(MLE), the FMM procedure chooses the prior distribution for the regression variables as $N(\hat{\beta}, 10\text{Var}[\hat{\beta}])$ where $\hat{\beta}$ is the vector of maximum likelihood estimates. The prior for the scale parameter is inverse gamma with parameters 1.28 and $0.36s^2$ where

$$s^2 = \frac{1}{n} \sum_{i=1}^n (y_i - \bar{y})^2$$

For further details, see Raftery (1996) and Frühwirth-Schnatter (2006, p. 179). If you specify PRIOROPTIONS(MLE) for the regression parameters, then the data-dependent prior is used for the scale parameter; see the PRIOROPTIONS(DEPENDENT) option above.

The MLE option is not available for mixture models in which the parameters are estimated directly on the data scale, such as homogeneous mixture models or mixtures of distributions without model effects for which a conjugate sampler is available. By using the [METROPOLIS](#) option, you can always force the FMM procedure to abandon a conjugate sampler in favor of a Metropolis-Hastings sampling algorithm to which the MLE option applies.

STATISTICS < (global-options) > = **ALL** | **NONE** | keyword | (keyword-list)

SUMMARIES < (global-options) > = **ALL** | **NONE** | keyword | (keyword-list)

controls the number of posterior statistics produced. Specifying STATISTICS=ALL is equivalent to specifying STATISTICS=(SUMMARY INTERVAL). To suppress the computation of posterior statistics, specify STATISTICS=NONE. The default is STATISTICS=(SUMMARY INTERVAL). See the section “[Summary Statistics](#)” on page 153 for more details.

The *global-options* include the following:

ALPHA=*numeric-list*

controls the coverage levels of the equal-tail credible intervals and the credible intervals of highest posterior density (HPD) credible intervals. The ALPHA= values must be between 0 and 1. Each ALPHA= value produces a pair of $100(1-\alpha)\%$ equal-tail and HPD credible intervals for each sampled parameter. The default is ALPHA=0.05, which results in 95% credible intervals for the parameters.

PERCENT=*numeric-list*

requests the percentile points of the posterior samples. The values in *numeric-list* must be between 0 and 100. The default is PERCENT=(25 50 75), which yields for each parameter the 25th, 50th, and 75th percentiles, respectively.

The list of *keywords* includes the following:

SUMMARY

produces the means, standard deviations, and percentile points for the posterior samples. The default is to produce the 25th, 50th, and 75th percentiles; you can modify this list with the global PERCENT= option.

INTERVAL

produces equal-tail and HPD credible intervals. The default is to produce the 95% equal-tail credible intervals and 95% HPD credible intervals, but you can use the `ALPHA= global-option` to request credible intervals for any probabilities.

THIN=*n***THINNING=*n***

controls the thinning of the Markov chain after the burn-in. Only one in every k samples is used when `THIN= k` , and if `NBI= n_0` and `NMC= n` , the number of samples kept is

$$\left[\frac{n_0 + n}{k} \right] - \left[\frac{n_0}{k} \right]$$

where $[a]$ represents the integer part of the number a . The default is `THIN=1`—that is, all samples are kept after the burn-in phase.

TIMEINC=*n*

specifies a time interval in seconds to report progress during the burn-in and sampling phase. The time interval is approximate, since the minimum time interval in which the FMM procedure can respond depends on the multithreading configuration.

BY Statement

BY variables ;

You can specify a BY statement with PROC FMM to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the `NOTSORTED` or `DESCENDING` option in the BY statement for the FMM procedure. The `NOTSORTED` option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

Because sorting the data changes the order in which PROC FMM reads observations, the sort order for the levels of the `CLASS` variable might be affected if you have specified `ORDER=DATA` in the `PROC FMM` statement.

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variables* < / **TRUNCATE** > ;

The CLASS statement names the classification variables to be used in the model. Typical classification variables are Treatment, Sex, Race, Group, and Replication. If you use the CLASS statement, it must appear before the [MODEL](#) statement.

Classification variables can be either character or numeric. By default, class levels are determined from the entire set of formatted values of the CLASS variables.

NOTE: Prior to SAS 9, class levels were determined by using no more than the first 16 characters of the formatted values. To revert to this previous behavior, you can use the TRUNCATE option in the CLASS statement.

In any case, you can use formats to group values into levels. See the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussions of the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference*. You can adjust the order of CLASS variable levels with the [ORDER=](#) option in the [PROC FMM](#) statement. You can specify the following option in the CLASS statement after a slash (/):

TRUNCATE

specifies that class levels should be determined by using only up to the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases prior to SAS 9.

FREQ Statement

FREQ *variable* ;

The *variable* in the FREQ statement identifies a numeric variable in the data set that contains the frequency of occurrence for each observation. PROC FMM treats each observation as if it appears f times, where f is the value of the FREQ variable for the observation. If it is not an integer, the frequency value is truncated to an integer. If the frequency value is less than 1 or missing, the observation is not used in the analysis. When the FREQ statement is not specified, each observation is assigned a frequency of 1.

ID Statement

ID *variables* ;

The ID statement specifies a list of variables that are included in the [OUT=](#) data set of the [OUTPUT](#) statement. If no ID statement is specified, all variables from the input data set are copied into the output data set.

MODEL Statement

MODEL *response* <(response-options)> = <effects> </model-options> ;

MODEL *events/trials* = <effects> </model-options> ;

MODEL + <effects> </model-options> ;

The MODEL statement defines elements of the mixture model, such as the model effects, the distribution, and the link function. At least one MODEL statement is required. You can specify more than one MODEL statement. Each MODEL statement identifies one or more components of a mixture. For example, if components differ in their distributions, link functions, or regressor variables, then you can use separate MODEL statements to define the components. If the finite mixture model is homogeneous—in the sense that all components share the same regressors, distribution, and link function—then you can specify the mixture model with a single MODEL statement by using the **K=** option.

An intercept is included in each model by default. It can be removed with the **NOINT** option.

The dependent variable can be specified by using either the *response* syntax or the *events/trials* syntax. The *events/trials* syntax is specific to models for binomial-type data. A $\text{binomial}(n, \pi)$ variable is the sum of n independent Bernoulli trials with event probability π . Each Bernoulli trial results in either an event or a nonevent (with probability $1 - \pi$). The value of the second variable, *trials*, gives the number n of Bernoulli trials. The value of the first variable, *events*, is the number of events out of n . The values of both *events* and (*trials*–*events*) must be nonnegative, and the value of *trials* must be positive. Other distributions that allow the *events/trials* syntax are the beta-binomial distribution and the binomial cluster model.

If the *events/trials* syntax is used, the FMM procedure defaults to the binomial distribution. If you use the *response* syntax, the procedure defaults to the normal distribution unless the response variable is a character variable or listed in the **CLASS** statement.

The FMM procedure supports a continuation-style syntax in MODEL statements. Since a mixture has only one response variable, it is sufficient to specify the response variable in one MODEL statement. Other MODEL statements can use the continuation symbol “+” before the specification of effects. For example, the following statements fit a three-component binomial mixture model:

```
class A;
model y/n = x / k=2;
model      + A;
```

The first MODEL statement uses the “=” sign to separate response from effect information and specifies the response variable by using the *events/trials* syntax. This determines the distribution as binomial. This MODEL statement adds two components to the mixture models with different intercepts and regression slopes. The second MODEL statement adds another component to the mixture where the mean is a function of the classification main effect for variable A. The response is also binomial; it is a continuation from the previous MODEL statement.

There are two sets of options in the MODEL statement. The *response-options* determine how the FMM procedure models probabilities for binary data. The *model-options* control other aspects of model formation and inference. Table 37.4 summarizes the *response-options* and *model-options* available in the MODEL statement. These are subsequently discussed in detail in alphabetical order by option category.

Table 37.4 Summary of MODEL Statement Options

Option	Description
Response Variable Options	
DESCENDING	Reverses the order of response categories
EVENT=	Specifies the event category in binary models
ORDER=	Specifies the sort order for the response variable
REFERENCE=	Specifies the reference category in categorical models
Model Building	
DIST=	Specifies the response distribution
LINK=	Specifies the link function
K=	Specifies the number of mixture components
KMAX=	Specifies the maximum number of mixture components
KMIN=	Specifies the minimum number of mixture components
KRESTART	Requests that the starting values for each analysis be determined separately instead of sequentially
NOINT	Excludes fixed-effect intercept from model
OFFSET=	Specifies the offset variable for linear predictor
Statistical Computations and Output	
ALPHA= α	Determines the confidence level ($1 - \alpha$)
CL	Displays confidence limits for fixed-effects parameter estimates
EQUATE=	Imposes simple equality constraints on parameters in this model
LABEL=	Identifies the model
PARMS	Provides starting values for the parameters in this model

Response Variable Options

Response variable options determine how the FMM procedure models probabilities for binary data.

You can specify the following *response-options* by enclosing them in parentheses after the *response* variable. The default is ORDER=FORMATTED.

DESCENDING

DESC

reverses the order of the response categories. If both the DESCENDING and ORDER= options are specified, PROC FMM orders the response categories according to the ORDER= option and then reverses that order.

EVENT=*'category'* | *keyword*

specifies the event category for the binary response model. PROC FMM models the probability of the event category. You can specify the value (formatted, if a format is applied) of the event category in quotes, or you can specify one of the following keywords:

FIRST

designates the first ordered category as the event. This is the default.

LAST

designates the last ordered category as the event.

ORDER=order-type

specifies the sort order for the levels of the response variable. You can specify the following values for *order-type*:

DATA

sorts the levels by order of appearance in the input data set.

FORMATTED

sorts the levels by external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value.

FREQ

sorts the levels by descending frequency count; levels with the most observations come first in the order.

INTERNAL

sorts the levels by unformatted value.

FREQDATA

sorts the levels by order of descending frequency count, and within counts by order of appearance in the input data set when counts are tied.

FREQFORMATTED

sorts the levels by order of descending frequency count, and within counts by formatted value (as above) when counts are tied.

FREQINTERNAL

sorts the levels by order of descending frequency count, and within counts by unformatted value when counts are tied.

When **ORDER=FORMATTED** (the default) for numeric variables for which you have supplied no explicit format (that is, for which there is no corresponding **FORMAT** statement in the current PROC FMM run or in the **DATA** step that created the data set), the levels are ordered by their internal (numeric) value. If you specify the **ORDER=** option in the **MODEL** statement and the **ORDER=** option in the **PROC FMM** statement, the former takes precedence.

By default, **ORDER=FORMATTED**. For the **FORMATTED** and **INTERNAL** values, the sort order is machine-dependent.

For more information about sort order, see the chapter on the **SORT** procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

REFERENCE='category' | keyword**REF='category' | keyword**

specifies the reference category for categorical models. For the binary response model, specifying one response category as the reference is the same as specifying the other response category as the event category. You can specify the value (formatted if a format is applied) of the reference category in quotes, or you can specify one of the following *keywords*:

FIRST

designates the first ordered category as the reference category.

LAST

designates the last ordered category as the reference category. This is the default.

Model Options**ALPHA=number**

requests that confidence intervals be constructed for each of the parameters with confidence level $1 - \text{number}$. The value of *number* must be between 0 and 1; the default is 0.05.

CL

requests that confidence limits be constructed for each of the parameter estimates. The confidence level is 0.95 by default; this can be changed with the **ALPHA=** option.

DISTRIBUTION=keyword**DIST=keyword**

specifies the probability distribution for a mixture component.

If you specify the **DIST=** option and you do not specify a link function with the **LINK=** option, a default link function is chosen according to [Table 37.5](#). If you do not specify a distribution, the FMM procedure defaults to the normal distribution for continuous response variables and to the binary distribution for classification or character variables, unless the *events/trial* syntax is used in the MODEL statement. If you choose the *events/trial* syntax, the FMM procedure defaults to the binomial distribution.

[Table 37.5](#) lists *keywords* that you can specify for the **DISTRIBUTION=** option and the corresponding default link functions. For generalized linear models with these distributions, you can find expressions for the log-likelihood functions in the section “[Log-Likelihood Functions for Response Distributions](#)” on page 2427.

Table 37.5 Keyword Values of the **DIST=** Option

<i>keyword</i>	<i>Alias</i>	<i>Distribution</i>	<i>Default Link Function</i>
BETA		Beta	Logit
BETABINOMIAL	BETABIN	Beta-binomial	Logit
BINARY	BERNOULLI	Binary	Logit
BINOMIAL	BIN	Binomial	Logit
BINOMCLUSTER	BINOMCLUS	Binomial cluster	Logit
CONSTANT <(c)>	DEGENERATE <(c)>	Degenerate	N/A
EXPONENTIAL	EXPO	Exponential	Log
FOLDEDNORMAL	FNORMAL	Folded normal	Identity
GAMMA	GAM	Gamma	Log
GAUSSIAN	NORMAL	Normal	Identity
GENPOISSON	GPOISSON	Generalized Poisson	Log
GEOMETRIC	GEOM	Geometric	Log
INVGAUSS	IGAUSSIAN, IG	Inverse Gaussian	Inverse squared (power(-2))

Table 37.5 continued

DIST=	Alias	Distribution	Default Link Function
LOGNORMAL	LOGN	Lognormal	Identity
NEGBINOMIAL	NEGBIN, NB	Negative binomial	Log
POISSON	POI	Poisson	Log
T <(v)>	STUDENT <(v)>	<i>t</i>	Identity
TRUNCEXPO <(a,b)>	TEXPO <(a,b)>	Truncated exponential	Log
TRUNCLOGN <(a,b)>	TLOGN <(a,b)>	Lognormal	Identity
TRUNCNEGBIN	TNEGBIN, TNB	Negative binomial	Log
TRUNCNORMAL <(a,b)>	TNORMAL <(a,b)>	Truncated normal	Identity
TRUNCPOISSON	TPOISSON, TPOI	Truncated Poisson	Log
UNIFORM <(a,b)>	UNIF <(a,b)>	Uniform	N/A
WEIBULL		Weibull	Log

Note that the PROC FMM default link for the gamma or exponential distribution is not the canonical link (the reciprocal link).

The binomial cluster model is a two-component model described in Morel and Nagaraj (1993); Morel and Neerchal (1997); Neerchal and Morel (1998). See [Example 37.1](#) for an application of the binomial cluster model in a teratological experiment.

If the *events/trials* syntax is used, the default distribution is the binomial and only the following choices are available: DIST=BINOMIAL, DIST=BETABINOMIAL, and DIST=BINOMCLUSTER. The *trials* variable is ignored for all other distributions. This enables you to fit models in which some components have a binomial or binomial-like distribution. For example, suppose that variable *n* is a binomial denominator and variable *logn* is its logarithm. Then the following statements model a two-component mixture of a binomial and Poisson count model:

```
model y/n = ;
model      + / dist=Poisson offset=logn;
```

The **OFFSET=** option is used in the second MODEL statement to specify that the Poisson counts refer to different base counts, since the trial variable *n* is ignored in the second model.

If DIST=BINOMIAL is specified without the *events/trials* syntax, then *n*=1 is used for the default number of trials.

DIST=TRUNCNEGBIN and DIST=TRUNCPOISSON are zero-truncated versions of DIST=NEGBINOMIAL and DIST=POISSON, respectively—that is, only the value of 0 is excluded from the support.

For DIST=TRUNCEXPO, DIST=TRUNCLOGN, and DIST=TRUNCNORMAL, you must specify the lower (*a*) and upper (*b*) truncation points of the distribution. For example:

```
DIST=TRUNCEXPO<(a,b)>
DIST=TRUNCLOGN<(a,b)>
DIST=TRUNCNORMAL<(a,b)>
```

Each of these distributions is the conditional version of its corresponding nontruncated distribution that is confined to the support $[a, b]$ (inclusive). You can specify a missing value (.) for either a or b to truncate only on the other side; that is, $a=.$ indicates a right-truncated distribution, and $b=.$ indicates a left-truncated distribution.

For several distribution specifications you can provide additional optional parameters to further define the distribution. These optional parameters are listed in the following:

DIST=CONSTANT<(c)> The number c specifies the value where the mass is concentrated. The default is **DIST=CONSTANT**(0), so you can add zero-inflation to any model by adding a **MODEL** statement with **DIST=CONSTANT**.

DIST=T<(v)> The number v specifies the degrees of freedom for the (shifted) t distribution. The default is **DIST=T**(3); this leads to a heavy-tailed distribution for which the variance is defined. See the section “[Log-Likelihood Functions for Response Distributions](#)” on page 2427 for the density function of the shifted t_v distribution.

DIST=UNIFORM<(a,b)> The values a and b define the support of the uniform distribution, $a < b$. By default, $a = 0$ and $b = 1$.

EQUATE=MEAN | SCALE | NONE

EQUATE=EFFECTS(*effect-list*)

specifies simple sets of parameter constraints across the components in a **MODEL** statement; the default is **EQUATE=NONE**. This option is available only for maximum likelihood estimation. If you specify **EQUATE=MEAN**, the parameters that determine the mean are reduced to a single set that is applicable to all components in the **MODEL** statement. If you specify **EQUATE=SCALE**, a single parameter represents the common scale for all components in the **MODEL** statement. The **EFFECTS** option enables you to force the parameters for the chosen model effects to be equal across components; however, the number of parameters is unaffected.

For example, the following statements fit a two-component multiple regression model in which the coefficients for variable `logd` vary by component and the intercepts and coefficients for variable `dose` are the same for the two components:

```
proc fmm;
  model num = dose logd / equate=effects(int dose) k=2;
run;
```

To fix all coefficients across the two components, you can write the **MODEL** statement as

```
model num = dose logd / equate=effects(int dose logd) k=2;
```

or

```
model num = dose logd / equate=mean k=2;
```

If you restrict all parameters in a k -component **MODEL** statement to be equal, the FMM procedure reduces the model to $k=1$.

K=*n***NUMBER=*n***

specifies the number of components the MODEL statement contributes to the overall mixture. For the binomial cluster model, this option is not available, since this model is a two-component model by definition.

KMAX=*n*

specifies the maximum number of components the MODEL statement contributes to the overall mixture.

If the maximum number of components in the mixture, as determined by all KMAX= options, is larger than the minimum number of components, the FMM procedure fits all possible models and displays summary fit information for the sequence of evaluated models. The “best” model according to the CRITERION= option in the PROC FMM statement is then chosen, and the remaining output and analyses performed by PROC FMM pertain to this “best” model.

The KMAX= option is available only for maximum likelihood estimation. When you estimate the parameters of a mixture by MCMC methods, you need to ensure that the chain for a given value of *k* has converged; otherwise, comparisons among models with varying number of components might not be meaningful.

If you specify the KMIN= option but not the KMAX= option, then the default value for the KMAX= option is the value of the KMIN= option (unless KMIN=0, in which case the KMAX= option is set to 1).

KMIN=*n*

specifies the minimum number of components the MODEL statement contributes to the overall mixture. This option is available only for maximum likelihood estimation. When you estimate the parameters of a mixture by MCMC methods, you need to ensure that the chain for a given value of *k* has converged; otherwise comparisons among models with varying number of components might not be meaningful.

KRESTART

requests that the starting values for each analysis (that is, for each unique number of components as determined by the KMIN= and KMAX= options) be determined separately, in the same way as if no other analyses were performed. If you do not specify the KRESTART option, then the starting values for each analysis are based on results from the previous analysis with one less component.

LABEL='label'

specifies an optional label for the model that is used to identify the model in printed output, on graphics, and in data sets created from ODS tables.

LINK=keyword

specifies the link function in the model. The keywords and expressions for the associated link functions are shown in Table 37.6.

Table 37.6 Link Functions in MODEL Statement of the FMM Procedure

LINK=	Alias	Link Function	$g(\mu) = \eta =$
CLOGLOG	CLL	Complementary log-log	$\log(-\log(1 - \mu))$
IDENTITY	ID	Identity	μ
LOG		Log	$\log(\mu)$
LOGIT		Logit	$\log(\mu/(1 - \mu))$
LOGLOG		Log-log	$-\log(-\log(\mu))$
PROBIT	NORMIT	Probit	$\Phi^{-1}(\mu)$
POWER(λ)	POW(λ)	Power with exponent $\lambda = \text{number}$	$\begin{cases} \mu^\lambda & \text{if } \lambda \neq 0 \\ \log(\mu) & \text{if } \lambda = 0 \end{cases}$
POWERMINUS2		Power with exponent -2	$1/\mu^2$
RECIPROCAL	INVERSE	Reciprocal	$1/\mu$

The default link functions for the various distributions are shown in [Table 37.5](#).

NOINT

requests that no intercept be included in the model. An intercept is included by default, unless the distribution is [DIST=CONSTANT](#) or [DIST=UNIFORM](#).

OFFSET=variable

specifies the offset variable function for the linear predictor in the model. An offset variable can be thought of as a regressor variable whose regression coefficient is known to be 1. For example, you can use an offset in a Poisson model when counts have been obtained in time intervals of different lengths. With a log link function, you can model the counts as Poisson variables with the logarithm of the time interval as the offset variable.

PARAMETERS(parameter-specification)

PARMS(parameter-specification)

specifies starting values for the model parameters. If no PARMS option is given, the FMM procedure determines starting values by a data-dependent algorithm. To determine initial values for the Markov chain with Bayes estimation, see also the [INITIAL=](#) option in the [BAYES](#) statement. The specification of the parameters takes the following form: parameters in the mean function precede the scale parameters, and parameters for different components are separated by commas.

The following statements specify starting parameters for a two-component normal model. The initial values for the intercepts are 1 and -3; the initial values for the variances are 0.5 and 4.

```
proc fmm;
  model y = / k=2 parms(1 0.5, -3 4);
run;
```

You can specify missing values for parameters whose starting values are to be determined by the default method. Only values for parameters that participate in the optimization are specified. The values for model effects are specified on the linear (linked) scale.

OUTPUT Statement

```
OUTPUT < OUT=SAS-data-set>
    < keyword< (keyword-options) > <=name>> ...
    < keyword< (keyword-options) > <=name>> </ options> ;
```

The OUTPUT statement creates a data set that contains observationwise statistics that are computed after fitting the model. By default, all variables in the original data set are included in the output data set. You can use the [ID](#) statement to limit the variables copied from the input data set to the output data set.

The output statistics are computed based on the parameter estimates of the converged model if the parameters are estimated by maximum likelihood. If a Bayesian analysis is performed, the output statistics are computed based on the arithmetic mean in the posterior sample. You can change to the maximum posterior estimate with the [ESTIMATE=MAP](#) option in the [BAYES](#) statement.

You can specify the following syntax elements in the OUTPUT statement before the slash (/).

OUT=SAS-data-set

specifies the name of the output data set. If the OUT= option is omitted, the procedure uses the *DATA**n* convention to name the output data set.

keyword< (keyword-options) > <=name>

specifies a statistic to include in the output data set and optionally assigns the variable the name *name*. If you do not provide a name, the FMM procedure assigns a default name based on the type of statistic requested. If you provide a name for a statistic that leads to multiple output statistics, the name is modified to index the associated component number.

You can use the *keyword-options* to control which type of a particular statistic is computed. The following are valid values for *keyword* and *keyword-options*:

PREDICTED< (COMPONENT | OVERALL) >

PRED< (COMPONENT | OVERALL) >

MEAN< (COMPONENT | OVERALL) >

requests predicted values (predicted means) for the response variable. The predictions in the output data set are mapped onto the data scale in all cases except for a binomial or binary response with *events/trials* syntax and when [PREDTYPE=COUNT](#) has not been specified. In that case the predictions are predicted success probabilities.

The default is to compute the predicted value for the mixture (OVERALL). You can request predictions for the means of the component distributions by adding the COMPONENT suboption in parentheses. The predicted values for some distributions are not identical to the parameter modeled as μ . For example, in the lognormal distribution the predicted mean is $\exp\{\mu + 0.5\phi\}$ where μ and ϕ are the parameters of an underlying normal process; see the section “[Log-Likelihood Functions for Response Distributions](#)” on page 2427 for details.

RESIDUAL< (COMPONENT | OVERALL) >

RESID< (COMPONENT | OVERALL) >

requests residuals for the response or residuals in the component distributions. Only “raw” residuals on the data scale are computed (observed minus predicted).

VARIANCE<(COMPONENT | OVERALL)>

VAR<(COMPONENT | OVERALL)>

requests variances for the mixture or the component distributions.

LOGLIKE<(COMPONENT | OVERALL)>

LOGL<(COMPONENT | OVERALL)>

requests values of the log-likelihood function for the mixture or the components. For observations used in the analysis, the overall computed value is the observations' contribution to the log likelihood; if a **FREQ** statement is present, the frequency is accounted for in the computed value. In other words, if all observations in the input data set have been used in the analysis, adding the value of the log-likelihood contributions in the OUTPUT data set produces the negative of the final objective function value in the "Iteration History" table. By default, the log-likelihood contribution to the mixture is computed. You can request the individual mixture component contributions with the **COMPONENT** suboption.

MIXPROBS<(COMPONENT | MAX)>

MIXPROB<(COMPONENT | MAX)>

PRIOR<(COMPONENT | MAX)>

MIXWEIGHTS<(COMPONENT | MAX)>

requests that the prior weights $\pi_j(\mathbf{z}, \boldsymbol{\alpha}_j)$ be added to the OUTPUT data set. By default, the probabilities are output for all components. You can limit the output to a single statistic, the largest mixing probability, with the **MAX** suboption.

NOTE: The keyword "prior" is used here because of long-standing practice to refer to the mixing probabilities as prior weights. This must not be confused with the prior distribution and its parameters in a Bayesian analysis.

POSTERIOR<(COMPONENT | MAX)>

POST<(COMPONENT | MAX)>

PROB<(COMPONENT | MAX)>

requests that the posterior weights

$$\frac{\pi_j(\mathbf{z}, \boldsymbol{\alpha}_j) p_j(y; \mathbf{x}'_j \boldsymbol{\beta}_j, \phi_j)}{\sum_{j=1}^k \pi_j(\mathbf{z}, \boldsymbol{\alpha}_j) p_j(y; \mathbf{x}'_j \boldsymbol{\beta}_j, \phi_j)}$$

be added to the OUTPUT data set. By default, the probabilities are output for all components. You can limit the output to a single statistic, the largest posterior probability, with the **MAX** suboption.

NOTE: The keyword "posterior" is used here because of long-standing practice to refer to these probabilities as posterior probabilities. This must not be confused with the posterior distribution in a Bayesian analysis.

LINP

XBETA

requests that the linear predictors for the models be added to the OUTPUT data set.

CLASS | CATEGORY | GROUP

adds the estimated component membership to the OUTPUT data set. An observation is associated with the component that has the highest posterior probability.

MAXPOST | MAXPROB

adds the highest posterior probability to the OUTPUT data set.

A *keyword* can appear multiple times. For example, the following OUTPUT statement requests predicted values for the mixture in addition to the predicted means in the individual components:

```
output out=fmmout pred=MixtureMean pred(component)=CompMean;
```

In a three-component model, this produces four variables in the fmmout data set: MixtureMean, CompMean_1, CompMean_2, and CompMean_3.

You can specify the following *options* in the OUTPUT statement after a slash (/).

ALLSTATS

requests that all statistics are computed. If you do not use a keyword to assign a name, the FMM procedure uses the default name.

NOVAR

requests that variables from the input data set not be added to the output data set. This option does not apply to variables listed in the **BY** statement or to variables listed in the **ID** statement.

PREDTYPE=PROB | COUNT

specifies the type of predicted values that are produced for a binomial or binary response with *events/trials* syntax. If PREDTYPE=PROB, the predicted values are success probabilities. If PREDTYPE=COUNT, the predicted values are success counts. The default is PREDTYPE=PROB.

PERFORMANCE Statement

```
PERFORMANCE < performance-options > ;
```

The PERFORMANCE statement enables you to control the performance characteristics of the FMM procedure (for example, the number of CPUs, the number of threads for multithreading, and so on). By default, the FMM procedure performs many analyses in multiple threads, and the number of threads equals the number of CPUs. Certain system and configuration options also can control the number of CPUs available to a SAS session or whether multithreaded computations are permissible. For example, you can set the number of available processors to two with

```
options cpucount=2;
```

The FMM procedure then acts as though two processors were available, regardless of the number of physically available processors.

The FMM procedure applies multithreading to the following analytical tasks:

Starting values: all starting value computations that require a pass through the data.

Optimization: all evaluations of objective function, gradient, and Hessian; computation of covariance matrix.

Bayesian analysis: all sample passes through the data, formation of cross-product matrices, sampling of latent variables, and posterior diagnostics.

Scoring and ODS Graphics: computation of all output statistics and statistics for the construction of graphics that require passes through the data.

You can specify the following *performance-options*:

CPUCOUNT=*n*

CPUCOUNT=ACTUAL

specifies the number of processors available to the FMM procedure; the number *n* must be between 1 and 1024. CPUCOUNT=ACTUAL sets the number of available processors equal to the number of physical processors.

DETAILS

requests a table with timing detail for the tasks performed by the FMM procedure.

NOTHEADS

disables multithreaded computations.

THREADS=YES

THREADS=NO

enables or disables multithreaded processing. The number of threads used by the FMM procedure is displayed in the “Bayes Information” or “Optimization Information” table. It typically equals the number of available CPUs, which can be different from the number of physical CPUs, and can be modified with the global CPUCOUNT SAS option or with the CPUCOUNT= option in the PERFORMANCE statement.

PROBMODEL Statement

PROBMODEL < *effects* > < / *probmodel-options* > ;

The PROBMODEL statement defines the model effects for the mixing probabilities and their link function and starting values. Model effects (other than the implied intercept) are not supported with Bayesian estimation. By default, the FMM procedure models mixing probabilities on the logit scale for two-component models and as generalized logit models in situations with more than two components. The PROBMODEL statement is not required.

The generalized logit model with *k* categories has a common vector of regressor or design variables, **z**, *k* – 1 parameter vectors that vary with category, and one linear predictor whose value is constant. The constant linear predictor is assigned by the FMM procedure to the last component in the model, and its value is zero ($\alpha_k = 0$). The probability of observing category $1 \leq j \leq k$ is then

$$\pi_j(\mathbf{z}, \boldsymbol{\alpha}_j) = \frac{\exp\{\mathbf{z}'\boldsymbol{\alpha}_j\}}{\sum_{i=1}^k \exp\{\mathbf{z}'\boldsymbol{\alpha}_i\}}$$

For $k=2$, the generalized logit model reduces to a model with the logit link (a logistic model); hence the attribute *generalized* logit.

By default, an intercept is included in the model for the mixing probabilities. If you suppress the intercept with the **NOINT** option, you must specify at least one effect in the statement.

You can specify the following *probmodel-options* in the **PROBMODEL** statement after the slash (/):

ALPHA=number

requests that confidence intervals be constructed for the parameters in the probability model with confidence level $1 - \text{number}$. The value of *number* must be between 0 and 1; the default is 0.05. If the probability model is simple—that is, it does not contain any effects, the confidence intervals are produced for the estimated parameters (on the logit scale) as well as for the mixing probabilities.

CL

requests that confidence limits be constructed for each of the parameter estimates. The confidence level is 0.95 by default; this can be changed with the **ALPHA=** option.

LINK=keyword

specifies the link function in the model for the mixing probabilities. The default is a logit link for models with two components. For models with more than two components, only the generalized logit link is available. The *keywords* and expressions for the associated link functions for two-component models are shown in Table 37.7.

Table 37.7 Link Functions in the **PROBMODEL** Statement

LINK=	Link Function	$g(\mu) = \eta =$
CLOGLOG CLL	Complementary log-log	$\log(-\log(1 - \mu))$
LOGIT	Logit	$\log(\mu/(1 - \mu))$
LOGLOG	Log-log	$-\log(-\log(\mu))$
PROBIT NORMIT	Probit	$\Phi^{-1}(\mu)$

NOINT

requests that no intercept be included in the model for the mixing probabilities. An intercept is included by default. If you suppress the intercept with the **NOINT** option, you must specify at least one other effect for the mixing probabilities—since an empty probability model is not meaningful.

PARAMETERS(parameter-specification)

PARMS(parameter-specification)

specifies starting values for the parameters. The specification of the parameters takes the following form: parameters in the mean function appear in a list, and parameters for different components are separated by commas. Starting values are given on the linked scale, not in terms of probabilities. Also, you need to specify starting values for only up to the first $k - 1$ components in a k -component model. The linear predictor for the last component is always assumed to be zero.

The following statements specify a three-component mixture of multiple regression models. The **PROBMODEL** statement does not list any effects, a standard “intercept-only” generalized logit model is used to model the mixing probabilities.

```
proc fmm;
  model y = x1 x2 / k=3;
  probmodel / parms(2, 1);
run;
```

There are three linear predictors in the model for the mixing probabilities, α_1 , α_2 , and α_3 . With starting values of $\alpha_1 = 2$, $\alpha_2 = 1$, and $\alpha_3 = 0$, this leads to initial mixing probabilities of

$$\pi_1 = \frac{e^2}{e^2 + e^1 + e^0} = 0.24$$

$$\pi_2 = \frac{e^1}{e^2 + e^1 + e^0} = 0.66$$

$$\pi_3 = \frac{e^0}{e^2 + e^1 + e^0} = 0.1$$

You can specify missing values for parameters whose starting values are to be determined by the default method.

RESTRICT Statement

RESTRICT <'label'> *constraint-specification* <, ..., *constraint-specification*>
 <operator <value>> </option> ;

The RESTRICT statement enables you to specify linear equality or inequality constraints among the parameters of a mixture model. These restrictions are incorporated into the maximum likelihood analysis. The RESTRICT statement is not available for a Bayesian analysis with the FMM procedure.

Following are reasons why you might want to place constraints and restrictions on the model parameters:

- to fix a parameter at a particular value
- to equate parameters in different components in a mixture
- to impose order conditions on the parameters in a model
- to specify contrasts among the parameters that the fitted model should honor

A restriction is composed of a left-hand side and a right-hand side, separated by an operator. If the operator and right-hand side are not specified, the restriction is assumed to be an equality constraint against zero. If the right-hand side is not specified, the value is assumed to be zero.

An individual *constraint-specification* is written in (nearly) the same form as estimable linear functions are specified in the ESTIMATE statement of the GLM, MIXED, or GLIMMIX procedure. The *constraint-specification* takes the form

model-effect value-list < ... *model-effect value-list* > <(SCALE= value)>

At least one *model-effect* must be specified followed by one or more values in the *value-list*. The values in the list correspond to the multipliers of the corresponding parameter that is associated with the position in the model effect. If you specify more values in the *value-list* than the *model-effect* occupies in the model design matrix, the extra coefficients are ignored.

To specify restrictions for effects in specific components in the model, separate the *constraint-specification* by commas. The following statements provide an example:

```
proc fmm;
  class A;
  model y/n = A x / k = 2;
  restrict A 1 0 -1;
  restrict x 2, x -1 >= 0.5;
run;
```

The linear predictors for this two-component model can be written as

$$\begin{aligned}\eta_1 &= \beta_{10} + \alpha_{11}A_1 + \cdots + \alpha_{1a}A_a + x\beta_{11} \\ \eta_2 &= \beta_{20} + \alpha_{21}A_1 + \cdots + \alpha_{2a}A_a + x\beta_{21}\end{aligned}$$

where A_k is the binary variable associated with the k th level of A.

The first RESTRICT statement applies only to the first component and specifies that the parameter estimates that are associated with the first and third level of the A effect are identical. In terms of the linear predictor, the restriction can be written as

$$\alpha_{11} - \alpha_{13} = 0$$

Now suppose that A has only two levels. Then the FMM procedure ignores the value -1 in the first RESTRICT statement and imposes the restriction

$$\alpha_{11} = 0$$

on the fitted model.

The second RESTRICT statement involves parameters in two different components of the model. In terms of the linear predictors, the restriction can be written as

$$2\beta_{11} - \beta_{21} \geq \frac{1}{2}$$

When restrictions are specified explicitly through the RESTRICT statement or implied through the `EQUATE=EFFECTS` option in the `MODEL` statement, the FMM procedure lists all restrictions after the model fit in a table of linear constraints and indicates whether a particular constraint is active at the converged solution.

The following operators can be specified to separate the left- and right-hand sides of the restriction: `=`, `>`, `<`, `>=`, `<=`.

Some distributions involve scale parameters (the parameter ϕ in the expressions of the log likelihood) and you can also use the *constraint-specification* to involve a component's scale parameter in a constraint. To this end, assign a value to the keyword `SCALE`, separated from the model effects and value lists with parentheses. The following statements fit a two-component normal model and restrict the component variances to be equal:

```
proc fmm;
  model y = / k=2;
  restrict int 0 (scale 1),
           int 0 (scale -1);
run;
```

The intercept specification is necessary because each *constraint-specification* requires at least one model effect. The zero coefficient ensures that the intercepts are not involved in the restriction. Instead, the RESTRICT statement leads to $\phi_1 - \phi_2 = 0$.

You can specify the following *option* in the RESTRICT statement after a slash (/).

DIVISOR=value

specifies a *value* by which all coefficients on the right-hand side and left-hand side of the restriction are divided.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement is used to perform a weighted analysis. Consult the section “[Log-Likelihood Functions for Response Distributions](#)” on page 2427 for expressions on how weight variables are included in the log-likelihood functions. Because the probability structure of a mixture model is different from that of a classical statistical model, the presence of a weight variable in a mixture model *cannot* be interpreted as altering the variance of an observation.

Observations with nonpositive or missing weights are not included in the PROC FMM analysis. If a WEIGHT statement is not included, all observations used in the analysis are assigned a weight of 1.

Details: FMM Procedure

A Gentle Introduction to Finite Mixture Models

The Form of the Finite Mixture Model

Suppose that you observe realizations of a random variable Y , the distribution of which depends on an unobservable random variable S that has a discrete distribution. S can occupy one of k states, the number of which might be unknown but is at least known to be finite. Since S is not observable, it is frequently referred to as a latent variable.

Let π_j denote the probability that S takes on state j . Conditional on $S = j$, the distribution of the response Y is assumed to be $f_j(y; \alpha_j, \beta_j | S = j)$. In other words, each distinct state j of the random variable S leads to a particular distributional form f_j and set of parameters $\{\alpha_j, \beta_j\}$ for Y .

Let $\{\alpha, \beta\}$ denote the collection of α_j and β_j parameters across all $j = 1$ to k . The marginal distribution of Y is obtained by summing the joint distribution of Y and S over the states in the support of S :

$$\begin{aligned} f(y; \alpha, \beta) &= \sum_{j=1}^k \Pr(S = j) f(y; \alpha_j, \beta_j | S = j) \\ &= \sum_{j=1}^k \pi_j f(y; \alpha_j, \beta_j | S = j) \end{aligned}$$

This is a mixture of distributions, and the π_j are called the mixture (or prior) probabilities. Because the number of states k of the latent variable S is finite, the entire model is termed a finite mixture (of distributions) model.

The finite mixture model can be expressed in a more general form by representing α and β in terms of regressor variables and parameters with optional additional scale parameters for β . The section “[Notation for the Finite Mixture Model](#)” on page 2358 develops this in detail.

Mixture Models Contrasted with Mixing and Mixed Models: Untangling the Terminology Web

Statistical terminology can have its limitations. The terms mixture, mixing, and mixed models are sometimes used interchangeably, causing confusion. Even worse, the terms arise in related situations. One application needs to be eliminated from the discussion in this documentation: mixture experiments, where design factors are the proportions with which components contribute to a blend, are not mixture models and do not fall under the purview of the FMM procedure. However, the data from a mixture experiment might be analyzed with a mixture model, a mixing model, or a mixed model, besides other types of statistical models.

Suppose that you observe realizations of random variable Y and assume that Y follows some distribution $f(y; \alpha, \beta)$ that depends on parameters α and β . Furthermore, suppose that the model is found to be deficient in the sense that the variability implied by the fitted model is less than the observed variability in the data, a condition known as overdispersion (see the section “[Overdispersion](#)” on page 2426). To tackle the problem the statistical model needs to be modified to allow for more variability. Clearly, one way of doing this is to introduce additional random variables into the process. Mixture, mixing, and mixed models are simply different ways of adding such random variables. The section “[The Form of the Finite Mixture Model](#)” on page 2423 explains how mixture models add a discrete state variable S . The following two subsections explain how mixing and mixed models instead assume variation for a natural parameter or in the mean function.

Mixing Models

Suppose that the model is modified to allow for some random quantity U , which might be one of the parameters of the model or a quantity related to the parameters. Now there are two distributions to cope with: the conditional distribution of the response given the random effect U ,

$$f(y; \alpha, \beta | u)$$

and the marginal distribution of the data. If U is continuous, the marginal distribution is obtained by integration:

$$f(y; \alpha, \beta) = \int f(y; \alpha, \beta | u) f(u) du$$

Otherwise, it is obtained by summation over the support of U :

$$f(y; \boldsymbol{\alpha}, \boldsymbol{\beta}) = \sum_u \Pr(U = u) f(y; \boldsymbol{\alpha}, \boldsymbol{\beta} | u)$$

The important entity for statistical estimation is the marginal distribution $f(y; \boldsymbol{\alpha}, \boldsymbol{\beta})$; the conditional distribution is often important for model description, genesis, and interpretation.

In a mixing model the marginal distribution is known and is typically of a well-known form. For example, if $Y|n$ has a binomial(n, μ) distribution and n follows a Poisson distribution, then the marginal distribution of Y is Poisson. The preceding operation is called *mixing* a binomial distribution with a Poisson distribution. Similarly, when mixing a Poisson(λ) distribution with a gamma(a, b) distribution for λ , a negative binomial distribution results as the marginal distribution. Other important mixing models involve mixing a binomial(n, μ) random variable with a beta(a, b) distribution for the binomial success probability μ . This results in a distribution known as the beta-binomial.

The finite mixtures have in common with the mixing models the introduction of random effects into the model to vary some or all of the parameters at random.

Mixed Models

The difference between a mixing and a mixed model is that the conditional distribution is not that important in the mixing model. It matters to motivate the overdispersed reference model and to arrive at the marginal distribution. Inferences with respect to the conditional distribution, such as predicting the random variable U , are not performed in mixing models. In a mixed model the random variable U typically follows a continuous distribution—almost always a normal distribution. The random effects usually do not model the natural parameters of the distribution; instead, they are involved in linear predictors that relate to the conditional mean. For example, a linear mixed model is a model in which the response and the random effects are normally distributed, and the random effects enter the conditional mean function linearly:

$$\begin{aligned} \mathbf{Y} &= \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{U} + \boldsymbol{\epsilon} \\ \mathbf{U} &\sim N(\mathbf{0}, \mathbf{G}) \\ \boldsymbol{\epsilon} &\sim N(\mathbf{0}, \mathbf{R}) \\ \text{Cov}[\mathbf{U}, \boldsymbol{\epsilon}] &= \mathbf{0} \end{aligned}$$

The conditional and marginal distributions are then

$$\begin{aligned} \mathbf{Y} | \mathbf{U} &\sim N(\mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{U} + \boldsymbol{\epsilon}, \mathbf{R}) \\ \mathbf{Y} &\sim N(\mathbf{X}\boldsymbol{\beta}, \mathbf{Z}\mathbf{G}\mathbf{Z}' + \mathbf{R}) \end{aligned}$$

For this model, because of the linearity in the mean and the normality of the random effects, you could also refer to mixing the normal vector \mathbf{Y} with the normal vector \mathbf{U} , since the marginal distribution is known. The linear mixed model can be fit with the MIXED procedure. When the conditional distribution is not normal and the random effects are normal, the marginal distribution does not have a closed form. In this class of mixed models, called generalized linear mixed models, model approximations and numerical integration methods are commonly used in model fitting; see for example, those models fit by the GLIMMIX and NLMIXED procedures. Chapter 6, “[Introduction to Mixed Modeling Procedures](#),” contains details about the various classes of mixed models and about the relevant SAS/STAT procedures.

The previous expression for the marginal variance in the linear mixed model, $\text{var}[\mathbf{Y}] = \mathbf{Z}\mathbf{G}\mathbf{Z}' + \mathbf{R}$, emphasizes again that the variability in the marginal distribution of a model that contains random effects exceeds the variability in a model without the random effects (\mathbf{R}).

The finite mixtures have in common with the mixed models that the marginal distribution is not necessarily a well-known model, but is expressed through a formal integration over the random-effects distribution. In contrast to the mixed models, in particular those involving nonnormal distributions or nonlinear elements, this integration is rather trivial; it reduces to a weighted and finite sum of densities or mass functions.

Overdispersion

Overdispersion is the condition by which the data are more dispersed than is permissible under a reference model. Overdispersion arises only if the variability a model can capture is limited (for example, because of a functional relationship between mean and variance). For example, a model for normal data can never be overdispersed in this sense, although the reasons that lead to overdispersion also negatively affect a misspecified model for normal data. For example, omitted variables increase the residual variance estimate because variability that should have been modeled through changes in the mean is now “picked up” as error variability.

Overdispersion is important because an overdispersed model can lead to misleading inferences and conclusions. However, diagnosing and remedying overdispersion is complicated. In order to handle it appropriately, the source of overdispersion must be identified. For example, overdispersion can arise from any of the following conditions alone or in combination:

- omitted variables and model effects
- omitted random effects (a source of random variation is not being modeled or is modeled as a fixed effect)
- correlation among the observations
- incorrect distributional assumptions
- incorrectly specified mean-variance relationships
- outliers in the data

As discussed in the previous section, introducing randomness into a system increases its variability. Mixture, mixed, and mixing models have thus been popular in modeling data that appear overdispersed. Finite mixture models are particularly powerful in this regard, because even low-order mixtures of basic, symmetric distributions (such as two- or three-component mixtures of normal or t distributions) enable you to model data with multiple modes, heavy tails, and skewness. In addition, the latent variable S provides a natural way to accommodate omitted, unobservable variables into the model.

One approach to remedy overdispersion is to apply simple modifications of the variance function of the reference model. For example, with binomial-type data this approach replaces the variance of the binomial count variable $Y \sim \text{Binomial}(n, \mu)$, $\text{Var}[Y] = n \times \mu(1 - \mu)$ with a scaled version, $\phi n \times \mu(1 - \mu)$, where ϕ is called an overdispersion parameter, $\phi > 0$.

In addressing overdispersion problems, it is important to tackle the problem at its root. A missing scale factor on the variance function is hardly ever the root cause of overdispersion; it is only the easiest remedy.

Log-Likelihood Functions for Response Distributions

The FMM procedure calculates the log likelihood that corresponds to a particular response distribution according to the following formulas. The response distribution is the distribution specified (or chosen by default) through the **DIST=** option in the **MODEL** statement. The parameterizations used for log-likelihood functions of these distributions were chosen to facilitate expressions in terms of mean parameters that are modeled through an (inverse) link functions and in terms of scale parameters. These are not necessarily the parameterizations in which parameters of prior distributions are specified in a Bayesian analysis of homogeneous mixtures. See the section “**Prior Distributions**” on page 2435 for details about the parameterizations of prior distributions.

The FMM procedure includes all constant terms in the computation of densities or mass functions. In the expressions that follow, l denotes the log-likelihood function, ϕ denotes a general scale parameter, μ_i is the “mean”, and w_i is a weight from the use of a **WEIGHT** statement.

For some distributions (for example, the Weibull distribution) μ_i is not the mean of the distribution. The parameter μ_i is the quantity that is modeled as $g^{-1}(\mathbf{x}'\boldsymbol{\beta})$, where $g^{-1}(\cdot)$ is the inverse link function and the \mathbf{x} vector is constructed based on the effects in the **MODEL** statement. Situations in which the parameter μ does not represent the mean of the distribution are explicitly mentioned in the list that follows.

The parameter ϕ is frequently labeled as a “Scale” parameter in output from the FMM procedure. It is not necessarily the scale parameter of the particular distribution.

Beta(μ, ϕ)

$$\begin{aligned} l(\mu_i, \phi; y_i, w_i) = & \log \left\{ \frac{\Gamma(\phi/w_i)}{\Gamma(\mu_i\phi/w_i)\Gamma((1-\mu_i)\phi/w_i)} \right\} \\ & + (\mu_i\phi/w_i - 1) \log\{y_i\} \\ & + ((1-\mu_i)\phi/w_i - 1) \log\{1-y_i\} \end{aligned}$$

This parameterization of the beta distribution is due to Ferrari and Cribari-Neto (2004) and has properties $E[Y] = \mu$, $\text{Var}[Y] = \mu(1-\mu)/(1+\phi)$, $\phi > 0$.

Beta-binomial($n; \mu, \phi$)

$$\begin{aligned} \phi &= (1-\rho^2)/\rho^2 \\ l(\mu_i, \rho; y_i) &= \log\{\Gamma(n_i+1)\} - \log\{\Gamma(y_i+1)\} \\ &\quad - \log\{\Gamma(n_i-y_i+1)\} \\ &\quad + \log\{\Gamma(\phi)\} - \log\{\Gamma(n_i+\phi)\} + \log\{\Gamma(y_i+\phi\mu_i)\} \\ &\quad + \log\{\Gamma(n_i-y_i+\phi(1-\mu_i))\} - \log\{\Gamma(\phi\mu_i)\} \\ &\quad - \log\{\Gamma(\phi(1-\mu_i))\} \\ l(\mu_i, \rho; y_i, w_i) &= w_i l(\mu_i, \rho; y_i) \end{aligned}$$

where y_i and n_i are the *events* and *trials* in the *events/trials* syntax and $0 < \mu < 1$. This parameterization of the beta-binomial model presents the distribution as a special case of the Dirichlet-Multinomial distribution—see, for example, Neerchal and Morel (1998). In this parameterization, $E[Y] = n\mu$ and $\text{Var}[Y] = n\mu(1-\mu)(1+(n-1)/(\phi+1))$, $0 \leq \rho \leq 1$. The FMM procedure models the parameter ϕ and labels it “Scale” on the procedure output. For other parameterizations of the beta-binomial model, see Griffiths (1973) or Williams (1975).

Binomial($n; \mu$)

$$\begin{aligned}
l(\mu_i; y_i) &= y_i \log\{\mu_i\} + (n_i - y_i) \log\{1 - \mu_i\} \\
&\quad + \log\{\Gamma(n_i + 1)\} - \log\{\Gamma(y_i + 1)\} \\
&\quad - \log\{\Gamma(n_i - y_i + 1)\} \\
l(\mu_i; y_i, w_i) &= w_i l(\mu_i; y_i)
\end{aligned}$$

where y_i and n_i are the *events* and *trials* in the *events/trials* syntax and $0 < \mu < 1$. In this parameterization $E[Y] = n\mu$, $\text{Var}[Y] = n\mu(1 - \mu)$.

Binomial cluster($n; \mu, \pi$)

$$\begin{aligned}
z &= \log\{\Gamma(n_i + 1)\} - \log\{\Gamma(y_i + 1)\} - \log\{\Gamma(n_i - y_i + 1)\} \\
\mu_i^* &= (1 - \mu_i)\pi \\
l(\mu_i, \pi; y_i) &= \log\{\pi\} + z + y_i \log\{\mu_i^* + \mu_i\} \\
&\quad + (n_i - y_i) \log\{1 - \mu_i^* - \mu_i\} \\
&\quad + \log\{1 - \pi\} + z + y_i \log\{\mu_i^*\} \\
&\quad + (n_i - y_i) \log\{1 - \mu_i^*\} \\
l(\mu_i, \pi; y_i, w_i) &= w_i l(\mu_i, \pi; y_i)
\end{aligned}$$

In this parameterization, $E[Y] = n\pi$ and $\text{Var}[Y] = n\pi(1 - \pi) \{1 + \mu^2(n - 1)\}$. The binomial cluster model is a two-component mixture of a binomial($n, \mu^* + \mu$) and a binomial(n, μ^*) random variable. This mixture is unusual in that it fixes the number of components and because the mixing probability π appears in the moments of the mixture components. For further details, see Morel and Nagaraj (1993); Morel and Neerchal (1997); Neerchal and Morel (1998) and [Example 37.1](#) in this chapter. The expressions for the mean and variance in the binomial cluster model are identical to those of the beta-binomial model shown previously, with $\pi_{bc} = \mu_{bb}$, $\mu_{bc} = \rho_{bb}$.

The FMM procedure models the parameter μ through the **MODEL** statement and the parameter π through the **PROBMODEL** statement.

Constant(c)

$$l(y_i) = \begin{cases} 0 & y_i = c \\ -1E20 & y_i \neq c \end{cases}$$

The extreme value when $y_i \neq c$ is chosen so that $\exp\{l(y_i)\}$ yields a likelihood of zero. You can change this value with the **INVALIDLOGL=** option in the **PROC FMM** statement. The constant distribution is useful for modeling overdispersion due to zero-inflation (or inflation of the process at support c).

Exponential(μ)

$$l(\mu_i; y_i, w_i) = \begin{cases} -\log\{\mu_i\} - y_i/\mu_i & w_i = 1 \\ w_i \log\left\{\frac{w_i y_i}{\mu_i}\right\} - \frac{w_i y_i}{\mu_i} - \log\{y_i \Gamma(w_i)\} & w_i \neq 1 \end{cases}$$

In this parameterization, $E[Y] = \mu$ and $\text{Var}[Y] = \mu^2$.

Folded normal(μ, ϕ)

$$l(\mu_i, \phi; y_i, w_i) = -\frac{1}{2} \log\{2\pi\} - \frac{1}{2} \log\{\phi/w_i\} \\ + \log \left\{ \exp \left\{ \frac{-w_i(y_i - \mu_i)^2}{2\phi} \right\} + \exp \left\{ \frac{-w_i(y_i + \mu_i)^2}{2\phi} \right\} \right\}$$

If X has a normal distribution with mean μ and variance ϕ , then $Y = |X|$ has a folded normal distribution and log-likelihood function $l(\mu, \phi; y, w)$ for $y \geq 0$. The folded normal distribution arises, for example, when normally distributed measurements are observed, but their signs are not observed. The mean and variance of the folded normal in terms of the underlying $N(\mu, \phi)$ distribution are

$$E[Y] = \frac{1}{\sqrt{2\pi\phi}} \exp \left\{ -\frac{\mu^2}{2\phi} \right\} + \mu \left(1 - 2\Phi \left(-\mu/\sqrt{\phi} \right) \right) \\ \text{Var}[Y] = \phi + \mu^2 - E[Y]^2$$

The FMM procedure models the folded normal distribution through the mean μ and variance ϕ of the underlying normal distribution. When the FMM procedure computes output statistics for the response variable (for example when you use the OUTPUT statement), the mean and variance of the response Y are reported. Similarly, the fit statistics apply to the distribution of $Y = |X|$, not the distribution of X . When you model a folded normal variable, the response input variable should be positive; the FMM procedure treats negative values of Y as a support violation.

Gamma(μ, ϕ)

$$l(\mu_i, \phi; y_i, w_i) = w_i \phi \log \left\{ \frac{w_i y_i \phi}{\mu_i} \right\} - \frac{w_i y_i \phi}{\mu_i} - \log\{y_i\} - \log\{\Gamma(w_i \phi)\}$$

In this parameterization, $E[Y] = \mu$ and $\text{Var}[Y] = \mu^2/\phi$, $\phi > 0$. This parameterization of the gamma distribution differs from that in the GLIMMIX procedure, which expresses the log-likelihood function in terms of $1/\phi$ in order to achieve a variance function suitable for mixed model analysis.

Geometric(μ)

$$l(\mu_i; y_i, w_i) = y_i \log \left\{ \frac{\mu_i}{w_i} \right\} - (y_i + w_i) \log \left\{ 1 + \frac{\mu_i}{w_i} \right\} \\ + \log \left\{ \frac{\Gamma(y_i + w_i)}{\Gamma(w_i)\Gamma(y_i + 1)} \right\}$$

In this parameterization, $E[Y] = \mu$ and $\text{Var}[Y] = \mu + \mu^2$. The geometric distribution is a special case of the negative binomial distribution with $\phi = 1$.

Generalized Poisson(μ, ϕ)

$$\xi_i = (1 - \exp\{-\phi\})/w_i \\ \mu_i^* = \mu_i - \xi(\mu_i - y_i) \\ l(\mu_i^*, \xi_i; y_i, w_i) = \log\{\mu_i^* - \xi_i y_i\} + (y_i - 1) \log\{\mu_i^*\} \\ - \mu_i^* - \log\{\Gamma(y_i + 1)\}$$

In this parameterization, $E[Y] = \mu$, $\text{Var}[Y] = \mu/(1 - \xi)^2$, and $\phi \geq 0$. The FMM procedure models the mean μ through the effects in the **MODEL** statement and applies a log link by default. The generalized Poisson distribution provides an overdispersed alternative to the Poisson distribution; $\phi = \xi_i = 0$ produces the mass function of a regular Poisson random variable. For details about the generalized Poisson distribution and a comparison with the negative binomial distribution, see Joe and Zhu (2005).

Inverse Gaussian(μ, ϕ)

$$l(\mu_i, \phi; y_i, w_i) = -\frac{1}{2} \left[\frac{w_i (y_i - \mu_i)^2}{y_i \phi \mu_i^2} + \log \left\{ \frac{\phi y_i^3}{w_i} \right\} + \log\{2\pi\} \right]$$

The variance is $\text{Var}[Y] = \phi \mu^3$, $\phi > 0$.

Lognormal(μ, ϕ)

$$z_i = \log\{y_i\} - \mu_i$$

$$l(\mu_i, \phi; y_i, w_i) = -\frac{1}{2} \left(2 \log\{y_i\} + \log \left\{ \frac{\phi}{w_i} \right\} + \log\{2\pi\} + \frac{w_i z_i^2}{\phi} \right)$$

If $X = \log\{Y\}$ has a normal distribution with mean μ and variance ϕ , then Y has the log-likelihood function $l(\mu_i, \phi; y_i, w_i)$. The FMM procedure models the lognormal distribution and not the “shortcut” version you can obtain by taking the logarithm of a random variable and modeling that as normally distributed. The two approaches are not equivalent, and the approach taken by PROC FMM is the actual lognormal distribution. Although the lognormal model is a member of the exponential family of distributions, it is not in the “natural” exponential family because it cannot be written in canonical form.

In terms of the parameters μ and ϕ of the underlying normal process for X , the mean and variance of Y are $E[Y] = \exp\{\mu\}\sqrt{\omega}$ and $\text{Var}[Y] = \exp\{2\mu\}\omega(\omega - 1)$, respectively, where $\omega = \exp\{\phi\}$. When you request predicted values with the **OUTPUT** statement, the FMM procedure computes $E[Y]$ and not μ .

Negative binomial(μ, ϕ)

$$l(\mu_i, \phi; y_i, w_i) = y_i \log \left\{ \frac{\phi \mu_i}{w_i} \right\} - (y_i + w_i/\phi) \log \left\{ 1 + \frac{\phi \mu_i}{w_i} \right\} \\ + \log \left\{ \frac{\Gamma(y_i + w_i/\phi)}{\Gamma(w_i/\phi)\Gamma(y_i + 1)} \right\}$$

The variance is $\text{Var}[Y] = \mu + \phi \mu^2$, $\phi > 0$.

For a given ϕ , the negative binomial distribution is a member of the exponential family. The parameter ϕ is related to the scale of the data because it is part of the variance function. However, it cannot be factored from the variance, as is the case with the ϕ parameter in many other distributions.

Normal(μ, ϕ)

$$l(\mu_i, \phi; y_i, w_i) = -\frac{1}{2} \left[\frac{w_i (y_i - \mu_i)^2}{\phi} + \log \left\{ \frac{\phi}{w_i} \right\} + \log\{2\pi\} \right]$$

The mean and variance are $E[Y] = \mu$ and $\text{Var}[Y] = \phi$, respectively, $\phi > 0$

Poisson(μ)

$$l(\mu_i; y_i, w_i) = w_i(y_i \log\{\mu_i\} - \mu_i - \log\{\Gamma(y_i + 1)\})$$

The mean and variance are $E[Y] = \mu$ and $\text{Var}[Y] = \mu$.

(Shifted) T($v; \mu, \phi$)

$$z_i = -0.5 \log\{\phi/\sqrt{w_i}\} + \log\{\Gamma(0.5(v+1))\} \\ - \log\{\Gamma(0.5v)\} - 0.5 \times \log\{\pi v\}$$

$$l(\mu_i, \phi; y_i, w_i) = -\left(\frac{v+1}{2}\right) \log\left\{1 + \frac{w_i(y_i - \mu_i)^2}{\phi}\right\} + z_i$$

In this parameterization $E[Y] = \mu$ and $\text{Var}[Y] = \phi v/(v-2)$, $\phi > 0$, $v > 0$. Note that this form of the t distribution is not a non-central distribution, but that of a shifted central t random variable.

Truncated Exponential($\mu; a, b$)

$$l(\mu_i; a, b, y_i, w_i) = w_i \log\left\{\frac{w_i y_i}{\mu_i}\right\} - \frac{w_i y_i}{\mu_i} - \log\{y_i \Gamma(w_i)\} \\ - \log\left[\frac{\gamma\left(w_i, \frac{w_i b}{\mu_i}\right)}{\Gamma(w_i)} - \frac{\gamma\left(w_i, \frac{w_i a}{\mu_i}\right)}{\Gamma(w_i)}\right]$$

where

$$\gamma(c_1, c_2) = \int_0^{c_2} t^{c_1-1} \exp(-t) dt$$

is the lower incomplete gamma function. The mean and variance are

$$E[Y] = \frac{(a + \mu_i) \exp(-a/\mu_i) - (b + \mu_i) \exp(-b/\mu_i)}{\exp(-a/\mu_i) - \exp(-b/\mu_i)} \\ \text{Var}[Y] = \frac{(a^2 + 2a\mu_i + 2\mu_i^2) \exp(-a/\mu_i) - (b^2 + 2b\mu_i + 2\mu_i^2) \exp(-b/\mu_i)}{\exp(-a/\mu_i) - \exp(-b/\mu_i)} \\ - (E[Y])^2$$

Truncated Lognormal($\mu, \phi; a, b$)

$$z_i = \log\{y_i\} - \mu_i$$

$$l(\mu_i, \phi; a, b, y_i, w_i) = -\frac{1}{2} \left(2 \log\{y_i\} + \log\left\{\frac{\phi}{w_i}\right\} + \log\{2\pi\} + \frac{w_i z_i^2}{\phi} \right) \\ - \log\left\{\Phi\left[\sqrt{w_i/\phi}(\log b - \mu_i)\right] - \Phi\left[\sqrt{w_i/\phi}(\log a - \mu_i)\right]\right\}$$

where $\Phi(\cdot)$ is the cumulative distribution function of the standard normal distribution. The mean and variance are

$$E[Y] = \exp(\mu_i + 0.5\phi) \frac{\Phi\left(\sqrt{\phi} - \frac{\log a - \mu_i}{\sqrt{\phi}}\right) - \Phi\left(\sqrt{\phi} - \frac{\log b - \mu_i}{\sqrt{\phi}}\right)}{\Phi\left(\frac{\log b - \mu_i}{\sqrt{\phi}}\right) - \Phi\left(\frac{\log a - \mu_i}{\sqrt{\phi}}\right)} \\ \text{Var}[Y] = \exp(2\mu_i + 2\phi) \frac{\Phi\left(2\sqrt{\phi} - \frac{\log a - \mu_i}{\sqrt{\phi}}\right) - \Phi\left(2\sqrt{\phi} - \frac{\log b - \mu_i}{\sqrt{\phi}}\right)}{\Phi\left(\frac{\log b - \mu_i}{\sqrt{\phi}}\right) - \Phi\left(\frac{\log a - \mu_i}{\sqrt{\phi}}\right)} - (E[Y])^2$$

Truncated Negative binomial(μ, ϕ)

$$l(\mu_i, \phi; y_i, w_i) = y_i \log \left\{ \frac{\phi \mu_i}{w_i} \right\} - (y_i + w_i/\phi) \log \left\{ 1 + \frac{\phi \mu_i}{w_i} \right\} \\ + \log \left\{ \frac{\Gamma(y_i + w_i/\phi)}{\Gamma(w_i/\phi) \Gamma(y_i + 1)} \right\} \\ - \log \left\{ 1 - \left(\frac{\phi \mu_i}{w_i} + 1 \right)^{-w_i/\phi} \right\}$$

The mean and variance are

$$E[Y] = \mu_i \left\{ 1 - (\phi \mu_i + 1)^{-1/\phi} \right\}^{-1} \\ \text{Var}[Y] = (1 + \phi \mu_i + \mu_i) E[Y] - (E[Y])^2$$

Truncated Normal($\mu, \phi; a, b$)

$$l(\mu_i, \phi; a, b, y_i, w_i) = -\frac{1}{2} \left[\frac{w_i (y_i - \mu_i)^2}{\phi} + \log \left\{ \frac{\phi}{w_i} \right\} + \log\{2\pi\} \right] \\ - \log \left\{ \Phi \left[\sqrt{w_i/\phi} (b - \mu_i) \right] - \Phi \left[\sqrt{w_i/\phi} (a - \mu_i) \right] \right\}$$

where $\Phi(\cdot)$ is the cumulative distribution function of the standard normal distribution.

The mean and variance are

$$E[Y] = \mu_i + \sqrt{\phi} \frac{\text{phi} \left(\frac{a - \mu_i}{\sqrt{\phi}} \right) - \text{phi} \left(\frac{b - \mu_i}{\sqrt{\phi}} \right)}{\Phi \left(\frac{b - \mu_i}{\sqrt{\phi}} \right) - \Phi \left(\frac{a - \mu_i}{\sqrt{\phi}} \right)} \\ \text{Var}[Y] = \phi \left[1 + \frac{\frac{a - \mu_i}{\sqrt{\phi}} \text{phi} \left(\frac{a - \mu_i}{\sqrt{\phi}} \right) - \frac{b - \mu_i}{\sqrt{\phi}} \text{phi} \left(\frac{b - \mu_i}{\sqrt{\phi}} \right)}{\Phi \left(\frac{b - \mu_i}{\sqrt{\phi}} \right) - \Phi \left(\frac{a - \mu_i}{\sqrt{\phi}} \right)} \right. \\ \left. - \left\{ \frac{\text{phi} \left(\frac{a - \mu_i}{\sqrt{\phi}} \right) - \text{phi} \left(\frac{b - \mu_i}{\sqrt{\phi}} \right)}{\Phi \left(\frac{b - \mu_i}{\sqrt{\phi}} \right) - \Phi \left(\frac{a - \mu_i}{\sqrt{\phi}} \right)} \right\}^2 \right]$$

where $\text{phi}(\cdot)$ is the probability density function of the standard normal distribution.

Truncated Poisson(μ)

$$l(\mu_i; y_i, w_i) = w_i (y_i \log\{\mu_i\} - \log\{\exp(\mu_i) - 1\} - \log\{\Gamma(y_i + 1)\})$$

The mean and variance are

$$E[Y] = \frac{\mu}{1 - \exp(-\mu)} \\ \text{Var}[Y] = \frac{\mu [1 - \exp(-\mu) - \mu \exp(-\mu)]}{[1 - \exp(-\mu)]^2}$$

Uniform(a, b)

$$l(\mu_i; y_i, w_i) = -\log\{b - a\}$$

The mean and variance are $E[Y] = 0.5(a + b)$ and $\text{Var}[Y] = (b - a)^2/12$.

Weibull(μ, ϕ)

$$l(\mu_i, \phi; y_i) = -\frac{\phi - 1}{\phi} \log \left\{ \frac{y_i}{\mu_i} \right\} - \log\{\mu_i \phi\} \\ - \exp \left\{ \log \left\{ \frac{y_i}{\mu_i} \right\} / \phi \right\}$$

In this particular parameterization of the two-parameter Weibull distribution, the mean and variance of the random variable Y are $E[Y] = \mu\Gamma(1 + \phi)$ and $\text{Var}[Y] = \mu^2 \{\Gamma(1 + 2\phi) - \Gamma^2(1 + \phi)\}$.

Bayesian Analysis

Conjugate Sampling

The FMM procedure uses Bayesian analysis via a conjugate Gibbs sampler if the model belongs to a small class of mixture models for which a conjugate sampler is available. See the section “[Gibbs Sampler](#)” on page 135 for a general discussion of Gibbs sampling. [Table 37.8](#) summarizes the models for which conjugate and Metropolis-Hastings samplers are available.

Table 37.8 Availability of Conjugate and Metropolis Samplers in the FMM Procedure

Effects (exclusive of intercept)	Distributions	Available Samplers
No	Normal or T	Conjugate or Metropolis-Hastings
Yes	Normal or T	Conjugate or Metropolis-Hastings
No	Binomial, binary, Poisson, exponential	Conjugate or Metropolis-Hastings
Yes	Binomial, binary, Poisson, exponential	Metropolis-Hastings only

The conjugate sampler enjoys greater efficiency than the Metropolis-Hastings sampler and has the advantage of sampling in terms of the natural parameters of the distribution.

You can always switch to the Metropolis-Hastings sampling algorithm in any model by adding the **METROPOLIS** option in the **BAYES** statement.

Metropolis-Hastings Algorithm

If Metropolis-Hastings is the only sampler available for the specified model (see [Table 37.8](#)) or if the **METROPOLIS** option is specified in the **BAYES** statement, PROC FMM uses the Metropolis-Hastings approach of Gamerman (1997). See the section “[Metropolis and Metropolis-Hastings Algorithms](#)” on page 134 for a general discussion of the Metropolis-Hastings algorithm.

The Gamerman (1997) algorithm derives a specific density that is used to generate proposals for the component-specific parameters β_j . The form of this proposal density is multivariate normal, with mean \mathbf{m}_j and covariance matrix \mathbf{C}_j derived as follows.

Suppose β_j is the vector of model coefficients in the j th component and suppose that β_j has prior distribution $N(\mathbf{a}, \mathbf{R})$. Consider a generalized linear model (GLM) with link function $g(\mu) = \eta = \mathbf{x}'\boldsymbol{\beta}$ and variance

function $a(\mu)$. The pseudo-response and weight in the GLM for a weighted least squares step are

$$y^* = \eta + (y - \mu) / \frac{\partial \mu}{\partial \eta}$$

$$w = \frac{\partial \mu}{\partial \eta} / a(\mu)$$

If the model contains offsets or **FREQ** or **WEIGHT** statements, or if a *trials* variable is involved, suitable adjustments are made to these quantities.

In each component, $j = 1, \dots, k$, form an adjusted cross-product matrix with a “pseudo” border

$$\begin{bmatrix} \mathbf{X}'_j \mathbf{W}_j \mathbf{X}_j + \mathbf{R}^{-1} & \mathbf{X}'_j \mathbf{W}_j \mathbf{y}^*_j + \mathbf{R}^{-1} \mathbf{a} \\ \mathbf{y}^{*'}_j \mathbf{W}_j \mathbf{X}_j + \mathbf{a}' \mathbf{R}^{-1} & c \end{bmatrix}$$

where \mathbf{W}_j is a diagonal matrix formed from the pseudo-weights w , \mathbf{y}^* is a vector of pseudo-responses, and c is arbitrary. This is basically a system of normal equations with ridging, and the degree of ridging is governed by the precision and mean of the normal prior distribution of the coefficients. Sweeping on the leading partition leads to

$$\mathbf{C}_j = (\mathbf{X}'_j \mathbf{W}_j \mathbf{X}_j + \mathbf{R}^{-1})^-$$

$$\mathbf{m}_j = \mathbf{C}_j (\mathbf{X}'_j \mathbf{W}_j \mathbf{y}^*_j + \mathbf{R}^{-1} \mathbf{a})$$

where the generalized inverse is a reflexive, g_2 -inverse (see the section “[Linear Model Theory](#)” on page 55 of Chapter 3, “[Introduction to Statistical Modeling with SAS/STAT Software](#),” for details).

PROC FMM then generates a proposed parameter vector from the resulting multivariate normal distribution, and then accepts or rejects this proposal according to the appropriate Metropolis-Hastings thresholds.

Latent Variables via Data Augmentation

In order to fit finite Bayesian mixture models, the FMM procedure treats the mixture model as a missing data problem and introduces an assignment variable \mathbf{S} as in Dempster, Laird, and Rubin (1977). Since \mathbf{S} is not observable, it is frequently referred to as a latent variable. The unobservable variable \mathbf{S} assigns an observation to a component in the mixture model. The number of states, k , might be unknown, but it is known to be finite. Conditioning on the latent variable \mathbf{S} , the component memberships of each observation is assumed to be known, and Bayesian estimation is straightforward for each component in the finite mixture model. That is, conditional on $S = j$, the distribution of the response is now assumed to be $f(y; \alpha_j, \beta_j | S = j)$. In other words, each distinct state of the random variable \mathbf{S} leads to a distinct set of parameters. The parameters in each component individually are then updated using a conjugate Gibbs sampler (where available) or a Metropolis-Hastings sampling algorithm.

The FMM procedure assumes that the random variable \mathbf{S} has a discrete multinomial distribution with probability π_j of belonging to a component j ; it can occupy one of k states. The distribution for the latent variable \mathbf{S} is

$$f(S_i = j | \pi_1, \dots, \pi_k) = \text{multinomial}(1, \pi_1, \dots, \pi_k)$$

where $f(\cdot | \cdot)$ denotes a conditional probability density. The parameters in the density π_j denote the probability that S takes on state j .

The FMM procedure assumes a conjugate Dirichlet prior distribution on the mixture proportions π_j written as:

$$p(\boldsymbol{\pi}) = \text{Dirichlet}(a_1, \dots, a_k)$$

where $p(\cdot)$ indicates a prior distribution.

Using Bayes' theorem, the likelihood function and prior distributions determine a conditionally conjugate posterior distribution of \mathbf{S} and $\boldsymbol{\pi}$ from the multinomial distribution and Dirichlet distribution, respectively.

Prior Distributions

The following list displays the parameterization of prior distributions for situations in which the FMM procedure uses a conjugate sampler in mixture models without model effects and certain basic distributions (binary, binomial, exponential, Poisson, normal, and t). You specify the parameters a and b in the formulas below in the **MUPRIORPARMS=** and **PHIPRIORPARMS=** options in the **BAYES** statement in these models.

Beta(a, b)

$$f(y) = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} y^{a-1} (1-y)^{b-1}$$

where $a > 0, b > 0$. In this parameterization, the mean and variance of the distribution are $\mu = a/(a+b)$ and $\mu(1-\mu)/(a+b+1)$, respectively. The beta distribution is the prior distribution for the success probability in binary and binomial distributions when conjugate sampling is used.

Dirichlet(a_1, \dots, a_k)

$$f(\mathbf{y}) = \frac{\Gamma\left(\sum_{i=1}^k a_i\right)}{\prod_{i=1}^k \Gamma(a_i)} y_1^{a_1-1} \dots y_k^{a_k-1}$$

where $\sum_{i=1}^k y_i = 1$ and the parameters $a_i > 0$. If any a_i were zero, an improper density would result. The Dirichlet density is the prior distribution for the mixture probabilities. You can affect the choice of the a_i through the **MIXPRIORPARMS** option in the **BAYES** statement. If $k=2$, the Dirichlet is the same as the beta(a, b) distribution.

Gamma(a, b)

$$f(y) = \frac{b^a}{\Gamma(a)} y^{a-1} \exp\{-by\}$$

where $a > 0, b > 0$. In this parameterization, the mean and variance of the distribution are $\mu = a/b$ and μ/b , respectively. The gamma distribution is the prior distribution for the mean parameter of the Poisson distribution when conjugate sampling is used.

Inverse gamma(a, b)

$$f(y) = \frac{b^a}{\Gamma(a)} y^{-a-1} \exp\{-b/y\}$$

where $a > 0$, $b > 0$. In this parameterization, the mean and variance of the distribution are $\mu = b/(a - 1)$ if $a > 1$ and $\mu^2/(a - 2)$ if $a > 2$, respectively. The inverse gamma distribution is the prior distribution for the mean parameter of the exponential distribution when conjugate sampling is used. It is also the prior distribution for the scale parameter ϕ in all models.

Multinomial(1, π_1, \dots, π_k)

$$f(\mathbf{y}) = \frac{1}{y_1! \cdots y_k!} \pi_1^{y_1} \cdots \pi_k^{y_k}$$

where $\sum_{j=1}^k y_j = n$, $y_j \geq 0$, $\sum_{j=1}^k \pi_j = 1$, and n is the number of observations included in the analysis. The multinomial density is the prior distribution for the mixture proportions. The mean and variance of Y_j are $\mu_j = \pi_j$ and $\mu_j(1 - \mu_j)$, respectively.

Normal(a, b)

$$f(y) = \frac{a}{\sqrt{2\pi b}} \exp \left\{ -\frac{1}{2} \frac{(y - a)^2}{b} \right\}$$

where $b > 0$. The mean and variance of the distribution are $\mu = a$ and b , respectively. The normal distribution is the prior distribution for the mean parameter of the normal and t distribution when conjugate sampling is used.

When a **MODEL** statement contains effects or if you specify the **METROPOLIS** option, the prior distribution for the regression parameters is multivariate normal, and you can specify the means and variances of the parameters in the **BETAPRIORPARMS=** option in the **BAYES** statement.

Parameterization of Model Effects

PROC FMM constructs a finite mixture model according to the specifications in the **CLASS**, **MODEL**, and **PROBMODEL** statements. Each effect in the **MODEL** statement generates one or more columns in the matrix **X** for that model. The same **X** matrix applies to all components that are associated with the **MODEL** statement. Each effect in the **PROBMODEL** statement generates one or more columns in the matrix **Z** from which the linear predictors in the model for the mixture probability models is formed. The same **Z** matrix applies to all components.

The formation of effects from continuous and classification variables in the FMM procedure follows the same general rules and techniques as for other linear modeling procedures. See the section “**GLM Parameterization of Classification Variables and Effects**” on page 383 of Chapter 19, “**Shared Concepts and Topics**.”

Default Output

The following sections describe the output that PROC FMM produces by default. The output is organized into various tables, which are discussed in the order of appearance for maximum likelihood and Bayes estimation, respectively.

Model Information

The “Model Information” table displays basic information about the model, such as the response variable, frequency variable, link function, and the model category that the FMM procedure determined based on your input and options. The “Model Information” table is one of a few tables that are produced irrespective of estimation technique. Most other tables are specific to Bayes or maximum likelihood estimation.

If the analysis depends on generated random numbers, the “Model Information” table also displays the random number seed used to initialize the random number generators. If you repeat the analysis and pass this seed value in the `SEED=` option in the `PROC FMM` statement, an identical stream of random numbers results.

Class Level Information

The “Class Level Information” table lists the levels of every variable specified in the `CLASS` statement. You should check this information to make sure that the data are correct. You can adjust the order of the `CLASS` variable levels with the `ORDER=` option in the `PROC FMM` statement. You can suppress the “Class Level Information” table completely or partially with the `NOCLPRINT` option in the `PROC FMM` statement.

Number of Observations

The “Number of Observations” table displays the number of observations read from the input data set and the number of observations used in the analysis. If you specify a `FREQ` statement, the table also displays the sum of frequencies read and used. If the *events/trials* syntax is used for the response, the table also displays the number of events and trials used in the analysis.

Note that the number of observations “used” in the analysis is not unambiguous in a mixture model. An observation that is “unusable” for one component distribution (because the response value is outside of the support of the distribution) might still be usable in the mixture model when the response value is in the support of another component distribution. You can affect the way in which `PROC FMM` handles exclusion of observations due to support violations with the `EXCLUSION=` option in the `PROC FMM` statement.

Response Profile

For binary data, the “Response Profile” table displays the ordered value from which the FMM procedure determines the probability being modeled as an event for binary data. For each response category level, the frequency used in the analysis is reported.

Default Output for Maximum Likelihood

Optimization Information

The “Optimization Information” table displays basic information about the optimization setup to determine the maximum likelihood estimates, such as the optimization technique, the parameters that participate in the optimization, and the number of threads used for the calculations. This table is not produced during model selection—that is, if the `KMAX=` option is specified in the `MODEL` statement.

Iteration History

The “Iteration History” table displays for each iteration of the optimization the number of function evaluations (including gradient and Hessian evaluations), the value of the objective function, the change in the objective function from the previous iteration, and the absolute value of the largest (projected) gradient

element. The objective function used in the optimization in the FMM procedure is the negative of the mixture log likelihood; consequently, PROC FMM performs a minimization. This table is not produced if the **KMAX=** option is specified in the **MODEL** statement.

Convergence Status

The convergence status table is a small ODS table that follows the “Iteration History” table in the default output. In the listing, it appears as a message that identifies whether the optimization succeeded and which convergence criterion was met. If the optimization fails, the message indicates the reason for the failure. If you save the “Convergence Status” table to an output data set, a numeric Status variable is added that allows you to assess convergence programmatically. The values of the Status variable encode the following:

- | | |
|---|---|
| 0 | Convergence was achieved or an optimization was not performed (because of TECHNIQUE=NONE). |
| 1 | The objective function could not be improved. |
| 2 | Convergence was not achieved because of a user interrupt or because a limit was exceeded, such as the maximum number of iterations or the maximum number of function evaluations. To modify these limits, see the MAXITER= , MAXFUNC= , and MAXTIME= options in the PROC FMM statement. |
| 3 | Optimization failed to converge because function or derivative evaluations failed at the starting values or during the iterations or because a feasible point that satisfies the parameter constraints could not be found in the parameter space. |

Fit Statistics

The “Fit Statistics” table displays a variety of fit measures based on the mixture log likelihood in addition to the Pearson statistic. All statistics are presented in “smaller is better” form. If you are fitting a single-component normal, gamma, or inverse gaussian model, the table also contains the unscaled Pearson statistic. If you are fitting a mixture model or the model has been fitted under restrictions, the table also contains the number of effective components and the number of effective parameters.

The calculation of the information criteria uses the following formulas, where p denotes the number of effective parameters, n denotes the number of observations used (or the sum of the frequencies used if a **FREQ** statement is present), and l is the log likelihood of the mixture evaluated at the converged estimates:

$$\begin{aligned} \text{AIC} &= -2l + 2p \\ \text{AICC} &= \begin{cases} -2l + 2pn/(n - p - 1) & n > p + 2 \\ -2l + 2p(p + 2) & \text{otherwise} \end{cases} \\ \text{BIC} &= -2l + p \log(n) \end{aligned}$$

The Pearson statistic is computed simply as

$$\text{Pearson statistic} = \sum_{i=1}^n f_i \frac{(y_i - \hat{\mu}_i)^2}{\widehat{\text{Var}}[Y_i]}$$

where n denotes the number of observations used in the analysis, f_i is the frequency associated with the i th observation (or 1 if no frequency is specified), μ_i is the mean of the mixture, and the denominator is the

variance of the i th observation in the mixture. Note that the mean and variance in this expression are not those of the component distributions, but the mean and variance of the mixture:

$$\mu_i = E[Y_i] = \sum_{j=1}^k \pi_{ij} \mu_{ij}$$

$$\text{Var}[Y_i] = -\mu_i^2 + \sum_{j=1}^k \pi_{ij} (\sigma_{ij}^2 + \mu_{ij}^2)$$

where μ_{ij} and σ_{ij}^2 are the mean and variance, respectively, for observation i in the j th component distribution and π_{ij} is the mixing probability for observation i in component j .

The unscaled Pearson statistic is computed with the same expression as the Pearson statistic with n , f_i , and μ_i as previously defined, but the scale parameter ϕ is set to 1 in the $\widehat{\text{Var}}[Y_i]$ expression.

The number of effective components and the number of effective parameters are determined by examining the converged solution for the parameters that are associated with model effects and the mixing probabilities. For example, if a component has an estimated mixing probability of zero, the values of its parameter estimates are immaterial. You might argue that all parameters should be counted towards the penalty in the information criteria. But a component with zero mixing probability in a k -component model effectively reduces the model to a $(k - 1)$ -component model. A situation of an overfit model, for which a parameter penalty needs to be taken when calculating the information criteria, is a different situation; here the mixing probability might be small, possibly close to zero.

Parameter Estimates

The parameter estimates, their estimated (asymptotic) standard errors, and p -values for the hypothesis that the parameter is zero are presented in the “Parameter Estimates” table. A separate table is produced for each **MODEL** statement, and the components that are associated with a **MODEL** statement are identified with an overall component count variable that counts across **MODEL** statements. If you assign a label to a model with the **LABEL=** option in the **MODEL** statement, the label appears in the title of the “Parameter Estimates” table. Otherwise, the internal label generated by the FMM procedure is used.

If the **MODEL** statement does not contain effects and the link function is not the identity, the inversely linked estimate is also displayed in the table. For many distributions, the inverse linked estimate is the estimated mean on the data scale. For example, in a binomial or binary model, it represents the estimated probability of an event. For some distributions (for example, the Weibull distribution), the inverse linked estimate is not the component distribution mean.

If you request confidence intervals with the **CL** or **ALPHA=** option in the **MODEL** statement, confidence limits are produced for the estimate on the linear scale. If the inverse linked estimate is displayed, confidence intervals for that estimate are also produced by inversely linking the confidence bounds on the linear scale.

Mixing Probabilities

If you fit a model with more than one component, the table of mixing probabilities is produced. If there are no effects in the **PROBMODEL** statement or if there is no **PROBMODEL** statement, the parameters are reported on the linear scale and as mixing probabilities. If model effects are present, only the linear parameters (on the scale of the logit, generalized logit, probit, and so on) are displayed.

Default Output for Bayes Estimation

Bayes Information

This table provides basic information about the sampling algorithm. The FMM procedure uses either a conjugate sampler or a Metropolis-Hastings sampling algorithm based on Gamerman (1997). The table reveals, for example, how many model parameters are sampled, how many parameters associated with mixing probabilities are sampled, and how many threads are used to perform multithreaded analysis.

Prior Distributions

The “Prior Distributions” table lists for each sampled parameter the prior distribution and its parameters. The mean and variance (if they exist) for those values of the parameters are also displayed, along with the initial value for the parameter in the Markov chain. The Component column in this table identifies the mixture component to which a particular parameter belongs. You can control how the FMM procedure determines initial values with the **INITIAL=** option in the **BAYES** statement.

Posterior Summaries

The arithmetic mean, standard deviation, and percentiles of the posterior distribution of the parameter estimates are displayed in the “Posterior Summaries” table. By default, the FMM procedure computes the 25th, 50th (median), and 75th percentiles of the sampling distribution. You can modify the percentiles through suboptions of the **STATISTICS** option in the **BAYES** statement. If a parameter corresponds to a singularity in the design and was removed from sampling for that purpose, it is also displayed in the table of posterior summaries (and in other tables that relate to output from the **BAYES** statement). The posterior sample size for such a parameter is shown as $N = 0$.

Posterior Intervals

The table of “Posterior Intervals” displays equal-tail intervals and intervals of highest posterior density for each parameter. By default, intervals are computed for an α -level of 0.05, which corresponds to 95% intervals. You can modify this confidence level by providing one or more α values in the **ALPHA=** suboption of the **STATISTICS** option in the **BAYES** statement. The computation of these intervals is detailed in section “Summary Statistics” on page 153 of Chapter 7, “Introduction to Bayesian Analysis Procedures.”

Posterior Autocorrelations

Autocorrelations for the posterior estimates are computed by default for autocorrelation lags 1, 5, 10, and 50, provided that a sufficient number of posterior samples is available. See the section “Assessing Markov Chain Convergence” on page 139 of Chapter 7, “Introduction to Bayesian Analysis Procedures,” for the computation of posterior autocorrelations and their utility in diagnosing convergence of Markov chains. You can modify the list of lags for which posterior autocorrelations are calculated with the **AUTOCORR** suboption of the **DIAGNOSTICS=** option in the **BAYES** statement.

ODS Table Names

Each table created by PROC FMM has a name associated with it, and you must use this name to reference the table when you use ODS statements. These names are listed in Table 37.9.

Table 37.9 ODS Tables Produced by PROC FMM

Table Name	Description	Required Statement / Option
Autocorr	Autocorrelation among posterior estimates	BAYES
BayesInfo	Basic information about Bayesian estimation	BAYES
ClassLevels	Level information from the CLASS statement	CLASS
CompDescription	Component description in models with varying number of components	KMAX= in MODEL with ML estimation
CompEvaluation	Comparison of mixture models with varying number of components	KMAX= in MODEL with ML estimation
CompInfo	Component information	COMPONENTINFO option in PROC FMM statement
ConvergenceStatus	Status of optimization at conclusion of optimization	Default output
Constraints	Linear equality and inequality constraints	RESTRICT statement or EQUATE=EFFECTS option in MODEL statement
Corr	Asymptotic correlation matrix of parameter estimates (ML) or empirical correlation matrix of the Bayesian posterior estimates	CORR option in PROC FMM statement
Cov	Asymptotic covariance matrix of parameter estimates (ML) or empirical covariance matrix of the Bayesian posterior estimates	COV option in PROC FMM statement
CovI	Inverse of the covariance matrix of the parameter estimates	COVI option in PROC FMM statement
ESS	Effective sample size	DIAG=ESS option in BAYES statement
FitStatistics	Fit statistics	Default output
Geweke	Geweke diagnostics (Geweke 1992) for Markov chain	DIAG=GEWEKE option in BAYES statement
Hessian	Hessian matrix from the maximum likelihood optimization, evaluated at the converged estimates	HESSIAN
IterHistory	Iteration history	Default output for ML estimation
MCSE	Monte Carlo standard errors	DIAG=MCERROR in BAYES statement

Table 37.9 continued

Table Name	Description	Required Statement / Option
MixingProbs	Solutions for the parameter estimates associated with effects in PROBMODEL statements	Default output for ML estimation if number of components is greater than 1
ModelInfo	Model information	Default output
NObs	Number of observations read and used, number of trials and events	Default output
OptInfo	Optimization information	Default output for ML estimation
ParameterEstimates	Solutions for the parameter estimates associated with effects in MODEL statements	Default output for ML estimation
ParameterMap	Mapping of parameter names to OUTPOST= data set	OUTPOST= option in BAYES statement
PriorInfo	Prior distributions and initial value of Markov chain	BAYES
PostSummaries	Summary statistics for posterior estimates	BAYES
PostIntervals	Equal-tail and highest posterior density intervals for posterior estimates	BAYES
ResponseProfile	Response categories and category modeled	Default output in models with binary response

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC FMM generates are listed in [Table 37.10](#), along with the required statements and options.

Table 37.10 Graphs Produced by PROC FMM

ODS Graph Name	Plot Description	Option
TADPanel	Panel of diagnostic graphics to assess convergence of Markov chains	BAYES
DensityPlot	Histogram and density with component distributions	Default plot for homogeneous mixtures

Examples: FMM Procedure

Example 37.1: Modeling Mixing Probabilities: All Mice Are Created Equal, but Some Are More Equal

This example demonstrates how you can model the means and mixture proportions separately in a binomial cluster model. It also compares the binomial cluster model to the beta-binomial model.

In a typical teratological experiment, the offspring of animals that were exposed to a toxin during pregnancy are studied for malformation. If you count the number of malformed offspring in a litter of size n , then this count is typically not binomially distributed. The responses of the offspring from the same litter are not independent; hence their sum does not constitute a binomial random variable. Relative to a binomial model, data from teratological experiments exhibit overdispersion because ignoring positive correlation among the responses tends to overstate the precision of the parameter estimates. Overdispersion mechanisms are briefly discussed in the section “[Overdispersion](#)” on page 2426.

In this application, the focus is on mixtures and models that involve a mixing mechanism. The mixing approach (Williams 1975; Haseman and Kupper 1979) supposes that the binomial success probability is a random variable that follows a $\text{beta}(\alpha, \beta)$ distribution:

$$\begin{aligned}
 Y|\mu &\sim \text{Binomial}(n, \mu) \\
 \mu &\sim \text{Beta}(\alpha, \beta) \\
 Y &\sim \text{Beta-binomial}(n, \mu, \phi) \\
 E[Y] &= n\pi \\
 \text{Var}[Y] &= n\pi(1 - \pi) \{1 + \mu^2(n - 1)\}
 \end{aligned}$$

If $\mu = 0$, then the beta-binomial distribution reduces to a standard binomial model with success probability π . The parameterization of the beta-binomial distribution used by the FMM procedure is based on Neerchal and Morel (1998), see the section “[Log-Likelihood Functions for Response Distributions](#)” on page 2427 for details.

Morel and Nagaraj (1993); Morel and Neerchal (1997); Neerchal and Morel (1998) propose a different model to capture dependency within binomial clusters. Their model is a two-component mixture that gives rise to the same mean and variance function as the beta-binomial model. The genesis is different, however.

In the binomial cluster model of Morel and Neerchal, suppose there is a cluster of n Bernoulli outcomes with success probability π . The number of responses in the cluster decomposes into $N \leq n$ outcomes that all respond with either “success” or “failure”; the important aspect is that they all respond identically. The remaining $n - N$ Bernoulli outcomes respond independently, so the sum of successes in this group is a $\text{binomial}(n - N, \pi)$ random variable. Denote the probability with which cluster members fall into the group of identical respondents as μ . Then $1 - \mu$ is the probability that a response belongs to the group of independent Bernoulli outcomes.

It is easy to see how this process of dividing the individual Bernoulli outcomes creates clustering. The binomial cluster model can be written as the two-component mixture

$$\Pr(Y = y) = \pi \Pr(U = y) + (1 - \pi) \Pr(V = y)$$

where $U \sim \text{Binomial}(n, \mu^* + \mu)$, $V \sim \text{Binomial}(n, \mu^*)$, and $\mu^* = (1 - \mu)\pi$. This mixture model is somewhat unusual because the mixing probability π appears as a parameter in the component distributions. The two probabilities involved, π and μ , have the following interpretation: π is the unconditional probability of success for any observation, and μ is the probability with which the Bernoulli observations respond identically. The complement of this probability, $1 - \mu$, is the probability with which the Bernoulli outcomes respond independently. If $\mu = 0$, then the two-component mixture reduces to a standard Binomial model with success probability π . Since both π and μ are involved in the success probabilities of the two Binomial variables in the mixture, you can affect these binomial means by specifying effects in the [PROBMODEL](#) statement (for the π s) or the [MODEL](#) statement (for the μ s). In a “straight” two-component Binomial mixture,

$$\pi \text{Binomial}(n, \mu_1) + (1 - \pi) \text{Binomial}(n, \mu_2)$$

you would vary the success probabilities μ_1 and μ_2 through the [MODEL](#) statement.

With the FMM procedure, you can fit the beta-binomial model by specifying [DIST=BETABIN](#) and the binomial cluster model by specifying [DIST=BINOMCLUS](#) in the [MODEL](#) statement.

Morel and Neerchal (1997) report data from a completely randomized design that studies the teratogenicity of phenytoin in 81 pregnant mice. The treatment structure of the experiment is an augmented factorial. In addition to an untreated control, mice received 60 mg/kg of phenytoin (PHT), 100 mg/kg of trichloropropene oxide (TCPO), and their combination. The design was augmented with a control group that was treated with water. As in Morel and Neerchal (1997), the two control groups are combined here into a single group.

The following DATA step creates the data for this analysis as displayed in Table 1 of Morel and Neerchal (1997). The second DATA step creates continuous variables x1–x3 to match the parameterization of these authors.

```

The FMM procedure models the mean parameters μ through the **MODEL** statement and the mixing proportions π through the **PROBMODEL** statement. In the binomial cluster model, you can place a regression structure on either set of probabilities, and the regression structure does not need to be the same. In the following statements, the unconditional probability of ossification is modeled as a two-way factorial, whereas the intralitter effect—the propensity to group within a cluster—is assumed to be constant:

```

proc fmm data=ossi;
  class pht tcpo;
  model y/m = / dist=binomcluster;
  probmodel pht tcpo pht*tcpo;
run;

```

The **CLASS** statement declares the PHT and TCPO variables as classification variables. They affect the analysis through their levels, not through their numeric values. The **MODEL** statement declares the distribution of the data to follow a binomial cluster model. The FMM procedure then automatically assumes that the model is a two-component mixture. An intercept is included by default. The **PROBMODEL** statement declares the effect structure for the mixing probabilities. The unconditional probability of ossification of a fetus depends on the main effects and the interaction in the factorial.

The “Model Information” table displays important details about the model fit with the FMM procedure (Output 37.1.1). Although no **K=** option was specified in the **MODEL** statement, the FMM procedure recognizes the model as a two-component model. The “Class Level Information” table displays the levels and values of the PHT and TCPO variables. Eighty-one observations are read from the data and are used in the analysis. These observations comprise 287 events and 585 total outcomes.

Output 37.1.1 Model Information in Binomial Cluster Model with Constant Clustering Probability

AICC (smaller is better)			315.9	
BIC (smaller is better)			327.0	
Pearson Statistic			89.2077	
Effective Parameters			5	
Effective Components			2	

After nine iterations, the iterative optimization converges. The -2 log likelihood at the converged solution is 305.1, and the Pearson statistic is 89.2077. The FMM procedure computes the Pearson statistic as a general goodness-of-fit measure that expresses the closeness of the fitted model to the data.

The estimates of the parameters in the conditional probability μ and in the unconditional probability π are given in [Output 37.1.3](#). The intercept estimate in the model for μ is 0.3356. Since the default link in the binomial cluster model is the logit link, the estimate of the conditional probability is

$$\hat{\mu} = \frac{1}{1 + \exp\{-0.3356\}} = 0.5831$$

This value is displayed in the “Inverse Linked Estimate” column. There is greater than a 50% chance that the individual fetuses in a litter provide the same response. The clustering tendency is substantial.

Output 37.1.3 Parameter Estimates in Binomial Cluster Model with Constant Clustering Probability

Parameter Estimates for 'Binomial Cluster' Model

The “Mixing Probabilities” table displays the estimates of the parameters in the model for π on the logit scale (Output 37.1.3). Table 37.11 constructs the estimates of the unconditional probabilities of ossification.

Table 37.11 Estimates of Ossification Probabilities

PHT	TCPO	$\hat{\eta}$	$\hat{\pi}$
0	0	$-1.2194 + 0.9129 + 0.3295 + 0.6162 = 0.6392$	0.6546
60	0	$-1.2194 + 0.3295 = -0.8899$	0.2911
0	100	$-1.2194 + 0.9129 = -0.3065$	0.4240
60	100	-1.2194	0.2280

Morel and Neerchal (1997) considered a model in which the intralitter effects also depend on the treatments. This model is fit with the FMM procedure with the following statements:

```
proc fmm data=ossi;
  class pht tcpo;
  model y/m = pht tcpo pht*tcpo / dist=binomcluster;
  probmodel pht tcpo pht*tcpo;
run;
```

The -2 log likelihood of this model is much reduced compared to the previous model with constant conditional probability (compare 287.8 in Output 37.1.4 with 305.1 in Output 37.1.2). The likelihood-ratio statistic of 17.3 is significant, $\Pr(\chi^2_3 > 17.3 = 0.0006)$. Varying the conditional probabilities by treatment improved the model fit significantly.

Output 37.1.4 Fit Statistics and Parameter Estimates in Binomial Cluster Model

Table 37.12 computes the conditional probabilities in the four treatment groups. Recall that the previous model estimated a constant clustering probability of 0.5831.

Table 37.12 Estimates of Clustering Probabilities

PHT	TCPO	$\hat{\eta}$	$\hat{\mu}$
0	0	$1.8213 - 1.4962 - 3.1828 + 3.3736 = 0.5159$	0.6262
60	0	$1.8213 - 3.1828 = -1.3615$	0.2040
0	100	$1.8213 - 1.4962 = 0.3251$	0.5806
60	100	1.8213	0.8607

The presence of phenytoin alone reduces the probability of response clustering within the litter. The presence of trichloropropene oxide alone does not have a strong effect on the clustering. The simultaneous presence of both agents substantially increases the probability of clustering.

The following statements fit the binomial cluster model in the parameterization of Morel and Neerchal (1997).

```
proc fmm data=ossi;
  model y/m = x1-x3 / dist=binomcluster;
  probmodel x1-x3;
run;
```

The model fit is the same as in the previous model (compare the “Fit Statistics” tables in [Output 37.1.5](#) and [Output 37.1.4](#)). The parameter estimates change due to the reparameterization of the treatment effects and match the results in Table III of Morel and Neerchal (1997).

Output 37.1.5 Fit Statistics and Estimates (Morel and Neerchal Parameterization)

The FMM Procedure					
Fit Statistics					
-2 Log Likelihood		287.8			
AIC (smaller is better)		303.8			
AICC (smaller is better)		305.8			
BIC (smaller is better)		323.0

Effective Parameters		8			
Effective Components		2			
Parameter Estimates for 'Binomial Cluster' Model					
Component	Effect	Estimate	Standard Error	z Value	Pr > z
1	Intercept	0.5159	0.2603	1.98	0.0475
1	x1	-0.1908	0.4006	-0.48	0.6339
1	x2	-1.8774	0.9946	-1.89	0.0591
1	x3	3.3736	1.1953	2.82	0.0048

Output 37.1.5 *continued*

Parameter Estimates for Mixing Probabilities				
Effect	Estimate	Standard Error	z Value	Pr > z
Intercept	0.5669	0.2455	2.31	0.0209
x1	-0.8712	0.3924	-2.22	0.0264
x2	-1.8405	0.3413	-5.39	<.0001
x3	1.4055	0.7080	1.99	0.0471

The following sets of statements fit the binomial and beta-binomial models, respectively, as single-component mixtures in the parameterization akin to the first binomial cluster model. Note that the model effects that affect the underlying Bernoulli success probabilities are specified in the **MODEL** statement, in contrast to the binomial cluster model.

```
proc fmm data=ossi;
  model y/m = x1-x3 / dist=binomial;
run;

proc fmm data=ossi;
  model y/m = x1-x3 / dist=betabinomial;
run;
```

The Pearson statistic for the beta-binomial model (Output 37.1.6) indicates a much better fit compared to the single-component binomial model (Output 37.1.7). This is not surprising since these data are obviously overdispersed relative to a binomial model because the Bernoulli outcomes are not independent. The difference between the binomial cluster and the beta-binomial model lies in the mechanism by which the correlations are induced:

- a mixing mechanism in the beta-binomial model that leads to a common shared random effect among all offspring in a cluster
- a mixture specification in the binomial cluster model that divides the offspring in a litter into identical and independent responders

Output 37.1.6 Fit Statistics in Binomial Model

Example 37.2: The Usefulness of Custom Starting Values: When Do Cows Eat?

This example with a mixture of normal and Weibull distributions illustrates the benefits of specifying starting values for some of the components.

The data for this example were generously provided by Dr. Luciano A. Gonzalez of the Lethbridge Research Centre of Agriculture and Agri-Food Canada and his collaborator, Dr. Bert Tolcamp, from the Scottish Agricultural College.

The outcome variable of interest is the logarithm of a time interval between consecutive visits by cattle to feeders. The intervals fall into three categories:

- short breaks within meals—such as when an animal stops eating for a moment and resumes shortly thereafter
- somewhat longer breaks when eating is interrupted to go have a drink of water
- long breaks between meals

Modeling such time interval data is important to understand the feeding behavior and biology of the animals and to derive other biological parameters such as the probability of an animal to stop eating after it has consumed a certain amount of a given food. Because there are three distinct biological categories, data of this nature are frequently modeled as three-component mixtures. The point at which the second and third components cross over is used to separate feeding events into meals.

The original data set comprises 141,414 observations of log feeding intervals. For the purpose of presentation in this document, where space is limited, the data have been rounded to precision 0.05 and grouped by frequency. The following DATA step displays the modified data used in this example. A comparison with the raw data and the results obtained in a full analysis of the original data show that the grouping does not alter the presentation or conclusions in a way that matters for the purpose of this example.

If you scan the columns for the Count variable in the DATA step, the prevalence of values between 2 and 5 units of LogInt is apparent, as is a long right tail. To explore these data graphically, the following statements produce a histogram of the data and a kernel density estimate of the density of the LogInt variable.

```
ods graphics on;
proc kde data=cattle;
  univar LogInt / bwm=4;
  freq count;
run;
```

Output 37.2.1 Histogram and Kernel Density for LogInt

Two modes are clearly visible in [Output 37.2.1](#). Given the biological background, one would expect that three components contribute to the mixture. The histogram would suggest either a two-component mixture with modes near 4 and 9, or a three-component mixture with modes near 3, 5, and 9.

Following Dr. Gonzalez' suggestion, the process is modeled as a three-component mixture of two normal distributions and a Weibull distribution. The Weibull distribution is chosen because it can have long left and right tails and it is popular in modeling data that relate to time intervals.

```
proc fmm data=cattle gconv=0;
  model LogInt = / dist=normal k=2 parms(3 1, 5 1);
  model          + / dist=weibull;
  freq count;
run;
```

The **GCONV=** convergence criterion is turned off in this PROC FMM run to avoid the early stoppage of the iterations when the relative gradient changes little between iterations. Turning the criterion off usually ensures that convergence is achieved with a small absolute gradient of the objective function. The **PARMS** option in the first **MODEL** statement provides starting values for the means and variances for the parameters of the normal distributions. The means for the two components are started at $\mu = 3$ and $\mu = 5$, respectively. Specifying starting values is generally not necessary. However, the choice of starting values can play an important role in modeling finite mixture models; the importance of the choice of starting values in this example is discussed further below.

The “Model Information” table shows that the model is a three-component mixture and that the FMM procedure considers the estimation of a density to be the purpose of modeling. The procedure draws this conclusion from the absence of effects in the **MODEL** statements. There are 187 observations in the data set, but these actually represent 141,414 measurements ([Output 37.2.2](#)).

Output 37.2.2 Model Information and Number of Observations

The FMM Procedure	
Model Information	
Data Set	WORK.CATTLE
Response Variable	LogInt
Frequency Variable	Count
Type of Model	Density Estimation
Components	3
Estimation Method	Maximum Likelihood
Number of Observations Read	187
Number of Observations Used	187
Sum of Frequencies Read	141414
Sum of Frequencies Used	141414

There are eight parameters in the optimization: the means and variances of the two normal distributions, the μ and ϕ parameter of the Weibull distribution, and the two mixing probabilities ([Output 37.2.3](#)). At the converged solution, the $-2 \log$ likelihood is 563,153 and all parameters and components are effective—that is, the model is not overspecified in the sense that components have collapsed during the model fitting. The Pearson statistic is close to the number of observations in the data set, indicating a good fit.

Output 37.2.3 Optimization Information and Fit Statistics

Optimization Information	
Optimization Technique	Dual Quasi-Newton
Parameters in Optimization	8
Mean Function Parameters	3
Scale Parameters	3
Mixing Prob Parameters	2
Lower Boundaries	3
Upper Boundaries	0
Number of Threads	2

Fit Statistics	
-2 Log Likelihood	563153
AIC (smaller is better)	563169
AICC (smaller is better)	563169
BIC (smaller is better)	563248
Pearson Statistic	141458
Effective Parameters	8
Effective Components	3

Output 37.2.4 displays the parameter estimates for the three models and for the mixing probabilities. The order in which the “Parameter Estimates” tables appear in the output corresponds to the order in which the **MODEL** statements were specified.

Output 37.2.4 Optimization Information and Fit Statistics

Parameter Estimates for 'Normal' Model					
Component	Parameter	Estimate	Standard Error	z Value	Pr > z
1	Intercept	3.3415	0.01260	265.16	<.0001
2	Intercept	4.8940	0.05447	89.84	<.0001
1	Variance	0.6718	0.01287		
2	Variance	1.4497	0.05247		

Parameter Estimates for 'Weibull' Model						
Component	Parameter	Estimate	Standard Error	z Value	Pr > z	Inverse Linked Estimate
3	Intercept	2.2531	0.000506	4452.11	<.0001	9.5174
3	Scale	0.06848	0.000427			

Output 37.2.4 *continued*

Parameter Estimates for Mixing Probabilities						
-----Linked Scale-----						
Component	Parameter	Estimate	Standard Error	z Value	Pr > z	Probability
1	Probability	0.8106	0.03409	23.78	<.0001	0.4545
2	Probability	0.5305	0.04640	11.43	<.0001	0.3435

The estimated means of the two normal components are 3.3415 and 4.8940, respectively. Note that the means are displayed here as Intercept. The inverse linked estimate is not produced because the default link for the normal distribution is the identity link; hence the Estimate column represents the means of the component distributions. The parameter estimates in the Weibull model are $\hat{\beta}_0 = 2.2531$, $\hat{\phi} = 0.06848$, and $\hat{\mu} = \exp\{\hat{\beta}_0\} = 9.5174$. In the Weibull distribution, the μ parameter does not estimate the mean of the distribution, the maximum likelihood estimate of the distribution's mean is $\hat{\mu}\Gamma(\hat{\phi} + 1) = 9.1828$.

The estimated mixing probabilities are $\hat{\pi}_1 = 0.4545$, $\hat{\pi}_2 = 0.3435$, and $\hat{\pi}_3 = 1 - \hat{\pi}_1 - \hat{\pi}_2 = 0.2020$. In other words, the estimated distribution of log feeding intervals is a 45:35:20 mixture of an N(3.3415, 0.6718), a N(4.8940, 1.4497), and a Weibull(9.5174, 0.06848) distribution.

You can obtain a graphical display of the observed and estimated distribution of these data by enabling ODS Graphics. The **PLOTS** option in the **PROC FMM** statement modifies the default density plot by adding the densities of the mixture components:

```
ods select DensityPlot;
proc fmm data=cattle gconv=0;
  model LogInt = / dist=normal k=2 parms(3 1, 5 1);
  model          + / dist=weibull;
  freq count;
run;
```

Output 37.2.5 Observed and Estimated Densities in the Three-Component Model

The estimated mixture density matches the histogram of the observed data closely ([Output 37.2.5](#)). The component densities are displayed in such a way that, at each point in the support of the LogInt variable, their sum combines to the overall mixture density. The three components in the mixtures are well separated.

The excellent quality of the fit is even more evident when the distributions are displayed cumulatively by adding the CUMULATIVE option in the [DENSITY](#) option ([Output 37.2.6](#)):

```
ods select DensityPlot;
proc fmm data=cattle plot=density(cumulative) gconv=0;
  model LogInt = / dist=normal k=2 parms(3 1, 5 1);
  model      + / dist=weibull;
  freq count;
run;
```

The component cumulative distribution functions are again scaled so that their sum produces the overall mixture cumulative distribution function. Because of this scaling, the percentage reached at the maximum value of LogInt corresponds to the mixing probabilities in [Output 37.2.4](#).

Output 37.2.6 Observed and Estimated Cumulative Densities in the Three-Component Model

The importance of starting values for the parameter estimates was mentioned previously. Suppose that different starting values are selected for the three components (for example, the default starting values).

```
proc fmm data=cattle gconv=0;
  model LogInt = / dist=normal k=2;
  model      + / dist=weibull;
  freq count;
run;
ods graphics off;
```

The fit statistics and parameter estimates from this run are displayed in [Output 37.2.7](#), and the density plot is shown in [Output 37.2.8](#).

Output 37.2.7 Fit Statistics and Parameter Estimates

The FMM Procedure						
Fit Statistics						
	-2 Log Likelihood	564431				
	AIC (smaller is better)	564447				
	AICC (smaller is better)	564447				
	BIC (smaller is better)	564526				
	Pearson Statistic	141228				
	Effective Parameters	8				
	Effective Components	3				
Parameter Estimates for 'Normal' Model						
Component	Parameter	Estimate	Standard Error	z Value	Pr > z	
1	Intercept	4.9106	0.02604	188.56	<.0001	
2	Intercept	9.2883	0.005031	1846.28	<.0001	
1	Variance	1.7410	0.02753			
2	Variance	0.4158	0.005086			
Parameter Estimates for 'Weibull' Model						
Component	Parameter	Estimate	Standard Error	z Value	Pr > z	Inverse Linked Estimate
3	Intercept	1.2908	0.002790	462.71	<.0001	3.6358
3	Scale	0.2093	0.001311			
Parameter Estimates for Mixing Probabilities						
-----Linked Scale-----						
Component	Parameter	Estimate	Standard Error	z Value	Pr > z	Probability
1	Probability	-0.1505	0.03678	-4.09	<.0001	0.3745
2	Probability	-0.8280	0.01922	-43.08	<.0001	0.1902

All components are active; no collapsing of components occurred. However, a closer look at the “Parameter Estimates” tables in [Output 37.2.7](#) shows an important difference from the tables in [Output 37.2.4](#). The means of the two normal distributions are now 4.9106 and 9.2883. Previously, the means were 3.3415 and 4.8940. The “position” of the Weibull distribution has moved from right to left, and the third component is now modeled by a symmetric normal distribution ([Output 37.2.8](#)). The mixture probabilities have also changed—in particular, for the first and third component.

Output 37.2.8 Three-Component Model with Default Starting Values

Such switching is not uncommon in mixture modeling. As judged by the information criteria, the model in which the Weibull distribution is the component with the smallest mean does not fit the data as well as the first model in which the specification of the starting values guided the optimization towards placing the normal distributions first. The converged solution found in the last FMM run represents a local minimum of the log-likelihood surface. There are other local minima—for example, when components are removed from the model, which is tantamount to estimating the associated mixture probabilities as zero.

Example 37.3: Enforcing Homogeneity Constraints: Count and Dispersion—It Is All Over!

The following example demonstrates how you can use either the `EQUATE=` option in the `MODEL` statement or the `RESTRICT` statement to impose homogeneity constraints on chosen model effects.

The data for this example were presented by Margolin, Kaplan, and Zeiger (1981) and analyzed by various authors applying a number of techniques. The following `DATA` step shows the number of revertant salmonella colonies (variable `num`) at six levels of quinoline dosing (variable `dose`). There are three replicate plates at each dose of quinoline.

```

data assay;
  label dose = 'Dose of quinoline (microg/plate)'
        num = 'Observed number of colonies';
  input dose @;
  logd = log(dose+10);
  do i=1 to 3; input num@; output; end;
  datalines;
  0 15 21 29
  10 16 18 21
  33 16 26 33
  100 27 41 60
  333 33 38 41
  1000 20 27 42
;

```

The basic notion is that the data are overdispersed relative to a Poisson distribution in which the logarithm of the mean count is modeled as a linear regression in dose (in $\mu g/\text{plate}$) and in the derived variable $\log\{\text{dose} + 10\}$ (Lawless 1987). The log of the expected count of revertants is thus

$$\beta_0 + \beta_1 \text{dose} + \beta_2 \log\{\text{dose} + 10\}$$

The following statements fit a standard Poisson regression model to these data:

```

proc fmm data=assay;
  model num = dose logd / dist=Poisson;
run;

```

The Pearson statistic for this model is rather large compared to the number of degrees of freedom ($18 - 3 = 15$). The ratio $46.2707/15 = 3.08$ indicates an overdispersion problem in the Poisson model (Output 37.3.1).

Output 37.3.1 Result of Fitting Poisson Regression Models

The FMM Procedure	
Number of Observations Read	18
Number of Observations Used	18
Fit Statistics	
-2 Log Likelihood	136.3
AIC (smaller is better)	142.3
AICC (smaller is better)	144.0
BIC (smaller is better)	144.9
Pearson Statistic	46.2707

Output 37.3.1 *continued*

Parameter Estimates for 'Poisson' Model				
Effect	Estimate	Standard Error	z Value	Pr > z
Intercept	2.1728	0.2184	9.95	<.0001
dose	-0.00101	0.000245	-4.13	<.0001
logd	0.3198	0.05700	5.61	<.0001

Breslow (1984) accounts for overdispersion by including a random effect in the predictor for the log rate and applying a quasi-likelihood technique to estimate the parameters. Wang et al. (1996) examine these data using mixtures of Poisson regression models. They fit several two- and three-component Poisson regression mixtures. Examining the log likelihoods, AIC, and BIC criteria, they eventually settle on a two-component model in which the intercepts vary by category and the regression coefficients are the same. This mixture model can be written as

$$f(y) = \pi \frac{1}{y!} \lambda_1^y \exp\{-\lambda_1\} + (1 - \pi) \frac{1}{y!} \lambda_2^y \exp\{-\lambda_2\}$$

$$\lambda_1 = \exp\{\beta_{01} + \beta_1 \text{dose} + \beta_2 \log\{\text{dose} + 10\}\}$$

$$\lambda_2 = \exp\{\beta_{02} + \beta_1 \text{dose} + \beta_2 \log\{\text{dose} + 10\}\}$$

This model is fit with the FMM procedure with the following statements:

```
proc fmm data=assay;
  model num = dose logd / dist=Poisson k=2
                        equate=effects(dose logd);
run;
```

The **EQUATE=** option in the **MODEL** statement places constraints on the optimization and makes the coefficients for dose and logd homogeneous across components in the model. [Output 37.3.2](#) displays the “Fit Statistics” and parameter estimates in the mixture. The Pearson statistic is drastically reduced compared to the Poisson regression model in [Output 37.3.1](#). With $18 - 5 = 13$ degrees of freedom, the ratio of the Pearson and the degrees of freedom is now $16.1573/13 = 1.2429$. Note that the effective number of parameters was used to compute the degrees of freedom, not the total number of parameters, because of the equality constraints.

Output 37.3.2 Result for Two-Component Poisson Regression Mixture

The FMM Procedure					
Fit Statistics					
		-2 Log Likelihood	121.8		
		AIC (smaller is better)	131.8		
		AICC (smaller is better)	136.8		
		BIC (smaller is better)	136.3		
		Pearson Statistic	16.1573		
		Effective Parameters	5		
		Effective Components	2		
Parameter Estimates for 'Poisson' Model					
Component	Effect	Estimate	Standard Error	z Value	Pr > z
1	Intercept	1.9097	0.2654	7.20	<.0001
1	dose	-0.00126	0.000273	-4.62	<.0001
1	logd	0.3639	0.06602	5.51	<.0001
2	Intercept	2.4770	0.2731	9.07	<.0001
2	dose	-0.00126	0.000273	-4.62	<.0001

-----Linked Scale-----					
Effect	Estimate	Standard Error	z Value	Pr > z	Probability
Intercept	1.4984	0.6875	2.18	0.0293	0.8173

You could also have used **RESTRICT** statements to impose the homogeneity constraints on the model fit, as shown in the following statements:

```
proc fmm data=assay;
  model num = dose logd / dist=Poisson k=2;
  restrict 'common dose' dose 1, dose -1;
  restrict 'common logd' logd 1, logd -1;
run;
```

The first **RESTRICT** statement equates the coefficients for the dose variable in the two components, and the second **RESTRICT** statement accomplishes the same for the coefficients of the logd variable. If the right-hand side of a restriction is not specified, PROC FMM defaults to equating the left-hand side of the restriction to zero. The “Linear Constraints” table in [Output 37.3.3](#) shows that both linear equality constraints are active. The parameter estimates match the previous FMM run.

Output 37.3.3 Result for Two-Component Mixture with RESTRICT Statements

The FMM Procedure

Intercept	1.4984	0.6875	2.18	0.0293	0.8173

Wang et al. (1996) note that observation 12 with a revertant colony count of 60 is comparably high. The following statements remove the observation from the analysis and fit their selected model:

```
proc fmm data=assay(where=(num ne 60));
  model num = dose logd / dist=Poisson k=2
          equate=effects(dose logd);
run;
```

Output 37.3.4 Result for Two-Component Model without Outlier

The FMM Procedure					
Fit Statistics					
		-2 Log Likelihood	111.5		
		AIC (smaller is better)	121.5		
		AICC (smaller is better)	126.9		
		BIC (smaller is better)	125.6		
		Pearson Statistic	16.5987		
		Effective Parameters	5		
		Effective Components	2		
Parameter Estimates for 'Poisson' Model					
Component	Effect	Estimate	Standard Error	z Value	Pr > z

-----Linked Scale-----					
Effect	Estimate	Standard Error	z Value	Pr > z	Probability
Intercept	0.3134	1.7261	0.18	0.8559	0.5777

The ratio of Pearson Statistic over degrees of freedom (12) is only slightly worse than in the previous model; the loss of 5% of the observations carries a price ([Output 37.3.4](#)). The parameter estimates for the two intercepts are now fairly close. If the intercepts were identical, then the two-component model would collapse to the Poisson regression model:

```
proc fmm data=assay(where=(num ne 60));
  model num = dose logd / dist=Poisson;
run;
```

Output 37.3.5 Result of Fitting Poisson Regression Model without Outlier

The FMM Procedure				
Number of Observations Read	17			
Number of Observations Used	17			
Fit Statistics				
-2 Log Likelihood	114.1			
AIC (smaller is better)	120.1			
AICC (smaller is better)	121.9			
BIC (smaller is better)	122.5			
Pearson Statistic	27.8008			
Parameter Estimates for 'Poisson' Model				
Effect	Estimate	Standard Error	z Value	Pr > z
Intercept	2.3164	0.2244	10.32	<.0001
dose	-0.00072	0.000258	-2.78	0.0055
logd	0.2603	0.05996	4.34	<.0001

Compared to the same model applied to the full data, the Pearson statistic is much reduced (compare 46.2707 in [Output 37.3.1](#) to 27.8008 in [Output 37.3.5](#)). The outlier—or *overcount*, if you will—induces at least some of the *overdispersion*.

Overview: FREQ Procedure

The FREQ procedure produces one-way to n -way frequency and contingency (crosstabulation) tables. For two-way tables, PROC FREQ computes tests and measures of association. For n -way tables, PROC FREQ provides stratified analysis by computing statistics across, as well as within, strata.

For one-way frequency tables, PROC FREQ computes goodness-of-fit tests for equal proportions or specified null proportions. For one-way tables, PROC FREQ also provides confidence limits and tests for binomial proportions, including tests for noninferiority and equivalence.

For contingency tables, PROC FREQ can compute various statistics to examine the relationships between two classification variables. For some pairs of variables, you might want to examine the existence or strength of any association between the variables. To determine if an association exists, chi-square tests are computed. To estimate the strength of an association, PROC FREQ computes measures of association that tend to be close to zero when there is no association and close to the maximum (or minimum) value when there is perfect association. The statistics for contingency tables include the following:

- chi-square tests and measures
- measures of association
- risks (binomial proportions) and risk differences for 2×2 tables
- odds ratios and relative risks for 2×2 tables
- tests for trend
- tests and measures of agreement
- Cochran-Mantel-Haenszel statistics

PROC FREQ computes asymptotic standard errors, confidence intervals, and tests for measures of association and measures of agreement. Exact p -values and confidence intervals are available for many test statistics and measures. PROC FREQ also performs analyses that adjust for any stratification variables by computing statistics across, as well as within, strata for n -way tables. These statistics include Cochran-Mantel-Haenszel statistics and measures of agreement.

In choosing measures of association to use in analyzing a two-way table, you should consider the study design (which indicates whether the row and column variables are dependent or independent), the measurement scale of the variables (nominal, ordinal, or interval), the type of association that each measure is designed to detect, and any assumptions required for valid interpretation of a measure. You should exercise care in selecting measures that are appropriate for your data.

Similar comments apply to the choice and interpretation of test statistics. For example, the Mantel-Haenszel chi-square statistic requires an ordinal scale for both variables and is designed to detect a linear association. The Pearson chi-square, on the other hand, is appropriate for all variables and can detect any kind of association, but it is less powerful for detecting a linear association because its power is dispersed over a greater number of degrees of freedom (except for 2×2 tables).

For more information about selecting the appropriate statistical analyses, see Agresti (2007) and Stokes, Davis, and Koch (2012).

Several SAS procedures produce frequency counts; only PROC FREQ computes chi-square tests for one-way to n -way tables and measures of association and agreement for contingency tables. Other procedures to consider for counting include the TABULATE and UNIVARIATE procedures. When you want to produce contingency tables and tests of association for sample survey data, use PROC SURVEYFREQ. See Chapter 14, “[Introduction to Survey Procedures](#),” for more information. When you want to fit models to categorical data, use a procedure such as CATMOD, GENMOD, GLIMMIX, LOGISTIC, PROBIT, or SURVEYLOGISTIC. See Chapter 8, “[Introduction to Categorical Data Analysis Procedures](#),” for more information.

PROC FREQ uses the Output Delivery System (ODS), a SAS subsystem that provides capabilities for displaying and controlling the output from SAS procedures. ODS enables you to convert any of the output from PROC FREQ into a SAS data set. See the section “[ODS Table Names](#)” on page 2617 for more information.

PROC FREQ uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For specific information about the statistical graphics available with the FREQ procedure, see the **PLOTS=** option in the TABLES statement and the section “[ODS Graphics](#)” on page 2621.

Getting Started: FREQ Procedure

Frequency Tables and Statistics

The FREQ procedure provides easy access to statistics for testing for association in a crosstabulation table.

In this example, high school students applied for courses in a summer enrichment program; these courses included journalism, art history, statistics, graphic arts, and computer programming. The students accepted were randomly assigned to classes with and without internships in local companies. Table 38.1 contains counts of the students who enrolled in the summer program by gender and whether they were assigned an internship slot.

Table 38.1 Summer Enrichment Data

Gender	Internship	Enrollment		
		Yes	No	Total
boys	yes	35	29	64
boys	no	14	27	41
girls	yes	32	10	42
girls	no	53	23	76

The SAS data set SummerSchool is created by inputting the summer enrichment data as cell count data, or providing the frequency count for each combination of variable values. The following DATA step statements create the SAS data set SummerSchool:

```
data SummerSchool;
  input Gender $ Internship $ Enrollment $ Count @@;
  datalines;
boys yes yes 35   boys yes no 29
boys no yes 14   boys no no 27
girls yes yes 32   girls yes no 10
girls no yes 53   girls no no 23
;
```

The variable Gender takes the values ‘boys’ or ‘girls,’ the variable Internship takes the values ‘yes’ and ‘no,’ and the variable Enrollment takes the values ‘yes’ and ‘no.’ The variable Count contains the number of students that correspond to each combination of data values. The double at sign (@@) indicates that more than one observation is included on a single data line. In this DATA step, two observations are included on each line.

Researchers are interested in whether there is an association between internship status and summer program enrollment. The Pearson chi-square statistic is an appropriate statistic to assess the association in the corresponding 2×2 table. The following PROC FREQ statements specify this analysis.

You specify the table for which you want to compute statistics with the TABLES statement. You specify the statistics you want to compute with options after a slash (/) in the TABLES statement.

```
proc freq data=SummerSchool order=data;
  tables Internship*Enrollment / chisq;
  weight Count;
run;
```

The ORDER= option controls the order in which variable values are displayed in the rows and columns of the table. By default, the values are arranged according to the alphanumeric order of their unformatted values. If you specify ORDER=DATA, the data are displayed in the same order as they occur in the input data set. Here, because 'yes' appears before 'no' in the data, 'yes' appears first in any table. Other options for controlling order include ORDER=FORMATTED, which orders according to the formatted values, and ORDER=FREQUENCY, which orders by descending frequency count.

In the TABLES statement, Internship*Enrollment specifies a table where the rows are internship status and the columns are program enrollment. The CHISQ option requests chi-square statistics for assessing association between these two variables. Because the input data are in cell count form, the WEIGHT statement is required. The WEIGHT statement names the variable Count, which provides the frequency of each combination of data values.

Figure 38.1 presents the crosstabulation of Internship and Enrollment. In each cell, the values printed under the cell count are the table percentage, row percentage, and column percentage, respectively. For example, in the first cell, 63.21 percent of the students offered courses with internships accepted them and 36.79 percent did not.

Figure 38.1 Crosstabulation Table

The FREQ Procedure				
Table of Internship by Enrollment				
Internship	Enrollment			
Frequency				
Percent				
Row Pct				
Col Pct	yes	no	Total	
-----+-----+-----+				
yes	67	39	106	
	30.04	17.49	47.53	
	63.21	36.79		
	50.00	43.82		
-----+-----+-----+				
no	67	50	117	
	30.04	22.42	52.47	
	57.26	42.74		
	50.00	56.18		
-----+-----+-----+				
Total	134	89	223	
	60.09	39.91	100.00	

Figure 38.2 displays the statistics produced by the CHISQ option. The Pearson chi-square statistic is labeled 'Chi-Square' and has a value of 0.8189 with 1 degree of freedom. The associated p -value is 0.3655, which means that there is no significant evidence of an association between internship status and program enrollment. The other chi-square statistics have similar values and are asymptotically equivalent. The other statistics (phi coefficient, contingency coefficient, and Cramér's V) are measures of association derived from the Pearson chi-square. For Fisher's exact test, the two-sided p -value is 0.4122, which also shows no association between internship status and program enrollment.

Figure 38.2 Statistics Produced with the CHISQ Option

Statistic	DF	Value	Prob
Chi-Square	1	0.8189	0.3655
Likelihood Ratio Chi-Square	1	0.8202	0.3651
Continuity Adj. Chi-Square	1	0.5899	0.4425
Mantel-Haenszel Chi-Square	1	0.8153	0.3666
Phi Coefficient		0.0606	
Contingency Coefficient		0.0605	
Cramer's V		0.0606	
Fisher's Exact Test			
Cell (1,1) Frequency (F)		67	
Left-sided Pr <= F		0.8513	
Right-sided Pr >= F		0.2213	
Table Probability (P)		0.0726	
Two-sided Pr <= P		0.4122	

The analysis, so far, has ignored gender. However, it might be of interest to ask whether program enrollment is associated with internship status after adjusting for gender. You can address this question by doing an analysis of a set of tables (in this case, by analyzing the set consisting of one for boys and one for girls). The Cochran-Mantel-Haenszel (CMH) statistic is appropriate for this situation: it addresses whether rows and columns are associated after controlling for the stratification variable. In this case, you would be stratifying by gender.

The PROC FREQ statements for this analysis are very similar to those for the first analysis, except that there is a third variable, Gender, in the TABLES statement. When you cross more than two variables, the two rightmost variables construct the rows and columns of the table, respectively, and the leftmost variables determine the stratification.

The following PROC FREQ statements also request frequency plots for the crosstabulation tables. PROC FREQ produces these plots by using ODS Graphics to create graphs as part of the procedure output. ODS Graphics must be enabled before producing plots. The PLOTS(ONLY)=FREQPLOT option requests frequency plots. The TWOWAY=CLUSTER *plot-option* specifies a cluster layout for the two-way frequency plots.

```
ods graphics on;
proc freq data=SummerSchool;
  tables Gender*Internship*Enrollment /
         chisq cmh plots(only)=freqplot (twoway=cluster);
  weight Count;
run;
ods graphics off;
```

This execution of PROC FREQ first produces two individual crosstabulation tables of Internship by Enrollment: one for boys and one for girls. Frequency plots and chi-square statistics are produced for each individual table. [Figure 38.3](#), [Figure 38.4](#), and [Figure 38.5](#) show the results for boys. Note that the chi-square statistic for boys is significant at the $\alpha = 0.05$ level of significance. Boys offered a course with an internship are more likely to enroll than boys who are not.

[Figure 38.4](#) displays the frequency plot of Internship by Enrollment for boys. By default, frequency plots are displayed as bar charts. You can use PLOTS= options to request dot plots instead of bar charts, to change the orientation of the bars from vertical to horizontal, and to change the scale from frequencies to percents. You can also use PLOTS= options to specify other two-way layouts (stacked, vertical groups, or horizontal groups) and to change the primary grouping from column levels to row levels.

[Figure 38.6](#), [Figure 38.7](#), and [Figure 38.8](#) display the crosstabulation table, frequency plot, and chi-square statistics for girls. You can see that there is no evidence of association between internship offers and program enrollment for girls.

Two-sided Pr <= P	0.5245	

These individual table results demonstrate the occasional problems with combining information into one table and not accounting for information in other variables such as Gender. Figure 38.9 contains the CMH results. There are three summary (CMH) statistics; which one you use depends on whether your rows and/or columns have an order in $r \times c$ tables. However, in the case of 2×2 tables, ordering does not matter and all three statistics take the same value. The CMH statistic follows the chi-square distribution under the hypothesis of no association, and here, it takes the value 4.0186 with 1 degree of freedom. The associated p -value is 0.0450, which indicates a significant association at the $\alpha = 0.05$ level.

Thus, when you adjust for the effect of gender in these data, there is an association between internship and program enrollment. But, if you ignore gender, no association is found. Note that the CMH option also produces other statistics, including estimates and confidence limits for relative risk and odds ratios for 2×2 tables and the Breslow-Day Test. These results are not displayed here.

Figure 38.9 Test for the Hypothesis of No Association

Cochran-Mantel-Haenszel Statistics (Based on Table Scores)				
Statistic	Alternative Hypothesis	DF	Value	Prob
1	Nonzero Correlation	1	4.0186	0.0450
2	Row Mean Scores Differ	1	4.0186	0.0450
3	General Association	1	4.0186	0.0450

Agreement Study

Medical researchers are interested in evaluating the efficacy of a new treatment for a skin condition. Dermatologists from participating clinics were trained to conduct the study and to evaluate the condition. After the training, two dermatologists examined patients with the skin condition from a pilot study and rated the same patients. The possible evaluations are terrible, poor, marginal, and clear. Table 38.2 contains the data.

Table 38.2 Skin Condition Data

Dermatologist 1	Dermatologist 2			
	Terrible	Poor	Marginal	Clear
Terrible	10	4	1	0
Poor	5	10	12	2
Marginal	2	4	12	5
Clear	0	2	6	13

The following DATA step statements create the SAS dataset `SkinCondition`. The dermatologists' evaluations of the patients are contained in the variables `Derm1` and `Derm2`; the variable `Count` is the number of patients given a particular pair of ratings.

```
data SkinCondition;
    input Derm1 $ Derm2 $ Count;
    datalines;
    terrible terrible 10
    terrible      poor 4
    terrible      marginal 1
    terrible      clear 0
    poor          terrible 5
    poor          poor 10
    poor          marginal 12
    poor          clear 2
    marginal      terrible 2
    marginal      poor 4
    marginal      marginal 12
    marginal      clear 5
    clear         terrible 0
    clear         poor 2
    clear         marginal 6
    clear         clear 13
    ;
```

The following PROC FREQ statements request an agreement analysis of the skin condition data. In order to evaluate the agreement of the diagnoses (a possible contribution to measurement error in the study), the *kappa coefficient* is computed.

The TABLES statement requests a crosstabulation of the variables `Derm1` and `Derm2`. The AGREE option in the TABLES statement requests the kappa coefficient, together with its standard error and confidence limits. The KAPPA option in the TEST statement requests a test for the null hypothesis that kappa equals zero, or that the agreement is purely by chance. The NOPRINT option in the TABLES statement suppresses the display of the two-way table. The PLOTS= option requests an agreement plot for the two dermatologists. ODS Graphics must be enabled before producing plots.

```
ods graphics on;
proc freq data=SkinCondition order=data;
    tables Derm1*Derm2 /
        agree noprint plots=agreeplot;
    test kappa;
    weight Count;
run;
ods graphics off;
```

Figure 38.10 and Figure 38.11 show the results. The kappa coefficient has the value 0.3449, which indicates some agreement between the dermatologists, and the hypothesis test confirms that you can reject the null hypothesis of no agreement. This conclusion is further supported by the confidence interval of (0.2030, 0.4868), which suggests that the true kappa is greater than zero. The AGREE option also produces Bowker's test for symmetry and the weighted kappa coefficient, but that output is not shown here. Figure 38.11 displays the agreement plot for the ratings of the two dermatologists.

Figure 38.10 Agreement Study

Figure 38.11 Agreement Plot

Syntax: FREQ Procedure

The following statements are available in the FREQ procedure:

```
PROC FREQ < options > ;
  BY variables ;
  EXACT statistic-options < / computation-options > ;
  OUTPUT < OUT=SAS-data-set > output-options ;
  TABLES requests < / options > ;
  TEST options ;
  WEIGHT variable < / option > ;
```

The PROC FREQ statement is the only required statement for the FREQ procedure. If you specify the following statements, PROC FREQ produces a one-way frequency table for each variable in the most recently created data set.

```
proc freq;
run;
```

The rest of this section gives detailed syntax information for the BY, EXACT, OUTPUT, TABLES, TEST, and WEIGHT statements in alphabetical order after the description of the PROC FREQ statement. Table 38.3 summarizes the basic function of each PROC FREQ statement.

Table 38.3 Summary of PROC FREQ Statements

Statement	Description
BY	Provides separate analyses for each BY group
EXACT	Requests exact tests
OUTPUT	Requests an output data set
TABLES	Specifies tables and requests analyses
TEST	Requests tests for measures of association and agreement
WEIGHT	Identifies a weight variable

PROC FREQ Statement

```
PROC FREQ < options > ;
```

The PROC FREQ statement invokes the FREQ procedure. Optionally, it also identifies the input data set. By default, the procedure uses the most recently created SAS data set.

Table 38.4 lists the *options* available in the PROC FREQ statement. Descriptions of the *options* follow in alphabetical order.

Table 38.4 PROC FREQ Statement Options

Option	Description
COMPRESS	Begins the next one-way table on the current page
DATA=	Names the input data set
FORMCHAR=	Specifies the outline and cell divider characters for crosstabulation tables
NLEVELS	Displays the number of levels for all TABLES variables
NOPRINT	Suppresses all displayed output
ORDER=	Specifies the order for reporting variable values
PAGE	Displays one table per page

You can specify the following *options* in the PROC FREQ statement.

COMPRESS

begins display of the next one-way frequency table on the same page as the preceding one-way table if there is enough space to begin the table. By default, the next one-way table begins on the current page only if the entire table fits on that page. The COMPRESS option is not valid with the [PAGE](#) option.

DATA=SAS-data-set

names the SAS data set to be analyzed by PROC FREQ. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

FORMCHAR(1,2,7)=*'formchar-string'*

defines the characters to be used for constructing the outlines and dividers for the cells of crosstabulation table displays. The *formchar-string* should be three characters long. The characters are used to draw the vertical separators (1), the horizontal separators (2), and the vertical-horizontal intersections (7). If you do not specify the FORMCHAR= option, PROC FREQ uses FORMCHAR(1,2,7)='|+-' by default. [Table 38.5](#) summarizes the formatting characters used by PROC FREQ.

Table 38.5 Formatting Characters Used by PROC FREQ

Position	Default	Used to Draw
1		Vertical separators
2	-	Horizontal separators
7	+	Intersections of vertical and horizontal separators

The FORMCHAR= option can specify 20 different SAS formatting characters used to display output; however, PROC FREQ uses only the first, second, and seventh formatting characters. Therefore, the proper specification for PROC FREQ is FORMCHAR(1,2,7)= *'formchar-string'*.

Specifying all blanks for *formchar-string* produces crosstabulation tables with no outlines or dividers—for example, FORMCHAR(1,2,7)=' '. You can use any character in *formchar-string*, including hexadecimal characters. If you use hexadecimal characters, you must put an *x* after the closing quote. For information about which hexadecimal codes to use for which characters, see the documentation for your hardware.

See the CALENDAR, PLOT, and TABULATE procedures in the *Base SAS Procedures Guide* for more information about form characters.

NLEVELS

displays the “Number of Variable Levels” table, which provides the number of levels for each variable named in the TABLES statements. See the section “[Number of Variable Levels Table](#)” on page 2609 for details. PROC FREQ determines the variable levels from the formatted variable values, as described in the section “[Grouping with Formats](#)” on page 2544.

NOPRINT

suppresses the display of all output. You can use the NOPRINT option when you only want to create an output data set. See the section “[Output Data Sets](#)” on page 2606 for information about the output data sets produced by PROC FREQ. Note that the NOPRINT option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 20, “[Using the Output Delivery System](#).”

NOTE: A **NOPRINT** option is also available in the **TABLES** statement. It suppresses display of the crosstabulation tables but allows display of the requested statistics.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the order of the variable levels in the frequency and crosstabulation tables, which you request in the **TABLES** statement.

The ORDER= option can take the following values:

Value of ORDER=	Levels Ordered By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=INTERNAL. The FORMATTED and INTERNAL orders are machine-dependent. The ORDER= option does not apply to missing values, which are always ordered first.

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PAGE

displays only one table per page. Otherwise, PROC FREQ displays multiple tables per page as space permits. The PAGE option is not valid with the **COMPRESS** option.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC FREQ to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the FREQ procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

EXACT Statement

EXACT *statistic-options* < / *computation-options* > ;

The EXACT statement requests exact tests and confidence limits for selected statistics. The *statistic-options* identify which statistics to compute, and the *computation-options* specify options for computing exact statistics. See the section “[Exact Statistics](#)” on page 2601 for details.

NOTE: PROC FREQ computes exact tests by using fast and efficient algorithms that are superior to direct enumeration. Exact tests are appropriate when a data set is small, sparse, skewed, or heavily tied. For some large problems, computation of exact tests might require a considerable amount of time and memory. Consider using asymptotic tests for such problems. Alternatively, when asymptotic methods might not be sufficient for such large problems, consider using Monte Carlo estimation of exact *p*-values. You can request Monte Carlo estimation by specifying the [MC computation-option](#) in the EXACT statement. See the section “[Computational Resources](#)” on page 2604 for more information.

Statistic Options

The *statistic-options* specify which exact tests and confidence limits to compute. [Table 38.6](#) lists the available *statistic-options* and the exact statistics that are computed. Descriptions of the *statistic-options* follow the table in alphabetical order.

For one-way tables, exact *p*-values are available for binomial proportion tests, the chi-square goodness-of-fit test, and the likelihood ratio chi-square test. Exact (Clopper-Pearson) confidence limits are available for the binomial proportion.

For two-way tables, exact *p*-values are available for the following tests: Pearson chi-square test, likelihood ratio chi-square test, Mantel-Haenszel chi-square test, Fisher’s exact test, Jonckheere-Terpstra test, and Cochran-Armitage test for trend. Exact *p*-values are also available for tests of the following statistics: Pearson correlation coefficient, Spearman correlation coefficient, Kendall’s tau-*b*, Stuart’s tau-*c*, Somers’ $D(C|R)$, Somers’ $D(R|C)$, simple kappa coefficient, and weighted kappa coefficient.

For 2×2 tables, PROC FREQ provides the exact McNemar’s test, exact confidence limits for the odds ratio, and Barnard’s unconditional exact test for the risk (proportion) difference. PROC FREQ also provides exact

unconditional confidence limits for the risk difference and for the relative risk (ratio of proportions). For stratified 2×2 tables, PROC FREQ provides Zelen's exact test for equal odds ratios, exact confidence limits for the common odds ratio, and an exact test for the common odds ratio.

Most of the *statistic-option* names listed in Table 38.6 are identical to the corresponding option names in the TABLES and OUTPUT statements. You can request exact computations for groups of statistics by using *statistic-options* that are identical to the TABLES statement options CHISQ, MEASURES, and AGREE. For example, when you specify the CHISQ *statistic-option* in the EXACT statement, PROC FREQ computes exact p -values for the Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square tests for two-way tables. You can request an exact test for an individual statistic by specifying the corresponding *statistic-option* from the list in Table 38.6.

Using the EXACT Statement with the TABLES Statement

You must use a TABLES statement with the EXACT statement. If you use only one TABLES statement, you do not need to specify the same options in both the TABLES and EXACT statements; when you specify a *statistic-option* in the EXACT statement, PROC FREQ automatically invokes the corresponding TABLES statement option. However, when you use an EXACT statement with multiple TABLES statements, you must specify options in the TABLES statements to request statistics. PROC FREQ then provides exact tests or confidence limits for those statistics that you also specify in the EXACT statement.

Table 38.6 EXACT Statement Statistic Options

Statistic Option	Exact Statistics
AGREE	McNemar's test (for 2×2 tables), simple kappa test, weighted kappa test
BARNARD	Barnard's test (for 2×2 tables)
BINOMIAL	Binomial proportion tests for one-way tables
CHISQ	Chi-square goodness-of-fit test for one-way tables; Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square tests for two-way tables
COMOR	Confidence limits for the common odds ratio, common odds ratio test (for $h \times 2 \times 2$ tables)
EQOR ZELN	Zelen's test for equal odds ratios (for $h \times 2 \times 2$ tables)
FISHER	Fisher's exact test
JT	Jonckheere-Terpstra test
KAPPA	Test for the simple kappa coefficient
KENTB	Test for Kendall's tau- b
LRCHI	Likelihood ratio chi-square test (one-way or two-way tables)
MCNEM	McNemar's test (for 2×2 tables)
MEASURES	Tests for the Pearson correlation and Spearman correlation, confidence limits for the odds ratio (for 2×2 tables)
MHCHI	Mantel-Haenszel chi-square test
OR	Confidence limits for the odds ratio (for 2×2 tables)
PCHI	Pearson chi-square test
PCORR	Test for the Pearson correlation coefficient
RELRISK	Confidence limits for the relative risk (for 2×2 tables)
RISKDIFF	Confidence limits for the proportion difference (for 2×2 tables)
SCORR	Test for the Spearman correlation coefficient

Table 38.6 *continued*

Statistic Option	Exact Statistics
SMDCR	Test for Somers' $D(C R)$
SMDRC	Test for Somers' $D(R C)$
STUTC	Test for Stuart's tau- c
TREND	Cochran-Armitage test for trend
WTKAP	Test for the weighted kappa coefficient

You can specify the following *statistic-options* in the EXACT statement.

AGREE

requests the exact McNemar's test and exact tests for the simple and weighted kappa coefficients. See the sections "[Tests and Measures of Agreement](#)" on page 2588 and "[Exact Statistics](#)" on page 2601 for details.

The **AGREE** option in the TABLES statement provides the asymptotic McNemar's test and the kappa estimates, standard errors, and confidence limits. The **AGREE** option in the TEST statement provides asymptotic tests for the kappa coefficients.

Kappa coefficients are defined only for square tables, where the number of rows equals the number of columns. McNemar's test is available for 2×2 tables.

BARNARD

requests Barnard's exact unconditional test for the risk (proportion) difference for 2×2 tables. See the section "[Barnard's Unconditional Exact Test](#)" on page 2581 for details. The **RISKDIFF** option in the TABLES statement provides risk difference estimates, confidence limits, and asymptotic tests. See the section "[Risks and Risk Differences](#)" on page 2572 for more information.

BINOMIAL

requests exact tests for the binomial proportion (for one-way tables). See the section "[Binomial Tests](#)" on page 2568 for details. The **BINOMIAL** option in the TABLES statement provides confidence limits and asymptotic tests for the binomial proportion. See the section "[Binomial Proportion](#)" on page 2565 for more information.

CHISQ

requests exact tests for the Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square for two-way tables. See the section "[Chi-Square Tests and Statistics](#)" on page 2550 for details. The **CHISQ** option in the TABLES statement provides asymptotic tests for these statistics.

For one-way tables, the **CHISQ** option requests the exact chi-square goodness-of-fit test. See the section "[Chi-Square Test for One-Way Tables](#)" on page 2551 for details.

COMOR

requests an exact test and exact confidence limits for the common odds ratio for multiway 2×2 tables. See the section "[Exact Confidence Limits for the Common Odds Ratio](#)" on page 2599 for details. The **CMH** option in the TABLES statement provides Mantel-Haenszel and logit estimates and asymptotic confidence limits for the common odds ratio.

EQOR

requests Zelen's exact test for equal odds ratios, which is available for multiway 2×2 tables. See the section "[Zelen's Exact Test for Equal Odds Ratios](#)" on page 2598 for details. The **CMH** option in the **TABLES** statement provides the asymptotic Breslow-Day test for homogeneity of odds ratios.

FISHER

request Fisher's exact test. See the sections "[Fisher's Exact Test](#)" on page 2554 and "[Exact Statistics](#)" on page 2601 for details. For 2×2 tables, the **CHISQ** option in the **TABLES** statement provides Fisher's exact test. For general $R \times C$ tables, Fisher's exact test is also known as the Freeman-Halton test.

JT

requests the exact Jonckheere-Terpstra test. See the sections "[Jonckheere-Terpstra Test](#)" on page 2586 and "[Exact Statistics](#)" on page 2601 for details. The **JT** option in the **TABLES** statement provides the asymptotic Jonckheere-Terpstra test.

KAPPA

requests an exact test for the simple kappa coefficient. See the sections "[Simple Kappa Coefficient](#)" on page 2589 and "[Exact Statistics](#)" on page 2601 for details. The **AGREE** option in the **TABLES** statement provides the simple kappa estimate, standard error, and confidence limits. The **KAPPA** option in the **TEST** statement provides the asymptotic test for the simple kappa coefficient.

Kappa coefficients are defined only for square tables, where the number of rows equals the number of columns. PROC FREQ does not compute kappa coefficients for tables that are not square.

KENTB

requests an exact test for Kendall's tau-*b*. See the sections "[Kendall's Tau-b](#)" on page 2558 and "[Exact Statistics](#)" on page 2601 for details. The **MEASURES** option in the **TABLES** statement provides the Kendall's tau-*b* estimate and standard error. The **KENTB** option in the **TEST** statement provides an asymptotic test for Kendall's tau-*b*.

LRCHI

requests an exact test for the likelihood ratio chi-square for two-way tables. See the sections "[Likelihood Ratio Chi-Square Test](#)" on page 2553 and "[Exact Statistics](#)" on page 2601 for details. For one-way tables, the **LRCHI** option requests an exact likelihood ratio goodness-of-fit test. See the section "[Likelihood Ratio Chi-Square Test for One-Way Tables](#)" on page 2552 for details.

The **CHISQ** option in the **TABLES** statement provides asymptotic likelihood ratio chi-square tests.

MCNEM

requests the exact McNemar's test. See the sections "[McNemar's Test](#)" on page 2588 and "[Exact Statistics](#)" on page 2601 for details. The **AGREE** option in the **TABLES** statement provides the asymptotic McNemar's test.

MEASURES

requests exact tests for the Pearson and Spearman correlations. See the sections "[Pearson Correlation Coefficient](#)" on page 2559, "[Spearman Rank Correlation Coefficient](#)" on page 2560, and "[Exact Statistics](#)" on page 2601 for details. The **PCORR** and **SCORR** options in the **TEST** statement provide asymptotic tests for the Pearson and Spearman correlations, respectively.

The **MEASURES** option also requests exact confidence limits for the odds ratio for 2×2 tables. See the sections "[Odds Ratio \(Case-Control Studies\)](#)" on page 2582 and "[Exact Confidence Limits for the Odds Ratio](#)" on page 2583 for details. The **MEASURES** and **RELRISK** options in the **TABLES** statement provide asymptotic confidence limits for the odds ratio.

MHCHI

requests an exact test for the Mantel-Haenszel chi-square. See the sections “[Mantel-Haenszel Chi-Square Test](#)” on page 2553 and “[Exact Statistics](#)” on page 2601 for details. The **CHISQ** option in the **TABLES** statement provides the asymptotic Mantel-Haenszel chi-square test.

OR

requests exact confidence limits for the odds ratio for 2×2 tables. See the sections “[Odds Ratio \(Case-Control Studies\)](#)” on page 2582 and “[Exact Confidence Limits for the Odds Ratio](#)” on page 2583 for details. The **MEASURES** and **RELRISK** options in the **TABLES** statement provide asymptotic confidence limits for the odds ratio.

PCHI

requests an exact test for the Pearson chi-square for two-way tables. See the sections “[Pearson Chi-Square Test for Two-Way Tables](#)” on page 2551 and “[Exact Statistics](#)” on page 2601 for details. For one-way tables, the **PCHI** option requests an exact chi-square goodness-of-fit test. See the section “[Chi-Square Test for One-Way Tables](#)” on page 2551 for details. The **CHISQ** option in the **TABLES** statement provides asymptotic chi-square tests.

PCORR

requests an exact test for the Pearson correlation coefficient. See the sections “[Pearson Correlation Coefficient](#)” on page 2559 and “[Exact Statistics](#)” on page 2601 for details. The **MEASURES** option in the **TABLES** statement provides the Pearson correlation estimate and standard error. The **PCORR** option in the **TEST** statement provides an asymptotic test for the Pearson correlation.

RELRISK <(options)>

requests exact unconditional confidence limits for the relative risk for 2×2 tables. **PROC FREQ** computes the confidence limits by inverting two separate one-sided exact tests (Santner and Snell 1980). By default, this computation uses the unstandardized relative risk as the test statistic. If you specify the **RELRISK(METHOD=SCORE)** option, the computation uses the score statistic (Chan and Zhang 1999). See the section “[Exact Unconditional Confidence Limits for the Relative Risk](#)” on page 2584 for more information.

You can set the confidence level by specifying the **ALPHA=** option in the **TABLES** statement. The default of **ALPHA=0.5** produces 95% confidence limits.

The **RELRISK** option in the **TABLES** statement provides asymptotic confidence limits for the relative risk. See the section “[Relative Risks \(Cohort Studies\)](#)” on page 2583 for more information.

You can specify the following *options* in parentheses after the **RELRISK** *statistic-option*:

COLUMN=1 | 2 | BOTH

specifies the 2×2 table column for which to compute the relative risk. The default is **COLUMN=1**, which provides exact confidence limits for the column 1 relative risk. If you specify **COLUMN=BOTH**, **PROC FREQ** provides exact confidence limits for both column 1 and column 2 relative risks.

METHOD=SCORE

requests exact unconditional confidence limits that are based on the score statistic (Chan and Zhang 1999). See the section “[Exact Unconditional Confidence Limits for the Relative Risk](#)” on page 2584 for more information. If you do not specify **METHOD=SCORE**, by default the exact confidence limit computations are based on the unstandardized relative risk.

RISKDIFF <(options)>

requests exact unconditional confidence limits for the risk difference for 2×2 tables. PROC FREQ computes the confidence limits by inverting two separate one-sided exact tests (Santner and Snell 1980). By default, this computation uses the unstandardized risk difference as the test statistic. If you specify the **RISKDIFF(METHOD=SCORE)** option, the computation uses the score statistic (Chan and Zhang 1999). See the section “Exact Unconditional Confidence Limits for the Risk Difference” on page 2580 for more information.

You can set the confidence level by specifying the **ALPHA=** option in the **TABLES** statement. The default of **ALPHA=0.5** produces 95% confidence limits.

The **RISKDIFF** option in the **TABLES** statement provides asymptotic confidence limits for the risk difference, including Wald, Newcombe, and Miettinen-Nurminen confidence limits. See the section “Risk Difference Confidence Limits” on page 2574 for more information.

You can specify the following *options* in parentheses after the **RISKDIFF** *statistic-option*:

COLUMN=1 | 2 | BOTH

specifies the 2×2 table column for which to compute the risk difference. The default is **COLUMN=BOTH**, which provides exact confidence limits for both column 1 and column 2 risk differences.

METHOD=SCORE

requests exact unconditional confidence limits that are based on the score statistic (Chan and Zhang 1999). See the section “Exact Unconditional Confidence Limits for the Risk Difference” on page 2580 for more information. If you do not specify **METHOD=SCORE**, by default the exact confidence limit computations are based on the unstandardized risk difference.

SCORR

requests an exact test for the Spearman correlation coefficient. See the sections “Spearman Rank Correlation Coefficient” on page 2560 and “Exact Statistics” on page 2601 for details. The **MEASURES** option in the **TABLES** statement provides the Spearman correlation estimate and standard error. The **SCORR** option in the **TEST** statement provides an asymptotic test for the Spearman correlation.

SMDCR

requests an exact test for Somers’ $D(C|R)$. See the sections “Somers’ D ” on page 2559 and “Exact Statistics” on page 2601 for details. The **MEASURES** option in the **TABLES** statement provides Somers’ $D(C|R)$ estimate and the standard error. The **SMDCR** option in the **TEST** statement provides an asymptotic test for Somers’ $D(C|R)$.

SMDRC

requests an exact test for Somers’ $D(R|C)$. See the sections “Somers’ D ” on page 2559 and “Exact Statistics” on page 2601 for details. The **MEASURES** option in the **TABLES** statement provides Somers’ $D(R|C)$ estimate and the standard error. The **SMDRC** option in the **TEST** statement requests an asymptotic test for Somers’ $D(R|C)$.

STUTC

requests an exact test for Stuart’s tau- c . See the sections “Stuart’s Tau- c ” on page 2558 and “Exact Statistics” on page 2601 for details. The **MEASURES** option in the **TABLES** statement provides Stuart’s tau- c estimate and the standard error. The **STUTC** option in the **TEST** statement provides an asymptotic test for Stuart’s tau- c .

TREND

requests the exact Cochran-Armitage test for trend. See the sections “[Cochran-Armitage Test for Trend](#)” on page 2585 and “[Exact Statistics](#)” on page 2601 for details. The **TREND** option in the TABLES statement provides the asymptotic Cochran-Armitage trend test. The trend test is available for tables of dimensions $2 \times C$ or $R \times 2$.

WTKAP

requests an exact test for the weighted kappa coefficient. See the sections “[Weighted Kappa Coefficient](#)” on page 2590 and “[Exact Statistics](#)” on page 2601 for details. The **AGREE** option in the TABLES statement provides the weighted kappa estimate, standard error, and confidence limits. The **WTKAP** option in the TEST statement provides the asymptotic test for the weighted kappa coefficient.

Kappa coefficients are defined only for square tables, where the number of rows equals the number of columns. PROC FREQ does not compute kappa coefficients for tables that are not square. For 2×2 tables, the weighted kappa coefficient equals the simple kappa coefficient, and PROC FREQ does not present separate results for the weighted kappa coefficient.

Computation Options

The *computation-options* specify options for computing exact statistics. You can specify the following *computation-options* in the EXACT statement after a slash (/).

ALPHA= α

specifies the level of the confidence limits for Monte Carlo p -value estimates. The value of α must be between 0 and 1, and the default is 0.01. A confidence level of α produces $100(1 - \alpha)\%$ confidence limits. The default of ALPHA=.01 produces 99% confidence limits for the Monte Carlo estimates.

The ALPHA= option invokes the **MC** option.

MAXTIME=value

specifies the maximum clock time (in seconds) that PROC FREQ can use to compute an exact p -value. If the procedure does not complete the computation within the specified time, the computation terminates. The value of MAXTIME= must be a positive number. The MAXTIME= option is valid for Monte Carlo estimation of exact p -values as well as for direct exact p -value computation. See the section “[Computational Resources](#)” on page 2604 for more information.

MC

6 requests Monte Carlo estimation of exact p -values instead of direct exact p -value computation. Monte Carlo estimation can be useful for large problems that require a considerable amount of time and memory for exact computations but for which asymptotic approximations might not be sufficient. See the section “[Monte Carlo Estimation](#)” on page 2604 for more information.

The MC option is available for all EXACT *statistic-options* except the BINOMIAL option and the following options that apply only to 2×2 or $h \times 2 \times 2$ tables: BARNARD, COMOR, EQOR, MCNEM, OR, RELRISK, and RISKDIFF. PROC FREQ computes only exact tests or confidence limits for these statistics.

The ALPHA=, N=, and SEED= options also invoke the MC option.

N=*n*

specifies the number of samples for Monte Carlo estimation. The value of *n* must be a positive integer, and the default is 10,000. Larger values of *n* produce more precise estimates of exact *p*-values. Because larger values of *n* generate more samples, the computation time increases.

The N= option invokes the [MC](#) option.

POINT

requests exact point probabilities for the test statistics.

The POINT option is available for all EXACT statement *statistic-options* except BARNARD, OR, RELRISK, and RISKDIFF. The POINT option is not available with the [MC](#) option.

SEED=*number*

specifies the initial seed for random number generation for Monte Carlo estimation. The value of the SEED= option must be an integer. If you do not specify the SEED= option or if the SEED= value is negative or zero, PROC FREQ uses the time of day from the computer's clock to obtain the initial seed.

The SEED= option invokes the [MC](#) option.

OUTPUT Statement

OUTPUT < **OUT=** *SAS-data-set* > *output-options* ;

The OUTPUT statement creates a SAS data set that contains statistics that are computed by PROC FREQ. [Table 38.7](#) lists the statistics that can be stored in the output data set. You identify which statistics to include by specifying *output-options*.

You must use a [TABLES](#) statement with the OUTPUT statement. The OUTPUT statement stores statistics for only one table request. If you use multiple TABLES statements, the contents of the output data set correspond to the last TABLES statement. If you use multiple table requests in a single TABLES statement, the contents of the output data set correspond to the last table request. Only one OUTPUT statement is allowed in a single invocation of the procedure.

For a one-way or two-way table, the output data set contains one observation that stores the requested statistics for the table. For a multiway table, the output data set contains an observation for each two-way table (stratum) of the multiway crosstabulation. If you request summary statistics for the multiway table, the output data set also contains an observation that stores the across-strata summary statistics. If you use a [BY](#) statement, the output data set contains an observation or set of observations for each BY group. For more information about the contents of the output data set, see the section “[Contents of the OUTPUT Statement Output Data Set](#)” on page 2608.

The output data set that is created by the OUTPUT statement is not the same as the output data set that is created by the [OUT=](#) option in the [TABLES](#) statement. The OUTPUT statement creates a data set that contains statistics (such as the Pearson chi-square and its *p*-value), and the [OUT=](#) option in the TABLES statement creates a data set that contains frequency table counts and percentages. See the section “[Output Data Sets](#)” on page 2606 for more information.

As an alternative to the OUTPUT statement, you can use the Output Delivery System (ODS) to store statistics that PROC FREQ computes. ODS can create a SAS data set from any table that PROC FREQ produces. See the section “[ODS Table Names](#)” on page 2617 for more information.

You can specify the following *options* in the OUTPUT statement:

OUT=SAS-data-set

specifies the name of the output data set. When you use an OUTPUT statement but do not use the OUT= option, PROC FREQ creates a data set and names it by using the *DATA**n* convention.

output-options

specify the statistics to include in the output data set. Table 38.7 lists the *output-options* that are available in the OUTPUT statement, together with the TABLES statement options that are required to produce the statistics. Descriptions of the *output-options* follow the table in alphabetical order.

You can specify *output-options* to request individual statistics, or you can request groups of statistics by using *output-options* that are identical to the group options in the TABLES statement (for example, the CHISQ, MEASURES, CMH, AGREE, and ALL options).

When you specify an *output-option*, the output data set includes statistics from the corresponding analysis. In addition to the estimate or test statistic, the output data set includes associated values such as standard errors, confidence limits, *p*-values, and degrees of freedom. See the section “Contents of the OUTPUT Statement Output Data Set” on page 2608 for details.

To store a statistic in the output data set, you must also request computation of that statistic with the appropriate TABLES, EXACT, or TEST statement option. For example, the PCHI *output-option* includes the Pearson chi-square in the output data set. You must also request computation of the Pearson chi-square by specifying the CHISQ option in the TABLES statement. Or, if you use only one TABLES statement, you can request computation of the Pearson chi-square by specifying the PCHI or CHISQ option in the EXACT statement. Table 38.7 lists the TABLES statement options that are required to produce the OUTPUT data set statistics.

Table 38.7 OUTPUT Statement Output Options

Output Option	Output Data Set Statistics	Required TABLES Statement Option
AGREE	McNemar's test (2×2 tables), Bowker's test, simple and weighted kappas; for multiple strata, overall simple and weighted kappas, tests for equal kappas, and Cochran's <i>Q</i> ($h \times 2 \times 2$ tables)	AGREE
AJCHI	Continuity-adjusted chi-square (2×2 tables)	CHISQ
ALL	CHISQ, MEASURES, and CMH statistics; N (number of nonmissing observations)	ALL
BDCHI BD	Breslow-Day test ($h \times 2 \times 2$ tables)	CMH, CMH1, or CMH2
BINOMIAL	Binomial statistics (one-way tables)	BINOMIAL
CHISQ	For one-way tables, goodness-of-fit test; for two-way tables, Pearson, likelihood ratio, continuity-adjusted, and Mantel-Haenszel chi-squares, Fisher's exact test (2×2 tables), phi and contingency coefficients, Cramér's <i>V</i>	CHISQ
CMH	Cochran-Mantel-Haenszel (CMH) correlation, row mean scores (ANOVA), and general association statistics; for 2×2 tables, logit and Mantel-Haenszel common odds ratios and relative risks, Breslow-Day test	CMH

Table 38.7 continued

Output Option	Output Data Set Statistics	Required TABLES Statement Option
CMH1	CMH statistics, except row mean scores (ANOVA) and general association statistics	CMH or CMH1
CMH2	CMH statistics, except general association statistic	CMH or CMH2
CMHCOR	CMH correlation statistic	CMH, CMH1, or CMH2
CMHGA	CMH general association statistic	CMH
CMHRMS	CMH row mean scores (ANOVA) statistic	CMH or CMH2
COCHQ	Cochran's Q ($h \times 2 \times 2$ tables)	AGREE
CONTGY	Contingency coefficient	CHISQ
CRAMV	Cramér's V	CHISQ
EQKAP	Test for equal simple kappas	AGREE
EQOR ZELEN	Zelen's test for equal odds ratios ($h \times 2 \times 2$ tables)	CMH and EXACT EQOR
EQWKP	Test for equal weighted kappas	AGREE
FISHER	Fisher's exact test	CHISQ or FISHER ¹
GAILSIMON GS	Gail-Simon test	CMH(GAILSIMON)
GAMMA	Gamma	MEASURES
JT	Jonckheere-Terpstra test	JT
KAPPA	Simple kappa coefficient	AGREE
KENTB TAUB	Kendall's tau- b	MEASURES
LAMCR	Lambda asymmetric ($C R$)	MEASURES
LAMDAS	Lambda symmetric	MEASURES
LAMRC	Lambda asymmetric ($R C$)	MEASURES
LGOR	Logit common odds ratio	CMH, CMH1, or CMH2
LGRRC1	Logit common relative risk, column 1	CMH, CMH1, or CMH2
LGRRC2	Logit common relative risk, column 2	CMH, CMH1, or CMH2
LRCHI	Likelihood ratio chi-square	CHISQ
MCNEM	McNemar's test (2×2 tables)	AGREE
MEASURES	Gamma, Kendall's tau- b , Stuart's tau- c , Somers' $D(C R)$ and $D(R C)$, Pearson and Spearman correlations, lambda asymmetric ($C R$) and ($R C$), lambda symmetric, uncertainty coefficients ($C R$) and ($R C$), symmetric uncertainty coefficient; odds ratio and relative risks (2×2 tables)	MEASURES
MHCHI	Mantel-Haenszel chi-square	CHISQ
MHOR COMOR	Mantel-Haenszel common odds ratio	CMH, CMH1, or CMH2
MHRRC1	Mantel-Haenszel common relative risk, column 1	CMH, CMH1, or CMH2
MHRRC2	Mantel-Haenszel common relative risk, column 2	CMH, CMH1, or CMH2
N	Number of nonmissing observations	
NMISS	Number of missing observations	
OR	Odds ratio (2×2 tables)	MEASURES or RELRISK

¹CHISQ computes Fisher's exact test for 2×2 tables. Use the FISHER option to compute Fisher's exact test for general $r \times c$ tables.

Table 38.7 continued

Output Option	Output Data Set Statistics	Required TABLES Statement Option
PCHI	Chi-square goodness-of-fit test (one-way tables), Pearson chi-square (two-way tables)	CHISQ
PCORR	Pearson correlation coefficient	MEASURES
PHI	Phi coefficient	CHISQ
PLCORR	Polychoric correlation coefficient	PLCORR
RDIF1	Column 1 risk difference (row 1 – row 2)	RISKDIFF
RDIF2	Column 2 risk difference (row 1 – row 2)	RISKDIFF
RELRISK	Odds ratio and relative risks (2×2 tables)	MEASURES or RELRISK
RISKDIFF	Risks and risk differences (2×2 tables)	RISKDIFF
RISKDIFF1	Risks and risk difference, column 1	RISKDIFF
RISKDIFF2	Risks and risk difference, column 2	RISKDIFF
RRC1 RELRISK1	Relative risk, column 1	MEASURES or RELRISK
RRC2 RELRISK2	Relative risk, column 2	MEASURES or RELRISK
RSK1 RISK1	Column 1 overall risk	RISKDIFF
RSK11 RISK11	Column 1 risk for row 1	RISKDIFF
RSK12 RISK12	Column 2 risk for row 1	RISKDIFF
RSK2 RISK2	Column 2 overall risk	RISKDIFF
RSK21 RISK21	Column 1 risk for row 2	RISKDIFF
RSK22 RISK22	Column 2 risk for row 2	RISKDIFF
SCORR	Spearman correlation coefficient	MEASURES
SMDCR	Somers' $D(C R)$	MEASURES
SMDRC	Somers' $D(R C)$	MEASURES
STUTC TAUC	Stuart's tau-c	MEASURES
TREND	Cochran-Armitage test for trend	TREND
TSYMM BOWKER	Bowker's test of symmetry	AGREE
U	Symmetric uncertainty coefficient	MEASURES
UCR	Uncertainty coefficient ($C R$)	MEASURES
URC	Uncertainty coefficient ($R C$)	MEASURES
WTKAP	Weighted kappa coefficient	AGREE

You can specify the following *output-options* in the OUTPUT statement.

AGREE

includes the following tests and measures of agreement in the output data set: McNemar's test (for 2×2 tables), Bowker's test of symmetry, the simple kappa coefficient, and the weighted kappa coefficient. For multiway tables, the AGREE option also includes the following statistics in the output data set: overall simple and weighted kappa coefficients, tests for equal simple and weighted kappa coefficients, and Cochran's Q test.

The AGREE option in the TABLES statement requests computation of tests and measures of agreement. See the section “Tests and Measures of Agreement” on page 2588 for details about these statistics.

AGREE statistics are computed only for square tables, where the number of rows equals the number of columns. PROC FREQ provides Bowker's test of symmetry and weighted kappa coefficients only

for tables larger than 2×2 . (For 2×2 tables, Bowker's test is identical to McNemar's test, and the weighted kappa coefficient equals the simple kappa coefficient.) Cochran's Q is available for multiway 2×2 tables.

AJCHI

includes the continuity-adjusted chi-square in the output data set. The continuity-adjusted chi-square is available for 2×2 tables and is provided by the **CHISQ** option in the **TABLES** statement. See the section “Continuity-Adjusted Chi-Square Test” on page 2553 for details.

ALL

includes all statistics that are requested by the **CHISQ**, **MEASURES**, and **CMH** *output-options* in the output data set. **ALL** also includes the number of nonmissing observations, which you can request individually by specifying the **N** *output-option*.

BDCHI | BD

includes the Breslow-Day test in the output data set. The Breslow-Day test for homogeneity of odds ratios is computed for multiway 2×2 tables and is provided by the **CMH**, **CMH1**, and **CMH2** options in the **TABLES** statement. See the section “Breslow-Day Test for Homogeneity of the Odds Ratios” on page 2598 for details.

BINOMIAL

includes the binomial proportion estimate, confidence limits, and tests in the output data set. The **BINOMIAL** option in the **TABLES** statement requests computation of binomial statistics, which are available for one-way tables. See the section “Binomial Proportion” on page 2565 for details.

CHISQ

includes the following chi-square tests and measures in the output data set for two-way tables: Pearson chi-square, likelihood ratio chi-square, Mantel-Haenszel chi-square, phi coefficient, contingency coefficient, and Cramér's V . For 2×2 tables, **CHISQ** also includes Fisher's exact test and the continuity-adjusted chi-square in the output data set. See the section “Chi-Square Tests and Statistics” on page 2550 for details. For one-way tables, **CHISQ** includes the chi-square goodness-of-fit test in the output data set. See the section “Chi-Square Test for One-Way Tables” on page 2551 for details. The **CHISQ** option in the **TABLES** statement requests computation of these statistics.

If you specify the **CHISQ(WARN=OUTPUT)** option in the **TABLES** statement, the **CHISQ** option also includes the variable **WARN_PCHI** in the output data set. This variable indicates the validity warning for the asymptotic Pearson chi-square test.

CMH

includes the following Cochran-Mantel-Haenszel statistics in the output data set: correlation, row mean scores (ANOVA), and general association. For 2×2 tables, the **CMH** option also includes the Mantel-Haenszel and logit estimates of the common odds ratio and relative risks. For multiway (stratified) 2×2 tables, the **CMH** option includes the Breslow-Day test for homogeneity of odds ratios. The **CMH** option in the **TABLES** statement requests computation of these statistics. See the section “Cochran-Mantel-Haenszel Statistics” on page 2592 for details.

If you specify the **CMH(MF)** option in the **TABLES** statement, the **CMH** option includes the Mantel-Fleiss analysis in the output data set. The variables **MF_CMH** and **WARN_CMH** contain the Mantel-Fleiss criterion and the warning indicator, respectively.

CMH1

includes the [CMH](#) statistics in the output data set, with the exception of the row mean scores (ANOVA) statistic and the general association statistic. The [CMH1](#) option in the [TABLES](#) statement requests computation of these statistics. See the section “[Cochran-Mantel-Haenszel Statistics](#)” on page 2592 for details.

CMH2

includes the [CMH](#) statistics in the output data set, with the exception of the general association statistic. The [CMH2](#) option in the [TABLES](#) statement requests computation of these statistics. See the section “[Cochran-Mantel-Haenszel Statistics](#)” on page 2592 for details.

CMHCOR

includes the Cochran-Mantel-Haenszel correlation statistic in the output data set. The [CMH](#) option in the [TABLES](#) statement requests computation of this statistic. See the section “[Correlation Statistic](#)” on page 2594 for details.

CMHGA

includes the Cochran-Mantel-Haenszel general association statistic in the output data set. The [CMH](#) option in the [TABLES](#) statement requests computation of this statistic. See the section “[General Association Statistic](#)” on page 2595 for details.

CMHRMS

includes the Cochran-Mantel-Haenszel row mean scores (ANOVA) statistic in the output data set. The [CMH](#) option in the [TABLES](#) statement requests computation of this statistic. See the section “[ANOVA \(Row Mean Scores\) Statistic](#)” on page 2594 for details.

COCHQ

includes Cochran’s Q test in the output data set. The [AGREE](#) option in the [TABLES](#) statement requests computation of this test, which is available for multiway 2×2 tables. See the section “[Cochran’s \$Q\$ Test](#)” on page 2592 for details.

CONTGY

includes the contingency coefficient in the output data set. The [CHISQ](#) option in the [TABLES](#) statement requests computation of the contingency coefficient. See the section “[Contingency Coefficient](#)” on page 2555 for details.

GRAMV

includes Cramér’s V in the output data set. The [CHISQ](#) option in the [TABLES](#) statement requests computation of Cramér’s V . See the section “[Cramér’s \$V\$ ” on page 2555 for details.](#)

EQKAP

includes the test for equal simple kappa coefficients in the output data set. The [AGREE](#) option in the [TABLES](#) statement requests computation of this test, which is available for multiway, square ($h \times r \times r$) tables. See the section “[Tests for Equal Kappa Coefficients](#)” on page 2591 for details.

EQOR | ZELEN

includes Zelen’s exact test for equal odds ratios in the output data set. The [EQOR](#) option in the [EXACT](#) statement requests computation of this test, which is available for multiway 2×2 tables. See the section “[Zelen’s Exact Test for Equal Odds Ratios](#)” on page 2598 for details.

EQWKP

includes the test for equal weighted kappa coefficients in the output data set. The [AGREE](#) option in the [TABLES](#) statement requests computation of this test. The test for equal weighted kappas is available for multiway, square ($h \times r \times r$) tables where $r > 2$. See the section “[Tests for Equal Kappa Coefficients](#)” on page 2591 for details.

FISHER

includes Fisher’s exact test in the output data set. For 2×2 tables, the [CHISQ](#) option in the [TABLES](#) statement provides Fisher’s exact test. For tables larger than 2×2 , the [FISHER](#) option in the [EXACT](#) statement provides Fisher’s exact test. See the section “[Fisher’s Exact Test](#)” on page 2554 for details.

GAILSIMON | GS

includes the Gail-Simon test for qualitative interaction in the output data set. The [CMH\(GAILSIMON\)](#) option in the [TABLES](#) statement requests computation of this test. See the section “[Gail-Simon Test for Qualitative Interactions](#)” on page 2601 for details.

GAMMA

includes the gamma statistic in the output data set. The [MEASURES](#) option in the [TABLES](#) statement requests computation of the gamma statistic. See the section “[Gamma](#)” on page 2557 for details.

JT

includes the Jonckheere-Terpstra test in the output data set. The [JT](#) option in the [TABLES](#) statement requests the Jonckheere-Terpstra test. See the section “[Jonckheere-Terpstra Test](#)” on page 2586 for details.

KAPPA

includes the simple kappa coefficient in the output data set. The [AGREE](#) option in the [TABLES](#) statement requests computation of kappa, which is available for square tables (where the number of rows equals the number of columns). For multiway square tables, the [KAPPA](#) option also includes the overall kappa coefficient in the output data set. See the sections “[Simple Kappa Coefficient](#)” on page 2589 and “[Overall Kappa Coefficient](#)” on page 2591 for details.

KENTB | TAUB

includes Kendall’s tau-*b* in the output data set. The [MEASURES](#) option in the [TABLES](#) statement requests computation of Kendall’s tau-*b*. See the section “[Kendall’s Tau-b](#)” on page 2558 for details.

LAMCR

includes the asymmetric lambda $\lambda(C|R)$ in the output data set. The [MEASURES](#) option in the [TABLES](#) statement requests computation of lambda. See the section “[Lambda \(Asymmetric\)](#)” on page 2563 for details.

LAMDAS

includes the symmetric lambda in the output data set. The [MEASURES](#) option in the [TABLES](#) statement requests computation of lambda. See the section “[Lambda \(Symmetric\)](#)” on page 2563 for details.

LAMRC

includes the asymmetric lambda $\lambda(R|C)$ in the output data set. The [MEASURES](#) option in the [TABLES](#) statement requests computation of lambda. See the section “[Lambda \(Asymmetric\)](#)” on page 2563 for details.

LGOR

includes the logit estimate of the common odds ratio in the output data set. The **CMH** option in the **TABLES** statement requests computation of this statistic, which is available for 2×2 tables. See the section “[Adjusted Odds Ratio and Relative Risk Estimates](#)” on page 2596 for details.

LGRRC1

includes the logit estimate of the common relative risk (column 1) in the output data set. The **CMH** option in the **TABLES** statement requests computation of this statistic, which is available for 2×2 tables. See the section “[Adjusted Odds Ratio and Relative Risk Estimates](#)” on page 2596 for details.

LGRRC2

includes the logit estimate of the common relative risk (column 2) in the output data set. The **CMH** option in the **TABLES** statement requests computation of this statistic, which is available for 2×2 tables. See the section “[Adjusted Odds Ratio and Relative Risk Estimates](#)” on page 2596 for details.

LRCHI

includes the likelihood ratio chi-square in the output data set. The **CHISQ** option in the **TABLES** statement requests computation of the likelihood ratio chi-square. See the section “[Likelihood Ratio Chi-Square Test](#)” on page 2553 for details.

MCNEM

includes McNemar’s test (for 2×2 tables) in the output data set. The **AGREE** option in the **TABLES** statement requests computation of McNemar’s test. See the section “[McNemar’s Test](#)” on page 2588 for details.

MEASURES

includes the following measures of association in the output data set: gamma, Kendall’s tau-*b*, Stuart’s tau-*c*, Somers’ $D(C|R)$, Somers’ $D(R|C)$, Pearson and Spearman correlation coefficients, lambda (symmetric and asymmetric), and uncertainty coefficients (symmetric and asymmetric). For 2×2 tables, the **MEASURES** option also includes the odds ratio, column 1 relative risk, and column 2 relative risk. The **MEASURES** option in the **TABLES** statement requests computation of these statistics. See the section “[Measures of Association](#)” on page 2556 for details.

MHCHI

includes the Mantel-Haenszel chi-square in the output data set. The **CHISQ** option in the **TABLES** statement requests computation of the Mantel-Haenszel chi-square. See the section “[Mantel-Haenszel Chi-Square Test](#)” on page 2553 for details.

MHOR | COMOR

includes the Mantel-Haenszel estimate of the common odds ratio in the output data set. The **CMH** option in the **TABLES** statement requests computation of this statistic, which is available for 2×2 tables. See the section “[Adjusted Odds Ratio and Relative Risk Estimates](#)” on page 2596 for details.

MHRC1

includes the Mantel-Haenszel estimate of the common relative risk (column 1) in the output data set. The **CMH** option in the **TABLES** statement requests computation of this statistic, which is available for 2×2 tables. See the section “[Adjusted Odds Ratio and Relative Risk Estimates](#)” on page 2596 for details.

MHRRC2

includes the Mantel-Haenszel estimate of the common relative risk (column 2) in the output data set. The **CMH** option in the **TABLES** statement requests computation of this statistic, which is available for 2×2 tables. See the section “[Adjusted Odds Ratio and Relative Risk Estimates](#)” on page 2596 for details.

N

includes the number of nonmissing observations in the output data set.

NMISS

includes the number of missing observations in the output data set. See the section “[Missing Values](#)” on page 2545 for details about how PROC FREQ handles missing values.

OR

includes the odds ratio (for 2×2 tables) in the output data set. The **MEASURES** and **REL RISK** options in the **TABLES** statement request this statistic. See the section “[Odds Ratio and Relative Risks for 2 x 2 Tables](#)” on page 2582 for details.

PCHI

includes the Pearson chi-square in the output data set for two-way tables. See the section “[Pearson Chi-Square Test for Two-Way Tables](#)” on page 2551 for details. For one-way tables, the **PCHI** option includes the chi-square goodness-of-fit test in the output data set. See the section “[Chi-Square Test for One-Way Tables](#)” on page 2551 for details. The **CHISQ** option in the **TABLES** statement requests computation of these statistics.

If you specify the **CHISQ(WARN=OUTPUT)** option in the **TABLES** statement, the **PCHI** option also includes the variable **WARN_PCHI** in the output data set. This variable indicates the validity warning for the asymptotic Pearson chi-square test.

PCORR

includes the Pearson correlation coefficient in the output data set. The **MEASURES** option in the **TABLES** statement requests computation of the Pearson correlation. See the section “[Pearson Correlation Coefficient](#)” on page 2559 for details.

PHI

includes the phi coefficient in the output data set. The **CHISQ** option in the **TABLES** statement requests computation of the phi coefficient. See the section “[Phi Coefficient](#)” on page 2555 for details.

PLCORR

includes the polychoric correlation coefficient in the output data set. For 2×2 tables, this statistic is known as the tetrachoric correlation coefficient. The **PLCORR** option in the **TABLES** statement requests computation of the polychoric correlation. See the section “[Polychoric Correlation](#)” on page 2562 for details.

RDIF1

includes the column 1 risk difference (row 1 – row 2) in the output data set. The **RISKDIFF** option in the **TABLES** statement requests computation of risks and risk differences, which are available for 2×2 tables. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

RDIF2

includes the column 2 risk difference (row 1 – row 2) in the output data set. The **RISKDIFF** option in the **TABLES** statement requests computation of risks and risk differences, which are available for 2×2 tables. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

RELRIK

includes the column 1 and column 2 relative risks (for 2×2 tables) in the output data set. The **MEASURES** and **RELRIK** options in the **TABLES** statement request these statistics. See the section “[Odds Ratio and Relative Risks for 2 x 2 Tables](#)” on page 2582 for details.

RISKDIFF

includes risks (binomial proportions) and risk differences for 2×2 tables in the output data set. These statistics include the row 1 risk, row 2 risk, total (overall) risk, and risk difference (row 1 – row 2) for column 1 and column 2. The **RISKDIFF** option in the **TABLES** statement requests computation of these statistics. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

RISKDIFF1

includes column 1 risks (binomial proportions) and risk differences for 2×2 tables in the output data set. These statistics include the row 1 risk, row 2 risk, total (overall) risk, and risk difference (row 1 – row 2). The **RISKDIFF** option in the **TABLES** statement requests computation of these statistics. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

RISKDIFF2

includes column 2 risks (binomial proportions) and risk differences for 2×2 tables in the output data set. These statistics include the row 1 risk, row 2 risk, total (overall) risk, and risk difference (row 1 – row 2). The **RISKDIFF** option in the **TABLES** statement requests computation of these statistics. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

RRC1 | RELRIK1

includes the column 1 relative risk in the output data set. The **MEASURES** and **RELRIK** options in the **TABLES** statement request relative risks, which are available for 2×2 tables. See the section “[Odds Ratio and Relative Risks for 2 x 2 Tables](#)” on page 2582 for details.

RRC2 | RELRIK2

includes the column 2 relative risk in the output data set. The **MEASURES** and **RELRIK** options in the **TABLES** statement request relative risks, which are available for 2×2 tables. See the section “[Odds Ratio and Relative Risks for 2 x 2 Tables](#)” on page 2582 for details.

RSK1 | RISK1

includes the overall column 1 risk in the output data set. The **RISKDIFF** option in the **TABLES** statement requests computation of risks and risk differences, which are available for 2×2 tables. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

RSK11 | RISK11

includes the column 1 risk for row 1 in the output data set. The **RISKDIFF** option in the **TABLES** statement requests computation of risks and risk differences, which are available for 2×2 tables. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

RSK12 | RISK12

includes the column 2 risk for row 1 in the output data set. The **RISKDIFF** option in the **TABLES** statement requests computation of risks and risk differences, which are available for 2×2 tables. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

RSK2 | RISK2

includes the overall column 2 risk in the output data set. The **RISKDIFF** option in the **TABLES** statement requests computation of risks and risk differences. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

RSK21 | RISK21

includes the column 1 risk for row 2 in the output data set. The **RISKDIFF** option in the **TABLES** statement requests computation of risks and risk differences, which are available for 2×2 tables. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

RSK22 | RISK22

includes the column 2 risk for row 2 in the output data set. The **RISKDIFF** option in the **TABLES** statement requests computation of risks and risk differences, which are available for 2×2 tables. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

SCORR

includes the Spearman correlation coefficient in the output data set. The **MEASURES** option in the **TABLES** statement requests computation of the Spearman correlation. See the section “[Spearman Rank Correlation Coefficient](#)” on page 2560 for details.

SMDCR

includes Somers’ $D(C|R)$ in the output data set. The **MEASURES** option in the **TABLES** statement requests computation of Somers’ D . See the section “[Somers’ \$D\$](#) ” on page 2559 for details.

SMDRC

includes Somers’ $D(R|C)$ in the output data set. The **MEASURES** option in the **TABLES** statement requests computation of Somers’ D . See the section “[Somers’ \$D\$](#) ” on page 2559 for details.

STUTC | TAUC

includes Stuart’s tau- c in the output data set. The **MEASURES** option in the **TABLES** statement requests computation of tau- c . See the section “[Stuart’s Tau- \$c\$](#) ” on page 2558 for details.

TREND

includes the Cochran-Armitage test for trend in the output data set. The **TREND** option in the **TABLES** statement requests computation of the trend test. This test is available for tables of dimension $2 \times C$ or $R \times 2$. See the section “[Cochran-Armitage Test for Trend](#)” on page 2585 for details.

TSYMM | BOWKER

includes Bowker’s test of symmetry in the output data set. The **AGREE** option in the **TABLES** statement requests computation of Bowker’s test. See the section “[Bowker’s Test of Symmetry](#)” on page 2588 for details.

U

includes the uncertainty coefficient (symmetric) in the output data set. The **MEASURES** option in the **TABLES** statement requests computation of the uncertainty coefficient. See the section “[Uncertainty Coefficient \(Symmetric\)](#)” on page 2565 for details.

UCR

includes the asymmetric uncertainty coefficient $U(C|R)$ in the output data set. The **MEASURES** option in the **TABLES** statement requests computation of the uncertainty coefficient. See the section “[Uncertainty Coefficients \(Asymmetric\)](#)” on page 2564 for details.

URC

includes the asymmetric uncertainty coefficient $U(R|C)$ in the output data set. The **MEASURES** option in the **TABLES** statement requests computation of the uncertainty coefficient. See the section “[Uncertainty Coefficients \(Asymmetric\)](#)” on page 2564 for details.

WTKAP

includes the weighted kappa coefficient in the output data set. The **AGREE** option in the **TABLES** statement requests computation of weighted kappa, which is available for square tables larger than 2×2 . For multiway tables, the **WTKAP** option also includes the overall weighted kappa coefficient in the output data set. See the sections “[Weighted Kappa Coefficient](#)” on page 2590 and “[Overall Kappa Coefficient](#)” on page 2591 for details.

TABLES Statement

TABLES *requests* *</ options>* ;

The **TABLES** statement requests one-way to n -way frequency and crosstabulation tables and statistics for those tables.

If you omit the **TABLES** statement, PROC FREQ generates one-way frequency tables for all data set variables that are not listed in the other statements.

The following argument is required in the **TABLES** statement.

requests

specify the frequency and crosstabulation tables to produce. A request is composed of one variable name or several variable names separated by asterisks. To request a one-way frequency table, use a single variable. To request a two-way crosstabulation table, use an asterisk between two variables. To request a multiway table (an n -way table, where $n > 2$), separate the desired variables with asterisks. The unique values of these variables form the rows, columns, and strata of the table. You can include up to 50 variables in a single multiway table request.

For two-way to multiway tables, the values of the last variable form the crosstabulation table columns, while the values of the next-to-last variable form the rows. Each level (or combination of levels) of the other variables forms one stratum. PROC FREQ produces a separate crosstabulation table for each stratum. For example, a specification of $A*B*C*D$ in a **TABLES** statement produces k tables, where k is the number of different combinations of values for A and B. Each table lists the values for C down the side and the values for D across the top.

You can use multiple TABLES statements in the PROC FREQ step. PROC FREQ builds all the table requests in one pass of the data, so that there is essentially no loss of efficiency. You can also specify any number of table requests in a single TABLES statement. To specify multiple table requests quickly, use a grouping syntax by placing parentheses around several variables and joining other variables or variable combinations. For example, the statements shown in Table 38.8 illustrate grouping syntax.

Table 38.8 Grouping Syntax

TABLES Request	Equivalent to
A*(B C)	A*B A*C
(A B)*(C D)	A*C B*C A*D B*D
(A B C)*D	A*D B*D C*D
A -- C	A B C
(A -- C)*D	A*D B*D C*D

The TABLES statement variables are one or more variables from the DATA= input data set. These variables can be either character or numeric, but the procedure treats them as categorical variables. PROC FREQ uses the formatted values of the TABLES variable to determine the categorical variable levels. So if you assign a format to a variable with a FORMAT statement, PROC FREQ formats the values before dividing observations into the levels of a frequency or crosstabulation table. See the FORMAT procedure in the *Base SAS Procedures Guide* and the FORMAT statement and SAS formats in *SAS Formats and Informats: Reference*.

If you use PROC FORMAT to create a user-written format that combines missing and nonmissing values into one category, PROC FREQ treats the entire category of formatted values as missing. See the discussion in the section “[Grouping with Formats](#)” on page 2544 for more information.

By default, the frequency or crosstabulation table lists the values of both character and numeric variables in ascending order based on internal (unformatted) variable values. You can change the order of the values in the table by specifying the [ORDER=](#) option in the PROC FREQ statement. To list the values in ascending order by formatted value, use ORDER=FORMATTED.

Without Options

If you request a one-way frequency table for a variable without specifying options, PROC FREQ produces frequencies, cumulative frequencies, percentages of the total frequency, and cumulative percentages for each value of the variable. If you request a two-way or an *n*-way crosstabulation table without specifying options, PROC FREQ produces crosstabulation tables that include cell frequencies, cell percentages of the total frequency, cell percentages of row frequencies, and cell percentages of column frequencies. The procedure excludes observations with missing values from the table but displays the total frequency of missing observations below each table.

Options

Table 38.9 lists the *options* available in the TABLES statement. Descriptions of the *options* follow in alphabetical order.

Table 38.9 TABLES Statement Options

Option	Description
Control Statistical Analysis	
AGREE	Requests tests and measures of classification agreement
ALL	Requests tests and measures of association produced by the CHISQ , MEASURES , and CMH options
ALPHA=	Sets the confidence level for confidence limits
BINOMIAL	Requests binomial proportions, confidence limits, and tests for one-way tables
CHISQ	Requests chi-square tests and measures based on chi-square
CL	Requests confidence limits for MEASURES statistics
CMH	Requests all Cochran-Mantel-Haenszel statistics
CMH1	Requests CMH correlation statistic, adjusted odds ratios, and adjusted relative risks
CMH2	Requests CMH correlation and row mean scores (ANOVA) statistics, adjusted odds ratios, and adjusted relative risks
CONVERGE=	Specifies convergence criterion for polychoric correlation
FISHER	Requests Fisher's exact test for tables larger than 2×2
GAILSIMON	Requests Gail-Simon test for qualitative interactions
JT	Requests Jonckheere-Terpstra test
MAXITER=	Specifies maximum number of iterations for polychoric correlation
MEASURES	Requests measures of association
MISSING	Treats missing values as nonmissing
PLCORR	Requests polychoric correlation
RELRISK	Requests odds ratios and relative risks for 2×2 tables
RISKDIFF	Requests risks and risk differences for 2×2 tables
SCORES=	Specifies the type of row and column scores
TREND	Requests Cochran-Armitage test for trend
Control Additional Table Information	
CELLCHI2	Displays cell contributions to the Pearson chi-square statistic
CUMCOL	Displays cumulative column percentages
DEVIATION	Displays deviations of cell frequencies from expected values
EXPECTED	Displays expected cell frequencies
MISSPRINT	Displays missing value frequencies
SPARSE	Includes all possible combinations of variable levels in the LIST table and OUT= data set
STDRES	Displays standardized residuals in the CROSSLIST table
TOTPCT	Displays percentages of total frequency for n -way tables ($n > 2$)
Control Displayed Output	
CONTENTS=	Specifies the contents label for crosstabulation tables
CROSSLIST	Displays crosstabulation tables in ODS column format
FORMAT=	Formats the frequencies in crosstabulation tables
LIST	Displays two-way to n -way tables in list format
MAXLEVELS=	Specifies maximum number of levels to display in one-way tables
NOCOL	Suppresses display of column percentages

Table 38.9 *continued*

Option	Description
NOCUM	Suppresses display of cumulative frequencies and percentages
NOFREQ	Suppresses display of frequencies
NOPERCENT	Suppresses display of percentages
NOPRINT	Suppresses display of crosstabulation tables but displays statistics
NOROW	Suppresses display of row percentages
NOSPARE	Suppresses zero frequency levels in the CROSSLIST table, LIST table, and OUT= data set
NOWARN	Suppresses log warning message for the chi-square test
PRINTKWT	Displays kappa coefficient weights
SCOROUT	Displays row and column scores
Produce Statistical Graphics	
PLOTS=	Requests plots from ODS Graphics
Create an Output Data Set	
OUT=	Names an output data set to contain frequency counts
OUTCUM	Includes cumulative frequencies and percentages in the output data set for one-way tables
OUTEXPECT	Includes expected frequencies in the output data set
OUTPCT	Includes row, column, and two-way table percentages in the output data set

You can specify the following *options* in a TABLES statement.

AGREE <(WT=FC)>

requests tests and measures of classification agreement for square tables. The AGREE option provides McNemar's test for 2×2 tables and Bowker's test of symmetry for square tables with more than two response categories. The AGREE option also produces the simple kappa coefficient, the weighted kappa coefficient, their asymptotic standard errors, and their confidence limits. When there are multiple strata, the AGREE option provides overall simple and weighted kappas as well as tests for equal kappas among strata. When there are multiple strata and two response categories, PROC FREQ computes Cochran's Q test. See the section "[Tests and Measures of Agreement](#)" on page 2588 for details about these statistics.

If you specify the WT=FC option in parentheses after the AGREE option, PROC FREQ uses Fleiss-Cohen weights to compute the weighted kappa coefficient. By default, PROC FREQ uses Cicchetti-Allison weights. See the section "[Weighted Kappa Coefficient](#)" on page 2590 for details. You can specify the [PRINTKWT](#) option to display the kappa coefficient weights.

AGREE statistics are computed only for square tables, where the number of rows equals the number of columns. If your table is not square due to observations with zero weights, you can specify the [ZEROS](#) option in the WEIGHT statement to include these observations. For more details, see the section "[Tables with Zero Rows and Columns](#)" on page 2592.

You can use the [TEST](#) statement to request asymptotic tests for the simple and weighted kappa coefficients. You can request exact p -values for the simple and weighted kappa coefficient tests, as well

as for McNemar's test, by specifying the corresponding options in the **EXACT** statement. See the section “[Exact Statistics](#)” on page 2601 for more information.

ALL

requests all tests and measures that are produced by the **CHISQ**, **MEASURES**, and **CMH** options. You can control the number of CMH statistics to compute by specifying the **CMH1** or **CMH2** option.

ALPHA= α

specifies the level of confidence limits. The value of α must be between 0 and 1, and the default is 0.05. A confidence level of α produces $100(1 - \alpha)\%$ confidence limits. The default of ALPHA=0.05 produces 95% confidence limits.

ALPHA= applies to confidence limits that are requested by TABLES statement options. There is a separate **ALPHA=** option in the EXACT statement that sets the level of confidence limits for Monte Carlo estimates of exact p -values, which you request by specifying the **MC** option in the EXACT statement.

BINOMIAL <(binomial-options)>

requests the binomial proportion for one-way tables. When you specify the BINOMIAL option, by default PROC FREQ also provides the asymptotic standard error, asymptotic Wald and exact (Clopper-Pearson) confidence limits, and the asymptotic equality test for the binomial proportion.

You can specify *binomial-options* in parentheses after the BINOMIAL option. The **LEVEL=** *binomial-option* identifies the variable level for which to compute the proportion. If you do not specify LEVEL=, PROC FREQ computes the proportion for the first level that appears in the output. The **P=** *binomial-option* specifies the null proportion for the binomial tests. If you do not specify P=, PROC FREQ uses P=0.5 by default.

You can also specify *binomial-options* to request additional tests and confidence limits for the binomial proportion. The **EQUIV**, **NONINF**, and **SUP** *binomial-options* request tests of equivalence, noninferiority, and superiority, respectively. The **CL=** *binomial-option* requests confidence limits for the binomial proportion. [Table 38.10](#) summarizes the *binomial-options*.

Available confidence limits for the binomial proportion include Agresti-Coull, exact (Clopper-Pearson), Jeffreys, Wald, and Wilson (score) confidence limits. You can specify more than one type of binomial confidence limits in the same analysis. If you do not specify any confidence limit requests, PROC FREQ computes Wald asymptotic confidence limits and exact (Clopper-Pearson) confidence limits by default. The **ALPHA=** option determines the confidence level, and the default of ALPHA=0.05 produces 95% confidence limits for the binomial proportion.

As part of the noninferiority, superiority, and equivalence analyses, PROC FREQ provides test-based confidence limits that have a confidence coefficient of $100(1 - 2\alpha)\%$ (Schuirmann 1999). The **ALPHA=** option determines the confidence level, and the default of ALPHA=0.05 produces 90% confidence limits. See the sections “[Noninferiority Test](#)” on page 2569 and “[Equivalence Test](#)” on page 2570 for details.

To request exact tests for the binomial proportion, specify the **BINOMIAL** option in the **EXACT** statement. PROC FREQ then computes exact p -values for all binomial tests that you request with *binomial-options*, which can include tests of noninferiority, superiority, and equivalence, in addition to the test of equality.

See the section “[Binomial Proportion](#)” on page 2565 for details.

Table 38.10 BINOMIAL Options

Option	Description
LEVEL=	Specifies the variable level
P=	Specifies the null proportion
CORRECT	Requests continuity correction
Request Confidence Limits	
CL=AGRESTICOULL AC	Requests Agresti-Coull confidence limits
CL=ALL	Requests all confidence limits
CL=EXACT CLOPPERPEARSON	Requests Clopper-Pearson confidence limits
CL=JEFFREYS J	Requests Jeffreys confidence limits
CL=WALD	Requests Wald confidence limits
CL=WILSON W	Requests Wilson (score) confidence limits
Request Tests	
EQUIV EQUIVALENCE	Requests an equivalence test
NONINF NONINFERIORITY	Requests a noninferiority test
SUP SUPERIORITY	Requests a superiority test
MARGIN=	Specifies the test margin
VAR=SAMPLE NULL	Specifies the test variance

You can specify the following *binomial-options* in parentheses after the BINOMIAL option:

CL=type | (types)

requests confidence limits for the binomial proportion. You can specify one or more *types* of confidence limits. When you specify only one *type*, you can omit the parentheses around the request.

PROC FREQ displays the confidence limits in the “Binomial Confidence Limits” table. The ALPHA= option determines the level of the confidence limits that the CL= *binomial-option* provides. The default of ALPHA=0.05 produces 95% confidence limits for the binomial proportion. This differs from the test-based confidence limits that are provided with the equivalence, noninferiority, and superiority tests (EQUIV, NONINF, and SUP), which have a confidence coefficient of $100(1-2\alpha)\%$ (Schuirmann 1999). See the sections “Equivalence Test” on page 2570 and “Noninferiority Test” on page 2569 for details.

You can specify the CL= *binomial-option* with or without requests for binomial tests. The confidence limits that CL= produces do not depend on the tests that you request and do not use the value of the test margin (which you specify by using the MARGIN= *binomial-option*).

The following *types* of binomial confidence limits are available:

AGRESTICOULL | AC

requests Agresti-Coull confidence limits for the binomial proportion. See the section “Agresti-Coull Confidence Limits” on page 2566 for details.

ALL

requests all available types of confidence limits for the binomial proportion. These include the following: Agresti-Coull, exact (Clopper-Pearson), Jeffreys, Wald, and Wilson (score) confidence limits.

EXACT | CLOPPERPEARSON

requests exact (Clopper-Pearson) confidence limits for the binomial proportion. See the section “[Exact \(Clopper-Pearson\) Confidence Limits](#)” on page 2567 for details. If you do not request any binomial confidence limits by specifying the `CL= binomial-option`, PROC FREQ produces Wald and exact (Clopper-Pearson) confidence limits by default. To request exact tests for the binomial proportion, specify the `BINOMIAL` option in the **EXACT** statement.

JEFFREYS | J

requests Jeffreys confidence limits for the binomial proportion. See the section “[Jeffreys Confidence Limits](#)” on page 2566 for details.

WALD < (CORRECT) >

requests Wald confidence limits for the binomial proportion. See the section “[Wald Confidence Limits](#)” on page 2566 for details. If you do not request any binomial confidence limits by specifying the `CL= binomial-option`, PROC FREQ produces Wald and exact (Clopper-Pearson) confidence limits by default.

If you specify `CL=WALD(CORRECT)`, the Wald confidence limits include a continuity correction. If you specify the `CORRECT binomial-option`, the Wald confidence limits and the Wald tests include continuity corrections.

WILSON | W | SCORE < (CORRECT) >

requests Wilson confidence limits for the binomial proportion. These are also known as *score* confidence limits. See the section “[Wilson \(Score\) Confidence Limits](#)” on page 2567 for details.

If you specify `CL=WILSON(CORRECT)` or the `CORRECT binomial-option`, the Wilson confidence limits include a continuity correction.

CORRECT

includes a continuity correction in the Wald confidence limits, Wald tests, and Wilson confidence limits.

You can request continuity corrections individually for Wald or Wilson confidence limits by specifying the `CL=WALD(CORRECT)` or `CL=WILSON(CORRECT) binomial-option`, respectively.

EQUIV | EQUIVALENCE

requests a test of equivalence for the binomial proportion. See the section “[Equivalence Test](#)” on page 2570 for details. You can specify the equivalence test margins, the null proportion, and the variance type with the `MARGIN=`, `P=`, and `VAR= binomial-options`, respectively. To request an exact equivalence test, specify the `BINOMIAL` option in the **EXACT** statement.

LEVEL=level-number | 'level-value'

specifies the variable level for the binomial proportion. By default, PROC FREQ computes the proportion of observations for the first variable level that appears in the output. To request a different level, use `LEVEL=level-number` or `LEVEL='level-value'`, where *level-number* is the variable level's number or order in the output, and *level-value* is the formatted value of the variable level. The value of *level-number* must be a positive integer. You must enclose *level-value* in single quotes.

MARGIN=*value* | (*lower,upper*)

specifies the margin for the noninferiority, superiority, and equivalence tests, which you request with the **NONINF**, **SUP**, and **EQUIV** *binomial-options*, respectively. If you do not specify **MARGIN=**, PROC FREQ uses a margin of 0.2 by default.

For noninferiority and superiority tests, specify a single *value* for the **MARGIN=** option. The **MARGIN=** *value* must be a positive number. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC FREQ converts that number to a proportion. The procedure treats the value 1 as 1%.

For noninferiority and superiority tests, the test limits must be between 0 and 1. The limits are determined by the null proportion value (which you can specify with the **P=** *binomial-option*) and by the margin value. The noninferiority limit equals the null proportion minus the margin. By default, the null proportion equals 0.5 and the margin equals 0.2, which gives a noninferiority limit of 0.3. The superiority limit equals the null proportion plus the margin, which is 0.7 by default.

For an equivalence test, you can specify a single **MARGIN=** *value*, or you can specify both *lower* and *upper* values. If you specify a single **MARGIN=** *value*, it must be a positive number, as described previously. If you specify a single **MARGIN=** *value* for an equivalence test, PROC FREQ uses $-value$ as the lower margin and *value* as the upper margin for the test. If you specify both *lower* and *upper* values for an equivalence test, you can specify them in proportion form as numbers between -1 or 1. Or you can specify them in percentage form as numbers between -100 and 100, and PROC FREQ converts the numbers to proportions. The value of *lower* must be less than the value of *upper*.

The equivalence limits must be between 0 and 1. The equivalence limits are determined by the null proportion value (which you can specify with the **P=** *binomial-option*) and by the margin values. The lower equivalence limit equals the null proportion plus the lower margin. By default, the null proportion equals 0.5 and the lower margin equals -0.2 , which gives a lower equivalence limit of 0.3. The upper equivalence limit equals the null proportion plus the upper margin, which is 0.7 by default.

See the sections “Noninferiority Test” on page 2569 and “Equivalence Test” on page 2570 for details.

NONINF | **NONINFERIORITY**

requests a test of noninferiority for the binomial proportion. See the section “Noninferiority Test” on page 2569 for details. You can specify the noninferiority test margin, the null proportion, and the variance type with the **MARGIN=**, **P=**, and **VAR=** *binomial-options*, respectively. To request an exact noninferiority test, specify the **BINOMIAL** option in the **EXACT** statement.

P=*value*

specifies the null hypothesis proportion for the binomial tests. If you omit the **P=** option, PROC FREQ uses 0.5 as the null proportion. The null proportion *value* must be a positive number. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC FREQ converts that number to a proportion. The procedure treats the value 1 as 1%.

SUP | SUPERIORITY

requests a test of superiority for the binomial proportion. See the section “[Superiority Test](#)” on page 2570 for details. You can specify the superiority test margin, the null proportion, and the variance type with the **MARGIN=**, **P=**, and **VAR=** *binomial-options*, respectively. To request an exact superiority test, specify the **BINOMIAL** option in the **EXACT** statement.

VAR=SAMPLE | NULL

specifies the type of variance estimate to use in the Wald tests of noninferiority, superiority, and equivalence. The default is **VAR=SAMPLE**, which estimates the variance from the sample proportion. **VAR=NULL** uses a test-based variance that is computed from the null hypothesis proportion (which is specified by the **P=** *binomial-option*). See the sections “[Noninferiority Test](#)” on page 2569 and “[Equivalence Test](#)” on page 2570 for details.

CELLCHI2

displays each crosstabulation table cell’s contribution to the total Pearson chi-square statistic. The cell contribution is computed as

$$(\text{frequency} - \text{expected})^2 / \text{expected}$$

where *frequency* is the table cell frequency or count and *expected* is the expected cell frequency, which is computed under the null hypothesis that the row and column variables are independent. See the section “[Pearson Chi-Square Test for Two-Way Tables](#)” on page 2551 for details.

The **CELLCHI2** option has no effect for one-way tables or for tables that are displayed with the **LIST** option.

CHISQ <(chisq-options)>

requests chi-square tests of homogeneity or independence and measures of association that are based on the chi-square statistic. For two-way tables, the chi-square tests include the Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square tests. The chi-square measures include the phi coefficient, contingency coefficient, and Cramér’s *V*. For 2×2 tables, the **CHISQ** option also provides Fisher’s exact test and the continuity-adjusted chi-square test. See the section “[Chi-Square Tests and Statistics](#)” on page 2550 for details.

For one-way tables, the **CHISQ** option provides the Pearson chi-square goodness-of-fit test. You can also request the likelihood ratio goodness-of-fit test for one-way tables by specifying the **LRCHISQ** *chisq-option* in parentheses after the **CHISQ** option. By default, the one-way chi-square tests are based on the null hypothesis of equal proportions. Alternatively, you can provide null hypothesis proportions or frequencies by specifying the **TESTP=** or **TESTF=** *chisq-option*, respectively. See the section “[Chi-Square Test for One-Way Tables](#)” on page 2551 for more information.

To request Fisher’s exact test for tables larger than 2×2 , specify the **FISHER** option in the **EXACT** statement. Exact *p*-values are also available for the Pearson, likelihood ratio, and Mantel-Haenszel chi-square tests. See the description of the **EXACT** statement for more information.

You can specify the following *chisq-options* in parentheses after the **CHISQ** option:

DF=df

specifies the degrees of freedom for the chi-square tests. The value of *df* must not be zero. If the value of *df* is positive, PROC FREQ uses *df* as the degrees of freedom for the chi-square tests. If the value of *df* is negative, PROC FREQ uses *df* to adjust the default degrees of freedom for the chi-square tests.

By default for one-way tables, the value of *df* is $(n - 1)$, where n is the number of variable levels in the table. By default for two-way tables, the value of *df* is $(r - 1)(c - 1)$, where r is the number of rows in the table and c is the number of columns. See the sections “[Chi-Square Test for One-Way Tables](#)” on page 2551 and “[Chi-Square Tests and Statistics](#)” on page 2550 for more information.

If you specify a negative value of *df*, PROC FREQ adjusts the default degrees of freedom by adding the (negative) value of *df* to the default value to produce the adjusted degrees of freedom. The adjusted degrees of freedom must be positive.

The *DF= chisq-option* specifies or adjusts the degrees of freedom for the following chi-square tests: the Pearson and likelihood ratio goodness-of-fit tests for one-way tables; and the Pearson, likelihood ratio, and Mantel-Haenszel chi-square tests for two-way tables.

LRCHISQ

requests the likelihood ratio goodness-of-fit test for one-way tables. See the section “[Likelihood Ratio Chi-Square Test for One-Way Tables](#)” on page 2552 for more information.

By default, this test is based on the null hypothesis of equal proportions. You can provide null hypothesis proportions or frequencies by specifying the *TESTP=* or *TESTF= chisq-option*, respectively. You can request an exact likelihood ratio goodness-of-fit test by specifying the *LRCHI* option in the EXACT statement.

TESTF=(values) | SAS-data-set

specifies null hypothesis frequencies for the one-way chi-square goodness-of-fit tests. See the section “[Chi-Square Test for One-Way Tables](#)” on page 2551 for details. You can list the null frequencies as *values* in parentheses after *TESTF=*. Or you can provide the null frequencies in a secondary input data set by specifying *TESTF=SAS-data-set*. The *TESTF=SAS-data-set* cannot be the same data set that you specify in the *DATA=* option. You can specify only one *TESTF=* or *TESTP=* data set in a single invocation of the procedure.

If you list the null frequencies as *values*, you can separate the *values* with blanks or commas. The *values* must be positive numbers. The number of *values* must equal the number of variable levels in the one-way table. The sum of the *values* must equal the total frequency for the one-way table. Order the *values* to match the order in which the corresponding variable levels appear in the one-way frequency table.

If you provide the null frequencies in a secondary input data set (*TESTF=SAS-data-set*), the variable that contains the null frequencies should be named *_TESTF_*, *TestFrequency*, or *Frequency*. The null frequencies must be positive numbers. The number of frequencies must equal the number of levels in the one-way frequency table, and the sum of the frequencies must equal the total frequency for the one-way table. Order the null frequencies in the data set to match the order in which the corresponding variable levels appear in the one-way frequency table.

TESTP=(values) | SAS-data-set

specifies null hypothesis proportions for the one-way chi-square goodness-of-fit tests. See the section “[Chi-Square Test for One-Way Tables](#)” on page 2551 for details. You can list the null proportions as *values* in parentheses after *TESTP=*. Or you can provide the null proportions in a secondary input data set by specifying *TESTP=SAS-data-set*. The *TESTP=SAS-data-set* cannot be the same data set that you specify in the *DATA=* option. You can specify only one *TESTF=* or *TESTP=* data set in a single invocation of the procedure.

If you list the null proportions as *values*, you can separate the *values* with blanks or commas. The *values* must be positive numbers. The number of *values* must equal the number of variable levels in the one-way table. Order the *values* to match the order in which the corresponding variable levels appear in the one-way frequency table. You can specify *values* in probability form as numbers between 0 and 1, where the proportions sum to 1. Or you can specify *values* in percentage form as numbers between 0 and 100, where the percentages sum to 100.

If you provide the null proportions in a secondary input data set (TESTP=SAS-data-set), the variable that contains the null proportions should be named _TESTP_, TestPercent, or Percent. The null proportions must be positive numbers. The number of proportions must equal the number of levels in the one-way frequency table. You can provide the proportions in probability form as numbers between 0 and 1, where the proportions sum to 1. Or you can provide the proportions in percentage form as numbers between 0 and 100, where the percentages sum to 100. Order the null proportions in the data set to match the order in which the corresponding variable levels appear in the one-way frequency table.

WARN=*value* | (*values*)

controls the warning message for the validity of the asymptotic Pearson chi-square test. By default, PROC FREQ displays a warning message when more than 20% of the table cells have expected frequencies that are less than 5. If you specify the **NOPRINT** option in the **PROC FREQ** statement, the procedure displays the warning in the log; otherwise, the procedure displays the warning as a footnote in the chi-square table. You can use the WARN= option to suppress the warning and to include a warning indicator in the output data set.

The WARN= option can take one or more of the following values. If you specify more than one value, enclose the values in parentheses after WARN=. For example, **warn = (output noprint)**.

Value of WARN=	Description
OUTPUT	Adds a warning indicator variable to the output data set
NOLOG	Suppresses the chi-square warning message in the log
NOPRINT	Suppresses the chi-square warning message in the display
NONE	Suppresses the chi-square warning message entirely

If you specify the WARN=OUTPUT option, the ODS output data set ChiSq contains a variable named Warning that equals 1 for the Pearson chi-square observation when more than 20% of the table cells have expected frequencies that are less than 5 and equals 0 otherwise. If you specify WARN=OUTPUT and also specify the CHISQ option in the **OUTPUT** statement, the statistics output data set contains a variable named WARN_PCHI that indicates the warning.

The WARN=NOLOG option has the same effect as the **NOWARN** option in the TABLES statement.

CL

requests confidence limits for the **MEASURES** statistics. If you omit the MEASURES option, the CL option invokes MEASURES. You can set the level of the confidence limits by using the **ALPHA=** option. The default of ALPHA=0.5 produces 95% confidence limits. See the sections “**Measures of Association**” on page 2556 and “**Confidence Limits**” on page 2556 for more information.

CMH <(cmh-options)>

requests Cochran-Mantel-Haenszel statistics, which test for association between the row and column variables after adjusting for the remaining variables in a multiway table. The Cochran-Mantel-Haenszel statistics include the nonzero correlation statistic, the row mean scores (ANOVA) statistic, and the general association statistic. In addition, for 2×2 tables, the CMH option provides the adjusted Mantel-Haenszel and logit estimates of the odds ratio and relative risks, together with their confidence limits. For stratified 2×2 tables, the CMH option provides the Breslow-Day test for homogeneity of odds ratios. (To request Tarone's adjustment for the Breslow-Day test, specify the **BDT** *cmh-option*.) See the section "[Cochran-Mantel-Haenszel Statistics](#)" on page 2592 for details.

You can use the **CMH1** or **CMH2** option to control the number of CMH statistics that PROC FREQ computes.

For stratified 2×2 tables, you can request Zelen's exact test for equal odds ratios by specifying the **EQOR** option in the **EXACT** statement. See the section "[Zelen's Exact Test for Equal Odds Ratios](#)" on page 2598 for details. You can request exact confidence limits for the common odds ratio by specifying the **COMOR** option in the **EXACT** statement. This option also provides a common odds ratio test. See the section "[Exact Confidence Limits for the Common Odds Ratio](#)" on page 2599 for details.

You can specify the following *cmh-options* in parentheses after the CMH option. These *cmh-options*, which apply to stratified 2×2 tables, are also available with the **CMH1** or **CMH2** option.

BDT

requests Tarone's adjustment in the Breslow-Day test for homogeneity of odds ratios. See the section "[Breslow-Day Test for Homogeneity of the Odds Ratios](#)" on page 2598 for details.

GAILSIMON | **GS** <(COLUMN=1 | 2)>

requests the Gail-Simon test for qualitative interaction, which applies to stratified 2×2 tables. See the section "[Gail-Simon Test for Qualitative Interactions](#)" on page 2601 for details.

The **COLUMN=** option specifies the column of the risk differences to use in computing the Gail-Simon test. By default, PROC FREQ uses column 1 risk differences. If you specify **COLUMN=2**, PROC FREQ uses column 2 risk differences.

The **GAILSIMON** *cmh-option* has the same effect as the **GAILSIMON** option in the **TABLES** statement.

MANTELFLEISS | **MF**

requests the Mantel-Fleiss criterion for the Mantel-Haenszel statistic for stratified 2×2 tables. See the section "[Mantel-Fleiss Criterion](#)" on page 2595 for details.

CMH1 <(cmh-options)>

requests the Cochran-Mantel-Haenszel correlation statistic. This option does not provide the CMH row mean scores (ANOVA) statistic or the general association statistic, which are provided by the **CMH** option. For tables larger than 2×2 , the CMH1 option requires less memory than the CMH option, which can require an enormous amount of memory for large tables.

For 2×2 tables, the CMH1 option also provides the adjusted Mantel-Haenszel and logit estimates of the odds ratio and relative risks, together with their confidence limits. For stratified 2×2 tables, the CMH1 option provides the Breslow-Day test for homogeneity of odds ratios.

The *cmh-options* for CMH1 are the same as the *cmh-options* that are available with the CMH option. See the description of the **CMH** option for details.

CMH2 <(*cmh-options*)>

requests the Cochran-Mantel-Haenszel correlation statistic and the row mean scores (ANOVA) statistic. This option does not provide the CMH general association statistic, which is provided by the [CMH](#) option. For tables larger than 2×2 , the CMH2 option requires less memory than the CMH option, which can require an enormous amount of memory for large tables.

For 2×2 tables, the CMH1 option also provides the adjusted Mantel-Haenszel and logit estimates of the odds ratio and relative risks, together with their confidence limits. For stratified 2×2 tables, the CMH1 option provides the Breslow-Day test for homogeneity of odds ratios.

The *cmh-options* for CMH2 are the same as the *cmh-options* that are available with the CMH option. See the description of the [CMH](#) option for details.

CONTENTS='string'

specifies the label to use for crosstabulation tables in the contents file, the Results window, and the trace record. For information about output presentation, see the *SAS Output Delivery System: User's Guide*.

If you omit the CONTENTS= option, the contents label for crosstabulation tables is “Cross-Tabular Freq Table” by default.

Note that contents labels for all crosstabulation tables that are produced by a single TABLES statement use the same text. To specify different contents labels for different crosstabulation tables, request the tables in separate TABLES statements and use the CONTENTS= option in each TABLES statement.

To remove the crosstabulation table entry from the contents file, you can specify a null label with CONTENTS=“.”

The CONTENTS= option affects only contents labels for crosstabulation tables. It does not affect contents labels for other PROC FREQ tables.

To specify the contents label for any PROC FREQ table, you can use PROC TEMPLATE to create a customized table definition. The CONTENTS_LABEL attribute in the DEFINE TABLE statement of PROC TEMPLATE specifies the contents label for the table. See the chapter “The TEMPLATE Procedure” in the *SAS Output Delivery System: User's Guide* for more information.

CONVERGE=value

specifies the convergence criterion for computing the polychoric correlation, which you request by specifying the [PLCORR](#) option. The CONVERGE= *value* must be a positive number. By default, CONVERGE=0.0001. Iterative computation of the polychoric correlation stops when the convergence measure falls below *value* or when the number of iterations exceeds the [MAXITER=](#) value, whichever happens first. For parameter values that are less than 0.01, the procedure evaluates convergence by using the absolute difference instead of the relative difference. See the section “[Polychoric Correlation](#)” on page 2562 for details.

CROSSLIST <STDRES>

displays crosstabulation tables in ODS column format instead of the default crosstabulation cell format. In the CROSSLIST table display, the rows correspond to the crosstabulation table cells, and the columns correspond to descriptive statistics such as Frequency and Percent. The CROSSLIST table displays the same information as the default crosstabulation table, but it uses an ODS column format instead of the table cell format. See the section “[Multiway Tables](#)” on page 2611 for details about the contents of the CROSSLIST table.

You can control the contents of a CROSSLIST table by specifying the same options available for the default crosstabulation table. These include the [NOFREQ](#), [NOPERCENT](#), [NOROW](#), and [NOCOL](#) options. You can request additional information in a CROSSLIST table by specifying the [CELLCHI2](#),

DEVIATION, EXPECTED, MISSPRINT, and TOTPCT options. You can also display standardized residuals in a CROSSLIST table by specifying the CROSSLIST(STDRES) option (which is not available for the default crosstabulation table).

The FORMAT= and CUMCOL options have no effect on CROSSLIST tables. You cannot specify both the LIST option and the CROSSLIST option in the same TABLES statement.

For CROSSLIST tables, you can use the NOSPARSE option to suppress display of variable levels that have zero frequencies. By default, PROC FREQ displays all levels of the column variable within each level of the row variable, including any levels that have zero frequencies. By default for multiway tables displayed as CROSSLIST tables, the procedure displays all levels of the row variable for each stratum of the table, including any row levels with zero frequencies in the stratum.

You can specify the following *option* in parentheses after the CROSSLIST option:

STDRES

displays the standardized residuals of the table cells in the CROSSLIST table. The standardized residual is the ratio of (*frequency* – *expected*) to its standard error, where *frequency* is the table cell frequency and *expected* is the expected table cell frequency, which is computed under the null hypothesis that the row and column variables are independent. See the section “Standardized Residuals” on page 2552 for more information.

CUMCOL

displays the cumulative column percentages in the cells of the crosstabulation table. The CUMCOL option does not apply to crosstabulation tables produced with the LIST or CROSSLIST option.

DEVIATION

displays the deviation of the frequency from the expected frequency for each cell of the crosstabulation table. See the section “Pearson Chi-Square Test for Two-Way Tables” on page 2551 for details. The DEVIATION option does not apply to crosstabulation tables produced with the LIST option.

EXPECTED

displays the expected cell frequencies under the hypothesis of independence (or homogeneity) for crosstabulation tables. See the section “Pearson Chi-Square Test for Two-Way Tables” on page 2551 for details. The EXPECTED option does not apply to tables produced with the LIST option.

FISHER | EXACT

requests Fisher’s exact test for tables that are larger than 2×2 . (For 2×2 tables, the CHISQ option provides Fisher’s exact test.) This test is also known as the Freeman-Halton test. See the sections “Fisher’s Exact Test” on page 2554 and “Exact Statistics” on page 2601 for more information.

If you omit the CHISQ option in the TABLES statement, the FISHER option invokes CHISQ. You can also request Fisher’s exact test by specifying the FISHER option in the EXACT statement.

NOTE: PROC FREQ computes exact tests by using fast and efficient algorithms that are superior to direct enumeration. Exact tests are appropriate when a data set is small, sparse, skewed, or heavily tied. For some large problems, computation of exact tests might require a substantial amount of time and memory. Consider using asymptotic tests for such problems. Alternatively, when asymptotic methods might not be sufficient for such large problems, consider using Monte Carlo estimation of exact *p*-values. You can request Monte Carlo estimation by specifying the MC *computation-option* in the EXACT statement. See the section “Computational Resources” on page 2604 for more information.

FORMAT=*format-name*

specifies a format for the following crosstabulation table cell values: frequency, expected frequency, and deviation. PROC FREQ also uses the specified format to display the row and column total frequencies and the overall total frequency in crosstabulation tables.

You can specify any standard SAS numeric format or a numeric format defined with the FORMAT procedure. The format length must not exceed 24. If you omit the FORMAT= option, by default PROC FREQ uses the BEST6. format to display frequencies less than 1E6, and the BEST7. format otherwise.

The FORMAT= option applies only to crosstabulation tables displayed in the default format. It does not apply to crosstabulation tables produced with the [LIST](#) or [CROSSLIST](#) option.

To change display formats in any FREQ table, you can use PROC TEMPLATE. See the chapter “The TEMPLATE Procedure” in the *SAS Output Delivery System: User’s Guide* for more information.

GAILSIMON | GS <(COLUMN=1 | 2)>

requests the Gail-Simon test for qualitative interaction, which applies to stratified 2×2 tables. See the section “[Gail-Simon Test for Qualitative Interactions](#)” on page 2601 for details.

The COLUMN= option specifies the column of the risk differences to use in computing the Gail-Simon test. By default, PROC FREQ uses column 1 risk differences. If you specify COLUMN=2, PROC FREQ uses column 2 risk differences.

JT

requests the Jonckheere-Terpstra test. See the section “[Jonckheere-Terpstra Test](#)” on page 2586 for details. To request exact p -values for the Jonckheere-Terpstra test, specify the JT option in the EXACT statement. See the section “[Exact Statistics](#)” on page 2601 for more information.

LIST

displays two-way to n -way crosstabulation tables in a list format instead of the default crosstabulation cell format. The LIST option displays the entire multiway table in one table, instead of displaying a separate two-way table for each stratum. See the section “[Multiway Tables](#)” on page 2611 for details.

The LIST option is not available when you also specify statistical options. You must use the standard crosstabulation table display or the [CROSSLIST](#) display when you request statistical tests or measures.

MAXITER=*number*

specifies the maximum number of iterations for computing the polychoric correlation, which you request by specifying the [PLCORR](#) option. The value of *number* must be a positive integer. By default MAXITER=20. Iterative computation of the polychoric correlation stops when the number of iterations exceeds the MAXITER= value or when the convergence measure falls below the [CONVERGE=](#) value, whichever happens first. See the section “[Polychoric Correlation](#)” on page 2562 for details.

MAXLEVELS=*n*

specifies the maximum number of variable levels to display in one-way frequency tables. The value of n must be a positive integer. PROC FREQ displays the first n variable levels, matching the order in which the levels appear in the one-way frequency table. (The [ORDER=](#) option controls the order of the variable levels. By default, ORDER=INTERNAL, which orders the variable levels by unformatted value.)

The MAXLEVELS= option also applies to one-way frequency plots, which you can request by specifying the **PLOTS=FREQPLOT** option when ODS Graphics is enabled.

If you specify the **MISSPRINT** option to display missing levels in the frequency table, the MAXLEVELS= option displays the first n nonmissing levels.

The MAXLEVELS= option does not apply to the **OUT=** output data set, which includes all variable levels. The MAXLEVELS= option does not affect the computation of percentages, statistics, or tests for the one-way table; these values are based on the complete table.

MEASURES

requests measures of association. The MEASURES option provides the following statistics and their asymptotic standard errors: gamma, Kendall's tau- b , Stuart's tau- c , Somers' $D(C|R)$, Somers' $D(R|C)$, Pearson and Spearman correlation coefficients, lambda (symmetric and asymmetric), and uncertainty coefficients (symmetric and asymmetric). To request confidence limits for these measures of association, you can specify the **CL** option.

For 2×2 tables, the MEASURES option also provides the odds ratio, column 1 relative risk, column 2 relative risk, and the corresponding confidence limits. Alternatively, you can request the odds ratio and relative risks separately (without the other measures of association), by specifying the **REL RISK** option.

See the section “[Measures of Association](#)” on page 2556 for details.

You can use the **TEST** statement to request asymptotic tests for the following measures of association: gamma, Kendall's tau- b , Stuart's tau- c , Somers' $D(C|R)$, Somers' $D(R|C)$, and Pearson and Spearman correlation coefficients. You can use the **EXACT** statement to request exact confidence limits for the odds ratio, exact unconditional confidence limits for the relative risks, and exact tests for the following measures of association: Kendall's tau- b , Stuart's tau- c , Somers' $D(C|R)$ and $D(R|C)$, and Pearson and Spearman correlation coefficients. See the descriptions of the **TEST** and **EXACT** statements for more information.

MISSING

treats missing values as a valid nonmissing level for all TABLES variables. The MISSING option displays the missing levels in frequency and crosstabulation tables and includes them in all calculations of percentages, tests, and measures.

By default, if you do not specify the MISSING or **MISSPRINT** option, an observation is excluded from a table if it has a missing value for any of the variables in the TABLES request. When PROC FREQ excludes observations with missing values, it displays the total frequency of missing observations below the table. See the section “[Missing Values](#)” on page 2545 for more information.

MISSPRINT

displays missing value frequencies in frequency and crosstabulation tables but does not include the missing value frequencies in any computations of percentages, tests, or measures.

By default, if you do not specify the **MISSING** or **MISSPRINT** option, an observation is excluded from a table if it has a missing value for any of the variables in the TABLES request. When PROC FREQ excludes observations with missing values, it displays the total frequency of missing observations below the table. See the section “[Missing Values](#)” on page 2545 for more information.

NOCOL

suppresses the display of column percentages in crosstabulation table cells.

NOCUM

suppresses the display of cumulative frequencies and percentages in one-way frequency tables. The NOCUM option also suppresses the display of cumulative frequencies and percentages in crosstabulation tables in list format, which you request with the [LIST](#) option.

NOFREQ

suppresses the display of cell frequencies in crosstabulation tables. The NOFREQ option also suppresses row total frequencies. This option has no effect for one-way tables or for crosstabulation tables in list format, which you request with the [LIST](#) option.

NOPERCENT

suppresses the display of overall percentages in crosstabulation tables. These percentages include the cell percentages of the total (two-way) table frequency, as well as the row and column percentages of the total table frequency. To suppress the display of cell percentages of row or column totals, use the [NOROW](#) or [NOCOL](#) option, respectively.

For one-way frequency tables and crosstabulation tables in list format, the NOPERCENT option suppresses the display of percentages and cumulative percentages.

NOPRINT

suppresses the display of frequency and crosstabulation tables but displays all requested tests and statistics. To suppress the display of all output, including tests and statistics, use the [NOPRINT](#) option in the PROC FREQ statement.

NOROW

suppresses the display of row percentages in crosstabulation table cells.

NOSPARE

suppresses the display of cells with a zero frequency count in [LIST](#) output and omits them from the [OUT=](#) data set. The NOSPARE option applies when you specify the [ZEROS](#) option in the [WEIGHT](#) statement to include observations with zero weights. By default, the ZEROS option invokes the [SPARSE](#) option, which displays table cells with a zero frequency count in the LIST output and includes them in the OUT= data set. See the description of the [ZEROS](#) option for more information.

The NOSPARE option also suppresses the display of variable levels with zero frequency in [CROSSLIST](#) tables. By default for CROSSLIST tables, PROC FREQ displays all levels of the column variable within each level of the row variable, including any column variable levels with zero frequency for that row. For multiway tables displayed with the CROSSLIST option, the procedure displays all levels of the row variable for each stratum of the table by default, including any row variable levels with zero frequency for the stratum.

NOWARN

suppresses the log warning message for the validity of the asymptotic Pearson chi-square test. By default, PROC FREQ provides a validity warning for the asymptotic Pearson chi-square test when more than 20 cells have expected frequencies that are less than 5. This warning message appears in the log if you specify the NOPRINT option in the PROC FREQ statement,

The NOWARN option is equivalent to the [CHISQ\(WARN=NOLOG\)](#) option. You can also use the [CHISQ\(WARN=\)](#) option to suppress the warning message in the display and to request a warning variable in the chi-square ODS output data set or in the OUTPUT data set.

OUT=SAS-data-set

names an output data set that contains frequency or crosstabulation table counts and percentages. If more than one table request appears in the TABLES statement, the contents of the OUT= data set correspond to the last table request in the TABLES statement. The OUT= data set variable COUNT contains the frequencies and the variable PERCENT contains the percentages. See the section “[Output Data Sets](#)” on page 2606 for details. You can specify the following options to include additional information in the OUT= data set: [OUTCUM](#), [OUTEXPECT](#), and [OUTPCT](#).

OUTCUM

includes cumulative frequencies and cumulative percentages in the [OUT=](#) data set for one-way tables. The variable CUM_FREQ contains the cumulative frequencies, and the variable CUM_PCT contains the cumulative percentages. See the section “[Output Data Sets](#)” on page 2606 for details. The OUTCUM option has no effect for two-way or multiway tables.

OUTEXPECT

includes expected cell frequencies in the [OUT=](#) data set for crosstabulation tables. The variable EXPECTED contains the expected cell frequencies. See the section “[Output Data Sets](#)” on page 2606 for details. The EXPECTED option has no effect for one-way tables.

OUTPCT

includes the following additional variables in the [OUT=](#) data set for crosstabulation tables:

PCT_COL	percentage of column frequency
PCT_ROW	percentage of row frequency
PCT_TABL	percentage of stratum (two-way table) frequency, for n -way tables where $n > 2$

See the section “[Output Data Sets](#)” on page 2606 for details. The OUTPCT option has no effect for one-way tables.

PLCORR

requests the polychoric correlation coefficient. For 2×2 tables, this statistic is more commonly known as the tetrachoric correlation coefficient, and it is labeled as such in the displayed output. See the section “[Polychoric Correlation](#)” on page 2562 for details.

The PLCORR option provides the polychoric correlation coefficient and its asymptotic standard error. If you also specify the [CL](#) option, PROC FREQ provides confidence limits for the polychoric correlation. You can specify the [PLCORR](#) option in the TEST statement, to request Wald and likelihood ratio tests for the polychoric correlation. If you omit the [MEASURES](#) option, the PLCORR option invokes the MEASURES option.

The [CONVERGE=](#) and [MAXITER=](#) options control the iterative computation of the polychoric correlation coefficient. The CONVERGE= option specifies the convergence criterion and the MAXITER= option specifies the maximum number of iterations. By default CONVERGE=0.0001 and MAXITER=20. Iterative computation of the polychoric correlation stops when the number of iterations exceeds the MAXITER= value or when the convergence measures falls below the CONVERGE= value, whichever happens first.

PLOTS < (*global-plot-options*) > < = *plot-request* < (*plot-options*) > >

PLOTS < (*global-plot-options*) >

< = (*plot-request* < (*plot-options*) > < ... *plot-request* < (*plot-options*) > >) >

controls the plots that are produced through ODS Graphics. *Plot-requests* identify the plots, and *plot-options* control the appearance and content of the plots. You can specify *plot-options* in parentheses after a *plot-request*. A *global-plot-option* applies to all plots for which it is available unless it is altered by a specific *plot-option*. You can specify *global-plot-options* in parentheses after the PLOTS option.

When you specify only one *plot-request*, you can omit the parentheses around the request. For example:

```
plots=all
plots=freqplot
plots=(freqplot oddsrationplot)
plots(only)=(cumfreqplot deviationplot)
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc freq;
  tables treatment*response / chisq plots=freqplot;
  weight wt;
run;
ods graphics off;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

If ODS Graphics is enabled but you do not specify the PLOTS= option, PROC FREQ produces all plots that are associated with the analyses that you request with the exception of the frequency, cumulative frequency, and mosaic plots. To produce a frequency plot or cumulative frequency plot when ODS Graphics is enabled, you must specify the [FREQPLOT](#) or [CUMFREQPLOT](#) *plot-request*, respectively, in the PLOTS= option, or you must specify the [PLOTS=ALL](#) option. To produce a mosaic plot when ODS Graphics is enabled, you must specify the [MOSAICPLOT](#) *plot-request* in the PLOTS= option, or you must specify the [PLOTS=ALL](#) option.

PROC FREQ produces the remaining plots (listed in [Table 38.11](#)) by default when you request the corresponding TABLES statement options. You can suppress default plots and request specific plots by using the [PLOTS\(ONLY\)=](#) option; [PLOTS\(ONLY\)=\(*plot-requests*\)](#) produces only the plots that are specified as *plot-requests*. You can suppress all plots by specifying the [PLOTS=NONE](#) option. The PLOTS= option has no effect when you specify the [NOPRINT](#) option in the [PROC FREQ](#) statement.

Plot Requests

[Table 38.11](#) lists the available *plot-requests* together with their required TABLES statement options. Descriptions of the *plot-requests* follow the table in alphabetical order.

Table 38.11 Plot Requests

Plot Request	Description	Required TABLES Statement Option
AGREEPLOT	Agreement plot	AGREE ($r \times r$ table)
ALL	All plots	None
CUMFREQPLOT	Cumulative frequency plot	One-way table request
DEVIATIONPLOT	Deviation plot	CHISQ (one-way table)
FREQPLOT	Frequency plot	Any table request
KAPPAPLOT	Kappa plot	AGREE ($h \times r \times r$ table)
MOSAICPLOT	Mosaic plot	Two-way or multiway table request
NONE	No plots	None
ODDSRATIOPLOT	Odds ratio plot	MEASURES or RELRISK ($h \times 2 \times 2$ table)
RELRIKSPLOT	Relative risk plot	MEASURES or RELRISK ($h \times 2 \times 2$ table)
RISKDIFFPLOT	Risk difference plot	RISKDIFF ($h \times 2 \times 2$ table)
WTKAPPAPLOT	Weighted kappa plot	AGREE ($h \times r \times r$ table, $r > 2$)

The following *plot-requests* are available with the PLOTS= option:

AGREEPLOT < (*plot-options*) >

requests an agreement plot (Bangdiwala and Bryan 1987). An agreement plot displays the strength of agreement in a two-way table, where the row and column variables represent two independent ratings of n subjects. For information about agreement plots, see Bangdiwala (1988); Bangdiwala et al. (2008), and Friendly (2000, Section 3.7.2).

To produce an agreement plot, you must also specify the **AGREE** option in the TABLES statement. Agreement statistics and plots are available for two-way square tables, where the number of rows equals the number of columns.

Table 38.12 lists the *plot-options* that are available for agreement plots. See the subsection “Plot Options” for descriptions of the *plot-options*.

Table 38.12 Plot Options for AGREEPLOT

Plot Option	Description	Values
LEGEND=	Legend	YES* or NO
PARTIAL=	Partial agreement	YES* or NO
SHOWSCALE=	Frequency scale	YES* or NO
STATS	Statistics	None

*Default

ALL

requests all plots that are associated with the specified analyses. If you specify the PLOTS=ALL option, PROC FREQ produces the frequency, cumulative frequency, and mosaic plots that are associated with the tables that you request. (PROC FREQ does not produce these plots by default when ODS Graphics is enabled.)

CUMFREQPLOT <(plot-options)>

requests a plot of cumulative frequencies. Cumulative frequency plots are available for one-way frequency tables.

To produce a cumulative frequency plot, you must specify the CUMFREQPLOT *plot-request* in the PLOTS= option, or you must specify the **PLOTS=ALL** option. PROC FREQ does not produce cumulative frequency plots by default when ODS Graphics is enabled.

Table 38.13 lists the *plot-options* that are available for cumulative frequency plots. See the subsection “Plot Options” for descriptions of the *plot-options*.

Table 38.13 Plot Options for CUMFREQPLOT

Plot Option	Description	Values
ORIENT=	Orientation	VERTICAL* or HORIZONTAL
SCALE=	Scale	FREQ* or PERCENT
TYPE=	Type	BARCHART* or DOTPLOT

*Default

DEVIATIONPLOT <(plot-options)>

requests a plot of relative deviations from expected frequencies. Deviation plots are available for chi-square analysis of one-way frequency tables. To produce a deviation plot, you must also specify the **CHISQ** option in the TABLES statement for a one-way frequency table.

Table 38.14 lists the *plot-options* that are available for deviation plots. See the subsection “Plot Options” for descriptions of the *plot-options*.

Table 38.14 Plot Options for DEVIATIONPLOT

Plot Option	Description	Values
NOSTAT	No statistic	None
ORIENT=	Orientation	VERTICAL* or HORIZONTAL
TYPE=	Type	BARCHART* or DOTPLOT

*Default

FREQPLOT <(plot-options)>

requests a frequency plot. Frequency plots are available for frequency and crosstabulation tables. For multiway crosstabulation tables, PROC FREQ provides a two-way frequency plot for each stratum (two-way table).

To produce a frequency plot, you must specify the FREQPLOT *plot-request* in the PLOTS= option, or you must specify the **PLOTS=ALL** option. PROC FREQ does not produce frequency plots by default when ODS Graphics is enabled.

By default, PROC FREQ displays frequency plots as bar charts. You can specify the **TYPE=DOTPLOT** *plot-option* to display frequency plots as dot plots. You can plot percentages instead of frequencies by specifying the **SCALE=PERCENT** *plot-option*. There are four frequency plot layouts available, which you can request by specifying the **TWOWAY=** *plot-option*. See the subsection “Plot Options” for more information.

By default, the primary grouping of graph cells in a two-way layout is by column variable. Row variable levels are then displayed within column variable levels. You can specify the **GROUPBY=ROW** *plot-option* to group first by row variable.

Table 38.15 lists the *plot-options* that are available for frequency plots. See the subsection “Plot Options” for descriptions of the *plot-options*.

The following *plot-options* are available for all frequency plots: **ORIENT=**, **SCALE=**, and **TYPE=**. The following *plot-options* are available for frequency plots of two-way (and multi-way) tables: **GROUPBY=**, **NPANELPOS=**, and **TWOWAY=**. The **NPANELPOS=** *plot-option* is not available with the **TWOWAY=CLUSTER** or **TWOWAY=STACKED** layout, which is always displayed in a single panel.

Table 38.15 Plot Options for FREQPLOT

Plot Option	Description	Values
GROUPBY=**	Primary group	COLUMN* or ROW
NPANELPOS=**	Sections per panel	Number (4*)
ORIENT=	Orientation	VERTICAL* or HORIZONTAL
SCALE=	Scale	FREQ* or PERCENT
TWOWAY=**	Two-way layout	CLUSTER, GROUPHORIZONTAL, GROUPVERTICAL*, or STACKED
TYPE=	Type	BARCHART* or DOTPLOT

*Default

**For two-way tables

KAPPAPLOT < (*plot-options*) >

requests a plot of kappa statistics with confidence limits. Kappa plots are available for multiway square tables and display the kappa statistic (with confidence limits) for each two-way table (stratum). Kappa plots also display the overall kappa statistic unless you specify the **COMMON=NO** *plot-option*. To produce a kappa plot, you must specify the **AGREE** option in the **TABLES** statement to compute kappa statistics.

Table 38.16 lists the *plot-options* that are available for kappa plots. See the subsection “Plot Options” for descriptions of the *plot-options*.

Table 38.16 Plot Options for KAPPAPLOT and WTKAPPAPLOT

Plot Option	Description	Values
CLDISPLAY=	Error bar type	SERIF*, LINE, or BAR
COMMON=	Overall kappa	YES* or NO
NPANELPOS=	Statistics per graphic	Number
ORDER=	Order of two-way levels	ASCENDING or DESCENDING
RANGE=	Range to display	Values or CLIP
STATS	Statistics	None

*Default

MOSAICPLOT < (*plot-option*) >

requests a mosaic plot. Mosaic plots are available for crosstabulation tables. For multiway tables, PROC FREQ provides a mosaic plot for each two-way table (stratum).

To produce a mosaic plot, you must specify the MOSAICPLOT *plot-request* in the PLOTS= option, or you must specify the **PLOTS=ALL** option. PROC FREQ does not produce mosaic plots by default when ODS Graphics is enabled.

Mosaic plots display tiles that correspond to the crosstabulation table cells. The areas of the tiles are proportional to the frequencies of the table cells. The column variable is displayed on the X axis, and the tile widths are proportional to the relative frequencies of the column variable levels. The row variable is displayed on the Y axis, and the tile heights are proportional to the relative frequencies of the row levels within column levels. The colors of the tiles correspond to the row variable levels. See Friendly (2000) for more information.

You can specify the following *plot-option* in parentheses after the MOSAICPLOT *plot-request*:

SQUARE

produces a square mosaic plot, where the height of the Y axis equals the width of the X axis. In a square mosaic plot, the scale of the relative frequencies is the same on both axes. By default, PROC FREQ produces a rectangular mosaic plot.

NONE

suppresses all plots.

ODDSRATIOPLOT < (*plot-options*) >

requests a plot of odds ratios with confidence limits. Odds ratio plots are available for multiway 2×2 tables and display the odds ratio (with confidence limits) for each 2×2 table (stratum). To produce an odds ratio plot, you must also specify the **MEASURES** or **RELRISK** option in the TABLES statement to compute odds ratios.

If you specify the **CMH** option in the TABLES statement to compute the common odds ratio for the multiway table, by default the plot displays the common odds ratio. The **COMMON=NO** *plot-option* suppresses display of the common odds ratio. If you do not specify the **CMH** option, the common odds ratio is not available to be displayed in the plot.

By default, odds ratio plots display asymptotic confidence limits. You can specify the **CL=EXACT** *plot-option* to display exact confidence limits for the odds ratios. You must also request computation of exact confidence limits by specifying the **OR** option in the EXACT statement. To display the common odds ratio with exact confidence limits, you must also specify the **COMOR** option in the EXACT statement.

Table 38.17 lists the *plot-options* that are available for odds ratio plots. See the subsection “Plot Options” for descriptions of the *plot-options*.

Table 38.17 Plot Options for ODDSRATIOPLOT, RELRISKPLOT, and RISKDIFFPLOT

Plot Option	Description	Values
CL=	Confidence limit type	Type
CLDISPLAY=	Error bar type	SERIF*, LINE, or BAR
COLUMN=**	Risk column	1* or 2
LOGBASE=***	Axis scale	2, E, or 10
NPANELPOS=	Statistics per graphic	Number (All*)
ORDER=	Order of two-way levels	ASCENDING or DESCENDING
RANGE=	Range to display	Values or CLIP
STATS	Statistics	None

*Default

** Available for RELRISKPLOT and RISKDIFFPLOT

*** Available for ODDSRATIOPLOT and RELRISKPLOT

RELRISKPLOT <(plot-options)>

requests a plot of relative risks with confidence limits. Relative risk plots are available for multiway 2×2 tables and display the relative risk (with confidence limits) for each 2×2 table (stratum). To produce a relative risk plot, you must also specify the **MEASURES** or **RELRISK** option in the TABLES statement to compute relative risks.

If you specify the **CMH** option in the TABLES statement to compute the common relative risk for the multiway table, by default the plot displays the common relative risk. The **COMMON=NO** *plot-option* suppresses display of the common relative risk. If you do not specify the **CMH** option, the common relative risk is not available to be displayed in the plot.

By default, relative risk plots display asymptotic confidence limits. You can specify the **CL=EXACT** *plot-option* to display exact confidence limits for the relative risks. You must also request computation of exact confidence limits by specifying the **RELRISK** option in the EXACT statement. When you specify the **CL=EXACT** *plot-option*, the relative risk plot does not display the common relative risk.

Table 38.17 lists the *plot-options* that are available for relative risk plots. See the subsection “Plot Options” for descriptions of the *plot-options*.

RISKDIFFPLOT <(plot-options)>

requests a plot of risk (proportion) differences with confidence limits. Risk difference plots are available for multiway 2×2 tables and display the risk difference (with confidence limits) for each 2×2 table (stratum). To produce a risk difference plot, you must also specify the **RISKDIFF** option in the TABLES statement to compute risk differences.

By default, risk difference plots display asymptotic Wald confidence limits. You can specify the **CL=EXACT** *plot-option* to display exact confidence limits for the risk differences. You must also request computation of exact confidence limits by specifying the **RISKDIFF** option in the EXACT statement.

In addition to Wald and exact confidence limits, you can display the following confidence limit types in a risk difference plot: Agresti-Caffo, Hauck-Anderson, Miettinen-Nurminen, and Newcombe. See the descriptions of the **CL=EXACT** *plot-option* and the **RISKDIFF** option for more information.

Table 38.17 lists the *plot-options* that are available for risk difference plots. See the subsection “Plot Options” for descriptions of the *plot-options*.

WTKAPPAPLOT <(plot-options)>

requests a plot of weighted kappa statistics with confidence limits. Weighted kappa plots are available for multiway square tables and display the weighted kappa statistic (with confidence limits) for each two-way table (stratum). Weighted kappa plots also display the overall weighted kappa statistic unless you specify the **COMMON=NO** *plot-option*.

To produce a weighted kappa plot, you must also specify the **AGREE** option in the TABLES statement to compute weighted kappa statistics. Simple kappa and weighted kappa statistics are equal for 2×2 tables; therefore, PROC FREQ displays weighted kappa statistics and plots only for tables that are larger than 2×2 .

Table 38.16 lists the *plot-options* that are available for weighted kappa plots. See the subsection “Plot Options” for descriptions of the *plot-options*.

Global Plot Options

A *global-plot-option* applies to all plots for which the option is available unless it is altered by an individual *plot-option*. You can specify *global-plot-options* in parentheses after the PLOTS option. For example:

```
plots(order=ascending stats)=(riskdiffplot oddsratioplot)
plots(only)=freqplot
```

The following *plot-options* are available as *global-plot-options*: **CLDISPLAY=**, **COLUMN=**, **COMMON=**, **EXACT**, **LOGBASE=**, **NPANELPOS=**, **ORDER=**, **ORIENT=**, **RANGE=**, **SCALE=**, **STATS**, and **TYPE=**. See the subsection “Plot Options” for description of these *plot-options*.

In addition to these *plot-options*, you can specify the following *global-plot-option* in parentheses after the PLOTS option:

ONLY

suppresses the default plots and requests only the plots that are specified as *plot-requests*.

Plot Options

You can specify the following *plot-options* in parentheses after a *plot-request*:

CL=type

specifies the type of confidence limits to display. The **CL=** *plot-option* is available for the following plots: **ODDSRATIOPLOT**, **RELRIKSPLOT**, and **RISKDIFFPLOT**.

For odds ratio and relative risk plots, the available confidence limit types are asymptotic and exact, which you can request by specifying **CL=ASYMPTOTIC** and **CL=EXACT**, respectively. By default, these plots display asymptotic confidence limits. When you specify **CL=EXACT** to display exact confidence limits, you must also request computation of exact confidence limits by specifying the corresponding option (**OR** or **RELRIKSPLOT**) in the EXACT statement. See the sections “Exact Confidence Limits for the Odds Ratio” on page 2583 and “Exact Unconditional Confidence Limits for the Relative Risk” on page 2584 for more information.

For risk difference plots, the available confidence limit types include the following: **CL=AC** (Agresti-Caffo), **CL=EXACT** (exact unconditional), **CL=HA** (Hauck-Anderson), **CL=MN**

(Miettinen-Nurminen), CL=NEWCOMBE (Newcombe), and CL=WALD (Wald). See the description of the **CL= riskdiff-option** and see the section “[Risk Difference Confidence Limits](#)” on page 2574 for more information. If you specify CL=EXACT to display exact confidence limits in the plot, you must also request computation of exact confidence limits by specifying the **RISKDIFF** option in the EXACT statement.

CLDISPLAY=SERIF | LINE | BAR < width >

controls the appearance of the confidence limit error bars. The CLDISPLAY= *plot-option* is available for the following plots: **KAPPAPLOT**, **ODDSRATIO**PLOT, **RELRISK**PLOT, **RISKDIFF**PLOT, and **WTKAPPAPLOT**.

The default value is CLDISPLAY=SERIF, which displays the confidence limits as lines with serifs. CLDISPLAY=LINE displays the confidence limits as plain lines without serifs.

CLDISPLAY=BAR displays the confidence limits as bars. By default, the width of the bars equals the size of the marker for the estimate. You can control the width of the bars and the size of the marker by specifying the value of *width* as a percentage of the distance between bars, $0 < width \leq 1$. The bar might disappear when the value of *width* is very small.

COLUMN=1 | 2

specifies the 2×2 table column to use to compute the risk (proportion). The COLUMN= *plot-option* is available for the relative risk plot (**RELRISK**PLOT) and the risk difference plot (**RISKDIFF**PLOT). If you specify COLUMN=1, the plot displays the column 1 relative risks or the column 1 risk difference. Similarly, if you specify COLUMN=2, the plot displays the column 2 relative risks or risk difference. The default is COLUMN=1.

COMMON=YES | NO

controls the display of the common (overall) statistic in plots that display stratum (two-way table) statistics for a multiway table. The COMMON= *plot-option* is available for the following plots: **KAPPAPLOT**, **ODDSRATIO**PLOT, **RELRISK**PLOT, and **WTKAPPAPLOT**.

By default, COMMON=YES and the plots display the common value when it is available. When you specify the **AGREE** option in the TABLES statement for a multiway table, PROC FREQ computes overall kappa statistics in addition to kappa statistics for each stratum. When you specify the **MEASURES** or **RELRISK** option in the TABLES statement, PROC FREQ computes only stratum-level odds ratios and relative risks; to compute common odds ratios and relative risks, you must also specify the **CMH** option in the TABLES statement.

COMMON=YES is not available for relative risk plots when you specify the CL=EXACT *plot-option* to display exact confidence limits.

EXACT

requests display of exact confidence limits instead of asymptotic confidence limits. The EXACT *plot-option* is available for the odds ratio plot (**ODDSRATIO**PLOT), relative risk plot (**RELRISK**PLOT), and risk difference plot (**RISKDIFF**PLOT). The EXACT *plot-option* is equivalent to the **CL=EXACT** *plot-option*.

When you specify the EXACT *plot-option*, you must also request computation of exact confidence limits by specifying the appropriate *statistic-option* in the **EXACT** statement.

GROUPBY=COLUMN | ROW

specifies the primary grouping for two-way frequency plots. The default is **GROUPBY=COLUMN**, which groups graph cells first by column variable and displays row variable levels within column variable levels. You can specify **GROUPBY=ROW** to group first by row variable. In two-way and multiway table requests, the column variable is the last variable specified and forms the columns of the crosstabulation table. The row variable is the next-to-last variable specified and forms the rows of the table.

By default for a bar chart that is displayed in the **TWOWAY=STACKED** layout, bars correspond to the column variable levels, and row levels are displayed (stacked) within each column bar. By default for a bar chart that is displayed in the **TWOWAY=CLUSTER** layout, bars are first grouped by column variable levels, and row levels are displayed as adjacent bars within each column-level group. You can reverse the default row and column variable grouping by specifying **GROUPBY=ROW**.

LOGBASE=2 | E | 10

applies to the odds ratio plot (**ODDSRATIOPLOT**) and the relative risk plot (**RELRIKSPLOT**). **LOGBASE=** displays the odds ratio or relative risk axis on the log scale that you specify.

LEGEND=YES | NO

applies to the agreement plot (**AGREEPLOT**). **LEGEND=NO** suppresses the legend that identifies the areas of exact and partial agreement. The default is **LEGEND=YES**.

NOSTAT

applies to the deviation plot (**DEVIATIONPLOT**). **NOSTAT** suppresses the chi-square *p*-value that deviation plot displays by default.

NPANELPOS=*n*

applies to the following plots: **FREQPLOT** (for two-way and multiway tables), **KAPPAPLOT**, **ODDSRATIOPLOT**, **RELRIKSPLOT**, **RISKDIFFPLOT**, and **WTKAPPAPLOT**.

For kappa, odds ratio, relative risk, risk difference, and weighted kappa plots, **NPANELPOS=** divides the plot into multiple panels that display at most $|n|$ statistics per panel. If *n* is positive, the number of statistics per panel is balanced; if *n* is negative, the number of statistics per panel is not balanced. For example, suppose you want to display 21 odds ratios. **NPANELPOS=20** displays two panels, the first with 11 odds ratios and the second with 10 odds ratios; **NPANELPOS=-20** displays 20 odds ratios in the first panel but only one in the second panel. By default, *n* = 0 and all statistics are displayed in a single panel.

For two-way frequency plots, the **NPANELPOS= plot-option** divides the plot into multiple panels that display at most $|n|$ sections per panel. Sections correspond to row or column variable levels, depending on the type of plot and the grouping.

The **NPANELPOS= plot-option** applies to two-way plots that are displayed in the **TWOWAY=GROUPVERTICAL** or **TWOWAY=GROUPHORIZONTAL** layout. The **NPANELPOS= plot-option** does not apply to the **TWOWAY=CLUSTER** and **TWOWAY=STACKED** layouts, which are always displayed in a single panel.

If *n* is positive, the number of sections per panel is balanced; if *n* is negative, the number of sections per panel is not balanced. By default for frequency plots, *n* = 4 and each panel includes at most four sections.

ORDER=ASCENDING | DESCENDING

displays the statistics in sorted order. By default, the statistics are displayed in the order in which the two-way table strata appear in the multiway table display. The ORDER= *plot-option* applies to the following plots: [KAPPAPLOT](#), [ODDSRATIOPLOT](#), [RELRIKSPLOT](#), [RISKDIFFPLOT](#), and [WTKAPPAPLOT](#).

ORIENT=HORIZONTAL | VERTICAL

controls the orientation of the plot. The ORIENT= *plot-option* applies to the following plots: [CUMFREQPLOT](#), [DEVIATIONPLOT](#), and [FREQPLOT](#).

ORIENT=HORIZONTAL places the variable levels on the Y axis and the frequencies, percentages, or statistic values on the X axis. ORIENT=VERTICAL places the variable levels on the X axis. The default orientation is ORIENT=VERTICAL for bar charts ([TYPE=BARCHART](#)) and ORIENT=HORIZONTAL for dot plots ([TYPE=DOTPLOT](#)).

PARTIAL=YES | NO

controls the display of partial agreement in the agreement plot ([AGREEPLOT](#)). PARTIAL=NO suppresses the display of partial agreement. When you specify PARTIAL=NO, the agreement plot displays only exact agreement. Exact agreement includes the diagonal cells of the square table, where the row and column variable levels are the same. Partial agreement includes the adjacent off-diagonal table cells, where the row and column values are within one level of exact agreement. The default is PARTIAL=YES.

RANGE=(*< min>* *< ,max>*) | CLIP

specifies the range of values to display. The RANGE= *plot-option* applies to the following plots: [KAPPAPLOT](#), [ODDSRATIOPLOT](#), [RELRIKSPLOT](#), [RISKDIFFPLOT](#), and [WTKAPPAPLOT](#). If you specify RANGE=CLIP, the confidence limits are clipped and the display range is determined by the minimum and maximum values of the statistics. By default, the display range includes all confidence limits.

SCALE=FREQ | LOG | PERCENT | SQRT

specifies the scale of the frequencies to display. The SCALE= *plot-option* applies to the frequency plot ([FREQPLOT](#)) and the cumulative frequency plot ([CUMFREQPLOT](#)).

The default is SCALE=FREQ, which displays unscaled frequencies. SCALE=LOG displays log (base 10) frequencies. SCALE=PERCENT displays percentages (relative frequencies). SCALE=SQRT displays square roots of the frequencies, which produces a plot known as a *rootogram*.

SHOWSCALE=YES | NO

controls the display of the cumulative frequency scale on the right side of the agreement plot ([AGREEPLOT](#)). SHOWSCALE=NO suppresses the display of the scale. The default is SHOWSCALE=YES.

SQUARE

requests a square mosaic plot ([MOSAICPLOT](#)), where the height of the Y axis equals the width of the X axis. In a square mosaic plot, the scale of the relative frequencies is the same on both axes. By default, the mosaic plot area is rectangular.

STATS

displays statistic values in the plot. For the following plots, the *STATS plot-option* displays the statistics and their confidence limits on the right side of the plot: [KAPPAPLOT](#), [ODDSRATIOPLLOT](#), [RELRISKPLLOT](#), [RISKDIFFPLLOT](#), and [WTKAPPAPLOT](#).

For the agreement plot ([AGREEPLLOT](#)), *STATS* displays the values of the kappa statistic, the weighted kappa statistic, and the B_n measure (Bangdiwala and Bryan 1987).

If you do not request the *STATS plot-option*, these plots do not display the statistic values.

TWOWAY=CLUSTER | GROUPTHORIZONTAL | GROUPTHVERTICAL | STACKED

specifies the layout for two-way frequency plots.

All *TWOWAY=* layouts are available for bar charts (*TYPE=BARCHART*). All *TWOWAY=* layouts except *TWOWAY=CLUSTER* are available for dot plots (*TYPE=DOTPLOT*). The *ORIENT=* and *GROUPBY=* *plot-options* are available for all *TWOWAY=* layouts.

The default two-way layout is *TWOWAY=GROUPTHVERTICAL*, which produces a grouped plot that has a vertical common baseline. By default for bar charts (*TYPE=BARCHART*, *ORIENT=VERTICAL*), the X axis displays column variable levels, and the Y axis displays frequencies. The plot includes a vertical (Y-axis) block for each row variable level. The relative positions of the graph cells in this plot layout are the same as the relative positions of the table cells in the crosstabulation table. You can reverse the default row and column grouping by specifying the *GROUPBY=ROW* *plot-option*.

The *TWOWAY=GROUPTHORIZONTAL* layout produces a grouped plot that has a horizontal common baseline. By default (*GROUPBY=COLUMN*), the plot displays a block on the X axis for each column variable level. Within each column-level block, the plot displays row variable levels.

The *TWOWAY=STACKED* layout produces stacked displays of frequencies. By default (*GROUPBY=COLUMN*) in a stacked bar chart, the bars correspond to column variable levels, and row levels are stacked within each column level. By default in a stacked dot plot, the dotted lines correspond to column levels, and cell frequencies are plotted as data dots on the corresponding column line. The dot color identifies the row level.

The *TWOWAY=CLUSTER* layout, which is available only for bar charts, displays groups of adjacent bars. By default, the primary grouping is by column variable level, and row levels are displayed within each column level.

You can reverse the default row and column grouping in any layout by specifying the *GROUPBY=ROW* *plot-option*. The default is *GROUPBY=COLUMN*, which groups first by column variable.

TYPE=BARCHART | DOTPLOT

specifies the plot type for frequency (*FREQPLOT*), cumulative frequency (*CUMFREQPLOT*), and deviation plots (*DEVIATIONPLOT*). *TYPE=BARCHART* produces a bar chart and *TYPE=DOTPLOT* produces a dot plot. The default is *TYPE=BARCHART*.

PRINTKWT

displays the weights that PROC FREQ uses to compute the weighted kappa coefficient. You must also specify the **AGREE** option to request the weighted kappa coefficient. You can specify (WT=FC) with the **AGREE** option to request Fleiss-Cohen weights. By default, PROC FREQ uses Cicchetti-Allison weights to compute the weighted kappa coefficient. See the section “[Weighted Kappa Coefficient](#)” on page 2590 for details.

RELRISK | OR

requests relative risk measures and their confidence limits for 2×2 tables. These measures include the odds ratio and the column 1 and 2 relative risks. See the section “[Odds Ratio and Relative Risks for \$2 \times 2\$ Tables](#)” on page 2582 for details.

You can also obtain the RELRISK measures by specifying the **MEASURES** option, which produces other measures of association in addition to the relative risks.

You can request exact confidence limits for the odds ratio by specifying the **OR** option in the **EXACT** statement. You can request exact unconditional confidence limits for the relative risks by specifying the **RELRISK** option in the **EXACT** statement. See the sections “[Exact Confidence Limits for the Odds Ratio](#)” on page 2583 and “[Exact Unconditional Confidence Limits for the Relative Risk](#)” on page 2584 for more information.

RISKDIFF <(riskdiff-options)>

requests risks (binomial proportions) and risk differences for 2×2 tables. When you specify the **RISKDIFF** option, PROC FREQ provides the row 1 risk, row 2 risk, total (overall) risk, and risk difference (row 1 – row 2), together with their asymptotic standard errors and Wald confidence limits. PROC FREQ also provides exact (Clopper-Pearson) confidence limits for the row 1, row 2, and total risks by default. You can request exact unconditional confidence limits for the risk difference by specifying the **RISKDIFF** option in the **EXACT** statement. See the section “[Risks and Risk Differences](#)” on page 2572 for details. PROC FREQ displays these results in the column 1 and column 2 “Risk Estimates” tables.

You can specify *riskdiff-options* in parentheses after the **RISKDIFF** option to request tests and additional confidence limits for the risk difference. [Table 38.18](#) summarizes the *riskdiff-options*.

The **EQUIV**, **NONINF**, and **SUP** *riskdiff-options* request tests of equivalence, noninferiority, and superiority, respectively, for the risk difference. Available test methods include Farrington-Manning (score), Hauck-Anderson, and Newcombe (hybrid-score), in addition to the Wald test.

As part of the noninferiority, superiority, and equivalence analyses, PROC FREQ provides test-based confidence limits that have a confidence coefficient of $100(1 - 2\alpha)\%$ (Schuirmann 1999). The **ALPHA=** option determines the confidence level, and the default of **ALPHA=0.05** produces 90% confidence limits. See the sections “[Noninferiority Tests](#)” on page 2577 and “[Equivalence Tests](#)” on page 2580 for details.

The **CL=** *riskdiff-option* requests confidence limits for the risk difference. Available confidence limit types include Agresti-Caffo, exact unconditional, Hauck-Anderson, Miettinen-Nurminen, Newcombe, and Wald. Continuity-corrected Newcombe and Wald confidence limits are also available. You can request more than one type of confidence limits in the same analysis. PROC FREQ displays the confidence limits in the “Proportion (Risk) Difference Confidence Limits” table.

The **ALPHA=** option determines the level of the confidence limits that the **CL= riskdiff-option** provides. The default of **ALPHA=0.05** produces 95% confidence limits for the risk difference.

The **CL=EXACT riskdiff-option** displays exact unconditional confidence limits in the “Proportion (Risk) Difference Confidence Limits” table. When you use **CL=EXACT**, you must also request computation of the exact confidence limits by specifying the **RISKDIFF** option in the **EXACT** statement.

Table 38.18 RISKDIFF (Proportion Difference) Options

Option	Description
COLUMN=1 2	Specifies the risk column
CORRECT	Requests continuity correction
NORISKS	Suppresses default risk tables
Request Confidence Limits	
CL=AC	Requests Agresti-Caffo confidence limits
CL=EXACT	Displays exact confidence limits
CL=HA	Requests Hauck-Anderson confidence limits
CL=MN	Requests Miettinen-Nurminen confidence limits
CL=NEWCOMBE	Requests Newcombe confidence limits
CL=WALD	Requests Wald confidence limits
Request Tests	
EQUAL	Requests an equality test
EQUIV EQUIVALENCE	Requests an equivalence test
NONINF NONINFERIORITY	Requests a noninferiority test
SUP SUPERIORITY	Requests a superiority test
MARGIN=	Specifies the test margin
METHOD=	Specifies the test method
VAR=SAMPLE NULL	Specifies the test variance

You can specify the following *riskdiff-options* in parentheses after the **RISKDIFF** option:

CL=type | (types)

requests confidence limits for the risk difference. You can specify one or more *types* of confidence limits. When you specify only one *type*, you can omit the parentheses around the request. PROC FREQ displays the confidence limits in the “Proportion (Risk) Difference Confidence Limits” table.

The **ALPHA=** option determines the confidence level, and the default of **ALPHA=0.05** produces 95% confidence limits for the risk difference. This differs from the test-based confidence limits that are provided with the equivalence, noninferiority, and superiority tests (**EQUIV**, **NONINF**, and **SUP**), which have a confidence coefficient of $100(1 - 2\alpha)\%$ (Schuirmann 1999).

You can specify **CL=** with or without requests for risk difference tests. The confidence limits produced by **CL=** do not depend on the tests that you request and do not use the value of the test margin (which you specify by using **MARGIN= riskdiff-option**).

You can control the risk column for the confidence limits by specifying the **COLUMN= riskdiff-option**. If you do not specify **COLUMN=**, PROC FREQ provides confidence limits for the column 1 risk difference by default.

The following *types* of confidence limits are available:

AC | AGRESTICAFFO

requests Agresti-Caffo confidence limits for the risk difference. See the subsection “Agresti-Caffo Confidence Limits” in the section “Risk Difference Confidence Limits” on page 2574 for details.

EXACT

displays exact unconditional confidence limits for the risk difference in the “Proportion (Risk) Difference Confidence Limits” table. You must also request computation of the exact confidence limits by specifying the **RISKDIFF** option in the **EXACT** statement.

PROC FREQ computes the confidence limits by inverting two separate one-sided exact tests (tail method), where the tests are based on the unstandardized risk difference by default. If you specify the **RISKDIFF(METHOD=SCORE)** option in the **EXACT** statement, the tests are based on the score statistic. See the **RISKDIFF** option in the **EXACT** statement and the section “Exact Unconditional Confidence Limits for the Risk Difference” on page 2580 for more information.

By default, PROC FREQ also displays these exact confidence limits in the “Risk Estimates” table. You can suppress this table by specifying the **NORISKS riskdiff-option**.

HA

requests Hauck-Anderson confidence limits for the risk difference. See the subsection “Hauck-Anderson Confidence Limits” in the section “Risk Difference Confidence Limits” on page 2574 for details.

MN < (CORRECT=NO | MEE) >

requests Miettinen-Nurminen confidence limits for the risk difference. See the subsection “Miettinen-Nurminen Confidence Limits” in the section “Risk Difference Confidence Limits” on page 2574 for details. By default, the Miettinen-Nurminen confidence limits include a bias correction factor (Miettinen and Nurminen 1985; Newcombe and Nurminen 2011). If you specify **CL=MN(CORRECT=NO)**, PROC FREQ provides the uncorrected form of the confidence limits (Mee 1984).

NEWCOMBE | SCORE | WILSON <(CORRECT)>

requests Newcombe hybrid-score confidence limits for the risk difference. If you specify **CL=NEWCOMBE(CORRECT)** or the **CORRECT riskdiff-option**, the Newcombe confidence limits include a continuity correction. See the subsection “Newcombe Confidence Limits” in the section “Risk Difference Confidence Limits” on page 2574 for details.

WALD < (CORRECT) >

requests Wald confidence limits for the risk difference. If you specify **CL=WALD(CORRECT)** or the **CORRECT riskdiff-option**, the Wald confidence limits include a continuity correction. See the subsection “Wald Confidence Limits” in the section “Risk Difference Confidence Limits” on page 2574 for details.

COLUMN=1 | 2 | BOTH

specifies the table column for which to compute the risk difference tests (**EQUAL**, **EQUIV**, **NONINF**, and **SUP**) and the risk difference confidence limits (which are requested by the **CL= riskdiff-option**).

If you do not specify `COLUMN=`, PROC FREQ provides the risk difference tests and confidence limits for column 1 by default. The `COLUMN=` option has no effect on the “Risk Estimates” table, which is produced for both column 1 and column 2. You can suppress the “Risk Estimates” table by specifying the [NORISKS riskdiff-option](#).

CORRECT

includes a continuity correction in the Wald confidence limits, Wald tests, and Newcombe confidence limits. See the section “[Risks and Risk Differences](#)” on page 2572 for details.

EQUAL

requests a test of the null hypothesis that the risk difference equals zero. PROC FREQ provides an asymptotic Wald test of equality. If you specify the [CORRECT riskdiff-option](#), the Wald test includes a continuity correction. If you specify the [VAR=NULL riskdiff-option](#), the test uses the null (test-based) variance instead of the sample-based variance. See the section “[Equality Test](#)” on page 2576 for details.

EQUIV | EQUIVALENCE

requests a test of equivalence for the risk difference. See the section “[Equivalence Tests](#)” on page 2580 for details. You can specify the equivalence test margins with the [MARGIN= riskdiff-option](#) and the test method with the [METHOD= riskdiff-option](#). PROC FREQ uses `METHOD=WALD` by default.

MARGIN=value | (lower,upper)

specifies the margin for the noninferiority, superiority, and equivalence tests, which you request with the [NONINF](#), [SUP](#), and [EQUIV riskdiff-options](#), respectively. If you do not specify `MARGIN=`, PROC FREQ uses a margin of 0.2 by default.

For noninferiority and superiority tests, specify a single *value* for `MARGIN=`. The `MARGIN=value` must be a positive number. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC FREQ converts that number to a proportion. The procedure treats the value 1 as 1%.

For an equivalence test, you can specify a single `MARGIN= value`, or you can specify both *lower* and *upper* values. If you specify a single `MARGIN= value`, it must be a positive number, as described previously. If you specify a single `MARGIN= value` for an equivalence test, PROC FREQ uses $-value$ as the lower margin and *value* as the upper margin for the test. If you specify both *lower* and *upper* values for an equivalence test, you can specify them in proportion form as numbers between -1 or 1 . Or you can specify them in percentage form as numbers between -100 and 100 , and PROC FREQ converts the numbers to proportions. The value of *lower* must be less than the value of *upper*.

METHOD=method

specifies the method for the noninferiority, superiority, and equivalence analyses, which you request with the [NONINF](#), [SUP](#), and [EQUIV riskdiff-options](#), respectively. If you do not specify the `METHOD= riskdiff-option`, PROC FREQ uses `METHOD=WALD` by default.

The following *methods* are available:

FM

requests Farrington-Manning (score) tests and test-based confidence limits for the equivalence, noninferiority, and superiority analyses. See the subsection “[Farrington-Manning Test](#)” in the section “[Noninferiority Tests](#)” on page 2577 for details.

HA

requests Hauck-Anderson tests and confidence limits for the equivalence, noninferiority, and superiority analyses. See the subsection “[Hauck-Anderson Test](#)” in the section “[Noninferiority Tests](#)” on page 2577 for details.

NEWCOMBE | SCORE | WILSON

requests Newcombe (hybrid-score) confidence limits for the equivalence, noninferiority, and superiority analyses. If you specify the [CORRECT riskdiff-option](#), the Newcombe confidence limits include a continuity correction. See the subsection “[Newcombe Noninferiority Analysis](#)” in the section “[Noninferiority Tests](#)” on page 2577 for details.

WALD

requests Wald tests and confidence limits for the equivalence, noninferiority, and superiority analyses. If you specify the [CORRECT riskdiff-option](#), the Wald confidence limits include a continuity correction. If you specify the [VAR=NULL riskdiff-option](#), the tests and confidence limits use the null (test-based) variance instead of the sample-based variance. See the subsection “[Wald Test](#)” in the section “[Noninferiority Tests](#)” on page 2577 for details.

NONINF | NONINFERIORITY

requests a test of noninferiority for the risk difference. See the section “[Noninferiority Tests](#)” on page 2577 for details. You can specify the test margin with the [MARGIN= riskdiff-option](#) and the test method with the [METHOD= riskdiff-option](#). PROC FREQ uses METHOD=WALD by default.

NORISKS

suppresses display of the “Risk Estimates” tables, which the RISKDIFF option produces by default for column 1 and column 2. The “Risk Estimates” tables contain the risks and risk differences, together with their asymptotic standard errors, Wald confidence limits, and exact confidence limits.

SUP | SUPERIORITY

requests a test of superiority for the binomial proportion. See the section “[Superiority Test](#)” on page 2579 for details. You can specify the test margin with the [MARGIN= riskdiff-option](#) and the test method with the [METHOD= riskdiff-option](#). PROC FREQ uses METHOD=WALD by default.

VAR=SAMPLE | NULL

specifies the type of variance estimate to use in the Wald tests of noninferiority, superiority, equivalence, and equality. The default is VAR=SAMPLE, which uses the sample-based variance. VAR=NULL uses a test-based variance that is computed from the null hypothesis risk difference value. See the sections “[Equality Test](#)” on page 2576 and “[Noninferiority Tests](#)” on page 2577 for details.

SCORES=type

specifies the type of row and column scores that PROC FREQ uses to compute the following statistics: Mantel-Haenszel chi-square, Pearson correlation, Cochran-Armitage test for trend, weighted kappa coefficient, and Cochran-Mantel-Haenszel statistics. The value of *type* can be one of the following:

- MODRIDIT
- RANK
- RIDIT
- TABLE

See the section “[Scores](#)” on page 2549 for descriptions of these score types.

If you do not specify the `SCORES=` option, PROC FREQ uses `SCORES=TABLE` by default. For character variables, the row and column TABLE scores are the row and column numbers. That is, the TABLE score is 1 for row 1, 2 for row 2, and so on. For numeric variables, the row and column TABLE scores equal the variable values. See the section “[Scores](#)” on page 2549 for details. Using MODRIDIT, RANK, or RIDIT scores yields nonparametric analyses.

You can use the `SCOROUT` option to display the row and column scores.

SCOROUT

displays the row and column scores that PROC FREQ uses to compute score-based tests and statistics. You can specify the score type with the `SCORES=` option. See the section “[Scores](#)” on page 2549 for details.

The scores are computed and displayed only when PROC FREQ computes statistics for two-way tables. You can use ODS to store the scores in an output data set. See the section “[ODS Table Names](#)” on page 2617 for more information.

SPARSE

reports all possible combinations of the variable values for an n -way table when $n > 1$, even if a combination does not occur in the data. The SPARSE option applies only to crosstabulation tables displayed in LIST format and to the `OUT=` output data set. If you do not use the `LIST` or `OUT=` option, the SPARSE option has no effect.

When you specify the SPARSE and LIST options, PROC FREQ displays all combinations of variable values in the table listing, including those with a frequency count of zero. By default, without the SPARSE option, PROC FREQ does not display zero-frequency levels in LIST output. When you use the SPARSE and `OUT=` options, PROC FREQ includes empty crosstabulation table cells in the output data set. By default, PROC FREQ does not include zero-frequency table cells in the output data set.

See the section “[Missing Values](#)” on page 2545 for more information.

TOTPCT

displays the percentage of the total multiway table frequency in crosstabulation tables for n -way tables, where $n > 2$. By default, PROC FREQ displays the percentage of the individual two-way table frequency but does not display the percentage of the total frequency for multiway crosstabulation tables. See the section “[Multiway Tables](#)” on page 2611 for more information.

The percentage of total multiway table frequency is displayed by default when you specify the `LIST` option. It is also provided by default in the PERCENT variable in the `OUT=` output data set.

TREND

requests the Cochran-Armitage test for trend. The table must be $2 \times C$ or $R \times 2$ to compute the trend test. See the section “[Cochran-Armitage Test for Trend](#)” on page 2585 for details. To request exact p -values for the trend test, specify the `TREND` option in the `EXACT` statement. See the section “[Exact Statistics](#)” on page 2601 for more information.

TEST Statement

TEST *test-options* ;

The TEST statement requests asymptotic tests for measures of association and measures of agreement. The *test-options* identify which tests to compute. Table 38.19 lists the available *test-options*, together with their corresponding TABLES statement options. Descriptions of the *test-options* follow the table in alphabetical order.

For each measure of association or agreement that you request in the TEST statement, PROC FREQ provides an asymptotic test that the measure equals zero. The procedure displays the asymptotic standard error under the null hypothesis, the test statistic, and the one-sided and two-sided *p*-values. Additionally, PROC FREQ reports the confidence limits for the measure. The ALPHA= option in the TABLES statement determines the confidence level, which by default equals 0.05 and provides 95% confidence limits. See the sections “Asymptotic Tests” on page 2556 and “Confidence Limits” on page 2556 for details. Also see the sections “Measures of Association” on page 2556 and “Tests and Measures of Agreement” on page 2588 for information about the individual measures.

You can also request exact tests for selected measures of association and agreement by using the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

Using the TEST Statement with the TABLES Statement

You must use a TABLES statement with the TEST statement. If you use only one TABLES statement, you do not need to specify the same options in both the TABLES and TEST statements; when you specify an option in the TEST statement, PROC FREQ automatically invokes the corresponding TABLES statement option. However, when you use the TEST statement with multiple TABLES statements, you must specify options in the TABLES statements to request statistics. PROC FREQ then provides asymptotic tests for those statistics that you also specify in the TEST statement.

Table 38.19 TEST Statement Options

Test Option	Asymptotic Tests	Required TABLES Statement Option
AGREE	Simple and weighted kappa coefficients	AGREE
GAMMA	Gamma	ALL or MEASURES
KAPPA	Simple kappa coefficient	AGREE
KENTB	Kendall's tau- <i>b</i>	ALL or MEASURES
MEASURES	Gamma, Kendall's tau- <i>b</i> , Stuart's tau- <i>c</i> , Somers' $D(C R)$, Somers' $D(R C)$, Pearson and Spearman correlations	ALL or MEASURES
PCORR	Pearson correlation coefficient	ALL or MEASURES
PLCORR	Polychoric correlation	PLCORR
SCORR	Spearman correlation coefficient	ALL or MEASURES
SMDCR	Somers' $D(C R)$	ALL or MEASURES
SMDRC	Somers' $D(R C)$	ALL or MEASURES
STUTC	Stuart's tau- <i>c</i>	ALL or MEASURES
WTKAP	Weighted kappa coefficient	AGREE

You can specify the following *test-options* in the TEST statement.

AGREE

requests asymptotic tests for the simple kappa coefficient and the weighted kappa coefficient. See the sections “[Simple Kappa Coefficient](#)” on page 2589 and “[Weighted Kappa Coefficient](#)” on page 2590 for details.

The **AGREE** option in the TABLES statement provides estimates, standard errors, and confidence limits for kappa coefficients. You can request exact tests for kappa coefficients by using the **EXACT** statement.

Kappa coefficients are defined only for square tables, where the number of rows equals the number of columns. Kappa coefficients are not computed for tables that are not square. For 2×2 tables, the weighted kappa coefficient is identical to the simple kappa coefficient, and PROC FREQ presents only the simple kappa coefficient.

GAMMA

requests an asymptotic test for the gamma statistic. See the section “[Gamma](#)” on page 2557 for details. The **MEASURES** option in the TABLES statement provides the gamma statistic and its asymptotic standard error.

KAPPA

requests an asymptotic test for the simple kappa coefficient. See the section “[Simple Kappa Coefficient](#)” on page 2589 for details.

The **AGREE** option in the TABLES statement provides the kappa statistic, its standard error, and its confidence limits. You can request an exact test for the simple kappa coefficient by specifying the **KAPPA** option in the EXACT statement.

Kappa coefficients are defined only for square tables, where the number of rows equals the number of columns. PROC FREQ does not compute kappa coefficients for tables that are not square.

KENTB | TAUB

requests an asymptotic test for Kendall’s tau-*b*. See the section “[Kendall’s Tau-b](#)” on page 2558 for details.

The **MEASURES** option in the TABLES statement provides Kendall’s tau-*b* and its standard error. You can request an exact test for Kendall’s tau-*b* by specifying the **KENTB** option in the EXACT statement.

MEASURES

requests asymptotic tests for the following measures of association: gamma, Kendall’s tau-*b*, Pearson correlation coefficient, Somers’ $D(C|R)$, Somers’ $D(R|C)$, Spearman correlation coefficient, and Stuart’s tau-*c*. See the section “[Measures of Association](#)” on page 2556 for details.

The **MEASURES** option in the TABLES statement provides measures of association and their asymptotic standard errors. You can request exact tests for selected measures by using the **EXACT** statement.

PCORR

requests an asymptotic test for the Pearson correlation coefficient. See the section “[Pearson Correlation Coefficient](#)” on page 2559 for details.

The **MEASURES** option in the TABLES statement provides the Pearson correlation and its standard error. You can request an exact test for the Pearson correlation by specifying the **PCORR** option in the EXACT statement.

PLCORR

requests Wald and likelihood ratio tests for the polychoric correlation coefficient. See the section “[Polychoric Correlation](#)” on page 2562 for details.

The **PLCORR** option in the TABLES statement provides the polychoric correlation and its standard error.

SCORR

requests an asymptotic test for the Spearman correlation coefficient. See the section “[Spearman Rank Correlation Coefficient](#)” on page 2560 for details.

The **MEASURES** option in the TABLES statement provides the Spearman correlation and its standard error. You can request an exact test for the Spearman correlation by specifying the **SCORR** option in the EXACT statement.

SMDCR

requests an asymptotic test for Somers’ $D(C|R)$. See the section “[Somers’ D](#)” on page 2559 for details.

The **MEASURES** option in the TABLES statement provides Somers’ $D(C|R)$ and its standard error. You can request an exact test for Somers’ $D(C|R)$ by specifying the **SMDCR** option in the EXACT statement.

SMDRC

requests an asymptotic test for Somers’ $D(R|C)$. See the section “[Somers’ D](#)” on page 2559 for details.

The **MEASURES** option in the TABLES statement provides Somers’ $D(R|C)$ and its standard error. You can request an exact test for Somers’ $D(R|C)$ by specifying the **SMDRC** option in the EXACT statement.

STUTC | TAUC

requests an asymptotic test for Stuart’s tau- c . See the section “[Stuart’s Tau-c](#)” on page 2558 for details.

The **MEASURES** option in the TABLES statement provides Stuart’s tau- c and its standard error. You can request an exact test for Stuart’s tau- c by specifying the **STUTC** option in the EXACT statement.

WTKAP

requests an asymptotic test for the weighted kappa coefficient. See the section “[Weighted Kappa Coefficient](#)” on page 2590 for details.

The **AGREE** option in the TABLES statement provides the weighted kappa statistic, its standard error, and its confidence limits. You can request an exact test for weighted kappa by specifying the **WTKAP** option in the EXACT statement.

Kappa coefficients are defined only for square tables, where the number of rows equals the number of columns. PROC FREQ does not compute kappa coefficients for tables that are not square. For 2×2 tables, the weighted kappa coefficient is identical to the simple kappa coefficient, and PROC FREQ presents only the simple kappa coefficient.

WEIGHT Statement

WEIGHT *variable* </ *option* > ;

The WEIGHT statement names a numeric variable that provides a weight for each observation in the input data set. The WEIGHT statement is most commonly used to input cell count data. See the section “[Inputting Frequency Counts](#)” on page 2544 for more information. If you use a WEIGHT statement, PROC FREQ assumes that an observation represents n observations, where n is the value of *variable*. The value of the WEIGHT variable is not required to be an integer.

If the value of the WEIGHT variable is missing, PROC FREQ does not use that observation in the analysis. If the value of the WEIGHT variable is zero, PROC FREQ ignores the observation unless you specify the **ZEROS** option, which includes observations with zero weights. If you do not specify a WEIGHT statement, PROC FREQ assigns a weight of one to each observation. The sum of the WEIGHT variable values represents the total number of observations.

If any value of the WEIGHT variable is negative, PROC FREQ displays the frequencies computed from the weighted values but does not compute percentages and statistics. If you create an output data set by using the **OUT=** option in the TABLES statement, PROC FREQ assigns missing values to the PERCENT variable. PROC FREQ also assigns missing values to the variables that the OUTEXPECT and OUTPCT options provide. If any value of the WEIGHT variable is negative, you cannot create an output data set by using the **OUTPUT** statement because statistics are not computed when there are negative weights.

You can specify the following *option* in the WEIGHT statement:

ZEROS

includes observations with zero weight values. By default, PROC FREQ ignores observations with zero weights.

If you specify the ZEROS option, frequency and crosstabulation tables display any levels corresponding to observations with zero weights. Without the ZEROS option, PROC FREQ does not process observations with zero weights, and so does not display levels that contain only observations with zero weights.

With the ZEROS option, PROC FREQ includes levels with zero weights in the chi-square goodness-of-fit test for one-way tables. Also, PROC FREQ includes any levels with zero weights in binomial computations for one-way tables. This makes it possible to compute binomial tests and estimates when the specified level contains no observations with positive weights.

For two-way tables, the ZEROS option enables computation of kappa statistics when there are levels that contain no observations with positive weight. For more information, see the section “[Tables with Zero Rows and Columns](#)” on page 2592.

Note that even with the ZEROS option, PROC FREQ does not compute the **CHISQ** or **MEASURES** statistics for two-way tables when the table has a zero row or zero column because most of these statistics are undefined in this case.

The ZEROS option invokes the **SPARSE** option in the TABLES statement, which includes table cells with a zero frequency count in the **LIST** output and in the **OUT=** data set. By default, without the SPARSE option, PROC FREQ does not include zero frequency cells in the LIST output or in the OUT= data set. If you specify the ZEROS option in the WEIGHT statement but do not want the SPARSE option, you can specify the **NOSPARSE** option in the TABLES statement.

Details: FREQ Procedure

Inputting Frequency Counts

PROC FREQ can use either raw data or cell count data to produce frequency and crosstabulation tables. *Raw data*, also known as case-record data, report the data as one record for each subject or sample member. *Cell count data* report the data as a table, listing all possible combinations of data values along with the frequency counts. This way of presenting data often appears in published results.

The following DATA step statements store raw data in a SAS data set:

```
data Raw;
  input Subject $ R C @@;
  datalines;
01 1 1  02 1 1  03 1 1  04 1 1  05 1 1
06 1 2  07 1 2  08 1 2  09 2 1  10 2 1
11 2 1  12 2 1  13 2 2  14 2 2  14 2 2
;
```

You can store the same data as cell counts by using the following DATA step statements:

```
data CellCounts;
  input R C Count @@;
  datalines;
1 1 5   1 2 3
2 1 4   2 2 3
;
```

The variable *R* contains the values for the rows, and the variable *C* contains the values for the columns. The variable *Count* contains the cell count for each row and column combination.

Both the *Raw* data set and the *CellCounts* data set produce identical frequency counts, two-way tables, and statistics. When using the *CellCounts* data set, you must include a *WEIGHT* statement to specify that the variable *Count* contains cell counts. For example, the following PROC FREQ statements create a two-way crosstabulation table by using the *CellCounts* data set:

```
proc freq data=CellCounts;
  tables R*C;
  weight Count;
run;
```

Grouping with Formats

PROC FREQ groups a variable's values according to its formatted values. If you assign a format to a variable with a *FORMAT* statement, PROC FREQ formats the variable values before dividing observations into the levels of a frequency or crosstabulation table.

For example, suppose that variable X has the values 1.1, 1.4, 1.7, 2.1, and 2.3. Each of these values appears as a level in the frequency table. If you decide to round each value to a single digit, include the following statement in the PROC FREQ step:

```
format X 1.;
```

Now the table lists the frequency count for formatted level 1 as two and for formatted level 2 as three.

PROC FREQ treats formatted character variables in the same way. The formatted values are used to group the observations into the levels of a frequency table or crosstabulation table. PROC FREQ uses the entire value of a character format to classify an observation.

You can also use the FORMAT statement to assign formats that were created with the FORMAT procedure to the variables. User-written formats determine the number of levels for a variable and provide labels for a table. If you use the same data with different formats, then you can produce frequency counts and statistics for different classifications of the variable values.

When you use PROC FORMAT to create a user-written format that combines missing and nonmissing values into one category, PROC FREQ treats the entire category of formatted values as missing. For example, a questionnaire codes 1 as yes, 2 as no, and 8 as a no answer. The following PROC FORMAT statements create a user-written format:

```
proc format;
  value Questfmt 1   ='Yes'
                2   ='No'
                8,. ='Missing';
run;
```

When you use a FORMAT statement to assign Questfmt. to a variable, the variable's frequency table no longer includes a frequency count for the response of 8. You must use the MISSING or MISSPRINT option in the TABLES statement to list the frequency for no answer. The frequency count for this level includes observations with either a value of 8 or a missing value (.).

The frequency or crosstabulation table lists the values of both character and numeric variables in ascending order based on internal (unformatted) variable values unless you change the order with the ORDER= option. To list the values in ascending order by formatted values, use ORDER=FORMATTED in the PROC FREQ statement.

For more information about the FORMAT statement, see *SAS Formats and Informats: Reference*.

Missing Values

When the value of the WEIGHT variable is missing, PROC FREQ does not include that observation in the analysis.

PROC FREQ treats missing BY variable values like any other BY variable value. The missing values form a separate BY group.

If an observation has a missing value for a variable in a TABLES request, by default PROC FREQ does not include that observation in the frequency or crosstabulation table. Also by default, PROC FREQ does not include observations with missing values in the computation of percentages and statistics. The procedure displays the number of missing observations below each table.

PROC FREQ also reports the number of missing values in output data sets. The TABLES statement OUT= data set includes an observation that contains the missing value frequency. The NMISS option in the OUTPUT statement provides an output data set variable that contains the missing value frequency.

The following options change the way in which PROC FREQ handles missing values of TABLES variables:

- MISSPRINT** displays missing value frequencies in frequency or crosstabulation tables but does not include them in computations of percentages or statistics.
- MISSING** treats missing values as a valid nonmissing level for all TABLES variables. Displays missing levels in frequency and crosstabulation tables and includes them in computations of percentages and statistics.

This example shows the three ways that PROC FREQ can handle missing values of TABLES variables. The following DATA step statements create a data set with a missing value for the variable A:

```
data one;
  input A Freq;
  datalines;
1 2
2 2
. 2
;
```

The following PROC FREQ statements request a one-way frequency table for the variable A. The first request does not specify a missing value option. The second request specifies the MISSPRINT option in the TABLES statement. The third request specifies the MISSING option in the TABLES statement.

```
proc freq data=one;
  tables A;
  weight Freq;
  title 'Default';
run;
proc freq data=one;
  tables A / missprint;
  weight Freq;
  title 'MISSPRINT Option';
run;
proc freq data=one;
  tables A / missing;
  weight Freq;
  title 'MISSING Option';
run;
```

Figure 38.12 displays the frequency tables produced by this example. The first table shows PROC FREQ's default behavior for handling missing values. The observation with a missing value of the TABLES variable A is not included in the table, and the frequency of missing values is displayed below the table. The second table, for which the MISSPRINT option is specified, displays the missing observation but does not include its frequency when computing the total frequency and percentages. The third table shows that PROC FREQ treats the missing level as a valid nonmissing level when the MISSING option is specified. The table displays the missing level, and PROC FREQ includes this level when computing frequencies and percentages.

Figure 38.12 Missing Values in Frequency Tables

Default				
The FREQ Procedure				
A	Frequency	Percent	Cumulative Frequency	Cumulative Percent
1	2	50.00	2	50.00
2	2	50.00	4	100.00
Frequency Missing = 2				
MISSPRINT Option				
The FREQ Procedure				
A	Frequency	Percent	Cumulative Frequency	Cumulative Percent
.	2	.	.	.
1	2	50.00	2	50.00
2	2	50.00	4	100.00
Frequency Missing = 2				
MISSING Option				
The FREQ Procedure				
A	Frequency	Percent	Cumulative Frequency	Cumulative Percent
.	2	33.33	2	33.33
1	2	33.33	4	66.67
2	2	33.33	6	100.00

When a combination of variable values for a two-way table is missing, PROC FREQ assigns zero to the frequency count for the table cell. By default, PROC FREQ does not display missing combinations in LIST format. Also, PROC FREQ does not include missing combinations in the OUT= output data set by default. To include missing combinations, you can specify the SPARSE option with the LIST or OUT= option in the TABLES statement.

In-Database Computation

The FREQ procedure can use in-database computation to construct frequency and crosstabulation tables when the **DATA=** input data set is stored as a table in a supported database management system (DBMS). Supported databases include Teradata, DB2 under UNIX, and Oracle. In-database computation can provide the advantages of faster processing and reduced data transfer between the database and SAS software. For information about in-database computation, see the section “In-Database Procedures” in *SAS/ACCESS for Relational Databases: Reference*.

PROC FREQ performs in-database computation by using SQL implicit pass-through. The procedure generates SQL queries that are based on the tables that you request in the **TABLES** statement. The database executes these SQL queries to construct initial summary tables, which are then transmitted to PROC FREQ. The procedure uses this summary information to perform the remaining analyses and tasks in the usual way (out of the database). So instead of transferring the entire data set over the network between the database and SAS software, the in-database method transfers only the summary tables. This can substantially reduce processing time when the dimensions of the summary tables (in terms of rows and columns) are much smaller than the dimensions of the entire database table (in terms of individual observations). Additionally, in-database summarization uses efficient parallel processing, which can also provide performance advantages.

In-database computation is controlled by the SQLGENERATION option, which you can specify in either a LIBNAME statement or an OPTIONS statement. See the section “In-Database Procedures” in *SAS/ACCESS for Relational Databases: Reference* for details about the SQLGENERATION option and other options that affect in-database computation. By default, PROC FREQ uses in-database computation when possible. There are no FREQ procedure options that control in-database computation.

PROC FREQ uses formatted values to group observations into the levels of frequency and crosstabulation tables. See the section “[Grouping with Formats](#)” on page 2544 for more information. If formats are available in the database, then in-database summarization uses the formats. If formats are not available in the database, then in-database summarization is based on the raw data values, and PROC FREQ performs the final, formatted classification (out of the database). For more information, see the section “Deploying and Using SAS Formats in Teradata” in *SAS/ACCESS for Relational Databases: Reference*.

The order of observations is not inherently defined for DBMS tables. The following options relate to the order of observations and therefore should not be specified for PROC FREQ in-database computation:

- If you specify the **FIRSTOBS=** or **OBS=** data set option, PROC FREQ does not perform in-database computation.
- If you specify the **NOTSORTED** option in the **BY** statement, PROC FREQ in-database computation ignores it and uses the default **ASCENDING** order for **BY** variables.
- If you specify the **ORDER=DATA** option for input data in a DBMS table, PROC FREQ computation might produce different results for separate runs of the same analysis. In addition to determining the order of variable levels in crosstabulation table displays, the **ORDER=** option can also affect the values of many of the test statistics and measures that PROC FREQ computes.

Statistical Computations

Definitions and Notation

A two-way table represents the crosstabulation of row variable X and column variable Y . Let the table row values or levels be denoted by $X_i, i = 1, 2, \dots, R$, and the column values by $Y_j, j = 1, 2, \dots, C$. Let n_{ij} denote the frequency of the table cell in the i th row and j th column and define the following notation:

$$n_{i.} = \sum_j n_{ij} \quad (\text{row totals})$$

$$n_{.j} = \sum_i n_{ij} \quad (\text{column totals})$$

$$n = \sum_i \sum_j n_{ij} \quad (\text{overall total})$$

$$p_{ij} = n_{ij}/n \quad (\text{cell percentages})$$

$$p_{i.} = n_{i.}/n \quad (\text{row percentages of total})$$

$$p_{.j} = n_{.j}/n \quad (\text{column percentages of total})$$

$$R_i = \text{score for row } i$$

$$C_j = \text{score for column } j$$

$$\bar{R} = \sum_i n_{i.} R_i / n \quad (\text{average row score})$$

$$\bar{C} = \sum_j n_{.j} C_j / n \quad (\text{average column score})$$

$$A_{ij} = \sum_{k>i} \sum_{l>j} n_{kl} + \sum_{k<i} \sum_{l<j} n_{kl}$$

$$D_{ij} = \sum_{k>i} \sum_{l<j} n_{kl} + \sum_{k<i} \sum_{l>j} n_{kl}$$

$$P = \sum_i \sum_j n_{ij} A_{ij} \quad (\text{twice the number of concordances})$$

$$Q = \sum_i \sum_j n_{ij} D_{ij} \quad (\text{twice the number of discordances})$$

Scores

PROC FREQ uses scores of the variable values to compute the Mantel-Haenszel chi-square, Pearson correlation, Cochran-Armitage test for trend, weighted kappa coefficient, and Cochran-Mantel-Haenszel statistics. The SCORES= option in the TABLES statement specifies the score type that PROC FREQ uses. The available score types are TABLE, RANK, RIDIT, and MODRIDIT scores. The default score type is TABLE. Using MODRIDIT, RANK, or RIDIT scores yields nonparametric analyses.

For numeric variables, table scores are the values of the row and column levels. If the row or column variable is formatted, then the table score is the internal numeric value corresponding to that level. If two or more numeric values are classified into the same formatted level, then the internal numeric value for that

level is the smallest of these values. For character variables, table scores are defined as the row numbers and column numbers (that is, 1 for the first row, 2 for the second row, and so on).

Rank scores, which you request with the SCORES=RANK option, are defined as

$$R_i^1 = \sum_{k < i} n_{k.} + (n_{i.} + 1)/2 \quad i = 1, 2, \dots, R$$

$$C_j^1 = \sum_{l < j} n_{.l} + (n_{.j} + 1)/2 \quad j = 1, 2, \dots, C$$

where R_i^1 is the rank score of row i , and C_j^1 is the rank score of column j . Note that rank scores yield midranks for tied values.

Ridit scores, which you request with the SCORES=RIDIT option, are defined as rank scores standardized by the sample size (Bross 1958; Mack and Skillings 1980). Ridit scores are derived from the rank scores as

$$R_i^2 = R_i^1/n \quad i = 1, 2, \dots, R$$

$$C_j^2 = C_j^1/n \quad j = 1, 2, \dots, C$$

Modified ridit scores (SCORES=MODRIDIT) represent the expected values of the order statistics of the uniform distribution on (0,1) (van Elteren 1960; Lehmann 2006). Modified ridit scores are derived from rank scores as

$$R_i^3 = R_i^1/(n + 1) \quad i = 1, 2, \dots, R$$

$$C_j^3 = C_j^1/(n + 1) \quad j = 1, 2, \dots, C$$

Chi-Square Tests and Statistics

The CHISQ option provides chi-square tests of homogeneity or independence and measures of association that are based on the chi-square statistic. When you specify the CHISQ option in the TABLES statement, PROC FREQ computes the following chi-square tests for each two-way table: Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square tests. PROC FREQ provides the following measures of association that are based on the Pearson chi-square statistic: phi coefficient, contingency coefficient, and Cramér's V . For 2×2 tables, the CHISQ option also provides Fisher's exact test and the continuity-adjusted chi-square statistic. You can request Fisher's exact test for general $R \times C$ tables by specifying the FISHER option in the TABLES or EXACT statement.

If you specify the CHISQ option for one-way tables, PROC FREQ provides a one-way Pearson chi-square goodness-of-fit test. If you specify the CHISQ(LRCHISQ) option for one-way tables, PROC FREQ also provides a one-way likelihood ratio chi-square test. The other tests and statistics that the CHISQ option produces are available only for two-way tables.

For two-way tables, the null hypothesis for the chi-square tests is no association between the row variable and the column variable. When the sample size n is large, the test statistics have asymptotic chi-square distributions under the null hypothesis. When the sample size is not large, or when the data set is sparse or heavily tied, exact tests might be more appropriate than asymptotic tests. PROC FREQ provides exact p -values for the Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square tests, in addition to Fisher's exact test. For one-way tables, PROC FREQ provides exact p -values for the Pearson and likelihood ratio chi-square goodness-of-fit tests. You can request these exact tests by specifying the

corresponding options in the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

The Mantel-Haenszel chi-square statistic is appropriate only when both variables lie on an ordinal scale. The other chi-square tests and statistics in this section are appropriate for either nominal or ordinal variables. The following sections give the formulas that PROC FREQ uses to compute the chi-square tests and statistics. For more information about these statistics, see Agresti (2007) and Stokes, Davis, and Koch (2012), and the other references cited.

Chi-Square Test for One-Way Tables

For one-way frequency tables, the CHISQ option in the TABLES statement provides a chi-square goodness-of-fit test. Let C denote the number of classes, or levels, in the one-way table. Let f_i denote the frequency of class i (or the number of observations in class i) for $i = 1, 2, \dots, C$. Then PROC FREQ computes the one-way chi-square statistic as

$$Q_P = \sum_{i=1}^C (f_i - e_i)^2 / e_i$$

where e_i is the expected frequency for class i under the null hypothesis.

In the test for equal proportions, which is the default for the CHISQ option, the null hypothesis specifies equal proportions of the total sample size for each class. Under this null hypothesis, the expected frequency for each class equals the total sample size divided by the number of classes,

$$e_i = n / C \quad \text{for } i = 1, 2, \dots, C$$

In the test for specified frequencies, which PROC FREQ computes when you input null hypothesis frequencies by using the TESTF= option, the expected frequencies are the TESTF= values that you specify. In the test for specified proportions, which PROC FREQ computes when you input null hypothesis proportions by using the TESTP= option, the expected frequencies are determined from the specified TESTP= proportions p_i as

$$e_i = p_i \times n \quad \text{for } i = 1, 2, \dots, C$$

Under the null hypothesis (of equal proportions, specified frequencies, or specified proportions), Q_P has an asymptotic chi-square distribution with $C-1$ degrees of freedom.

In addition to the asymptotic test, you can request an exact one-way chi-square test by specifying the CHISQ option in the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

Pearson Chi-Square Test for Two-Way Tables

The Pearson chi-square for two-way tables involves the differences between the observed and expected frequencies, where the expected frequencies are computed under the null hypothesis of independence. The Pearson chi-square statistic is computed as

$$Q_P = \sum_i \sum_j (n_{ij} - e_{ij})^2 / e_{ij}$$

where n_{ij} is the observed frequency in table cell (i, j) and e_{ij} is the expected frequency for table cell (i, j) . The expected frequency is computed under the null hypothesis that the row and column variables are independent,

$$e_{ij} = (n_{i.} n_{.j}) / n$$

When the row and column variables are independent, Q_P has an asymptotic chi-square distribution with $(R-1)(C-1)$ degrees of freedom. For large values of Q_P , this test rejects the null hypothesis in favor of the alternative hypothesis of general association.

In addition to the asymptotic test, you can request an exact Pearson chi-square test by specifying the PCHI or CHISQ option in the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

For 2×2 tables, the Pearson chi-square is also appropriate for testing the equality of two binomial proportions. For $R \times 2$ and $2 \times C$ tables, the Pearson chi-square tests the homogeneity of proportions. See Fienberg (1980) for details.

Standardized Residuals

When you specify the CROSSLIST(STDRES) option in the TABLES statement for two-way or multiway tables, PROC FREQ displays the standardized residuals in the CROSSLIST table.

The standardized residual of a crosstabulation table cell is the ratio of (*frequency* – *expected*) to its standard error, where *frequency* is the table cell frequency and *expected* is the estimated expected cell frequency. The expected frequency is computed under the null hypothesis that the row and column variables are independent. See the section “Pearson Chi-Square Test for Two-Way Tables” on page 2551 for more information.

PROC FREQ computes the standardized residual of table cell (i, j) as

$$(n_{ij} - e_{ij}) / \sqrt{e_{ij}(1 - p_{i.})(1 - p_{.j})}$$

where n_{ij} is the observed frequency of table cell (i, j) , e_{ij} is the expected frequency of the table cell, $p_{i.}$ is the proportion in row i ($n_{i.}/n$), and $p_{.j}$ is the proportion in column j ($n_{.j}/n$). The expected frequency of table cell (i, j) is computed as

$$e_{ij} = (n_{i.} n_{.j}) / n$$

Under the null hypothesis of independence, each standardized residual has an asymptotic standard normal distribution. See section 2.4.5 of Agresti (2007) for more information.

Likelihood Ratio Chi-Square Test for One-Way Tables

For one-way frequency tables, the CHISQ(LRCHISQ) option in the TABLES statement provides a likelihood ratio chi-square goodness-of-fit test. By default, the likelihood ratio test is based on the null hypothesis of equal proportions in the C classes (levels) of the one-way table. If you specify null hypothesis proportions or frequencies by using the CHISQ(TESTP=) or CHISQ(TESTF=) option, respectively, the likelihood ratio test is based on the null hypothesis values that you specify.

PROC FREQ computes the one-way likelihood ratio test as

$$G^2 = 2 \sum_{i=1}^C f_i \ln(f_i / e_i)$$

where f_i is the observed frequency of class i , and e_i is the expected frequency of class i under the null hypothesis.

For the null hypothesis of equal proportions, the expected frequency of each class equals the total sample size divided by the number of classes,

$$e_i = n / C \quad \text{for } i = 1, 2, \dots, C$$

If you provide null hypothesis frequencies by specifying the CHISQ(TESTF=) option in the TABLES statement, the expected frequencies are the TESTF= values that you specify. If you provide null hypothesis proportions by specifying the CHISQ(ATESTP=) option in the TABLES statement, PROC FREQ computes the expected frequencies as

$$e_i = p_i \times n \quad \text{for } i = 1, 2, \dots, C$$

where the proportions p_i are the TESTP= values that you specify.

Under the null hypothesis (of equal proportions, specified frequencies, or specified proportions), the likelihood ratio statistic G^2 has an asymptotic chi-square distribution with $C-1$ degrees of freedom.

In addition to the asymptotic test, you can request an exact one-way likelihood ratio chi-square test by specifying the LRCHISQ option in the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

Likelihood Ratio Chi-Square Test

The likelihood ratio chi-square involves the ratios between the observed and expected frequencies. The likelihood ratio chi-square statistic is computed as

$$G^2 = 2 \sum_i \sum_j n_{ij} \ln(n_{ij}/e_{ij})$$

where n_{ij} is the observed frequency in table cell (i, j) and e_{ij} is the expected frequency for table cell (i, j) .

When the row and column variables are independent, G^2 has an asymptotic chi-square distribution with $(R-1)(C-1)$ degrees of freedom.

In addition to the asymptotic test, you can request an exact likelihood ratio chi-square test by specifying the LRCHI or CHISQ option in the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

Continuity-Adjusted Chi-Square Test

The continuity-adjusted chi-square for 2×2 tables is similar to the Pearson chi-square, but it is adjusted for the continuity of the chi-square distribution. The continuity-adjusted chi-square is most useful for small sample sizes. The use of the continuity adjustment is somewhat controversial; this chi-square test is more conservative (and more like Fisher’s exact test) when the sample size is small. As the sample size increases, the continuity-adjusted chi-square becomes more like the Pearson chi-square.

The continuity-adjusted chi-square statistic is computed as

$$Q_C = \sum_i \sum_j (\max(0, |n_{ij} - e_{ij}| - 0.5))^2 / e_{ij}$$

Under the null hypothesis of independence, Q_C has an asymptotic chi-square distribution with $(R-1)(C-1)$ degrees of freedom.

Mantel-Haenszel Chi-Square Test

The Mantel-Haenszel chi-square statistic tests the alternative hypothesis that there is a linear association between the row variable and the column variable. Both variables must lie on an ordinal scale. The Mantel-Haenszel chi-square statistic is computed as

$$Q_{MH} = (n-1)r^2$$

where r is the Pearson correlation between the row variable and the column variable. For a description of the Pearson correlation, see the “[Pearson Correlation Coefficient](#)” on page 2559. The Pearson correlation and thus the Mantel-Haenszel chi-square statistic use the scores that you specify in the SCORES= option in the TABLES statement. See Mantel and Haenszel (1959) and Landis, Heyman, and Koch (1978) for more information.

Under the null hypothesis of no association, Q_{MH} has an asymptotic chi-square distribution with one degree of freedom.

In addition to the asymptotic test, you can request an exact Mantel-Haenszel chi-square test by specifying the MHCHI or CHISQ option in the EXACT statement. See the section “[Exact Statistics](#)” on page 2601 for more information.

Fisher's Exact Test

Fisher's exact test is another test of association between the row and column variables. This test assumes that the row and column totals are fixed, and then uses the hypergeometric distribution to compute probabilities of possible tables conditional on the observed row and column totals. Fisher's exact test does not depend on any large-sample distribution assumptions, and so it is appropriate even for small sample sizes and for sparse tables.

2 × 2 Tables For 2 × 2 tables, PROC FREQ gives the following information for Fisher's exact test: table probability, two-sided p -value, left-sided p -value, and right-sided p -value. The table probability equals the hypergeometric probability of the observed table, and is in fact the value of the test statistic for Fisher's exact test.

Where p is the hypergeometric probability of a specific table with the observed row and column totals, Fisher's exact p -values are computed by summing probabilities p over defined sets of tables,

$$\text{Prob} = \sum_A p$$

The two-sided p -value is the sum of all possible table probabilities (conditional on the observed row and column totals) that are less than or equal to the observed table probability. For the two-sided p -value, the set A includes all possible tables with hypergeometric probabilities less than or equal to the probability of the observed table. A small two-sided p -value supports the alternative hypothesis of association between the row and column variables.

For 2 × 2 tables, one-sided p -values for Fisher's exact test are defined in terms of the frequency of the cell in the first row and first column of the table, the (1,1) cell. Denoting the observed (1,1) cell frequency by n_{11} , the left-sided p -value for Fisher's exact test is the probability that the (1,1) cell frequency is less than or equal to n_{11} . For the left-sided p -value, the set A includes those tables with a (1,1) cell frequency less than or equal to n_{11} . A small left-sided p -value supports the alternative hypothesis that the probability of an observation being in the first cell is actually less than expected under the null hypothesis of independent row and column variables.

Similarly, for a right-sided alternative hypothesis, A is the set of tables where the frequency of the (1,1) cell is greater than or equal to that in the observed table. A small right-sided p -value supports the alternative that the probability of the first cell is actually greater than that expected under the null hypothesis.

Because the (1,1) cell frequency completely determines the 2 × 2 table when the marginal row and column sums are fixed, these one-sided alternatives can be stated equivalently in terms of other cell probabilities or

ratios of cell probabilities. The left-sided alternative is equivalent to an odds ratio less than 1, where the odds ratio equals $(n_{11}n_{22}/n_{12}n_{21})$. Additionally, the left-sided alternative is equivalent to the column 1 risk for row 1 being less than the column 1 risk for row 2, $p_{1|1} < p_{1|2}$. Similarly, the right-sided alternative is equivalent to the column 1 risk for row 1 being greater than the column 1 risk for row 2, $p_{1|1} > p_{1|2}$. See Agresti (2007) for details.

R × C Tables Fisher's exact test was extended to general $R \times C$ tables by Freeman and Halton (1951), and this test is also known as the Freeman-Halton test. For $R \times C$ tables, the two-sided p -value definition is the same as for 2×2 tables. The set A contains all tables with p less than or equal to the probability of the observed table. A small p -value supports the alternative hypothesis of association between the row and column variables. For $R \times C$ tables, Fisher's exact test is inherently two-sided. The alternative hypothesis is defined only in terms of general, and not linear, association. Therefore, Fisher's exact test does not have right-sided or left-sided p -values for general $R \times C$ tables.

For $R \times C$ tables, PROC FREQ computes Fisher's exact test by using the network algorithm of Mehta and Patel (1983), which provides a faster and more efficient solution than direct enumeration. See the section "Exact Statistics" on page 2601 for more details.

Phi Coefficient

The phi coefficient is a measure of association derived from the Pearson chi-square. The range of the phi coefficient is $-1 \leq \phi \leq 1$ for 2×2 tables. For tables larger than 2×2 , the range is $0 \leq \phi \leq \min(\sqrt{R-1}, \sqrt{C-1})$ (Liebetrau 1983). The phi coefficient is computed as

$$\phi = (n_{11}n_{22} - n_{12}n_{21}) / \sqrt{n_{1.}n_{2.}n_{.1}n_{.2}} \quad \text{for } 2 \times 2 \text{ tables}$$

$$\phi = \sqrt{Q_P/n} \quad \text{otherwise}$$

See Fleiss, Levin, and Paik (2003, pp. 98–99) for more information.

Contingency Coefficient

The contingency coefficient is a measure of association derived from the Pearson chi-square. The range of the contingency coefficient is $0 \leq P \leq \sqrt{(m-1)/m}$, where $m = \min(R, C)$ (Liebetrau 1983). The contingency coefficient is computed as

$$P = \sqrt{Q_P / (Q_P + n)}$$

See Kendall and Stuart (1979, pp. 587–588) for more information.

Cramér's V

Cramér's V is a measure of association derived from the Pearson chi-square. It is designed so that the attainable upper bound is always 1. The range of Cramér's V is $-1 \leq V \leq 1$ for 2×2 tables; for tables larger than 2×2 , the range is $0 \leq V \leq 1$. Cramér's V is computed as

$$V = \phi \quad \text{for } 2 \times 2 \text{ tables}$$

$$V = \sqrt{\frac{Q_P/n}{\min(R-1, C-1)}} \quad \text{otherwise}$$

See Kendall and Stuart (1979, p. 588) for more information.

Measures of Association

When you specify the MEASURES option in the TABLES statement, PROC FREQ computes several statistics that describe the association between the row and column variables of the contingency table. The following are measures of ordinal association that consider whether the column variable *Y* tends to increase as the row variable *X* increases: gamma, Kendall's tau-*b*, Stuart's tau-*c*, and Somers' *D*. These measures are appropriate for ordinal variables, and they classify pairs of observations as *concordant* or *discordant*. A pair is concordant if the observation with the larger value of *X* also has the larger value of *Y*. A pair is discordant if the observation with the larger value of *X* has the smaller value of *Y*. See Agresti (2007) and the other references cited for the individual measures of association.

The Pearson correlation coefficient and the Spearman rank correlation coefficient are also appropriate for ordinal variables. The Pearson correlation describes the strength of the linear association between the row and column variables, and it is computed by using the row and column scores specified by the SCORES= option in the TABLES statement. The Spearman correlation is computed with rank scores. The polychoric correlation (requested by the PLCORR option) also requires ordinal variables and assumes that the variables have an underlying bivariate normal distribution. The following measures of association do not require ordinal variables and are appropriate for nominal variables: lambda asymmetric, lambda symmetric, and the uncertainty coefficients.

PROC FREQ computes estimates of the measures according to the formulas given in the following sections. For each measure, PROC FREQ computes an asymptotic standard error (ASE), which is the square root of the asymptotic variance denoted by Var in the following sections.

Confidence Limits

If you specify the CL option in the TABLES statement, PROC FREQ computes asymptotic confidence limits for all MEASURES statistics. The confidence coefficient is determined according to the value of the ALPHA= option, which, by default, equals 0.05 and produces 95% confidence limits.

The confidence limits are computed as

$$\text{Est} \pm (z_{\alpha/2} \times \text{ASE})$$

where Est is the estimate of the measure, $z_{\alpha/2}$ is the 100(1 - $\alpha/2$) percentile of the standard normal distribution, and ASE is the asymptotic standard error of the estimate.

Asymptotic Tests

For each measure that you specify in the TEST statement, PROC FREQ computes an asymptotic test of the null hypothesis that the measure equals zero. Asymptotic tests are available for the following measures of association: gamma, Kendall's tau-*b*, Stuart's tau-*c*, Somers' $D(C|R)$, Somers' $D(R|C)$, the Pearson correlation coefficient, and the Spearman rank correlation coefficient. To compute an asymptotic test, PROC FREQ uses a standardized test statistic *z*, which has an asymptotic standard normal distribution under the null hypothesis. The test statistic is computed as

$$z = \text{Est} / \sqrt{\text{Var}_0(\text{Est})}$$

where Est is the estimate of the measure and $\text{Var}_0(\text{Est})$ is the variance of the estimate under the null hypothesis. Formulas for $\text{Var}_0(\text{Est})$ for the individual measures of association are given in the following sections.

Note that the ratio of Est to $\sqrt{\text{Var}_0(\text{Est})}$ is the same for the following measures: gamma, Kendall's tau-*b*, Stuart's tau-*c*, Somers' $D(C|R)$, and Somers' $D(R|C)$. Therefore, the tests for these measures are identical. For example, the *p*-values for the test of H_0 : gamma = 0 equal the *p*-values for the test of H_0 : tau-*b* = 0.

PROC FREQ computes one-sided and two-sided *p*-values for each of these tests. When the test statistic *z* is greater than its null hypothesis expected value of zero, PROC FREQ displays the right-sided *p*-value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided *p*-value supports the alternative hypothesis that the true value of the measure is greater than zero. When the test statistic is less than or equal to zero, PROC FREQ displays the left-sided *p*-value, which is the probability of a smaller value of the statistic occurring under the null hypothesis. A small left-sided *p*-value supports the alternative hypothesis that the true value of the measure is less than zero. The one-sided *p*-value P_1 can be expressed as

$$P_1 = \begin{cases} \text{Prob}(Z > z) & \text{if } z > 0 \\ \text{Prob}(Z < z) & \text{if } z \leq 0 \end{cases}$$

where *Z* has a standard normal distribution. The two-sided *p*-value P_2 is computed as

$$P_2 = \text{Prob}(|Z| > |z|)$$

Exact Tests

Exact tests are available for the following measures of association: Kendall's tau-*b*, Stuart's tau-*c*, Somers' $D(C|R)$ and $(R|C)$, the Pearson correlation coefficient, and the Spearman rank correlation coefficient. If you request an exact test for a measure of association in the EXACT statement, PROC FREQ computes the exact test of the hypothesis that the measure equals zero. See the section "Exact Statistics" on page 2601 for details.

Gamma

The gamma (Γ) statistic is based only on the number of concordant and discordant pairs of observations. It ignores tied pairs (that is, pairs of observations that have equal values of *X* or equal values of *Y*). Gamma is appropriate only when both variables lie on an ordinal scale. The range of gamma is $-1 \leq \Gamma \leq 1$. If the row and column variables are independent, then gamma tends to be close to zero. Gamma is computed as

$$G = (P - Q) / (P + Q)$$

and the asymptotic variance is

$$\text{Var}(G) = \frac{16}{(P + Q)^4} \sum_i \sum_j n_{ij} (QA_{ij} - PD_{ij})^2$$

For 2×2 tables, gamma is equivalent to Yule's *Q*. See Goodman and Kruskal (1979) and Agresti (2002) for more information.

The variance under the null hypothesis that gamma equals zero is computed as

$$\text{Var}_0(G) = \frac{4}{(P + Q)^2} \left(\sum_i \sum_j n_{ij} (A_{ij} - D_{ij})^2 - (P - Q)^2/n \right)$$

See Brown and Benedetti (1977) for details.

Kendall's Tau-b

Kendall's tau- b (τ_b) is similar to gamma except that tau- b uses a correction for ties. Tau- b is appropriate only when both variables lie on an ordinal scale. The range of tau- b is $-1 \leq \tau_b \leq 1$. Kendall's tau- b is computed as

$$t_b = (P - Q) / \sqrt{w_r w_c}$$

and the asymptotic variance is

$$\text{Var}(t_b) = \frac{1}{w^4} \left(\sum_i \sum_j n_{ij} (2w d_{ij} + t_b v_{ij})^2 - n^3 t_b^2 (w_r + w_c)^2 \right)$$

where

$$\begin{aligned} w &= \sqrt{w_r w_c} \\ w_r &= n^2 - \sum_i n_{i.}^2 \\ w_c &= n^2 - \sum_j n_{.j}^2 \\ d_{ij} &= A_{ij} - D_{ij} \\ v_{ij} &= n_{i.} w_c + n_{.j} w_r \end{aligned}$$

See Kendall (1955) for more information.

The variance under the null hypothesis that tau- b equals zero is computed as

$$\text{Var}_0(t_b) = \frac{4}{w_r w_c} \left(\sum_i \sum_j n_{ij} (A_{ij} - D_{ij})^2 - (P - Q)^2 / n \right)$$

See Brown and Benedetti (1977) for details.

PROC FREQ also provides an exact test for the Kendall's tau- b . You can request this test by specifying the KENTB option in the EXACT statement. See the section “[Exact Statistics](#)” on page 2601 for more information.

Stuart's Tau-c

Stuart's tau- c (τ_c) makes an adjustment for table size in addition to a correction for ties. Tau- c is appropriate only when both variables lie on an ordinal scale. The range of tau- c is $-1 \leq \tau_c \leq 1$. Stuart's tau- c is computed as

$$t_c = m(P - Q) / n^2(m - 1)$$

and the asymptotic variance is

$$\text{Var}(t_c) = \frac{4m^2}{(m - 1)^2 n^4} \left(\sum_i \sum_j n_{ij} d_{ij}^2 - (P - Q)^2 / n \right)$$

where $m = \min(R, C)$ and $d_{ij} = A_{ij} - D_{ij}$. The variance under the null hypothesis that tau- c equals zero is the same as the asymptotic variance Var,

$$\text{Var}_0(t_c) = \text{Var}(t_c)$$

See Brown and Benedetti (1977) for details.

PROC FREQ also provides an exact test for the Stuart's tau- c . You can request this test by specifying the STUTC option in the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

Somers' D

Somers' $D(C|R)$ and Somers' $D(R|C)$ are asymmetric modifications of tau- b . $C|R$ indicates that the row variable X is regarded as the independent variable and the column variable Y is regarded as dependent. Similarly, $R|C$ indicates that the column variable Y is regarded as the independent variable and the row variable X is regarded as dependent. Somers' D differs from tau- b in that it uses a correction only for pairs that are tied on the independent variable. Somers' D is appropriate only when both variables lie on an ordinal scale. The range of Somers' D is $-1 \leq D \leq 1$. Somers' $D(C|R)$ is computed as

$$D(C|R) = (P - Q) / w_r$$

and its asymptotic variance is

$$\text{Var}(D(C|R)) = \frac{4}{w_r^4} \sum_i \sum_j n_{ij} (w_r d_{ij} - (P - Q)(n - n_{i.}))^2$$

where $d_{ij} = A_{ij} - D_{ij}$ and

$$w_r = n^2 - \sum_i n_{i.}^2.$$

For more information, see Somers (1962); Goodman and Kruskal (1979); Liebetrau (1983).

The variance under the null hypothesis that $D(C|R)$ equals zero is computed as

$$\text{Var}_0(D(C|R)) = \frac{4}{w_r^2} \left(\sum_i \sum_j n_{ij} (A_{ij} - D_{ij})^2 - (P - Q)^2 / n \right)$$

See Brown and Benedetti (1977) for details.

Formulas for Somers' $D(R|C)$ are obtained by interchanging the indices.

PROC FREQ also provides exact tests for Somers' $D(C|R)$ and $(R|C)$. You can request these tests by specifying the SMDCR and SMDCR options in the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

Pearson Correlation Coefficient

The Pearson correlation coefficient (ρ) is computed by using the scores specified in the SCORES= option. This measure is appropriate only when both variables lie on an ordinal scale. The range of the Pearson correlation is $-1 \leq \rho \leq 1$. The Pearson correlation coefficient is computed as

$$r = v/w = ss_{rc} / \sqrt{ss_r ss_c}$$

and its asymptotic variance is

$$\text{Var}(r) = \frac{1}{w^4} \sum_i \sum_j n_{ij} \left(w(R_i - \bar{R})(C_j - \bar{C}) - \frac{b_{ij}v}{2w} \right)^2$$

where R_i and C_j are the row and column scores and

$$ss_r = \sum_i \sum_j n_{ij} (R_i - \bar{R})^2$$

$$ss_c = \sum_i \sum_j n_{ij} (C_j - \bar{C})^2$$

$$ss_{rc} = \sum_i \sum_j n_{ij} (R_i - \bar{R})(C_j - \bar{C})$$

$$b_{ij} = (R_i - \bar{R})^2 ss_c + (C_j - \bar{C})^2 ss_r$$

$$v = ss_{rc}$$

$$w = \sqrt{ss_r ss_c}$$

See Snedecor and Cochran (1989) for more information.

The SCORES= option in the TABLES statement determines the type of row and column scores used to compute the Pearson correlation (and other score-based statistics). The default is SCORES=TABLE. See the section “[Scores](#)” on page 2549 for details about the available score types and how they are computed.

The variance under the null hypothesis that the correlation equals zero is computed as

$$\text{Var}_0(r) = \left(\sum_i \sum_j n_{ij} (R_i - \bar{R})^2 (C_j - \bar{C})^2 - ss_{rc}^2 / n \right) / ss_r ss_c$$

Note that this expression for the variance is derived for multinomial sampling in a contingency table framework, and it differs from the form obtained under the assumption that both variables are continuous and normally distributed. See Brown and Benedetti (1977) for details.

PROC FREQ also provides an exact test for the Pearson correlation coefficient. You can request this test by specifying the PCORR option in the EXACT statement. See the section “[Exact Statistics](#)” on page 2601 for more information.

Spearman Rank Correlation Coefficient

The Spearman correlation coefficient (ρ_s) is computed by using rank scores, which are defined in the section “[Scores](#)” on page 2549. This measure is appropriate only when both variables lie on an ordinal scale. The range of the Spearman correlation is $-1 \leq \rho_s \leq 1$. The Spearman correlation coefficient is computed as

$$r_s = v / w$$

and its asymptotic variance is

$$\text{Var}(r_s) = \frac{1}{n^2 w^4} \sum_i \sum_j n_{ij} (z_{ij} - \bar{z})^2$$

where R_i^1 and C_j^1 are the row and column rank scores and

$$v = \sum_i \sum_j n_{ij} R(i) C(j)$$

$$w = \frac{1}{12} \sqrt{FG}$$

$$F = n^3 - \sum_i n_{i.}^3$$

$$G = n^3 - \sum_j n_{.j}^3$$

$$R(i) = R_i^1 - n/2$$

$$C(j) = C_j^1 - n/2$$

$$\bar{z} = \frac{1}{n} \sum_i \sum_j n_{ij} z_{ij}$$

$$z_{ij} = w v_{ij} - v w_{ij}$$

$$v_{ij} = n \left(R(i) C(j) + \frac{1}{2} \sum_l n_{il} C(l) + \frac{1}{2} \sum_k n_{kj} R(k) + \right. \\ \left. \sum_l \sum_{k>i} n_{kl} C(l) + \sum_k \sum_{l>j} n_{kl} R(k) \right)$$

$$w_{ij} = \frac{-n}{96w} (F n_{.j}^2 + G n_{i.}^2)$$

See Snedecor and Cochran (1989) for more information.

The variance under the null hypothesis that the correlation equals zero is computed as

$$\text{Var}_0(r_s) = \frac{1}{n^2 w^2} \sum_i \sum_j n_{ij} (v_{ij} - \bar{v})^2$$

where

$$\bar{v} = \sum_i \sum_j n_{ij} v_{ij} / n$$

Note that the asymptotic variance is derived for multinomial sampling in a contingency table framework, and it differs from the form obtained under the assumption that both variables are continuous and normally distributed. See Brown and Benedetti (1977) for details.

PROC FREQ also provides an exact test for the Spearman correlation coefficient. You can request this test by specifying the SCORR option in the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

Polychoric Correlation

When you specify the PLCORR option in the TABLES statement, PROC FREQ computes the polychoric correlation and its standard error. The polychoric correlation is based on the assumption that the two ordinal, categorical variables of the frequency table have an underlying bivariate normal distribution. The polychoric correlation coefficient is the maximum likelihood estimate of the product-moment correlation between the underlying normal variables. The range of the polychoric correlation is from -1 to 1 . For 2×2 tables, the polychoric correlation is also known as the tetrachoric correlation (and it is labeled as such in the displayed output). See Drasgow (1986) for an overview of polychoric correlation coefficient.

Olsson (1979) gives the likelihood equations and the asymptotic standard errors for estimating the polychoric correlation. The underlying continuous variables relate to the observed crosstabulation table through thresholds, which define a range of numeric values that correspond to each categorical (table) level. PROC FREQ uses Olsson’s maximum likelihood method for simultaneous estimation of the polychoric correlation and the thresholds. (Olsson also presents a two-step method that estimates the thresholds first.)

PROC FREQ iteratively solves the likelihood equations by using a Newton-Raphson algorithm. The initial estimates of the thresholds are computed from the inverse of the normal distribution function at the cumulative marginal proportions of the table. Iterative computation of the polychoric correlation stops when the convergence measure falls below the convergence criterion or when the maximum number of iterations is reached, whichever occurs first. For parameter values that are less than 0.01, the procedure evaluates convergence by using the absolute difference instead of the relative difference. The PLCORR(CONVERGE=) option specifies the convergence criterion, which is 0.0001 by default. The PLCORR(MAXITER=) option specifies the maximum number of iterations, which is 20 by default.

If you specify the CL option in the TABLES statement, PROC FREQ provides confidence limits for the polychoric correlation. The confidence limits are computed as

$$\hat{\rho} \pm (z_{\alpha/2} \times SE(\hat{\rho}))$$

where $\hat{\rho}$ is the estimate of the polychoric correlation, $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the standard normal distribution, and $SE(\hat{\rho})$ is the standard error of the polychoric correlation estimate.

If you specify the PLCORR option in the TEST statement, PROC FREQ provides Wald and likelihood ratio tests of the null hypothesis that the polychoric correlation equals 0. The Wald test statistic is computed as

$$z = \hat{\rho} / SE(\hat{\rho})$$

which has a standard normal distribution under the null hypothesis. PROC FREQ computes one-sided and two-sided p -values for the Wald test. When the test statistic z is greater than its null expected value of 0, PROC FREQ displays the right-sided p -value. When the test statistic is less than or equal to 0, PROC FREQ displays the left-sided p -value.

The likelihood ratio statistic for the polychoric correlation is computed as

$$G^2 = -2 \ln(L_0/L_1)$$

where L_0 is the value of the likelihood function (Olsson 1979) when the polychoric correlation is 0, and L_1 is the value of the likelihood function at the maximum (where all parameters are replaced by their maximum likelihood estimates). Under the null hypothesis, the likelihood ratio statistic has an asymptotic chi-square distribution with one degree of freedom.

Lambda (Asymmetric)

Asymmetric lambda, $\lambda(C|R)$, is interpreted as the probable improvement in predicting the column variable Y given knowledge of the row variable X . The range of asymmetric lambda is $0 \leq \lambda(C|R) \leq 1$. Asymmetric lambda $\lambda(C|R)$ is computed as

$$\lambda(C|R) = \frac{\sum_i r_i - r}{n - r}$$

and its asymptotic variance is

$$\text{Var}(\lambda(C|R)) = \frac{n - \sum_i r_i}{(n - r)^3} \left(\sum_i r_i + r - 2 \sum_i (r_i | l_i = l) \right)$$

where

$$r_i = \max_j(n_{ij})$$

$$r = \max_j(n_{.j})$$

$$c_j = \max_i(n_{ij})$$

$$c = \max_i(n_{i.})$$

The values of l_i and l are determined as follows. Denote by l_i the unique value of j such that $r_i = n_{ij}$, and let l be the unique value of j such that $r = n_{.j}$. Because of the uniqueness assumptions, ties in the frequencies or in the marginal totals must be broken in an arbitrary but consistent manner. In case of ties, l is defined as the smallest value of j such that $r = n_{.j}$.

For those columns containing a cell (i, j) for which $n_{ij} = r_i = c_j$, cs_j records the row in which c_j is assumed to occur. Initially cs_j is set equal to -1 for all j . Beginning with $i=1$, if there is at least one value j such that $n_{ij} = r_i = c_j$, and if $cs_j = -1$, then l_i is defined to be the smallest such value of j , and cs_j is set equal to i . Otherwise, if $n_{il} = r_i$, then l_i is defined to be equal to l . If neither condition is true, then l_i is taken to be the smallest value of j such that $n_{ij} = r_i$.

The formulas for lambda asymmetric $\lambda(R|C)$ can be obtained by interchanging the indices.

See Goodman and Kruskal (1979) for more information.

Lambda (Symmetric)

The nondirectional lambda is the average of the two asymmetric lambdas, $\lambda(C|R)$ and $\lambda(R|C)$. Its range is $0 \leq \lambda \leq 1$. Lambda symmetric is computed as

$$\lambda = \frac{\sum_i r_i + \sum_j c_j - r - c}{2n - r - c} = \frac{w - v}{w}$$

and its asymptotic variance is computed as

$$\text{Var}(\lambda) = \frac{1}{w^4} \left(wvy - 2w^2 \left(n - \sum_i \sum_j (n_{ij} \mid j = l_i, i = k_j) \right) - 2v^2(n - n_{kl}) \right)$$

where

$$r_i = \max_j(n_{ij})$$

$$r = \max_j(n_{.j})$$

$$c_j = \max_i(n_{ij})$$

$$c = \max_i(n_{i.})$$

$$w = 2n - r - c$$

$$v = 2n - \sum_i r_i - \sum_j c_j$$

$$x = \sum_i (r_i \mid l_i = l) + \sum_j (c_j \mid k_j = k) + r_k + c_l$$

$$y = 8n - w - v - 2x$$

The definitions of l_i and l are given in the previous section. The values k_j and k are defined in a similar way for lambda asymmetric ($R|C$).

See Goodman and Kruskal (1979) for more information.

Uncertainty Coefficients (Asymmetric)

The uncertainty coefficient $U(C|R)$ measures the proportion of uncertainty (entropy) in the column variable Y that is explained by the row variable X. Its range is $0 \leq U(C|R) \leq 1$. The uncertainty coefficient is computed as

$$U(C|R) = (H(X) + H(Y) - H(XY)) / H(Y) = v/w$$

and its asymptotic variance is

$$\text{Var}(U(C|R)) = \frac{1}{n^2 w^4} \sum_i \sum_j n_{ij} \left(H(Y) \ln \left(\frac{n_{ij}}{n_{i.}} \right) + (H(X) - H(XY)) \ln \left(\frac{n_{.j}}{n} \right) \right)^2$$

where

$$\begin{aligned}
 v &= H(X) + H(Y) - H(XY) \\
 w &= H(Y) \\
 H(X) &= -\sum_i \left(\frac{n_{i\cdot}}{n}\right) \ln\left(\frac{n_{i\cdot}}{n}\right) \\
 H(Y) &= -\sum_j \left(\frac{n_{\cdot j}}{n}\right) \ln\left(\frac{n_{\cdot j}}{n}\right) \\
 H(XY) &= -\sum_i \sum_j \left(\frac{n_{ij}}{n}\right) \ln\left(\frac{n_{ij}}{n}\right)
 \end{aligned}$$

The formulas for the uncertainty coefficient $U(R|C)$ can be obtained by interchanging the indices.

See Theil (1972, pp. 115–120) and Goodman and Kruskal (1979) for more information.

Uncertainty Coefficient (Symmetric)

The uncertainty coefficient U is the symmetric version of the two asymmetric uncertainty coefficients. Its range is $0 \leq U \leq 1$. The uncertainty coefficient is computed as

$$U = 2 (H(X) + H(Y) - H(XY)) / (H(X) + H(Y))$$

and its asymptotic variance is

$$\text{Var}(U) = 4 \sum_i \sum_j \frac{n_{ij} \left(H(XY) \ln\left(\frac{n_{i\cdot} n_{\cdot j}}{n^2}\right) - (H(X) + H(Y)) \ln\left(\frac{n_{ij}}{n}\right) \right)^2}{n^2 (H(X) + H(Y))^4}$$

where $H(X)$, $H(Y)$, and $H(XY)$ are defined in the previous section. See Goodman and Kruskal (1979) for more information.

Binomial Proportion

If you specify the BINOMIAL option in the TABLES statement, PROC FREQ computes the binomial proportion for one-way tables. By default, this is the proportion of observations in the first variable level that appears in the output. (You can use the LEVEL= option to specify a different level for the proportion.) The binomial proportion is computed as

$$\hat{p} = n_1 / n$$

where n_1 is the frequency of the first (or designated) level and n is the total frequency of the one-way table. The standard error of the binomial proportion is computed as

$$\text{se}(\hat{p}) = \sqrt{\hat{p} (1 - \hat{p}) / n}$$

Binomial Confidence Limits

By default, PROC FREQ provides Wald and exact (Clopper-Pearson) confidence limits for the binomial proportion. If you do not specify any confidence limit requests with the `CL= binomial-option`, PROC FREQ computes Wald asymptotic confidence limits. You can also request Agresti-Coull, Jeffreys, and Wilson (score) confidence limits for the binomial proportion. For details about these binomial confidence limits, including comparisons of their performance, see Brown, Cai, and DasGupta (2001); Agresti and Coull (1998); Newcombe (1998b).

Wald Confidence Limits Wald asymptotic confidence limits are based on the normal approximation to the binomial distribution. PROC FREQ computes the Wald confidence limits for the binomial proportion as

$$\hat{p} \pm (z_{\alpha/2} \times \text{se}(\hat{p}))$$

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the standard normal distribution. The confidence level α is determined by the `ALPHA=` option, which, by default, equals 0.05 and produces 95% confidence limits.

If you specify `CL=WALD(CORRECT)` or the `CORRECT binomial-option`, PROC FREQ includes a continuity correction of $1/2n$ in the Wald asymptotic confidence limits. The purpose of this correction is to adjust for the difference between the normal approximation and the discrete binomial distribution. See Fleiss, Levin, and Paik (2003) for more information. The continuity-corrected Wald confidence limits for the binomial proportion are computed as

$$\hat{p} \pm (z_{\alpha/2} \times \text{se}(\hat{p}) + (1/2n))$$

Agresti-Coull Confidence Limits If you specify the `CL=AGRESTICOULL binomial-option`, PROC FREQ computes Agresti-Coull confidence limits for the binomial proportion as

$$\tilde{p} \pm (z_{\alpha/2} \times \sqrt{\tilde{p}(1 - \tilde{p}) / \tilde{n}})$$

where

$$\begin{aligned}\tilde{n}_1 &= n_1 + z_{\alpha/2}^2/2 \\ \tilde{n} &= n + z_{\alpha/2}^2 \\ \tilde{p} &= \tilde{n}_1 / \tilde{n}\end{aligned}$$

The Agresti-Coull confidence interval has the same general form as the standard Wald interval but uses \tilde{p} in place of \hat{p} . For $\alpha = 0.05$, the value of $z_{\alpha/2}$ is close to 2, and this interval is the “add 2 successes and 2 failures” adjusted Wald interval of Agresti and Coull (1998).

Jeffreys Confidence Limits If you specify the `CL=JEFFREYS binomial-option`, PROC FREQ computes Jeffreys confidence limits for the binomial proportion as

$$(\beta(\alpha/2, n_1 + 1/2, n - n_1 + 1/2), \beta(1 - \alpha/2, n_1 + 1/2, n - n_1 + 1/2))$$

where $\beta(\alpha, b, c)$ is the α percentile of the beta distribution with shape parameters b and c . The lower confidence limit is set to 0 when $n_1 = 0$, and the upper confidence limit is set to 1 when $n_1 = n$. This is an equal-tailed interval based on the noninformative Jeffreys prior for a binomial proportion. See Brown, Cai, and DasGupta (2001) for details. See Berger (1985) for information about using beta priors for inference on the binomial proportion.

Wilson (Score) Confidence Limits If you specify the CL=WILSON *binomial-option*, PROC FREQ computes Wilson confidence limits for the binomial proportion. These are also known as score confidence limits (Wilson 1927). The confidence limits are based on inverting the normal test that uses the null proportion in the variance (the score test). Wilson confidence limits are the roots of

$$|p - \hat{p}| = z_{\alpha/2} \sqrt{p(1-p)/n}$$

and are computed as

$$\left(\hat{p} + z_{\alpha/2}^2/2n \pm z_{\alpha/2} \sqrt{(\hat{p}(1-\hat{p}) + z_{\alpha/2}^2/4n)/n} \right) / \left(1 + z_{\alpha/2}^2/n \right)$$

If you specify CL=WILSON(CORRECT) or the CORRECT *binomial-option*, PROC FREQ provides continuity-corrected Wilson confidence limits, which are computed as the roots of

$$|p - \hat{p}| - 1/2n = z_{\alpha/2} \sqrt{p(1-p)/n}$$

The Wilson interval has been shown to have better performance than the Wald interval and the exact (Clopper-Pearson) interval. For more information, see Agresti and Coull (1998); Brown, Cai, and DasGupta (2001); Newcombe (1998b).

Exact (Clopper-Pearson) Confidence Limits Exact (Clopper-Pearson) confidence limits for the binomial proportion are constructed by inverting the equal-tailed test based on the binomial distribution. This method is attributed to Clopper and Pearson (1934). The exact confidence limits p_L and p_U satisfy the following equations, for $n_1 = 1, 2, \dots, n-1$:

$$\sum_{x=n_1}^n \binom{n}{x} p_L^x (1-p_L)^{n-x} = \alpha/2$$

$$\sum_{x=0}^{n_1} \binom{n}{x} p_U^x (1-p_U)^{n-x} = \alpha/2$$

The lower confidence limit equals 0 when $n_1 = 0$, and the upper confidence limit equals 1 when $n_1 = n$.

PROC FREQ computes the exact (Clopper-Pearson) confidence limits by using the F distribution as

$$p_L = \left(1 + \frac{n - n_1 + 1}{n_1 F(\alpha/2, 2n_1, 2(n - n_1 + 1))} \right)^{-1}$$

$$p_U = \left(1 + \frac{n - n_1}{(n_1 + 1) F(1 - \alpha/2, 2(n_1 + 1), 2(n - n_1))} \right)^{-1}$$

where $F(\alpha/2, b, c)$ is the $\alpha/2$ percentile of the F distribution with b and c degrees of freedom. See Leemis and Trivedi (1996) for a derivation of this expression. Also see Collett (1991) for more information about exact binomial confidence limits.

Because this is a discrete problem, the confidence coefficient (coverage probability) of the exact (Clopper-Pearson) interval is not exactly $(1 - \alpha)$ but is at least $(1 - \alpha)$. Thus, this confidence interval is conservative. Unless the sample size is large, the actual coverage probability can be much larger than the target value. For more information about the performance of these confidence limits, see Agresti and Coull (1998); Brown, Cai, and DasGupta (2001); Leemis and Trivedi (1996).

Binomial Tests

The BINOMIAL option provides an asymptotic equality test for the binomial proportion by default. You can also specify *binomial-options* to request tests of noninferiority, superiority, and equivalence for the binomial proportion. If you specify the BINOMIAL option in the EXACT statement, PROC FREQ also computes exact p -values for the tests that you request with the *binomial-options*.

Equality Test PROC FREQ computes an asymptotic test of the hypothesis that the binomial proportion equals p_0 , where you can specify the value of p_0 with the $P=$ *binomial-option*. If you do not specify a null value with $P=$, PROC FREQ uses $p_0 = 0.5$ by default. The binomial test statistic is computed as

$$z = (\hat{p} - p_0)/se$$

By default, the standard error is based on the null hypothesis proportion as

$$se = \sqrt{p_0(1 - p_0)/n}$$

If you specify the VAR=SAMPLE *binomial-option*, the standard error is computed from the sample proportion as

$$se = \sqrt{\hat{p}(1 - \hat{p})/n}$$

If you specify the CORRECT *binomial-option*, PROC FREQ includes a continuity correction in the asymptotic test statistic, towards adjusting for the difference between the normal approximation and the discrete binomial distribution. See Fleiss, Levin, and Paik (2003) for details. The continuity correction of $(1/2n)$ is subtracted from the numerator of the test statistic if $(\hat{p} - p_0)$ is positive; otherwise, the continuity correction is added to the numerator.

PROC FREQ computes one-sided and two-sided p -values for this test. When the test statistic z is greater than zero (its expected value under the null hypothesis), PROC FREQ computes the right-sided p -value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided p -value supports the alternative hypothesis that the true value of the proportion is greater than p_0 . When the test statistic is less than or equal to zero, PROC FREQ computes the left-sided p -value, which is the probability of a smaller value of the statistic occurring under the null hypothesis. A small left-sided p -value supports the alternative hypothesis that the true value of the proportion is less than p_0 . The one-sided p -value P_1 can be expressed as

$$P_1 = \begin{cases} \text{Prob}(Z > z) & \text{if } z > 0 \\ \text{Prob}(Z < z) & \text{if } z \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided p -value is computed as $P_2 = 2 \times P_1$.

If you specify the BINOMIAL option in the EXACT statement, PROC FREQ also computes an exact test of the null hypothesis $H_0: p = p_0$. To compute the exact test, PROC FREQ uses the binomial probability function,

$$\text{Prob}(X = x \mid p_0) = \binom{n}{x} p_0^x (1 - p_0)^{(n-x)} \quad \text{for } x = 0, 1, 2, \dots, n$$

where the variable X has a binomial distribution with parameters n and p_0 . To compute the left-sided p -value, $\text{Prob}(X \leq n_1)$, PROC FREQ sums the binomial probabilities over x from zero to n_1 . To compute

the right-sided p -value, $\text{Prob}(X \geq n_1)$, PROC FREQ sums the binomial probabilities over x from n_1 to n . The exact one-sided p -value is the minimum of the left-sided and right-sided p -values,

$$P_1 = \min(\text{Prob}(X \leq n_1 | p_0), \text{Prob}(X \geq n_1 | p_0))$$

and the exact two-sided p -value is computed as $P_2 = 2 \times P_1$.

Noninferiority Test If you specify the NONINF *binomial-option*, PROC FREQ provides a noninferiority test for the binomial proportion. The null hypothesis for the noninferiority test is

$$H_0: p - p_0 \leq -\delta$$

versus the alternative

$$H_a: p - p_0 > -\delta$$

where δ is the noninferiority margin and p_0 is the null proportion. Rejection of the null hypothesis indicates that the binomial proportion is not inferior to the null value. See Chow, Shao, and Wang (2003) for more information.

You can specify the value of δ with the MARGIN= *binomial-option*, and you can specify p_0 with the P= *binomial-option*. By default, $\delta = 0.2$ and $p_0 = 0.5$.

PROC FREQ provides an asymptotic Wald test for noninferiority. The test statistic is computed as

$$z = (\hat{p} - p_0^*) / \text{se}$$

where p_0^* is the noninferiority limit,

$$p_0^* = p_0 - \delta$$

By default, the standard error is computed from the sample proportion as

$$\text{se} = \sqrt{\hat{p}(1 - \hat{p})/n}$$

If you specify the VAR=NULL *binomial-option*, the standard error is based on the noninferiority limit (determined by the null proportion and the margin) as

$$\text{se} = \sqrt{p_0^*(1 - p_0^*)/n}$$

If you specify the CORRECT *binomial-option*, PROC FREQ includes a continuity correction in the asymptotic test statistic z . The continuity correction of $(1/2n)$ is subtracted from the numerator of the test statistic if $(\hat{p} - p_0^*)$ is positive; otherwise, the continuity correction is added to the numerator.

The p -value for the noninferiority test is

$$P_z = \text{Prob}(Z > z)$$

where Z has a standard normal distribution.

As part of the noninferiority analysis, PROC FREQ provides asymptotic Wald confidence limits for the binomial proportion. These confidence limits are computed as described in the section “[Wald Confidence Limits](#)” on page 2566 but use the same standard error (VAR=NULL or VAR=SAMPLE) as the noninferiority

test statistic z . The confidence coefficient is $100(1 - 2\alpha)\%$ (Schuirmann 1999). By default, if you do not specify the ALPHA= option, the noninferiority confidence limits are 90% confidence limits. You can compare the confidence limits to the noninferiority limit, $p_0^* = p_0 - \delta$.

If you specify the BINOMIAL option in the EXACT statement, PROC FREQ provides an exact noninferiority test for the binomial proportion. The exact p -value is computed by using the binomial probability function with parameters p_0^* and n ,

$$P_x = \sum_{k=n_1}^{k=n} \binom{n}{k} (p_0^*)^k (1 - p_0^*)^{(n-k)}$$

See Chow, Shao, and Wang (2003, p. 116) for details. If you request exact binomial statistics, PROC FREQ also includes exact (Clopper-Pearson) confidence limits for the binomial proportion in the equivalence analysis display. See the section “[Exact \(Clopper-Pearson\) Confidence Limits](#)” on page 2567 for details.

Superiority Test If you specify the SUP *binomial-option*, PROC FREQ provides a superiority test for the binomial proportion. The null hypothesis for the superiority test is

$$H_0: p - p_0 \leq \delta$$

versus the alternative

$$H_a: p - p_0 > \delta$$

where δ is the superiority margin and p_0 is the null proportion. Rejection of the null hypothesis indicates that the binomial proportion is superior to the null value. You can specify the value of δ with the MARGIN= *binomial-option*, and you can specify the value of p_0 with the P= *binomial-option*. By default, $\delta = 0.2$ and $p_0 = 0.5$.

The superiority analysis is identical to the noninferiority analysis but uses a positive value of the margin δ in the null hypothesis. The superiority limit equals $p_0 + \delta$. The superiority computations follow those in the section “[Noninferiority Test](#)” on page 2569 but replace $-\delta$ with δ . See Chow, Shao, and Wang (2003) for more information.

Equivalence Test If you specify the EQUIV *binomial-option*, PROC FREQ provides an equivalence test for the binomial proportion. The null hypothesis for the equivalence test is

$$H_0: p - p_0 \leq \delta_L \quad \text{or} \quad p - p_0 \geq \delta_U$$

versus the alternative

$$H_a: \delta_L < p - p_0 < \delta_U$$

where δ_L is the lower margin, δ_U is the upper margin, and p_0 is the null proportion. Rejection of the null hypothesis indicates that the binomial proportion is equivalent to the null value. See Chow, Shao, and Wang (2003) for more information.

You can specify the value of the margins δ_L and δ_U with the MARGIN= *binomial-option*. If you do not specify MARGIN=, PROC FREQ uses lower and upper margins of -0.2 and 0.2 by default. If you specify a single margin value δ , PROC FREQ uses lower and upper margins of $-\delta$ and δ . You can specify the null proportion p_0 with the P= *binomial-option*. By default, $p_0 = 0.5$.

PROC FREQ computes two one-sided tests (TOST) for equivalence analysis (Schuirmann 1987). The TOST approach includes a right-sided test for the lower margin and a left-sided test for the upper margin. The overall p -value is taken to be the larger of the two p -values from the lower and upper tests.

For the lower margin, the asymptotic Wald test statistic is computed as

$$z_L = (\hat{p} - p_L^*) / \text{se}$$

where the lower equivalence limit is

$$p_L^* = p_0 + \delta_L$$

By default, the standard error is computed from the sample proportion as

$$\text{se} = \sqrt{\hat{p}(1 - \hat{p})/n}$$

If you specify the VAR=NULL *binomial-option*, the standard error is based on the lower equivalence limit (determined by the null proportion and the lower margin) as

$$\text{se} = \sqrt{p_L^*(1 - p_L^*)/n}$$

If you specify the CORRECT *binomial-option*, PROC FREQ includes a continuity correction in the asymptotic test statistic z_L . The continuity correction of $(1/2n)$ is subtracted from the numerator of the test statistic $(\hat{p} - p_L^*)$ if the numerator is positive; otherwise, the continuity correction is added to the numerator.

The p -value for the lower margin test is

$$P_{z,L} = \text{Prob}(Z > z_L)$$

The asymptotic test for the upper margin is computed similarly. The Wald test statistic is

$$z_U = (\hat{p} - p_U^*) / \text{se}$$

where the upper equivalence limit is

$$p_U^* = p_0 + \delta_U$$

By default, the standard error is computed from the sample proportion. If you specify the VAR=NULL *binomial-option*, the standard error is based on the upper equivalence limit as

$$\text{se} = \sqrt{p_U^*(1 - p_U^*)/n}$$

If you specify the CORRECT *binomial-option*, PROC FREQ includes a continuity correction of $(1/2n)$ in the asymptotic test statistic z_U .

The p -value for the upper margin test is

$$P_{z,U} = \text{Prob}(Z < z_U)$$

Based on the two one-sided tests (TOST), the overall p -value for the test of equivalence equals the larger p -value from the lower and upper margin tests, which can be expressed as

$$P_z = \max(P_{z,L}, P_{z,U})$$

As part of the equivalence analysis, PROC FREQ provides asymptotic Wald confidence limits for the binomial proportion. These confidence limits are computed as described in the section “[Wald Confidence Limits](#)” on page 2566, but use the same standard error (VAR=NULL or VAR=SAMPLE) as the equivalence test statistics and have a confidence coefficient of $100(1 - 2\alpha)\%$ (Schuirmann 1999). By default, if you do not specify the ALPHA= option, the equivalence confidence limits are 90% limits. If you specify VAR=NULL, separate standard errors are computed for the lower and upper margin tests, each based on the null proportion and the corresponding (lower or upper) margin. The confidence limits are computed by using the maximum of these two standard errors. You can compare the confidence limits to the equivalence limits, $(p_0 + \delta_L, p_0 + \delta_U)$.

If you specify the BINOMIAL option in the EXACT statement, PROC FREQ also provides an exact equivalence test by using two one-sided exact tests (TOST). The procedure computes lower and upper margin exact tests by using the binomial probability function as described in the section “[Noninferiority Test](#)” on page 2569. The overall exact p -value for the equivalence test is taken to be the larger p -value from the lower and upper margin exact tests. If you request exact statistics, PROC FREQ also includes exact (Clopper-Pearson) confidence limits in the equivalence analysis display. The confidence coefficient is $100(1 - 2\alpha)\%$ (Schuirmann 1999). See the section “[Exact \(Clopper-Pearson\) Confidence Limits](#)” on page 2567 for details.

Risks and Risk Differences

The RISKDIFF option in the TABLES statement provides estimates of risks (binomial proportions) and risk differences for 2×2 tables. This analysis might be appropriate when comparing the proportion of some characteristic for two groups, where row 1 and row 2 correspond to the two groups, and the columns correspond to two possible characteristics or outcomes. For example, the row variable might be a treatment or dose, and the column variable might be the response. For more information, see Collett (1991); Fleiss, Levin, and Paik (2003); Stokes, Davis, and Koch (2012).

Let the frequencies of the 2×2 table be represented as follows.

	Column 1	Column 2	Total
Row 1	n_{11}	n_{12}	$n_{1\cdot}$
Row 2	n_{21}	n_{22}	$n_{2\cdot}$
Total	$n_{\cdot 1}$	$n_{\cdot 2}$	n

By default when you specify the RISKDIFF option, PROC FREQ provides estimates of the row 1 risk (proportion), the row 2 risk, the overall risk, and the risk difference for column 1 and for column 2 of the 2×2 table. The risk difference is defined as the row 1 risk minus the row 2 risk. The risks are binomial proportions of their rows (row 1, row 2, or overall), and the computation of their standard errors and Wald confidence limits follow the binomial proportion computations, which are described in the section “[Binomial Proportion](#)” on page 2565.

The column 1 risk for row 1 is the proportion of row 1 observations classified in column 1,

$$\hat{p}_1 = n_{11} / n_{1\cdot}$$

which estimates the conditional probability of the column 1 response, given the first level of the row variable. The column 1 risk for row 2 is the proportion of row 2 observations classified in column 1,

$$\hat{p}_2 = n_{21} / n_{2\cdot}$$

The overall column 1 risk is the proportion of all observations classified in column 1,

$$\hat{p} = n_{.1} / n$$

The column 1 risk difference compares the risks for the two rows, and it is computed as the column 1 risk for row 1 minus the column 1 risk for row 2,

$$\hat{d} = \hat{p}_1 - \hat{p}_2$$

The standard error of the column 1 risk for row i is computed as

$$se(\hat{p}_i) = \sqrt{\hat{p}_i (1 - \hat{p}_i) / n_{i.}}$$

The standard error of the overall column 1 risk is computed as

$$se(\hat{p}) = \sqrt{\hat{p} (1 - \hat{p}) / n}$$

Where the two rows represent independent binomial samples, the standard error of the column 1 risk difference is computed as

$$se(\hat{d}) = \sqrt{\hat{p}_1(1 - \hat{p}_1) + \hat{p}_2(1 - \hat{p}_2)}$$

The computations are similar for the column 2 risks and risk difference.

Confidence Limits

By default, the RISKDIFF option provides Wald asymptotic confidence limits for the risks (row 1, row 2, and overall) and the risk difference. By default, the RISKDIFF option also provides exact (Clopper-Pearson) confidence limits for the risks. You can suppress the display of this information by specifying the NORISKS *riskdiff-option*. You can specify *riskdiff-options* to request tests and other types of confidence limits for the risk difference. See the sections “[Risk Difference Confidence Limits](#)” on page 2574 and “[Risk Difference Tests](#)” on page 2576 for more information.

The risks are equivalent to the binomial proportions of their corresponding rows. This section describes the Wald confidence limits that are provided by default when you specify the RISKDIFF option. The BINOMIAL option provides additional confidence limit types and tests for risks (binomial proportions). See the sections “[Binomial Confidence Limits](#)” on page 2566 and “[Binomial Tests](#)” on page 2568 for details.

The Wald confidence limits are based on the normal approximation to the binomial distribution. PROC FREQ computes the Wald confidence limits for the risks and risk differences as

$$\text{Est} \pm (z_{\alpha/2} \times se(\text{Est}))$$

where Est is the estimate, $z_{\alpha/2}$ is the 100(1 - $\alpha/2$) percentile of the standard normal distribution, and $se(\text{Est})$ is the standard error of the estimate. The confidence level α is determined by the value of the ALPHA= option; the default of ALPHA=0.5 produces 95% confidence limits.

If you specify the CORRECT *riskdiff-option*, PROC FREQ includes continuity corrections in the Wald confidence limits for the risks and risk differences. The purpose of a continuity correction is to adjust for the difference between the normal approximation and the binomial distribution, which is discrete. See Fleiss, Levin, and Paik (2003) for more information. The continuity-corrected Wald confidence limits are computed as

$$\text{Est} \pm (z_{\alpha/2} \times se(\text{Est}) + cc)$$

where cc is the continuity correction. For the row 1 risk, $cc = (1/2n_{1.})$; for the row 2 risk, $cc = (1/2n_{2.})$; for the overall risk, $cc = (1/2n)$; and for the risk difference, $cc = ((1/n_{1.} + 1/n_{2.})/2)$. The column 1 and column 2 risks use the same continuity corrections.

By default when you specify the RISKDIFF option, PROC FREQ also provides exact (Clopper-Pearson) confidence limits for the column 1, column 2, and overall risks. These confidence limits are constructed by inverting the equal-tailed test that is based on the binomial distribution. See the section “[Exact \(Clopper-Pearson\) Confidence Limits](#)” on page 2567 for details.

Risk Difference Confidence Limits You can request additional confidence limits for the risk difference by specifying the `CL= riskdiff-option`. Available confidence limit types include Agresti-Caffo, exact unconditional, Hauck-Anderson, Miettinen-Nurminen, Newcombe (hybrid-score), and Wald confidence limits. Continuity-corrected Newcombe and Wald confidence limits are also available.

The confidence coefficient for the confidence limits produced by the `CL= riskdiff-option` is $100(1 - \alpha)\%$, where the value of α is determined by the `ALPHA=` option. The default of `ALPHA=0.05` produces 95% confidence limits. This differs from the test-based confidence limits that are provided with the equivalence, noninferiority, and superiority tests, which have a confidence coefficient of $100(1 - 2\alpha)\%$ (Schuirmann 1999). See the section “[Risk Difference Tests](#)” on page 2576 for details.

The section “[Exact Unconditional Confidence Limits for the Risk Difference](#)” on page 2580 describes the computation of the exact confidence limits. The confidence limits are constructed by inverting two separate one-sided exact tests (tail method). By default, the tests are based on the unstandardized risk difference. If you specify the `RISKDIFF(METHOD=SCORE)` option, the tests are based on the score statistic.

The following sections describe the computation of the Agresti-Coull, Hauck-Anderson, Miettinen-Nurminen, Newcombe (hybrid-score), and Wald confidence limits for the risk difference.

Agresti-Caffo Confidence Limits The Agresti-Caffo confidence limits for the risk difference are computed as

$$\tilde{d} \pm (z_{\alpha/2} \times \text{se}(\tilde{d}))$$

where $\tilde{d} = \tilde{p}_1 - \tilde{p}_2$, $\tilde{p}_i = (n_{i1} + 1)/(n_{i.} + 2)$,

$$\text{se}(\tilde{d}) = \sqrt{\tilde{p}_1(1 - \tilde{p}_1)/(n_{1.} + 2) + \tilde{p}_2(1 - \tilde{p}_2)/(n_{2.} + 2)}$$

and $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the standard normal distribution.

The Agresti-Caffo interval adjusts the Wald interval for the risk difference by adding a pseudo-observation of each type (success and failure) to each sample. See Agresti and Caffo (2000) and Agresti and Coull (1998) for more information.

Hauck-Anderson Confidence Limits The Hauck-Anderson confidence limits for the risk difference are computed as

$$\hat{d} \pm (cc + z_{\alpha/2} \times \text{se}(\hat{d}))$$

where $\hat{d} = \hat{p}_1 - \hat{p}_2$ and $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the standard normal distribution. The standard error is computed from the sample proportions as

$$\text{se}(\hat{d}) = \sqrt{\hat{p}_1(1 - \hat{p}_1)/(n_{1.} - 1) + \hat{p}_2(1 - \hat{p}_2)/(n_{2.} - 1)}$$

The Hauck-Anderson continuity correction cc is computed as

$$cc = 1 / (2 \min(n_{1.}, n_{2.}))$$

See Hauck and Anderson (1986) for more information. The subsection “[Hauck-Anderson Test](#)” in the section “[Noninferiority Tests](#)” on page 2577 describes the corresponding noninferiority test.

Miettinen-Nurminen Confidence Limits The Miettinen-Nurminen confidence limits for the risk difference (Miettinen and Nurminen 1985; Newcombe and Nurminen 2011) are based on the likelihood score test for the null hypothesis that the risk difference is zero. The test statistic is

$$T(\delta) = (\hat{d} - \delta) / \sqrt{\widetilde{\text{Var}}(\delta)}$$

where \hat{d} is the observed value of the risk difference ($\hat{p}_1 - \hat{p}_2$),

$$\widetilde{\text{Var}}(\delta) = (n/(n-1)) (\tilde{p}_1(\delta)(1 - \tilde{p}_1(\delta))/n_1 + \tilde{p}_2(\delta)(1 - \tilde{p}_2(\delta))/n_2)$$

and $\tilde{p}_1(\delta)$ and $\tilde{p}_2(\delta)$ are the maximum likelihood estimates of the risks (proportions) when the risk difference is δ . PROC FREQ computes the maximum likelihood estimates $\tilde{p}_1(\delta)$ and $\tilde{p}_2(\delta)$ as described in the subsection “[Farrington-Manning Test](#)” in the section “[Noninferiority Tests](#)” on page 2577.

The $100(1 - \alpha)\%$ confidence interval for the risk difference consists of all values of δ for which the score test statistic $T(\delta)$ falls in the acceptance region,

$$\{\delta : T(\delta) < z_{\alpha/2}\}$$

PROC FREQ finds the confidence limits by iterative computation, which stops when the iteration increment falls below the convergence criterion or when the maximum number of iterations is reached, whichever occurs first. By default, the convergence criterion is 0.00000001 and the maximum number of iterations is 100.

By default, the Miettinen-Nurminen confidence limits include the bias correction factor $n/(n-1)$ in the computation of $\widetilde{\text{Var}}(\delta)$, as given by Miettinen and Nurminen (1985, p. 216). See Newcombe and Nurminen (2011) for more information. If you specify the `CL=MN(CORRECT=NO) riskdiff-option`, PROC FREQ does not include the bias correction factor in the computation of the confidence limits (Mee 1984). See also Agresti (2002, p. 77). The uncorrected confidence limits are labeled as “Miettinen-Nurminen-Mee” confidence limits in the displayed output.

Newcombe Confidence Limits Newcombe (hybrid-score) confidence limits for the risk difference are constructed from the Wilson score confidence limits for each of the two individual proportions. The confidence limits for the individual proportions are used in the standard error terms of the Wald confidence limits for the proportion difference. See Newcombe (1998a) and Barker et al. (2001) for more information.

Wilson score confidence limits for p_1 and p_2 are the roots of

$$|p_i - \hat{p}_i| = z_{\alpha/2} \sqrt{p_i(1 - p_i)/n_i}$$

for $i = 1, 2$. The confidence limits are computed as

$$\left(\hat{p}_i + z_{\alpha/2}^2/2n_i \pm z_{\alpha/2} \sqrt{(\hat{p}_i(1 - \hat{p}_i) + z_{\alpha/2}^2/4n_i)/n_i} \right) / \left(1 + z_{\alpha/2}^2/n_i \right)$$

See the section “[Wilson \(Score\) Confidence Limits](#)” on page 2567 for details.

Denote the lower and upper Wilson score confidence limits for p_1 as L_1 and U_1 , and denote the lower and upper confidence limits for p_2 as L_2 and U_2 . The Newcombe confidence limits for the proportion difference ($d = p_1 - p_2$) are computed as

$$d_L = (\hat{p}_1 - \hat{p}_2) - \sqrt{(\hat{p}_1 - L_1)^2 + (U_2 - \hat{p}_2)^2}$$

$$d_U = (\hat{p}_1 - \hat{p}_2) + \sqrt{(U_1 - \hat{p}_1)^2 + (\hat{p}_2 - L_2)^2}$$

If you specify the **CORRECT** *riskdiff-option*, PROC FREQ provides continuity-corrected Newcombe confidence limits. By including a continuity correction of $1/2n_{i\cdot}$, the Wilson score confidence limits for the individual proportions are computed as the roots of

$$|p_i - \hat{p}_i| - 1/2n_{i\cdot} = z_{\alpha/2} \sqrt{p_i(1 - p_i)/n_{i\cdot}}$$

The continuity-corrected confidence limits for the individual proportions are then used to compute the proportion difference confidence limits d_L and d_U .

Wald Confidence Limits The Wald confidence limits for the risk difference are computed as

$$\hat{d} \pm (z_{\alpha/2} \times \text{se}(\hat{d}))$$

where $\hat{d} = \hat{p}_1 - \hat{p}_2$, $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the standard normal distribution, and the standard error is computed from the sample proportions as

$$\text{se}(\hat{d}) = \sqrt{\hat{p}_1(1 - \hat{p}_1)/n_{1\cdot} + \hat{p}_2(1 - \hat{p}_2)/n_{2\cdot}}$$

If you specify the **CORRECT** *riskdiff-option*, the Wald confidence limits include a continuity correction cc ,

$$\hat{d} \pm (cc + z_{\alpha/2} \times \text{se}(\hat{d}))$$

where $cc = (1/n_{1\cdot} + 1/n_{2\cdot})/2$.

The subsection “**Wald Test**” in the section “**Noninferiority Tests**” on page 2577 describes the corresponding noninferiority test.

Risk Difference Tests

You can specify *riskdiff-options* to request tests of the risk (proportion) difference. You can request tests of equality, noninferiority, superiority, and equivalence for the risk difference. The test of equality is a standard Wald asymptotic test, available with or without a continuity correction. For noninferiority, superiority, and equivalence tests of the risk difference, the following test methods are provided: Wald (with and without continuity correction), Hauck-Anderson, Farrington-Manning (score), and Newcombe (with and without continuity correction). You can specify the test method with the **METHOD=** *riskdiff-option*. By default, PROC FREQ uses **METHOD=WALD**.

Equality Test If you specify the **EQUAL** *riskdiff-option*, PROC FREQ computes a test of equality, or a test of the null hypothesis that the risk difference equals zero. For the column 1 (or 2) risk difference, this test can be expressed as $H_0: d = 0$ versus the alternative $H_a: d \neq 0$, where $d = p_1 - p_2$ denotes the column 1 (or 2) risk difference. PROC FREQ provides a Wald asymptotic test of equality. The test statistic is computed as

$$z = \hat{d} / \text{se}(\hat{d})$$

By default, the standard error is computed from the sample proportions as

$$se(\hat{d}) = \sqrt{\hat{p}_1(1 - \hat{p}_1)/n_{1\cdot} + \hat{p}_2(1 - \hat{p}_2)/n_{2\cdot}}.$$

If you specify the VAR=NULL *riskdiff-option*, the standard error is based on the null hypothesis that the row 1 and row 2 risks are equal,

$$se(\hat{d}) = \sqrt{\hat{p}(1 - \hat{p}) \times (1/n_{1\cdot} + 1/n_{2\cdot})}$$

where $\hat{p} = n_{\cdot 1}/n$ estimates the overall column 1 risk.

If you specify the CORRECT *riskdiff-option*, PROC FREQ includes a continuity correction in the test statistic. If $\hat{d} > 0$, the continuity correction is subtracted from \hat{d} in the numerator of the test statistic; otherwise, the continuity correction is added to the numerator. The value of the continuity correction is $(1/n_{1\cdot} + 1/n_{2\cdot})/2$.

PROC FREQ computes one-sided and two-sided p -values for this test. When the test statistic z is greater than 0, PROC FREQ displays the right-sided p -value, which is the probability of a larger value occurring under the null hypothesis. The one-sided p -value can be expressed as

$$P_1 = \begin{cases} \text{Prob}(Z > z) & \text{if } z > 0 \\ \text{Prob}(Z < z) & \text{if } z \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided p -value is computed as $P_2 = 2 \times P_1$.

Noninferiority Tests If you specify the NONINF *riskdiff-option*, PROC FREQ provides a noninferiority test for the risk difference, or the difference between two proportions. The null hypothesis for the noninferiority test is

$$H_0: p_1 - p_2 \leq -\delta$$

versus the alternative

$$H_a: p_1 - p_2 > -\delta$$

where δ is the noninferiority margin. Rejection of the null hypothesis indicates that the row 1 risk is not inferior to the row 2 risk. See Chow, Shao, and Wang (2003) for more information.

You can specify the value of δ with the MARGIN= *riskdiff-option*. By default, $\delta = 0.2$. You can specify the test method with the METHOD= *riskdiff-option*. The following methods are available for the risk difference noninferiority analysis: Wald (with and without continuity correction), Hauck-Anderson, Farrington-Manning (score), and Newcombe (with and without continuity correction). The Wald, Hauck-Anderson, and Farrington-Manning methods provide tests and corresponding test-based confidence limits; the Newcombe method provides only confidence limits. If you do not specify METHOD=, PROC FREQ uses the Wald test by default.

The confidence coefficient for the test-based confidence limits is $100(1 - 2\alpha)\%$ (Schuirmann 1999). By default, if you do not specify the ALPHA= option, these are 90% confidence limits. You can compare the confidence limits to the noninferiority limit, $-\delta$.

The following sections describe the noninferiority analysis methods for the risk difference.

Wald Test If you specify the METHOD=WALD *riskdiff-option*, PROC FREQ provides an asymptotic Wald test of noninferiority for the risk difference. This is also the default method. The Wald test statistic is computed as

$$z = (\hat{d} + \delta) / \text{se}(\hat{d})$$

where $(\hat{d} = \hat{p}_1 - \hat{p}_2)$ estimates the risk difference and δ is the noninferiority margin.

By default, the standard error for the Wald test is computed from the sample proportions as

$$\text{se}(\hat{d}) = \sqrt{\hat{p}_1(1 - \hat{p}_1)/n_{1\cdot} + \hat{p}_2(1 - \hat{p}_2)/n_{2\cdot}}$$

If you specify the VAR=NULL *riskdiff-option*, the standard error is based on the null hypothesis that the risk difference equals $-\delta$ (Dunnett and Gent 1977). The standard error is computed as

$$\text{se}(\hat{d}) = \sqrt{\tilde{p}(1 - \tilde{p})/n_{2\cdot} + (\tilde{p} - \delta)(1 - \tilde{p} + \delta)/n_{1\cdot}}$$

where

$$\tilde{p} = (n_{11} + n_{21} + \delta n_{1\cdot})/n$$

If you specify the CORRECT *riskdiff-option*, the test statistic includes a continuity correction. The continuity correction is subtracted from the numerator of the test statistic if the numerator is greater than zero; otherwise, the continuity correction is added to the numerator. The value of the continuity correction is $(1/n_{1\cdot} + 1/n_{2\cdot})/2$.

The p -value for the Wald noninferiority test is $P_z = \text{Prob}(Z > z)$, where Z has a standard normal distribution.

Hauck-Anderson Test If you specify the METHOD=HA *riskdiff-option*, PROC FREQ provides the Hauck-Anderson test for noninferiority. The Hauck-Anderson test statistic is computed as

$$z = (\hat{d} + \delta \pm cc) / \text{se}(\hat{d})$$

where $\hat{d} = \hat{p}_1 - \hat{p}_2$ and the standard error is computed from the sample proportions as

$$\text{se}(\hat{d}) = \sqrt{\hat{p}_1(1 - \hat{p}_1)/(n_{1\cdot} - 1) + \hat{p}_2(1 - \hat{p}_2)/(n_{2\cdot} - 1)}$$

The Hauck-Anderson continuity correction cc is computed as

$$cc = 1 / (2 \min(n_{1\cdot}, n_{2\cdot}))$$

The p -value for the Hauck-Anderson noninferiority test is $P_z = \text{Prob}(Z > z)$, where Z has a standard normal distribution. See Hauck and Anderson (1986) and Schuirmann (1999) for more information.

Farrington-Manning Test If you specify the METHOD=FM *riskdiff-option*, PROC FREQ provides the Farrington-Manning (score) test of noninferiority for the risk difference. The score test statistic is computed as

$$z = (\hat{d} + \delta) / \text{se}(\hat{d})$$

where $\hat{d} = \hat{p}_1 - \hat{p}_2$ and

$$\text{se}(\hat{d}) = \sqrt{\tilde{p}_1(1 - \tilde{p}_1)/n_{1\cdot} + \tilde{p}_2(1 - \tilde{p}_2)/n_{2\cdot}}$$

where \tilde{p}_1 and \tilde{p}_2 are the maximum likelihood estimators of p_1 and p_2 under the null hypothesis that the risk difference equals $-\delta$ (Miettinen and Nurminen 1985; Farrington and Manning 1990; Dann and Koch 2005). The p -value for the noninferiority test is then $P_z = \text{Prob}(Z > z)$, where Z has a standard normal distribution.

From Farrington and Manning (1990, p. 1453), the solution to the maximum likelihood equation is

$$\tilde{p}_1 = 2u \cos(w) - b/3a \quad \text{and} \quad \tilde{p}_2 = \tilde{p}_1 + \delta$$

where

$$\begin{aligned} w &= (\pi + \cos^{-1}(v/u^3))/3 \\ v &= b^3/(3a)^3 - bc/6a^2 + d/2a \\ u &= \text{sign}(v) \sqrt{b^2/(3a)^2 - c/3a} \\ a &= 1 + \theta \\ b &= -(1 + \theta + \hat{p}_1 + \theta \hat{p}_2 - \delta(\theta + 2)) \\ c &= \delta^2 - \delta(2\hat{p}_1 + \theta + 1) + \hat{p}_1 + \theta \hat{p}_2 \\ d &= \hat{p}_1 \delta(1 - \delta) \\ \theta &= n_{2\cdot}/n_{1\cdot}. \end{aligned}$$

Newcombe Noninferiority Analysis If you specify the `METHOD=NEWCOMBE riskdiff-option`, PROC FREQ provides a noninferiority analysis that is based on Newcombe hybrid-score confidence limits for the risk difference. The confidence coefficient for the confidence limits is $100(1 - 2\alpha)\%$ (Schuirmann 1999). By default, if you do not specify the `ALPHA=` option, these are 90% confidence limits. You can compare the confidence limits with the noninferiority limit, $-\delta$. If you specify the `CORRECT riskdiff-option`, the confidence limits includes a continuity correction. See the subsection “Newcombe Confidence Limits” in the section “[Risk Difference Confidence Limits](#)” on page 2574 for more information.

Superiority Test If you specify the `SUP riskdiff-option`, PROC FREQ provides a superiority test for the risk difference. The null hypothesis is

$$H_0: p_1 - p_2 \leq \delta$$

versus the alternative

$$H_a: p_1 - p_2 > \delta$$

where δ is the superiority margin. Rejection of the null hypothesis indicates that the row 1 proportion is superior to the row 2 proportion. You can specify the value of δ with the `MARGIN= riskdiff-option`. By default, $\delta = 0.2$.

The superiority analysis is identical to the noninferiority analysis but uses a positive value of the margin δ in the null hypothesis. The superiority computations follow those in the section “[Noninferiority Tests](#)” on page 2577 by replacing $-\delta$ by δ . See Chow, Shao, and Wang (2003) for more information.

Equivalence Tests If you specify the *EQUIV riskdiff-option*, PROC FREQ provides an equivalence test for the risk difference, or the difference between two proportions. The null hypothesis for the equivalence test is

$$H_0: p_1 - p_2 \leq -\delta_L \quad \text{or} \quad p_1 - p_2 \geq \delta_U$$

versus the alternative

$$H_a: \delta_L < p_1 - p_2 < \delta_U$$

where δ_L is the lower margin and δ_U is the upper margin. Rejection of the null hypothesis indicates that the two binomial proportions are equivalent. See Chow, Shao, and Wang (2003) for more information.

You can specify the value of the margins δ_L and δ_U with the *MARGIN= riskdiff-option*. If you do not specify *MARGIN=*, PROC FREQ uses lower and upper margins of -0.2 and 0.2 by default. If you specify a single margin value δ , PROC FREQ uses lower and upper margins of $-\delta$ and δ . You can specify the test method with the *METHOD= riskdiff-option*. The following methods are available for the risk difference equivalence analysis: Wald (with and without continuity correction), Hauck-Anderson, Farrington-Manning, and Newcombe (with and without continuity correction). The Wald, Hauck-Anderson, and Farrington-Manning methods provide tests and corresponding test-based confidence limits; the Newcombe method provides only confidence limits. If you do not specify *METHOD=*, PROC FREQ uses the Wald test by default.

PROC FREQ computes two one-sided tests (TOST) for equivalence analysis (Schuirmann 1987). The TOST approach includes a right-sided test for the lower margin δ_L and a left-sided test for the upper margin δ_U . The overall p -value is taken to be the larger of the two p -values from the lower and upper tests.

The section “**Noninferiority Tests**” on page 2577 gives details about the Wald, Hauck-Anderson, Farrington-Manning and Newcombe methods for the risk difference. The lower margin equivalence test statistic takes the same form as the noninferiority test statistic but uses the lower margin value δ_L in place of $-\delta$. The upper margin equivalence test statistic take the same form as the noninferiority test statistic but uses the upper margin value δ_U in place of $-\delta$.

The test-based confidence limits for the risk difference are computed according to the equivalence test method that you select. If you specify *METHOD=WALD* with *VAR=NULL*, or *METHOD=FM*, separate standard errors are computed for the lower and upper margin tests. In this case, the test-based confidence limits are computed by using the maximum of these two standard errors. The confidence limits have a confidence coefficient of $100(1 - 2\alpha)\%$ (Schuirmann 1999). By default, if you do not specify the *ALPHA=* option, these are 90% confidence limits. You can compare the confidence limits to the equivalence limits, (δ_L, δ_U) .

Exact Unconditional Confidence Limits for the Risk Difference

If you specify the *RISKDIFF* option in the *EXACT* statement, PROC FREQ provides exact unconditional confidence limits for the risk difference. PROC FREQ computes the confidence limits by inverting two separate one-sided tests (tail method), where the size of each test is at most $\alpha/2$ and the confidence coefficient is at least $(1 - \alpha)$. Exact conditional methods, described in the section “**Exact Statistics**” on page 2601, do not apply to the risk difference due to the presence of a nuisance parameter (Agresti 1992). The unconditional approach eliminates the nuisance parameter by maximizing the p -value over all possible values of the parameter (Santner and Snell 1980).

By default, PROC FREQ uses the unstandardized risk difference as the test statistic in the confidence limit computations. If you specify the *RISKDIFF(METHOD=SCORE)* option, the procedure uses the score

statistic (Chan and Zhang 1999). The score statistic is a less discrete statistic than the raw risk difference and produces less conservative confidence limits (Agresti and Min 2001). See also Santner et al. (2007) for comparisons of methods for computing exact confidence limits for the risk difference.

PROC FREQ computes the confidence limits as follows. The risk difference is defined as the difference between the row 1 and row 2 risks (proportions), $d = p_1 - p_2$, and n_1 and n_2 denote the row totals of the 2×2 table. The joint probability function for the table can be expressed in terms of the table cell frequencies, the risk difference, and the nuisance parameter p_2 as

$$f(n_{11}, n_{21}; n_1, n_2, d, p_2) = \binom{n_1}{n_{11}} (d + p_2)^{n_{11}} (1 - d - p_2)^{n_1 - n_{11}} \times \binom{n_2}{n_{21}} p_2^{n_{21}} (1 - p_2)^{n_2 - n_{21}}$$

The $100(1 - \alpha/2)\%$ confidence limits for the risk difference are computed as

$$\begin{aligned} d_L &= \sup (d_* : P_U(d_*) > \alpha/2) \\ d_U &= \inf (d_* : P_L(d_*) > \alpha/2) \end{aligned}$$

where

$$\begin{aligned} P_U(d_*) &= \sup_{p_2} \left(\sum_{A, T(a) \geq t_0} f(n_{11}, n_{21}; n_1, n_2, d_*, p_2) \right) \\ P_L(d_*) &= \sup_{p_2} \left(\sum_{A, T(a) \leq t_0} f(n_{11}, n_{21}; n_1, n_2, d_*, p_2) \right) \end{aligned}$$

The set A includes all 2×2 tables with row sums equal to n_1 and n_2 , and $T(a)$ denotes the value of the test statistic for table a in A . To compute $P_U(d_*)$, the sum includes probabilities of those tables for which $(T(a) \geq t_0)$, where t_0 is the value of the test statistic for the observed table. For a fixed value of d_* , $P_U(d_*)$ is taken to be the maximum sum over all possible values of p_2 .

By default, PROC FREQ uses the unstandardized risk difference as the test statistic T . If you specify the `RISKDIFF(METHOD=SCORE)` option, the procedure uses the risk difference score statistic as the test statistic (Chan and Zhang 1999). The computation of the risk difference score statistic is described in the subsection “[Farrington-Manning Test](#)” in the section “[Noninferiority Tests](#)” on page 2577. See Miettinen and Nurminen (1985) and Farrington and Manning (1990) for more information.

Barnard’s Unconditional Exact Test

The BARNARD option in the EXACT statement provides an unconditional exact test for the risk (proportion) difference for 2×2 tables. The reference set for the unconditional exact test consists of all 2×2 tables that have the same row sums as the observed table (Barnard 1945, 1947, 1949). This differs from the reference set for exact conditional inference, which is restricted to the set of tables that have the same row sums and the same column sums as the observed table. See the sections “[Fisher’s Exact Test](#)” on page 2554 and “[Exact Statistics](#)” on page 2601 for more information.

The test statistic is the standardized risk difference, which is computed as

$$T = d / \sqrt{p_{\cdot 1}(1 - p_{\cdot 1})(1/n_1 + 1/n_2)}$$

where the risk difference d is defined as the difference between the row 1 and row 2 risks (proportions), $d = (n_{11}/n_1 - n_{21}/n_2)$; n_1 and n_2 are the row 1 and row 2 totals, respectively; and $p_{.1}$ is the overall proportion in column 1, $(n_{11} + n_{21})/n$.

Under the null hypothesis that the risk difference is 0, the joint probability function for a table can be expressed in terms of the table cell frequencies, the row totals, and the unknown parameter π as

$$f(n_{11}, n_{21}; n_1, n_2, \pi) = \binom{n_1}{n_{11}} \binom{n_2}{n_{21}} \pi^{n_{11}+n_{21}} (1-\pi)^{n-n_{11}-n_{21}}$$

where π is the common value of the risk (proportion).

PROC FREQ sums the table probabilities over the reference set for those tables where the test statistic is greater than or equal to the observed value of the test statistic. This sum can be expressed as

$$\text{Prob}(\pi) = \sum_{A, T(a) \geq t_0} f(n_{11}, n_{21}; n_1, n_2, \pi)$$

where the set A contains all 2×2 tables with row sums equal to n_1 and n_2 , and $T(a)$ denotes the value of the test statistic for table a in A . The sum includes probabilities of those tables for which $(T(a) \geq t_0)$, where t_0 is the value of the test statistic for the observed table.

The sum $\text{Prob}(\pi)$ depends on the unknown value of π . To compute the exact p -value, PROC FREQ eliminates the nuisance parameter π by taking the maximum value of $\text{Prob}(\pi)$ over all possible values of π ,

$$\text{Prob} = \sup_{(0 \leq \pi \leq 1)} (\text{Prob}(\pi))$$

See Suissa and Shuster (1985) and Mehta and Senchaudhuri (2003).

Odds Ratio and Relative Risks for 2 x 2 Tables

Odds Ratio (Case-Control Studies)

The odds ratio is a useful measure of association for a variety of study designs. For a retrospective design called a *case-control study*, the odds ratio can be used to estimate the relative risk when the probability of positive response is small (Agresti 2002). In a case-control study, two independent samples are identified based on a binary (yes-no) response variable, and the conditional distribution of a binary explanatory variable is examined, within fixed levels of the response variable. See Stokes, Davis, and Koch (2012) and Agresti (2007).

The odds of a positive response (column 1) in row 1 is n_{11}/n_{12} . Similarly, the odds of a positive response in row 2 is n_{21}/n_{22} . The odds ratio is formed as the ratio of the row 1 odds to the row 2 odds. The odds ratio for a 2×2 table is defined as

$$OR = \frac{n_{11}/n_{12}}{n_{21}/n_{22}} = \frac{n_{11} n_{22}}{n_{12} n_{21}}$$

The odds ratio can be any nonnegative number. When the row and column variables are independent, the true value of the odds ratio equals 1. An odds ratio greater than 1 indicates that the odds of a positive response are higher in row 1 than in row 2. Values less than 1 indicate the odds of positive response are higher in row 2. The strength of association increases with the deviation from 1.

The transformation $G = (OR - 1)/(OR + 1)$ transforms the odds ratio to the range $(-1, 1)$ with $G = 0$ when $OR = 1$; $G = -1$ when $OR = 0$; and G approaches 1 as OR approaches infinity. G is the gamma statistic, which PROC FREQ computes when you specify the MEASURES option.

The asymptotic $100(1 - \alpha)\%$ confidence limits for the odds ratio are

$$(OR \times \exp(-z\sqrt{v}), OR \times \exp(z\sqrt{v}))$$

where

$$v = \text{Var}(\ln OR) = \frac{1}{n_{11}} + \frac{1}{n_{12}} + \frac{1}{n_{21}} + \frac{1}{n_{22}}$$

and z is the $100(1 - \alpha/2)$ percentile of the standard normal distribution. If any of the four cell frequencies are zero, the estimates are not computed.

Exact Confidence Limits for the Odds Ratio When you specify the OR option in the EXACT statement, PROC FREQ computes exact confidence limits for the odds ratio. Because this is a discrete problem, the confidence coefficient for the exact confidence interval is not exactly $(1 - \alpha)$ but is at least $(1 - \alpha)$. Thus, these confidence limits are conservative. See Agresti (1992) for more information.

PROC FREQ computes exact confidence limits for the odds ratio by using an algorithm based on Thomas (1971). See also Gart (1971). The following two equations are solved iteratively to determine the lower and upper confidence limits, ϕ_1 and ϕ_2 :

$$\sum_{i=n_{11}}^{n_{1\cdot}} \binom{n_{1\cdot}}{i} \binom{n_{2\cdot}}{n_{1\cdot}-i} \phi_1^i / \sum_{i=0}^{n_{1\cdot}} \binom{n_{1\cdot}}{i} \binom{n_{2\cdot}}{n_{1\cdot}-i} \phi_1^i = \alpha/2$$

$$\sum_{i=0}^{n_{11}} \binom{n_{1\cdot}}{i} \binom{n_{2\cdot}}{n_{1\cdot}-i} \phi_2^i / \sum_{i=0}^{n_{1\cdot}} \binom{n_{1\cdot}}{i} \binom{n_{2\cdot}}{n_{1\cdot}-i} \phi_2^i = \alpha/2$$

When the odds ratio equals zero, which occurs when either $n_{11} = 0$ or $n_{22} = 0$, PROC FREQ sets the lower exact confidence limit to zero and determines the upper limit with level α . Similarly, when the odds ratio equals infinity, which occurs when either $n_{12} = 0$ or $n_{21} = 0$, PROC FREQ sets the upper exact confidence limit to infinity and determines the lower limit with level α .

Relative Risks (Cohort Studies)

These measures of relative risk are useful in *cohort* (prospective) study designs, where two samples are identified based on the presence or absence of an explanatory factor. The two samples are observed in future time for the binary (yes-no) response variable under study. Relative risk measures are also useful in cross-sectional studies, where two variables are observed simultaneously. See Stokes, Davis, and Koch (2012) and Agresti (2007) for more information.

The column 1 relative risk is the ratio of the column 1 risk for row 1 to row 2. The column 1 risk for row 1 is the proportion of the row 1 observations classified in column 1,

$$p_1 = n_{11} / n_{1\cdot}$$

Similarly, the column 1 risk for row 2 is

$$p_2 = n_{21} / n_{2\cdot}$$

The column 1 relative risk is computed as

$$RR_1 = p_1 / p_2$$

A relative risk greater than 1 indicates that the probability of positive response is greater in row 1 than in row 2. Similarly, a relative risk less than 1 indicates that the probability of positive response is less in row 1 than in row 2. The strength of association increases with the deviation from 1.

Asymptotic $100(1 - \alpha)\%$ confidence limits for the column 1 relative risk are computed as

$$(RR_1 \times \exp(-z\sqrt{v}), RR_1 \times \exp(z\sqrt{v}))$$

where

$$v = \text{Var}(\ln RR_1) = ((1 - p_1)/n_{11}) + ((1 - p_2)/n_{21})$$

and z is the $100(1 - \alpha/2)$ percentile of the standard normal distribution. If either n_{11} or n_{21} is zero, the estimates are not computed.

PROC FREQ computes the column 2 relative risks in the same way.

Exact Unconditional Confidence Limits for the Relative Risk If you specify the RELRISK option in the EXACT statement, PROC FREQ provides exact unconditional confidence limits for the relative risk. PROC FREQ computes the confidence limits by inverting two separate one-sided tests (tail method), where the size of each test is at most $\alpha/2$ and the confidence coefficient is at least $(1 - \alpha)$. Exact conditional methods, described in the section “Exact Statistics” on page 2601, do not apply to the relative risk due to the presence of a nuisance parameter (Agresti 1992). The unconditional approach eliminates the nuisance parameter by maximizing the p -value over all possible values of the parameter (Santner and Snell 1980).

By default, PROC FREQ uses the unstandardized relative risk as the test statistic in the confidence limit computations. If you specify the RELRISK(METHOD=SCORE) option, the procedure uses the relative risk score statistic (Chan and Zhang 1999). The score statistic is a less discrete statistic than the raw relative risk and produces less conservative confidence limits (Agresti and Min 2001). See also Santner et al. (2007) for comparisons of methods for computing exact confidence limits.

See the section “Exact Unconditional Confidence Limits for the Risk Difference” on page 2580 for a description of the method that PROC FREQ uses to compute confidence limits for the relative risk. The test statistic for the relative risk computation is either the unstandardized relative risk (by default) or the relative risk score statistic (if you specify the RELRISK(METHOD=SCORE) option). PROC FREQ uses the following form of the unstandardized relative risk, which adds 0.05 to each frequency, to ensure that the statistic is defined when there are zero table cells (Gart and Nam 1988):

$$rr = \frac{(n_{11} + 0.5) / (n_{1\cdot} + 0.5)}{(n_{21} + 0.5) / (n_{2\cdot} + 0.5)}$$

If you specify the RELRISK(METHOD=SCORE) option, PROC FREQ uses the relative risk score statistic (Miettinen and Nurminen 1985; Farrington and Manning 1990). This test statistic is computed as

$$z = (\hat{p}_1 - R_0 \hat{p}_2) / \text{se}(rr)$$

where

$$se(rr) = \sqrt{\tilde{p}_1(1 - \tilde{p}_1)/n_{1\cdot} + R_0^2 \tilde{p}_2(1 - \tilde{p}_2)/n_{2\cdot}}$$

where \tilde{p}_1 and \tilde{p}_2 are the maximum likelihood estimators of p_1 and p_2 under the null hypothesis that the relative risk equals R_0 . From Farrington and Manning (1990, p. 1454), the maximum likelihood solution is

$$\tilde{p}_1 = (-b - \sqrt{b^2 - 4ac})/2a \quad \text{and} \quad \tilde{p}_2 = \tilde{p}_1/R_0$$

where

$$\begin{aligned} a &= 1 + \theta \\ b &= -(R_0(1 + \theta \hat{p}_2) + \theta + \hat{p}_1) \\ c &= R_0(\hat{p}_1 + \theta \hat{p}_2) \\ \theta &= n_{2\cdot}/n_{1\cdot}. \end{aligned}$$

Cochran-Armitage Test for Trend

The TREND option in the TABLES statement provides the Cochran-Armitage test for trend, which tests for trend in binomial proportions across levels of a single factor or covariate. This test is appropriate for a two-way table where one variable has two levels and the other variable is ordinal. The two-level variable represents the response, and the other variable represents an explanatory variable with ordered levels. When the two-way has two columns and R rows, PROC FREQ tests for trend across the R levels of the row variable, and the binomial proportion is computed as the proportion of observations in the first column. When the table has two rows and C columns, PROC FREQ tests for trend across the C levels of the column variable, and the binomial proportion is computed as the proportion of observations in the first row.

The trend test is based on the regression coefficient for the weighted linear regression of the binomial proportions on the scores of the explanatory variable levels. See Margolin (1988) and Agresti (2002) for details. If the table has two columns and R rows, the trend test statistic is computed as

$$T = \sum_{i=1}^R n_{i1}(R_i - \bar{R}) / \sqrt{p_{\cdot 1}(1 - p_{\cdot 1}) s^2}$$

where R_i is the score of row i , \bar{R} is the average row score, and

$$s^2 = \sum_{i=1}^R n_{i\cdot}(R_i - \bar{R})^2$$

The SCORES= option in the TABLES statement determines the type of row scores used in computing the trend test (and other score-based statistics). The default is SCORES=TABLE. See the section “[Scores](#)” on page 2549 for details. For character variables, the table scores for the row variable are the row numbers (for example, 1 for the first row, 2 for the second row, and so on). For numeric variables, the table score for each row is the numeric value of the row level. When you perform the trend test, the explanatory variable might be numeric (for example, dose of a test substance), and the variable values might be appropriate scores. If

the explanatory variable has ordinal levels that are not numeric, you can assign meaningful scores to the variable levels. Sometimes equidistant scores, such as the table scores for a character variable, might be appropriate. For more information on choosing scores for the trend test, see Margolin (1988).

The null hypothesis for the Cochran-Armitage test is no trend, which means that the binomial proportion $p_{i1} = n_{i1}/n_i$ is the same for all levels of the explanatory variable. Under the null hypothesis, the trend statistic has an asymptotic standard normal distribution.

PROC FREQ computes one-sided and two-sided p -values for the trend test. When the test statistic is greater than its null hypothesis expected value of zero, PROC FREQ displays the right-sided p -value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided p -value supports the alternative hypothesis of increasing trend in proportions from row 1 to row R . When the test statistic is less than or equal to zero, PROC FREQ displays the left-sided p -value. A small left-sided p -value supports the alternative of decreasing trend.

The one-sided p -value for the trend test is computed as

$$P_1 = \begin{cases} \text{Prob}(Z > T) & \text{if } T > 0 \\ \text{Prob}(Z < T) & \text{if } T \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided p -value is computed as

$$P_2 = \text{Prob}(|Z| > |T|)$$

PROC FREQ also provides exact p -values for the Cochran-Armitage trend test. You can request the exact test by specifying the TREND option in the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

Jonckheere-Terpstra Test

The JT option in the TABLES statement provides the Jonckheere-Terpstra test, which is a nonparametric test for ordered differences among classes. It tests the null hypothesis that the distribution of the response variable does not differ among classes. It is designed to detect alternatives of ordered class differences, which can be expressed as $\tau_1 \leq \tau_2 \leq \dots \leq \tau_R$ (or $\tau_1 \geq \tau_2 \geq \dots \geq \tau_R$), with at least one of the inequalities being strict, where τ_i denotes the effect of class i . For such ordered alternatives, the Jonckheere-Terpstra test can be preferable to tests of more general class difference alternatives, such as the Kruskal-Wallis test (produced by the WILCOXON option in the NPAR1WAY procedure). See Pirie (1983) and Hollander and Wolfe (1999) for more information about the Jonckheere-Terpstra test.

The Jonckheere-Terpstra test is appropriate for a two-way table in which an ordinal column variable represents the response. The row variable, which can be nominal or ordinal, represents the classification variable. The levels of the row variable should be ordered according to the ordering you want the test to detect. The order of variable levels is determined by the ORDER= option in the PROC FREQ statement. The default is ORDER=INTERNAL, which orders by unformatted values. If you specify ORDER=DATA, PROC FREQ orders values according to their order in the input data set. For more information about how to order variable levels, see the ORDER= option.

The Jonckheere-Terpstra test statistic is computed by first forming $R(R-1)/2$ Mann-Whitney counts $M_{i,i'}$, where $i < i'$, for pairs of rows in the contingency table,

$$\begin{aligned} M_{i,i'} &= \{ \text{number of times } X_{i,j} < X_{i',j'}, \quad j = 1, \dots, n_i; \quad j' = 1, \dots, n_{i'} \} \\ &+ \frac{1}{2} \{ \text{number of times } X_{i,j} = X_{i',j'}, \quad j = 1, \dots, n_i; \quad j' = 1, \dots, n_{i'} \} \end{aligned}$$

where $X_{i,j}$ is response j in row i . The Jonckheere-Terpstra test statistic is computed as

$$J = \sum_{1 \leq i < i' \leq R} \sum M_{i,i'}$$

This test rejects the null hypothesis of no difference among classes for large values of J . Asymptotic p -values for the Jonckheere-Terpstra test are obtained by using the normal approximation for the distribution of the standardized test statistic. The standardized test statistic is computed as

$$J^* = (J - E_0(J)) / \sqrt{\text{Var}_0(J)}$$

where $E_0(J)$ and $\text{Var}_0(J)$ are the expected value and variance of the test statistic under the null hypothesis,

$$E_0(J) = \left(n^2 - \sum_i n_{i.}^2 \right) / 4$$

$$\text{Var}_0(J) = A/72 + B/(36n(n-1)(n-2)) + C/(8n(n-1))$$

where

$$A = n(n-1)(2n+5) - \sum_i n_{i.}(n_{i.}-1)(2n_{i.}+5) - \sum_j n_{.j}(n_{.j}-1)(2n_{.j}+5)$$

$$B = \left(\sum_i n_{i.}(n_{i.}-1)(n_{i.}-2) \right) \left(\sum_j n_{.j}(n_{.j}-1)(n_{.j}-2) \right)$$

$$C = \left(\sum_i n_{i.}(n_{i.}-1) \right) \left(\sum_j n_{.j}(n_{.j}-1) \right)$$

PROC FREQ computes one-sided and two-sided p -values for the Jonckheere-Terpstra test. When the standardized test statistic is greater than its null hypothesis expected value of zero, PROC FREQ displays the right-sided p -value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided p -value supports the alternative hypothesis of increasing order from row 1 to row R . When the standardized test statistic is less than or equal to zero, PROC FREQ displays the left-sided p -value. A small left-sided p -value supports the alternative of decreasing order from row 1 to row R .

The one-sided p -value for the Jonckheere-Terpstra test, P_1 , is computed as

$$P_1 = \begin{cases} \text{Prob}(Z > J^*) & \text{if } J^* > 0 \\ \text{Prob}(Z < J^*) & \text{if } J^* \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided p -value, P_2 , is computed as

$$P_2 = \text{Prob}(|Z| > |J^*|)$$

PROC FREQ also provides exact p -values for the Jonckheere-Terpstra test. You can request the exact test by specifying the JT option in the EXACT statement. See the section “[Exact Statistics](#)” on page 2601 for more information.

Tests and Measures of Agreement

When you specify the AGREE option in the TABLES statement, PROC FREQ computes tests and measures of agreement for square tables (that is, for tables where the number of rows equals the number of columns). For two-way tables, these tests and measures include McNemar's test for 2×2 tables, Bowker's test of symmetry, the simple kappa coefficient, and the weighted kappa coefficient. For multiple strata (n -way tables, where $n > 2$), PROC FREQ also computes the overall simple kappa coefficient and the overall weighted kappa coefficient, as well as tests for equal kappas (simple and weighted) among strata. Cochran's Q is computed for multiway tables when each variable has two levels, that is, for $h \times 2 \times 2$ tables.

PROC FREQ computes the kappa coefficients (simple and weighted), their asymptotic standard errors, and their confidence limits when you specify the AGREE option in the TABLES statement. If you also specify the KAPPA option in the TEST statement, then PROC FREQ computes the asymptotic test of the hypothesis that simple kappa equals zero. Similarly, if you specify the WTKAP option in the TEST statement, PROC FREQ computes the asymptotic test for weighted kappa.

In addition to the asymptotic tests described in this section, PROC FREQ provides exact p -values for McNemar's test, the simple kappa coefficient test, and the weighted kappa coefficient test. You can request these exact tests by specifying the corresponding options in the EXACT statement. See the section "Exact Statistics" on page 2601 for more information.

The following sections provide the formulas that PROC FREQ uses to compute the AGREE statistics. For information about the use and interpretation of these statistics, see Agresti (2002, 2007); Fleiss, Levin, and Paik (2003), and the other references cited for each statistic.

McNemar's Test

PROC FREQ computes McNemar's test for 2×2 tables when you specify the AGREE option. McNemar's test is appropriate when you are analyzing data from matched pairs of subjects with a dichotomous (yes-no) response. It tests the null hypothesis of marginal homogeneity, or $p_{1\cdot} = p_{\cdot 1}$. McNemar's test is computed as

$$Q_M = (n_{12} - n_{21})^2 / (n_{12} + n_{21})$$

Under the null hypothesis, Q_M has an asymptotic chi-square distribution with one degree of freedom. See McNemar (1947), as well as the general references cited in the preceding section. In addition to the asymptotic test, PROC FREQ also computes the exact p -value for McNemar's test when you specify the MCNEM option in the EXACT statement.

Bowker's Test of Symmetry

For Bowker's test of symmetry, the null hypothesis is that the cell proportions are symmetric, or that $p_{ij} = p_{ji}$ for all pairs of table cells. For 2×2 tables, Bowker's test is identical to McNemar's test, and so PROC FREQ provides Bowker's test for square tables larger than 2×2 .

Bowker's test of symmetry is computed as

$$Q_B = \sum_{i < j} \sum (n_{ij} - n_{ji})^2 / (n_{ij} + n_{ji})$$

For large samples, Q_B has an asymptotic chi-square distribution with $R(R-1)/2$ degrees of freedom under the null hypothesis of symmetry. See Bowker (1948) for details.

Simple Kappa Coefficient

The simple kappa coefficient, introduced by Cohen (1960), is a measure of interrater agreement. PROC FREQ computes the simple kappa coefficient as

$$\hat{\kappa} = (P_o - P_e) / (1 - P_e)$$

where $P_o = \sum_i p_{ii}$ and $P_e = \sum_i p_{i\cdot} p_{\cdot i}$. If the two response variables are viewed as two independent ratings of the n subjects, the kappa coefficient equals +1 when there is complete agreement of the raters. When the observed agreement exceeds chance agreement, kappa is positive, with its magnitude reflecting the strength of agreement. Although this is unusual in practice, kappa is negative when the observed agreement is less than chance agreement. The minimum value of kappa is between -1 and 0, depending on the marginal proportions.

The asymptotic variance of the simple kappa coefficient is computed as

$$\text{Var}(\hat{\kappa}) = (A + B - C) / (1 - P_e)^2 n$$

where

$$A = \sum_i p_{ii} (1 - (p_{i\cdot} + p_{\cdot i})(1 - \hat{\kappa}))^2$$

$$B = (1 - \hat{\kappa})^2 \sum_{i \neq j} p_{ij} (p_{\cdot i} + p_{\cdot j})^2$$

$$C = (\hat{\kappa} - P_e(1 - \hat{\kappa}))^2$$

See Fleiss, Cohen, and Everitt (1969) for details.

PROC FREQ computes confidence limits for the simple kappa coefficient as

$$\hat{\kappa} \pm (z_{\alpha/2} \times \sqrt{\text{Var}(\hat{\kappa})})$$

where $z_{\alpha/2}$ is the 100(1 - $\alpha/2$) percentile of the standard normal distribution. The value of α is determined by the value of the ALPHA= option, which, by default, equals 0.05 and produces 95% confidence limits.

To compute an asymptotic test for the kappa coefficient, PROC FREQ uses the standardized test statistic $\hat{\kappa}^*$, which has an asymptotic standard normal distribution under the null hypothesis that kappa equals zero. The standardized test statistic is computed as

$$\hat{\kappa}^* = \hat{\kappa} / \sqrt{\text{Var}_0(\hat{\kappa})}$$

where $\text{Var}_0(\hat{\kappa})$ is the variance of the kappa coefficient under the null hypothesis,

$$\text{Var}_0(\hat{\kappa}) = \left(P_e + P_e^2 - \sum_i p_{i\cdot} p_{\cdot i} (p_{i\cdot} + p_{\cdot i}) \right) / (1 - P_e)^2 n$$

See Fleiss, Levin, and Paik (2003) for details.

PROC FREQ also provides an exact test for the simple kappa coefficient. You can request the exact test by specifying the KAPPA or AGREE option in the EXACT statement. See the section “Exact Statistics” on page 2601 for more information.

Weighted Kappa Coefficient

The weighted kappa coefficient is a generalization of the simple kappa coefficient that uses weights to quantify the relative difference between categories. For 2×2 tables, the weighted kappa coefficient equals the simple kappa coefficient. PROC FREQ displays the weighted kappa coefficient only for tables larger than 2×2 . PROC FREQ computes the kappa weights from the column scores, by using either Cicchetti-Allison weights or Fleiss-Cohen weights, both of which are described in the following section. The weights w_{ij} are constructed so that $0 \leq w_{ij} < 1$ for all $i \neq j$, $w_{ii} = 1$ for all i , and $w_{ij} = w_{ji}$. The weighted kappa coefficient is computed as

$$\hat{\kappa}_w = (P_{o(w)} - P_{e(w)}) / (1 - P_{e(w)})$$

where

$$P_{o(w)} = \sum_i \sum_j w_{ij} p_{ij}$$

$$P_{e(w)} = \sum_i \sum_j w_{ij} p_{i \cdot} p_{\cdot j}$$

The asymptotic variance of the weighted kappa coefficient is

$$\text{Var}(\hat{\kappa}_w) = \left(\sum_i \sum_j p_{ij} (w_{ij} - (\bar{w}_{i \cdot} + \bar{w}_{\cdot j})(1 - \hat{\kappa}_w))^2 - (\hat{\kappa}_w - P_{e(w)}(1 - \hat{\kappa}_w))^2 \right) / (1 - P_{e(w)})^2 n$$

where

$$\bar{w}_{i \cdot} = \sum_j p_{\cdot j} w_{ij}$$

$$\bar{w}_{\cdot j} = \sum_i p_{i \cdot} w_{ij}$$

See Fleiss, Cohen, and Everitt (1969) for details.

PROC FREQ computes confidence limits for the weighted kappa coefficient as

$$\hat{\kappa}_w \pm (z_{\alpha/2} \times \sqrt{\text{Var}(\hat{\kappa}_w)})$$

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the standard normal distribution. The value of α is determined by the value of the ALPHA= option, which, by default, equals 0.05 and produces 95% confidence limits.

To compute an asymptotic test for the weighted kappa coefficient, PROC FREQ uses the standardized test statistic $\hat{\kappa}_w^*$, which has an asymptotic standard normal distribution under the null hypothesis that weighted kappa equals zero. The standardized test statistic is computed as

$$\hat{\kappa}_w^* = \hat{\kappa}_w / \sqrt{\text{Var}_0(\hat{\kappa}_w)}$$

where $\text{Var}_0(\hat{\kappa}_w)$ is the variance of the weighted kappa coefficient under the null hypothesis,

$$\text{Var}_0(\hat{\kappa}_w) = \left(\sum_i \sum_j p_{i \cdot} p_{\cdot j} (w_{ij} - (\bar{w}_{i \cdot} + \bar{w}_{\cdot j}))^2 - P_{e(w)}^2 \right) / (1 - P_{e(w)})^2 n$$

See Fleiss, Levin, and Paik (2003) for details.

PROC FREQ also provides an exact test for the weighted kappa coefficient. You can request the exact test by specifying the WTKAPPA or AGREE option in the EXACT statement. See the section “[Exact Statistics](#)” on page 2601 for more information.

Weights PROC FREQ computes kappa coefficient weights by using the column scores and one of the two available weight types. The column scores are determined by the SCORES= option in the TABLES statement. The two available types of kappa weights are Cicchetti-Allison and Fleiss-Cohen weights. By default, PROC FREQ uses Cicchetti-Allison weights. If you specify (WT=FC) with the AGREE option, then PROC FREQ uses Fleiss-Cohen weights to compute the weighted kappa coefficient.

PROC FREQ computes Cicchetti-Allison kappa coefficient weights as

$$w_{ij} = 1 - \frac{|C_i - C_j|}{C_C - C_1}$$

where C_i is the score for column i and C is the number of categories or columns. See Cicchetti and Allison (1971) for details.

The SCORES= option in the TABLES statement determines the type of column scores used to compute the kappa weights (and other score-based statistics). The default is SCORES=TABLE. See the section “Scores” on page 2549 for details. For numeric variables, table scores are the values of the variable levels. You can assign numeric values to the levels in a way that reflects their level of similarity. For example, suppose you have four levels and order them according to similarity. If you assign them values of 0, 2, 4, and 10, the Cicchetti-Allison kappa weights take the following values: $w_{12} = 0.8$, $w_{13} = 0.6$, $w_{14} = 0$, $w_{23} = 0.8$, $w_{24} = 0.2$, and $w_{34} = 0.4$. Note that when there are only two categories (that is, $C = 2$), the weighted kappa coefficient is identical to the simple kappa coefficient.

If you specify (WT=FC) with the AGREE option in the TABLES statement, PROC FREQ computes Fleiss-Cohen kappa coefficient weights as

$$w_{ij} = 1 - \frac{(C_i - C_j)^2}{(C_C - C_1)^2}$$

See Fleiss and Cohen (1973) for details.

For the preceding example, the Fleiss-Cohen kappa weights are: $w_{12} = 0.96$, $w_{13} = 0.84$, $w_{14} = 0$, $w_{23} = 0.96$, $w_{24} = 0.36$, and $w_{34} = 0.64$.

Overall Kappa Coefficient

When there are multiple strata, PROC FREQ combines the stratum-level estimates of kappa into an overall estimate of the supposed common value of kappa. Assume there are q strata, indexed by $h = 1, 2, \dots, q$, and let $\text{Var}(\hat{\kappa}_h)$ denote the variance of $\hat{\kappa}_h$. The estimate of the overall kappa coefficient is computed as

$$\hat{\kappa}_T = \sum_{h=1}^q \frac{\hat{\kappa}_h}{\text{Var}(\hat{\kappa}_h)} / \sum_{h=1}^q \frac{1}{\text{Var}(\hat{\kappa}_h)}$$

See Fleiss, Levin, and Paik (2003) for details.

PROC FREQ computes an estimate of the overall weighted kappa in the same way.

Tests for Equal Kappa Coefficients

When there are multiple strata, the following chi-square statistic tests whether the stratum-level values of kappa are equal:

$$Q_K = \sum_{h=1}^q (\hat{\kappa}_h - \hat{\kappa}_T)^2 / \text{Var}(\hat{\kappa}_h)$$

Under the null hypothesis of equal kappas for the q strata, Q_K has an asymptotic chi-square distribution with $q-1$ degrees of freedom. See Fleiss, Levin, and Paik (2003) for more information. PROC FREQ computes a test for equal weighted kappa coefficients in the same way.

Cochran's Q Test

Cochran's Q is computed for multiway tables when each variable has two levels, that is, for $2 \times 2 \cdots \times 2$ tables. Cochran's Q statistic is used to test the homogeneity of the one-dimensional margins. Let m denote the number of variables and N denote the total number of subjects. Cochran's Q statistic is computed as

$$Q_C = m(m-1) \left(\sum_{j=1}^m T_j^2 - T^2 \right) / \left(mT - \sum_{k=1}^N S_k^2 \right)$$

where T_j is the number of positive responses for variable j , T is the total number of positive responses over all variables, and S_k is the number of positive responses for subject k . Under the null hypothesis, Cochran's Q has an asymptotic chi-square distribution with $m-1$ degrees of freedom. See Cochran (1950) for details. When there are only two binary response variables ($m=2$), Cochran's Q simplifies to McNemar's test. When there are more than two response categories, you can test for marginal homogeneity by using the repeated measures capabilities of the CATMOD procedure.

Tables with Zero Rows and Columns

The AGREE statistics are defined only for square tables, where the number of rows equals the number of columns. If the table is not square, PROC FREQ does not compute AGREE statistics. In the kappa statistic framework, where two independent raters assign ratings to each of n subjects, suppose one of the raters does not use all possible r rating levels. If the corresponding table has r rows but only $r-1$ columns, then the table is not square and PROC FREQ does not compute AGREE statistics. To create a square table in this situation, use the ZEROS option in the WEIGHT statement, which requests that PROC FREQ include observations with zero weights in the analysis. Include zero-weight observations in the input data set to represent any rating levels that are not used by a rater, so that the input data set has at least one observation for each possible rater and rating combination. The analysis then includes all rating levels, even when all levels are not actually assigned by both raters. The resulting table (of rater 1 by rater 2) is a square table, and AGREE statistics can be computed.

For more information, see the description of the ZEROS option. By default, PROC FREQ does not process observations that have zero weights, because these observations do not contribute to the total frequency count, and because any resulting zero-weight row or column causes many of the tests and measures of association to be undefined. However, kappa statistics are defined for tables with a zero-weight row or column, and the ZEROS option makes it possible to input zero-weight observations and construct the tables needed to compute kappas.

Cochran-Mantel-Haenszel Statistics

The CMH option in the TABLES statement gives a stratified statistical analysis of the relationship between the row and column variables after controlling for the strata variables in a multiway table. For example, for the table request $A*B*C*D$, the CMH option provides an analysis of the relationship between C and D , after controlling for A and B . The stratified analysis provides a way to adjust for the possible confounding effects of A and B without being forced to estimate parameters for them.

The CMH analysis produces Cochran-Mantel-Haenszel statistics, which include the correlation statistic, the ANOVA (row mean scores) statistic, and the general association statistic. For 2×2 tables, the CMH option

also provides Mantel-Haenszel and logit estimates of the common odds ratio and the common relative risks, as well as the Breslow-Day test for homogeneity of the odds ratios.

Exact statistics are also available for stratified 2×2 tables. If you specify the EQOR option in the EXACT statement, PROC FREQ provides Zelen's exact test for equal odds ratios. If you specify the COMOR option in the EXACT statement, PROC FREQ provides exact confidence limits for the common odds ratio and an exact test that the common odds ratio equals one.

Let the number of strata be denoted by q , indexing the strata by $h = 1, 2, \dots, q$. Each stratum contains a contingency table with X representing the row variable and Y representing the column variable. For table h , denote the cell frequency in row i and column j by n_{hij} , with corresponding row and column marginal totals denoted by $n_{hi\cdot}$ and $n_{h\cdot j}$, and the overall stratum total by n_h .

Because the formulas for the Cochran-Mantel-Haenszel statistics are more easily defined in terms of matrices, the following notation is used. Vectors are presumed to be column vectors unless they are transposed ($'$).

$$\begin{aligned} \mathbf{n}'_{hi} &= (n_{hi1}, n_{hi2}, \dots, n_{hiC}) & (1 \times C) \\ \mathbf{n}'_h &= (\mathbf{n}'_{h1}, \mathbf{n}'_{h2}, \dots, \mathbf{n}'_{hR}) & (1 \times RC) \\ p_{hi\cdot} &= n_{hi\cdot} / n_h & (1 \times 1) \\ p_{h\cdot j} &= n_{h\cdot j} / n_h & (1 \times 1) \\ \mathbf{P}'_{h*} &= (p_{h1\cdot}, p_{h2\cdot}, \dots, p_{hR\cdot}) & (1 \times R) \\ \mathbf{P}'_{h*} &= (p_{h\cdot 1}, p_{h\cdot 2}, \dots, p_{h\cdot C}) & (1 \times C) \end{aligned}$$

Assume that the strata are independent and that the marginal totals of each stratum are fixed. The null hypothesis, H_0 , is that there is no association between X and Y in any of the strata. The corresponding model is the multiple hypergeometric; this implies that, under H_0 , the expected value and covariance matrix of the frequencies are, respectively,

$$\begin{aligned} \mathbf{m}_h &= \mathbf{E}[\mathbf{n}_h \mid H_0] = n_h (\mathbf{P}_{h*} \otimes \mathbf{P}_{h*}) \\ \text{Var}[\mathbf{n}_h \mid H_0] &= c \left((\mathbf{D}_{\mathbf{P}_{h*}} - \mathbf{P}_{h*} \mathbf{P}'_{h*}) \otimes (\mathbf{D}_{\mathbf{P}_{h*}} - \mathbf{P}_{h*} \mathbf{P}'_{h*}) \right) \end{aligned}$$

where

$$c = n_h^2 / (n_h - 1)$$

and where \otimes denotes Kronecker product multiplication and \mathbf{D}_a is a diagonal matrix with the elements of \mathbf{a} on the main diagonal.

The generalized CMH statistic (Landis, Heyman, and Koch 1978) is defined as

$$Q_{CMH} = \mathbf{G}' \mathbf{V}_G^{-1} \mathbf{G}$$

where

$$\begin{aligned} \mathbf{G} &= \sum_h \mathbf{B}_h (\mathbf{n}_h - \mathbf{m}_h) \\ \mathbf{V}_G &= \sum_h \mathbf{B}_h (\text{Var}[\mathbf{n}_h \mid H_0]) \mathbf{B}'_h \end{aligned}$$

and where

$$\mathbf{B}_h = \mathbf{C}_h \otimes \mathbf{R}_h$$

is a matrix of fixed constants based on column scores \mathbf{C}_h and row scores \mathbf{R}_h . When the null hypothesis is true, the CMH statistic has an asymptotic chi-square distribution with degrees of freedom equal to the rank of \mathbf{B}_h . If \mathbf{V}_G is found to be singular, PROC FREQ prints a message and sets the value of the CMH statistic to missing.

PROC FREQ computes three CMH statistics by using this formula for the generalized CMH statistic, with different row and column score definitions for each statistic. The CMH statistics that PROC FREQ computes are the correlation statistic, the ANOVA (row mean scores) statistic, and the general association statistic. These statistics test the null hypothesis of no association against different alternative hypotheses. The following sections describe the computation of these CMH statistics.

CAUTION: The CMH statistics have low power for detecting an association in which the patterns of association for some of the strata are in the opposite direction of the patterns displayed by other strata. Thus, a nonsignificant CMH statistic suggests either that there is no association or that no pattern of association has enough strength or consistency to dominate any other pattern.

Correlation Statistic

The correlation statistic, popularized by Mantel and Haenszel, has one degree of freedom and is known as the Mantel-Haenszel statistic (Mantel and Haenszel 1959; Mantel 1963).

The alternative hypothesis for the correlation statistic is that there is a linear association between X and Y in at least one stratum. If either X or Y does not lie on an ordinal (or interval) scale, then this statistic is not meaningful.

To compute the correlation statistic, PROC FREQ uses the formula for the generalized CMH statistic with the row and column scores determined by the SCORES= option in the TABLES statement. See the section “Scores” on page 2549 for more information about the available score types. The matrix of row scores \mathbf{R}_h has dimension $1 \times R$, and the matrix of column scores \mathbf{C}_h has dimension $1 \times C$.

When there is only one stratum, this CMH statistic reduces to $(n - 1)r^2$, where r is the Pearson correlation coefficient between X and Y . When nonparametric (RANK or RIDIT) scores are specified, the statistic reduces to $(n - 1)r_s^2$, where r_s is the Spearman rank correlation coefficient between X and Y . When there is more than one stratum, this CMH statistic becomes a stratum-adjusted correlation statistic.

ANOVA (Row Mean Scores) Statistic

The ANOVA statistic can be used only when the column variable Y lies on an ordinal (or interval) scale so that the mean score of Y is meaningful. For the ANOVA statistic, the mean score is computed for each row of the table, and the alternative hypothesis is that, for at least one stratum, the mean scores of the R rows are unequal. In other words, the statistic is sensitive to location differences among the R distributions of Y .

The matrix of column scores \mathbf{C}_h has dimension $1 \times C$, and the column scores are determined by the SCORES= option.

The matrix of row scores \mathbf{R}_h has dimension $(R - 1) \times R$ and is created internally by PROC FREQ as

$$\mathbf{R}_h = [\mathbf{I}_{R-1}, -\mathbf{J}_{R-1}]$$

where \mathbf{I}_{R-1} is an identity matrix of rank $R - 1$ and \mathbf{J}_{R-1} is an $(R - 1) \times 1$ vector of ones. This matrix has the effect of forming $R - 1$ independent contrasts of the R mean scores.

When there is only one stratum, this CMH statistic is essentially an analysis of variance (ANOVA) statistic in the sense that it is a function of the variance ratio F statistic that would be obtained from a one-way ANOVA on the dependent variable Y . If nonparametric scores are specified in this case, then the ANOVA statistic is a Kruskal-Wallis test.

If there is more than one stratum, then this CMH statistic corresponds to a stratum-adjusted ANOVA or Kruskal-Wallis test. In the special case where there is one subject per row and one subject per column in the contingency table of each stratum, this CMH statistic is identical to Friedman's chi-square. See [Example 38.9](#) for an illustration.

General Association Statistic

The alternative hypothesis for the general association statistic is that, for at least one stratum, there is some kind of association between X and Y . This statistic is always interpretable because it does not require an ordinal scale for either X or Y .

For the general association statistic, the matrix \mathbf{R}_h is the same as the one used for the ANOVA statistic. The matrix \mathbf{C}_h is defined similarly as

$$\mathbf{C}_h = [\mathbf{I}_{C-1}, -\mathbf{J}_{C-1}]$$

PROC FREQ generates both score matrices internally. When there is only one stratum, then the general association CMH statistic reduces to $Q_P(n-1)/n$, where Q_P is the Pearson chi-square statistic. When there is more than one stratum, then the CMH statistic becomes a stratum-adjusted Pearson chi-square statistic. Note that a similar adjustment can be made by summing the Pearson chi-squares across the strata. However, the latter statistic requires a large sample size in each stratum to support the resulting chi-square distribution with $q(R-1)(C-1)$ degrees of freedom. The CMH statistic requires only a large overall sample size because it has only $(R-1)(C-1)$ degrees of freedom.

See Cochran (1954); Mantel and Haenszel (1959); Mantel (1963); Birch (1965); Landis, Heyman, and Koch (1978).

Mantel-Fleiss Criterion

If you specify the CMH(MANTELFLISS) option in the TABLES statement, PROC FREQ computes the Mantel-Fleiss criterion for stratified 2×2 tables. The Mantel-Fleiss criterion can be used to assess the validity of the chi-square approximation for the distribution of the Mantel-Haenszel statistic for 2×2 tables. For details, see Mantel and Fleiss (1980); Mantel and Haenszel (1959); Stokes, Davis, and Koch (2012); Dmitrienko et al. (2005).

The Mantel-Fleiss criterion is computed as

$$MF = \min \left(\left[\sum_h m_{h11} - \sum_h (n_{h11})_L \right], \left[\sum_h (n_{h11})_U - \sum_h m_{h11} \right] \right)$$

where m_{h11} is the expected value of n_{h11} under the hypothesis of no association between the row and column variables in table h , $(n_{h11})_L$ is the minimum possible value of the table cell frequency, and $(n_{h11})_U$ is the maximum possible value,

$$m_{h11} = n_{h1\cdot} \cdot n_{h\cdot 1} / n_h$$

$$(n_{h11})_L = \max(0, n_{h1\cdot} - n_{h\cdot 2})$$

$$(n_{h11})_U = \min(n_{h\cdot 1}, n_{h1\cdot})$$

The Mantel-Fleiss guideline accepts the validity of the Mantel-Haenszel approximation when the value of the criterion is at least 5. When the criterion is less than 5, PROC FREQ displays a warning.

Adjusted Odds Ratio and Relative Risk Estimates

The CMH option provides adjusted odds ratio and relative risk estimates for stratified 2×2 tables. For each of these measures, PROC FREQ computes a Mantel-Haenszel estimate and a logit estimate. These estimates apply to n -way table requests in the TABLES statement, when the row and column variables both have two levels.

For example, for the table request A*B*C*D, if the row and column variables C and D both have two levels, PROC FREQ provides odds ratio and relative risk estimates, adjusting for the confounding variables A and B.

The choice of an appropriate measure depends on the study design. For case-control (retrospective) studies, the odds ratio is appropriate. For cohort (prospective) or cross-sectional studies, the relative risk is appropriate. See the section “Odds Ratio and Relative Risks for 2×2 Tables” on page 2582 for more information on these measures.

Throughout this section, z denotes the $100(1 - \alpha/2)$ percentile of the standard normal distribution.

Odds Ratio, Case-Control Studies PROC FREQ provides Mantel-Haenszel and logit estimates for the common odds ratio for stratified 2×2 tables.

Mantel-Haenszel Estimator The Mantel-Haenszel estimate of the common odds ratio is computed as

$$OR_{MH} = \left(\sum_h n_{h11} n_{h22} / n_h \right) / \left(\sum_h n_{h12} n_{h21} / n_h \right)$$

It is always computed unless the denominator is zero. See Mantel and Haenszel (1959) and Agresti (2002) for details.

To compute confidence limits for the common odds ratio, PROC FREQ uses the Robins, Breslow, and Greenland (1986) variance estimate for $\ln(OR_{MH})$. The $100(1 - \alpha/2)\%$ confidence limits for the common odds ratio are

$$(OR_{MH} \times \exp(-z\hat{\sigma}), OR_{MH} \times \exp(z\hat{\sigma}))$$

where

$$\begin{aligned} \hat{\sigma}^2 &= \widehat{\text{Var}}(\ln(OR_{MH})) \\ &= \frac{\sum_h (n_{h11} + n_{h22})(n_{h11} n_{h22}) / n_h^2}{2 (\sum_h n_{h11} n_{h22} / n_h)^2} \\ &\quad + \frac{\sum_h [(n_{h11} + n_{h22})(n_{h12} n_{h21}) + (n_{h12} + n_{h21})(n_{h11} n_{h22})] / n_h^2}{2 (\sum_h n_{h11} n_{h22} / n_h) (\sum_h n_{h12} n_{h21} / n_h)} \\ &\quad + \frac{\sum_h (n_{h12} + n_{h21})(n_{h12} n_{h21}) / n_h^2}{2 (\sum_h n_{h12} n_{h21} / n_h)^2} \end{aligned}$$

Note that the Mantel-Haenszel odds ratio estimator is less sensitive to small n_h than the logit estimator.

Logit Estimator The adjusted logit estimate of the common odds ratio (Woolf 1955) is computed as

$$OR_L = \exp \left(\sum_h w_h \ln(OR_h) / \sum_h w_h \right)$$

and the corresponding $100(1 - \alpha)\%$ confidence limits are

$$\left(OR_L \times \exp \left(-z / \sqrt{\sum_h w_h} \right), OR_L \times \exp \left(z / \sqrt{\sum_h w_h} \right) \right)$$

where OR_h is the odds ratio for stratum h , and

$$w_h = 1/\text{Var}(\ln(OR_h))$$

If any table cell frequency in a stratum h is zero, PROC FREQ adds 0.5 to each cell of the stratum before computing OR_h and w_h (Haldane 1955) for the logit estimate. The procedure prints a warning when this occurs.

Relative Risks, Cohort Studies PROC FREQ provides Mantel-Haenszel and logit estimates of the common relative risks for stratified 2×2 tables.

Mantel-Haenszel Estimator The Mantel-Haenszel estimate of the common relative risk for column 1 is computed as

$$RR_{MH} = \left(\sum_h n_{h11} n_{h2\cdot} / n_h \right) / \left(\sum_h n_{h21} n_{h1\cdot} / n_h \right)$$

It is always computed unless the denominator is zero. See Mantel and Haenszel (1959) and Agresti (2002) for more information.

To compute confidence limits for the common relative risk, PROC FREQ uses the Greenland and Robins (1985) variance estimate for $\log(RR_{MH})$. The $100(1 - \alpha/2)\%$ confidence limits for the common relative risk are

$$(RR_{MH} \times \exp(-z\hat{\sigma}), RR_{MH} \times \exp(z\hat{\sigma}))$$

where

$$\hat{\sigma}^2 = \widehat{\text{Var}}(\ln(RR_{MH})) = \frac{\sum_h (n_{h1\cdot} n_{h2\cdot} n_{h\cdot 1} - n_{h11} n_{h21} n_h) / n_h^2}{(\sum_h n_{h11} n_{h2\cdot} / n_h) (\sum_h n_{h21} n_{h1\cdot} / n_h)}$$

Logit Estimator The adjusted logit estimate of the common relative risk for column 1 is computed as

$$RR_L = \exp \left(\sum_h w_h \ln(RR_h) / \sum_h w_h \right)$$

and the corresponding $100(1 - \alpha)\%$ confidence limits are

$$\left(RR_L \times \exp \left(-z / \sqrt{\sum_h w_h} \right), RR_L \times \exp \left(z / \sqrt{\sum_h w_h} \right) \right)$$

where RR_h is the column 1 relative risk estimate for stratum h and

$$w_h = 1 / \text{Var}(\ln(RR_h))$$

If n_{h11} or n_{h21} is zero, then PROC FREQ adds 0.5 to each cell of the stratum before computing RR_h and w_h for the logit estimate. The procedure prints a warning when this occurs. See Kleinbaum, Kupper, and Morgenstern (1982, Sections 17.4 and 17.5) for details.

Breslow-Day Test for Homogeneity of the Odds Ratios

When you specify the CMH option, PROC FREQ computes the Breslow-Day test for stratified 2×2 tables. It tests the null hypothesis that the odds ratios for the q strata are equal. When the null hypothesis is true, the statistic has approximately a chi-square distribution with $q-1$ degrees of freedom. See Breslow and Day (1980) and Agresti (2007) for more information.

The Breslow-Day statistic is computed as

$$Q_{BD} = \sum_h (n_{h11} - E(n_{h11} | OR_{MH}))^2 / \text{Var}(n_{h11} | OR_{MH})$$

where E and Var denote expected value and variance, respectively. The summation does not include any table with a zero row or column. If OR_{MH} equals zero or if it is undefined, then PROC FREQ does not compute the statistic and prints a warning message.

For the Breslow-Day test to be valid, the sample size should be relatively large in each stratum, and at least 80% of the expected cell counts should be greater than 5. Note that this is a stricter sample size requirement than the requirement for the Cochran-Mantel-Haenszel test for $q \times 2 \times 2$ tables, in that each stratum sample size (not just the overall sample size) must be relatively large. Even when the Breslow-Day test is valid, it might not be very powerful against certain alternatives, as discussed in Breslow and Day (1980).

If you specify the BDT option, PROC FREQ computes the Breslow-Day test with Tarone's adjustment, which subtracts an adjustment factor from Q_{BD} to make the resulting statistic asymptotically chi-square. The Breslow-Day-Tarone statistic is computed as

$$Q_{BDT} = Q_{BD} - \left(\sum_h (n_{h11} - E(n_{h11} | OR_{MH})) \right)^2 / \sum_h \text{Var}(n_{h11} | OR_{MH})$$

See Tarone (1985); Jones et al. (1989); Breslow (1996) for more information.

Zelen's Exact Test for Equal Odds Ratios

If you specify the EQOR option in the EXACT statement, PROC FREQ computes Zelen's exact test for equal odds ratios for stratified 2×2 tables. Zelen's test is an exact counterpart to the Breslow-Day asymptotic test for equal odds ratios. The reference set for Zelen's test includes all possible $q \times 2 \times 2$ tables with the same row, column, and stratum totals as the observed multiway table and with the same sum of cell (1,1) frequencies as the observed table. The test statistic is the probability of the observed $q \times 2 \times 2$ table conditional on the fixed margins, which is a product of hypergeometric probabilities.

The p -value for Zelen's test is the sum of all table probabilities that are less than or equal to the observed table probability, where the sum is computed over all tables in the reference set determined by the fixed margins and the observed sum of cell (1,1) frequencies. This test is similar to Fisher's exact test for two-way tables. For more information, see Zelen (1971); Hirji (2006); Agresti (1992). PROC FREQ computes Zelen's exact test by using the polynomial multiplication algorithm of Hirji et al. (1996).

Exact Confidence Limits for the Common Odds Ratio

If you specify the COMOR option in the EXACT statement, PROC FREQ computes exact confidence limits for the common odds ratio for stratified 2×2 tables. This computation assumes that the odds ratio is constant over all the 2×2 tables. Exact confidence limits are constructed from the distribution of $S = \sum_h n_{h11}$, conditional on the marginal totals of the 2×2 tables.

Because this is a discrete problem, the confidence coefficient for these exact confidence limits is not exactly $(1 - \alpha)$ but is at least $(1 - \alpha)$. Thus, these confidence limits are conservative. See Agresti (1992) for more information.

PROC FREQ computes exact confidence limits for the common odds ratio by using an algorithm based on Vollset, Hirji, and Elashoff (1991). See also Mehta, Patel, and Gray (1985).

Conditional on the marginal totals of 2×2 table h , let the random variable S_h denote the frequency of table cell (1,1). Given the row totals $n_{h1\cdot}$ and $n_{h2\cdot}$ and column totals $n_{h\cdot 1}$ and $n_{h\cdot 2}$, the lower and upper bounds for S_h are l_h and u_h ,

$$\begin{aligned} l_h &= \max(0, n_{h1\cdot} - n_{h\cdot 2}) \\ u_h &= \min(n_{h1\cdot}, n_{h\cdot 1}) \end{aligned}$$

Let C_{s_h} denote the hypergeometric coefficient,

$$C_{s_h} = \binom{n_{h\cdot 1}}{s_h} \binom{n_{h\cdot 2}}{n_{h1\cdot} - s_h}$$

and let ϕ denote the common odds ratio. Then the conditional distribution of S_h is

$$P(S_h = s_h | n_{1\cdot}, n_{\cdot 1}, n_{\cdot 2}) = C_{s_h} \phi^{s_h} / \sum_{x=l_h}^{x=u_h} C_x \phi^x$$

Summing over all the 2×2 tables, $S = \sum_h S_h$, and the lower and upper bounds of S are l and u ,

$$l = \sum_h l_h \quad \text{and} \quad u = \sum_h u_h$$

The conditional distribution of the sum S is

$$P(S = s | n_{h1\cdot}, n_{h\cdot 1}, n_{h\cdot 2}; h = 1, \dots, q) = C_s \phi^s / \sum_{x=l}^{x=u} C_x \phi^x$$

where

$$C_s = \sum_{s_1 + \dots + s_q = s} \left(\prod_h C_{s_h} \right)$$

Let s_0 denote the observed sum of cell (1,1) frequencies over the q tables. The following two equations are solved iteratively for lower and upper confidence limits for the common odds ratio, ϕ_1 and ϕ_2 :

$$\begin{aligned} \sum_{x=s_0}^{x=u} C_x \phi_1^x / \sum_{x=l}^{x=u} C_x \phi_1^x &= \alpha/2 \\ \sum_{x=l}^{x=s_0} C_x \phi_2^x / \sum_{x=l}^{x=u} C_x \phi_2^x &= \alpha/2 \end{aligned}$$

When the observed sum s_0 equals the lower bound l , PROC FREQ sets the lower confidence limit to zero and determines the upper limit with level α . Similarly, when the observed sum s_0 equals the upper bound u , PROC FREQ sets the upper confidence limit to infinity and determines the lower limit with level α .

When you specify the COMOR option in the EXACT statement, PROC FREQ also computes the exact test that the common odds ratio equals one. Setting $\phi = 1$, the conditional distribution of the sum S under the null hypothesis becomes

$$P_0(S = s \mid n_{h1\cdot}, n_{h\cdot 1}, n_{h\cdot 2}; h = 1, \dots, q) = C_s / \sum_{x=l}^{x=u} C_x$$

The point probability for this exact test is the probability of the observed sum s_0 under the null hypothesis, conditional on the marginals of the stratified 2×2 tables, and is denoted by $P_0(s_0)$. The expected value of S under the null hypothesis is

$$E_0(S) = \sum_{x=l}^{x=u} x C_x / \sum_{x=l}^{x=u} C_x$$

The one-sided exact p -value is computed from the conditional distribution as $P_0(S \geq s_0)$ or $P_0(S \leq s_0)$, depending on whether the observed sum s_0 is greater or less than $E_0(S)$,

$$P_1 = P_0(S \geq s_0) = \sum_{x=s_0}^{x=u} C_x / \sum_{x=l}^{x=u} C_x \quad \text{if } s_0 > E_0(S)$$

$$P_1 = P_0(S \leq s_0) = \sum_{x=l}^{x=s_0} C_x / \sum_{x=l}^{x=u} C_x \quad \text{if } s_0 \leq E_0(S)$$

PROC FREQ computes two-sided p -values for this test according to three different definitions. A two-sided p -value is computed as twice the one-sided p -value, setting the result equal to one if it exceeds one,

$$P_2^a = 2 \times P_1$$

Additionally, a two-sided p -value is computed as the sum of all probabilities less than or equal to the point probability of the observed sum s_0 , summing over all possible values of s , $l \leq s \leq u$,

$$P_2^b = \sum_{l \leq s \leq u: P_0(s) \leq P_0(s_0)} P_0(s)$$

Also, a two-sided p -value is computed as the sum of the one-sided p -value and the corresponding area in the opposite tail of the distribution, equidistant from the expected value,

$$P_2^c = P_0(|S - E_0(S)| \geq |s_0 - E_0(S)|)$$

Gail-Simon Test for Qualitative Interactions

The GAILSIMON option in the TABLES statement provides the Gail-Simon test for qualitative interaction for stratified 2×2 tables. For details, see Gail and Simon (1985); Silvapulle (2001); Dmitrienko et al. (2005).

The Gail-Simon test is based on the risk differences in stratified 2×2 tables, where the risk difference is defined as the row 1 risk (proportion in column 1) minus the row 2 risk. See the section “[Risks and Risk Differences](#)” on page 2572 for details. By default, the procedure uses column 1 risks to compute the Gail-Simon test. If you specify the GAILSIMON(COLUMN=2) option, the procedure uses column 2 risks.

PROC FREQ computes the Gail-Simon test statistics as described in Gail and Simon (1985),

$$Q- = \sum_h (d_h/s_h)^2 I(d_h > 0)$$

$$Q+ = \sum_h (d_h/s_h)^2 I(d_h < 0)$$

$$Q = \min(Q-, Q+)$$

where d_h is the risk difference in table h , s_h is the standard error of the risk difference, and $I(d_h > 0)$ equals 1 if $d_h > 0$ and 0 otherwise. Similarly, $I(d_h < 0)$ equals 1 if $d_h < 0$ and 0 otherwise. The q 2×2 tables (strata) are indexed by $h = 1, 2, \dots, q$.

The p -values for the Gail-Simon statistics are computed as

$$p(Q-) = \sum_h (1 - F_h(Q-)) B(h; n = q, p = 0.5)$$

$$p(Q+) = \sum_h (1 - F_h(Q+)) B(h; n = q, p = 0.5)$$

$$p(Q) = \sum_{h=1}^{q-1} (1 - F_h(Q)) B(h; n = (q - 1), p = 0.5)$$

where $F_h(\cdot)$ is the cumulative chi-square distribution function with h degrees of freedom and $B(h; n, p)$ is the binomial probability function with parameters n and p . The statistic Q tests the null hypothesis of no qualitative interaction. The statistic $Q-$ tests the null hypothesis of positive risk differences. A small p -value for $Q-$ indicates negative differences; similarly, a small p -value for $Q+$ indicates positive risk differences.

Exact Statistics

Exact statistics can be useful in situations where the asymptotic assumptions are not met, and so the asymptotic p -values are not close approximations for the true p -values. Standard asymptotic methods involve the assumption that the test statistic follows a particular distribution when the sample size is sufficiently large. When the sample size is not large, asymptotic results might not be valid, with the asymptotic p -values

differing perhaps substantially from the exact p -values. Asymptotic results might also be unreliable when the distribution of the data is sparse, skewed, or heavily tied. See Agresti (2007) and Bishop, Fienberg, and Holland (1975) for more information. Exact computations are based on the statistical theory of exact conditional inference for contingency tables, reviewed by Agresti (1992).

In addition to computation of exact p -values, PROC FREQ provides the option of estimating exact p -values by Monte Carlo simulation. This can be useful for problems that are so large that exact computations require a great amount of time and memory, but for which asymptotic approximations might not be sufficient.

Exact statistics are available for many PROC FREQ tests. For one-way tables, PROC FREQ provides exact p -values for the binomial proportion tests and the chi-square goodness-of-fit test. Exact (Clopper-Pearson) confidence limits are available for the binomial proportion. For two-way tables, PROC FREQ provides exact p -values for the following tests: Pearson chi-square test, likelihood ratio chi-square test, Mantel-Haenszel chi-square test, Fisher's exact test, Jonckheere-Terpstra test, and Cochran-Armitage test for trend. PROC FREQ also computes exact p -values for tests of the following statistics: Kendall's tau- b , Stuart's tau- c , Somers' $D(C|R)$, Somers' $D(R|C)$, Pearson correlation coefficient, Spearman correlation coefficient, simple kappa coefficient, and weighted kappa coefficient. For 2×2 tables, PROC FREQ provides McNemar's exact test and exact confidence limits for the odds ratio. PROC FREQ also provides exact unconditional confidence limits for the proportion (risk) difference and for the relative risk. For stratified 2×2 tables, PROC FREQ provides Zelen's exact test for equal odds ratios, exact confidence limits for the common odds ratio, and an exact test for the common odds ratio.

The following sections summarize the exact computational algorithms, define the exact p -values that PROC FREQ computes, discuss the computational resource requirements, and describe the Monte Carlo estimation option.

Computational Algorithms

PROC FREQ computes exact p -values for general $R \times C$ tables by using the network algorithm developed by Mehta and Patel (1983). This algorithm provides a substantial advantage over direct enumeration, which can be very time-consuming and feasible only for small problems. See Agresti (1992) for a review of algorithms for computation of exact p -values, and see Mehta, Patel, and Tsiatis (1984) and Mehta, Patel, and Senchaudhuri (1991) for information about the performance of the network algorithm.

The reference set for a given contingency table is the set of all contingency tables with the observed marginal row and column sums. Corresponding to this reference set, the network algorithm forms a directed acyclic network consisting of nodes in a number of stages. A path through the network corresponds to a distinct table in the reference set. The distances between nodes are defined so that the total distance of a path through the network is the corresponding value of the test statistic. At each node, the algorithm computes the shortest and longest path distances for all the paths that pass through that node. For statistics that can be expressed as a linear combination of cell frequencies multiplied by increasing row and column scores, PROC FREQ computes shortest and longest path distances by using the algorithm of Agresti, Mehta, and Patel (1990). For statistics of other forms, PROC FREQ computes an upper bound for the longest path and a lower bound for the shortest path by following the approach of Valz and Thompson (1994).

The longest and shortest path distances or bounds for a node are compared to the value of the test statistic to determine whether all paths through the node contribute to the p -value, none of the paths through the node contribute to the p -value, or neither of these situations occurs. If all paths through the node contribute, the p -value is incremented accordingly, and these paths are eliminated from further analysis. If no paths contribute, these paths are eliminated from the analysis. Otherwise, the algorithm continues, still processing this node and the associated paths. The algorithm finishes when all nodes have been accounted for.

In applying the network algorithm, PROC FREQ uses full numerical precision to represent all statistics, row and column scores, and other quantities involved in the computations. Although it is possible to use rounding to improve the speed and memory requirements of the algorithm, PROC FREQ does not do this because it can result in reduced accuracy of the p -values.

For one-way tables, PROC FREQ computes the exact chi-square goodness-of-fit test by the method of Radlow and Alf (1975). PROC FREQ generates all possible one-way tables with the observed total sample size and number of categories. For each possible table, PROC FREQ compares its chi-square value with the value for the observed table. If the table's chi-square value is greater than or equal to the observed chi-square, PROC FREQ increments the exact p -value by the probability of that table, which is calculated under the null hypothesis by using the multinomial frequency distribution. By default, the null hypothesis states that all categories have equal proportions. If you specify null hypothesis proportions or frequencies by using the TESTP= or TESTF= option in the TABLES statement, then PROC FREQ calculates the exact chi-square test based on that null hypothesis.

Other exact computations are described in sections about the individual statistics. See the section “[Binomial Proportion](#)” on page 2565 for details about how PROC FREQ computes exact confidence limits and tests for the binomial proportion. See the section “[Odds Ratio and Relative Risks for 2 x 2 Tables](#)” on page 2582 for information about computation of exact confidence limits for the odds ratio for 2×2 tables. Also, see the sections “[Exact Unconditional Confidence Limits for the Risk Difference](#)” on page 2580, “[Exact Confidence Limits for the Common Odds Ratio](#)” on page 2599, and “[Zelen's Exact Test for Equal Odds Ratios](#)” on page 2598.

Definition of p -Values

For several tests in PROC FREQ, the test statistic is nonnegative, and large values of the test statistic indicate a departure from the null hypothesis. Such nondirectional tests include the Pearson chi-square, the likelihood ratio chi-square, the Mantel-Haenszel chi-square, Fisher's exact test for tables larger than 2×2 , McNemar's test, and the one-way chi-square goodness-of-fit test. The exact p -value for a nondirectional test is the sum of probabilities for those tables having a test statistic greater than or equal to the value of the observed test statistic.

There are other tests where it might be appropriate to test against either a one-sided or a two-sided alternative hypothesis. For example, when you test the null hypothesis that the true parameter value equals 0 ($T = 0$), the alternative of interest might be one-sided ($T \leq 0$, or $T \geq 0$) or two-sided ($T \neq 0$). Such tests include the Pearson correlation coefficient, Spearman correlation coefficient, Jonckheere-Terpstra test, Cochran-Armitage test for trend, simple kappa coefficient, and weighted kappa coefficient. For these tests, PROC FREQ displays the right-sided p -value when the observed value of the test statistic is greater than its expected value. The right-sided p -value is the sum of probabilities for those tables for which the test statistic is greater than or equal to the observed test statistic. Otherwise, when the observed test statistic is less than or equal to the expected value, PROC FREQ displays the left-sided p -value. The left-sided p -value is the sum of probabilities for those tables for which the test statistic is less than or equal to the one observed. The one-sided p -value P_1 can be expressed as

$$P_1 = \begin{cases} \text{Prob}(\text{Test Statistic} \geq t) & \text{if } t > E_0(T) \\ \text{Prob}(\text{Test Statistic} \leq t) & \text{if } t \leq E_0(T) \end{cases}$$

where t is the observed value of the test statistic and $E_0(T)$ is the expected value of the test statistic under the null hypothesis. PROC FREQ computes the two-sided p -value as the sum of the one-sided p -value and the corresponding area in the opposite tail of the distribution of the statistic, equidistant from the expected

value. The two-sided p -value P_2 can be expressed as

$$P_2 = \text{Prob} (|\text{Test Statistic} - E_0(T)| \geq |t - E_0(T)|)$$

If you specify the POINT option in the EXACT statement, PROC FREQ also displays exact point probabilities for the test statistics. The exact point probability is the exact probability that the test statistic equals the observed value.

Computational Resources

PROC FREQ uses relatively fast and efficient algorithms for exact computations. These recently developed algorithms, together with improvements in computer power, now make it feasible to perform exact computations for data sets where previously only asymptotic methods could be applied. Nevertheless, there are still large problems that might require a prohibitive amount of time and memory for exact computations, depending on the speed and memory available on your computer. For large problems, consider whether exact methods are really needed or whether asymptotic methods might give results quite close to the exact results, while requiring much less computer time and memory. When asymptotic methods might not be sufficient for such large problems, consider using Monte Carlo estimation of exact p -values, as described in the section “[Monte Carlo Estimation](#)” on page 2604.

A formula does not exist that can predict in advance how much time and memory are needed to compute an exact p -value for a certain problem. The time and memory required depend on several factors, including which test is being performed, the total sample size, the number of rows and columns, and the specific arrangement of the observations into table cells. Generally, larger problems (in terms of total sample size, number of rows, and number of columns) tend to require more time and memory. Additionally, for a fixed total sample size, time and memory requirements tend to increase as the number of rows and columns increases, because this corresponds to an increase in the number of tables in the reference set. Also for a fixed sample size, time and memory requirements increase as the marginal row and column totals become more homogeneous. See Agresti, Mehta, and Patel (1990) and Gail and Mantel (1977) for more information.

At any time while PROC FREQ is computing exact p -values, you can terminate the computations by pressing the system interrupt key sequence (see the *SAS Companion* for your system) and choosing to stop computations. After you terminate exact computations, PROC FREQ completes all other remaining tasks. The procedure produces the requested output and reports missing values for any exact p -values that were not computed by the time of termination.

You can also use the MAXTIME= option in the EXACT statement to limit the amount of time PROC FREQ uses for exact computations. You specify a MAXTIME= value that is the maximum amount of clock time (in seconds) that PROC FREQ can use to compute an exact p -value. If PROC FREQ does not finish computing an exact p -value within that time, it terminates the computation and completes all other remaining tasks.

Monte Carlo Estimation

If you specify the option MC in the EXACT statement, PROC FREQ computes Monte Carlo estimates of the exact p -values instead of directly computing the exact p -values. Monte Carlo estimation can be useful for large problems that require a great amount of time and memory for exact computations but for which asymptotic approximations might not be sufficient. To describe the precision of each Monte Carlo estimate, PROC FREQ provides the asymptotic standard error and $100(1 - \alpha)\%$ confidence limits. The confidence level α is determined by the ALPHA= option in the EXACT statement, which, by default, equals 0.01 and produces 99% confidence limits. The N= n option in the EXACT statement specifies the number of samples that PROC FREQ uses for Monte Carlo estimation; the default is 10000 samples. You can specify a larger value for n to improve the precision of the Monte Carlo estimates. Because larger values of n generate more

samples, the computation time increases. Alternatively, you can specify a smaller value of n to reduce the computation time.

To compute a Monte Carlo estimate of an exact p -value, PROC FREQ generates a random sample of tables with the same total sample size, row totals, and column totals as the observed table. PROC FREQ uses the algorithm of Agresti, Wackerly, and Boyett (1979), which generates tables in proportion to their hypergeometric probabilities conditional on the marginal frequencies. For each sample table, PROC FREQ computes the value of the test statistic and compares it to the value for the observed table. When estimating a right-sided p -value, PROC FREQ counts all sample tables for which the test statistic is greater than or equal to the observed test statistic. Then the p -value estimate equals the number of these tables divided by the total number of tables sampled.

$$\begin{aligned}\hat{P}_{MC} &= M / N \\ M &= \text{number of samples with (Test Statistic} \geq t) \\ N &= \text{total number of samples} \\ t &= \text{observed Test Statistic}\end{aligned}$$

PROC FREQ computes left-sided and two-sided p -value estimates in a similar manner. For left-sided p -values, PROC FREQ evaluates whether the test statistic for each sampled table is less than or equal to the observed test statistic. For two-sided p -values, PROC FREQ examines the sample test statistics according to the expression for P_2 given in the section “[Definition of \$p\$ -Values](#)” on page 2603.

The variable M is a binomially distributed variable with N trials and success probability p . It follows that the asymptotic standard error of the Monte Carlo estimate is

$$se(\hat{P}_{MC}) = \sqrt{\hat{P}_{MC} (1 - \hat{P}_{MC}) / (N - 1)}$$

PROC FREQ constructs asymptotic confidence limits for the p -values according to

$$\hat{P}_{MC} \pm (z_{\alpha/2} \times se(\hat{P}_{MC}))$$

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the standard normal distribution and the confidence level α is determined by the ALPHA= option in the EXACT statement.

When the Monte Carlo estimate \hat{P}_{MC} equals 0, PROC FREQ computes the confidence limits for the p -value as

$$(0, 1 - \alpha^{(1/N)})$$

When the Monte Carlo estimate \hat{P}_{MC} equals 1, PROC FREQ computes the confidence limits as

$$(\alpha^{(1/N)}, 1)$$

Computational Resources

For each variable in a table request, PROC FREQ stores all of the levels in memory. If all variables are numeric and not formatted, this requires about 84 bytes for each variable level. When there are character variables or formatted numeric variables, the memory that is required depends on the formatted variable lengths, with longer formatted lengths requiring more memory. The number of levels for each variable is limited only by the largest integer that your operating environment can store.

For any single crosstabulation table requested, PROC FREQ builds the entire table in memory, regardless of whether the table has zero cell counts. Thus, if the numeric variables A, B, and C each have 10 levels, PROC FREQ requires 2520 bytes to store the variable levels for the table request A*B*C, as follows:

3 variables * 10 levels/variable * 84 bytes/level

In addition, PROC FREQ requires 8000 bytes to store the table cell frequencies

1000 cells * 8 bytes/cell

even though there might be only 10 observations.

When the variables have many levels or when there are many multiway tables, your computer might not have enough memory to construct the tables. If PROC FREQ runs out of memory while constructing tables, it stops collecting levels for the variable with the most levels and returns the memory that is used by that variable. The procedure then builds the tables that do not contain the disabled variables.

If there is not enough memory for your table request and if increasing the available memory is impractical, you can reduce the number of multiway tables or variable levels. If you are not using the CMH or AGREE option in the TABLES statement to compute statistics across strata, reduce the number of multiway tables by using PROC SORT to sort the data set by one or more of the variables or by using the DATA step to create an index for the variables. Then remove the sorted or indexed variables from the TABLES statement and include a BY statement that uses these variables. You can also reduce memory requirements by using a FORMAT statement in the PROC FREQ step to reduce the number of levels. Additionally, reducing the formatted variable lengths reduces the amount of memory that is needed to store the variable levels. For more information about using formats, see the section “[Grouping with Formats](#)” on page 2544.

Output Data Sets

PROC FREQ produces two types of output data sets that you can use with other statistical and reporting procedures. You can request these data sets as follows:

- Specify the OUT= option in a TABLES statement. This creates an output data set that contains frequency or crosstabulation table counts and percentages
- Specify an OUTPUT statement. This creates an output data set that contains statistics.

PROC FREQ does not display the output data sets. Use PROC PRINT, PROC REPORT, or any other SAS reporting tool to display an output data set.

In addition to these two output data sets, you can create a SAS data set from any piece of PROC FREQ output by using the Output Delivery System. See the section “[ODS Table Names](#)” on page 2617 for more information.

Contents of the TABLES Statement Output Data Set

The OUT= option in the TABLES statement creates an output data set that contains one observation for each combination of variable values (or table cell) in the last table request. By default, each observation contains the frequency and percentage for the table cell. When the input data set contains missing values, the output data set also contains an observation with the frequency of missing values. The output data set includes the following variables:

- BY variables
- table request variables, such as A, B, C, and D in the table request A*B*C*D
- COUNT, which contains the table cell frequency
- PERCENT, which contains the table cell percentage

If you specify the OUTEXPECT option in the TABLES statement for a two-way or multiway table, the output data set also includes expected frequencies. If you specify the OUTPCT option for a two-way or multiway table, the output data set also includes row, column, and table percentages. The additional variables are as follows:

- EXPECTED, which contains the expected frequency
- PCT_TABL, which contains the percentage of two-way table frequency, for n -way tables where $n > 2$
- PCT_ROW, which contains the percentage of row frequency
- PCT_COL, which contains the percentage of column frequency

If you specify the OUTCUM option in the TABLES statement for a one-way table, the output data set also includes cumulative frequencies and cumulative percentages. The additional variables are as follows:

- CUM_FREQ, which contains the cumulative frequency
- CUM_PCT, which contains the cumulative percentage

The OUTCUM option has no effect for two-way or multiway tables.

The following PROC FREQ statements create an output data set of frequencies and percentages:

```
proc freq;
  tables A A*B / out=D;
run;
```

The output data set D contains frequencies and percentages for the table of A by B, which is the last table request listed in the TABLES statement. If A has two levels (1 and 2), B has three levels (1,2, and 3), and no table cell count is zero or missing, then the output data set D includes six observations, one for each combination of A and B levels. The first observation corresponds to A=1 and B=1; the second observation corresponds to A=1 and B=2; and so on. The data set includes the variables COUNT and PERCENT. The value of COUNT is the number of observations with the given combination of A and B levels. The value of PERCENT is the percentage of the total number of observations with that A and B combination.

When PROC FREQ combines different variable values into the same formatted level, the output data set contains the smallest internal value for the formatted level. For example, suppose a variable X has the values 1.1, 1.4, 1.7, 2.1, and 2.3. When you submit the statement

```
format X 1.;
```

in a PROC FREQ step, the formatted levels listed in the frequency table for X are 1 and 2. If you create an output data set with the frequency counts, the internal values of the levels of X are 1.1 and 1.7. To report the internal values of X when you display the output data set, use a format of 3.1 for X.

Contents of the OUTPUT Statement Output Data Set

The **OUTPUT** statement creates a SAS data set that contains statistics computed by PROC FREQ. [Table 38.7](#) lists the statistics that can be stored in the output data set. You identify which statistics to include by specifying *output-options*. See the description of the OUTPUT statement for details.

If you specify multiple **TABLES** statements or multiple table requests in a single TABLES statement, the contents of the output data set correspond to the last table request.

For a one-way table or a two-way table, the output data set contains one observation that stores the requested statistics for the table. For a multiway table, the output data set contains an observation for each two-way table (stratum) of the multiway crosstabulation. If you request summary statistics for the multiway table, the output data set also contains an observation that stores the across-strata summary statistics. If you use a BY statement, the output data set contains an observation (for one-way or two-way tables) or set of observations (for multiway tables) for each BY group.

The OUTPUT data set can include the following variables:

- BY variables
- Variables that identify the stratum for multiway tables, such as A and B in the table request A*B*C*D
- Variables that contain the specified statistics

In addition to the specified estimate or test statistic, the output data set includes associated values such as standard errors, confidence limits, *p*-values, and degrees of freedom.

PROC FREQ constructs variable names for the statistics in the output data set by enclosing the *output-option* names in underscores. Variable names for the corresponding standard errors, confidence limits, *p*-values, and degrees of freedom are formed by combining the *output-option* names with prefixes that identify the associated values. [Table 38.20](#) lists the prefixes and their descriptions.

Table 38.20 Output Data Set Variable Name Prefixes

Prefix	Description
E_	Asymptotic standard error (ASE)
L_	Lower confidence limit
U_	Upper confidence limit
E0_	Null hypothesis ASE
Z_	Standardized value
DF_	Degrees of freedom
P_	<i>p</i> -value
P2_	Two-sided <i>p</i> -value
PL_	Left-sided <i>p</i> -value
PR_	Right-sided <i>p</i> -value
XP_	Exact <i>p</i> -value
XP2_	Exact two-sided <i>p</i> -value
XPL_	Exact left-sided <i>p</i> -value
XPR_	Exact right-sided <i>p</i> -value
XPT_	Exact point probability
XL_	Exact lower confidence limit
XU_	Exact upper confidence limit

For example, the **PCHI** *output-option* in the **OUTPUT** statement includes the Pearson chi-square test in the output data set. The variable names for the Pearson chi-square statistic, its degrees of freedom, and the corresponding *p*-value are **_PCHI_**, **DF_PCHI**, and **P_PCHI**, respectively. If the length of the prefix plus the *output-option* name exceeds eight characters, PROC FREQ truncates the variable name to eight characters.

Displayed Output

Number of Variable Levels Table

If you specify the **NLEVELS** option in the PROC FREQ statement, PROC FREQ displays the “Number of Variable Levels” table. This table provides the number of levels for all variables named in the TABLES statements. PROC FREQ determines the variable levels from the formatted variable values. See “[Grouping with Formats](#)” on page 2544 for details. The “Number of Variable Levels” table contains the following information:

- Variable name
- Levels, which is the total number of levels of the variable
- Number of Nonmissing Levels, if there are missing levels for any of the variables
- Number of Missing Levels, if there are missing levels for any of the variables

One-Way Frequency Tables

PROC FREQ displays one-way frequency tables for all one-way table requests in the **TABLES** statements, unless you specify the **NOPRINT** option in the PROC FREQ statement or the **NOPRINT** option in the TABLES statement. For a one-way table showing the frequency distribution of a single variable, PROC FREQ displays the name of the variable and its values. For each variable value or level, PROC FREQ displays the following information:

- Frequency count, which is the number of observations in the level
- Test Frequency count, if you specify the **CHISQ** and **TESTF=** options to request a chi-square goodness-of-fit test for specified frequencies
- Percent, which is the percentage of the total number of observations. (The **NOPERCENT** option suppresses this information.)
- Test Percent, if you specify the **CHISQ** and **TESTP=** options to request a chi-square goodness-of-fit test for specified percents. (The **NOPERCENT** option suppresses this information.)
- Cumulative Frequency count, which is the sum of the frequency counts for that level and all other levels listed above it in the table. The last cumulative frequency is the total number of nonmissing observations. (The **NOCUM** option suppresses this information.)
- Cumulative Percent, which is the percentage of the total number of observations in that level and in all other levels listed above it in the table. (The **NOCUM** or the **NOPERCENT** option suppresses this information.)

The one-way table also displays the Frequency Missing, which is the number of observations with missing values.

Statistics for One-Way Frequency Tables

For one-way tables, two statistical options are available in the **TABLES** statement. The **CHISQ** option provides a chi-square goodness-of-fit test, and the **BINOMIAL** option provides binomial proportion statistics and tests. PROC FREQ displays the following information, unless you specify the **NOPRINT** option in the PROC FREQ statement:

- If you specify the **CHISQ** option for a one-way table, PROC FREQ provides a chi-square goodness-of-fit test, displaying the Chi-Square statistic, the degrees of freedom (DF), and the probability value ($Pr > ChiSq$). If you specify the **CHISQ** option in the **EXACT** statement, PROC FREQ also displays the exact probability value for this test. If you specify the **POINT** option with the **CHISQ** option in the **EXACT** statement, PROC FREQ displays the exact point probability for the test statistic.
- If you specify the **BINOMIAL** option for a one-way table, PROC FREQ displays the estimate of the binomial Proportion, which is the proportion of observations in the first class listed in the one-way table. PROC FREQ also displays the asymptotic standard error (ASE) and the asymptotic (Wald) and exact (Clopper-Pearson) confidence limits by default. For the binomial proportion test, PROC FREQ displays the asymptotic standard error under the null hypothesis (ASE Under H0), the standardized test statistic (Z), and the one-sided and two-sided probability values.

If you specify the BINOMIAL option in the EXACT statement, PROC FREQ also displays the exact one-sided and two-sided probability values for this test. If you specify the POINT option with the BINOMIAL option in the EXACT statement, PROC FREQ displays the exact point probability for the test.

- If you request additional binomial confidence limits by specifying *binomial-options*, PROC FREQ provides a table that displays the lower and upper confidence limits for each type that you request. In addition to the Wald and exact (Clopper-Pearson) confidence limits, you can request Agresti-Coull, Jeffreys, and Wilson (score) confidence limits for the binomial proportion.
- If you request a binomial noninferiority or superiority test by specifying the NONINF or SUP *binomial-option*, PROC FREQ displays the following information: the binomial Proportion, the test ASE (under H0 or Sample), the test statistic Z, the probability value, the noninferiority or superiority limit, and the test confidence limits. If you specify the BINOMIAL option in the EXACT statement, PROC FREQ also provides the exact probability value for the test, and exact test confidence limits.
- If you request a binomial equivalence test by specifying the EQUIV *binomial-option*, PROC FREQ displays the binomial Proportion and the test ASE (under H0 or Sample). PROC FREQ displays two one-sided tests (TOST) for equivalence, which include test statistics (Z) and probability values for the Lower and Upper tests, together with the Overall probability value. PROC FREQ also displays the equivalence limits and the test-based confidence limits. If you specify the BINOMIAL option in the EXACT statement, PROC FREQ provides exact probability values for the TOST and exact test-based confidence limits.

Multiway Tables

PROC FREQ displays all multiway table requests in the TABLES statements, unless you specify the NO-PRINT option in the PROC FREQ statement or the NOPRINT option in the TABLES statement.

For two-way to multiway crosstabulation tables, the values of the last variable in the table request form the table columns. The values of the next-to-last variable form the rows. Each level (or combination of levels) of the other variables forms one stratum.

There are three ways to display multiway tables in PROC FREQ. By default, PROC FREQ displays multiway tables as separate two-way crosstabulation tables for each stratum of the multiway table. Also by default, PROC FREQ displays these two-way crosstabulation tables in table cell format. Alternatively, if you specify the CROSSLIST option, PROC FREQ displays the two-way crosstabulation tables in ODS column format. If you specify the LIST option, PROC FREQ displays multiway tables in list format, which presents the entire multiway crosstabulation in a single table.

Crosstabulation Tables

By default, PROC FREQ displays two-way crosstabulation tables in table cell format. The row variable values are listed down the side of the table, the column variable values are listed across the top of the table, and each row and column variable level combination forms a table cell.

Each cell of a crosstabulation table can contain the following information:

- Frequency, which is the number of observations in the table cell. (The NOFREQ option suppresses this information.)

- Expected frequency under the hypothesis of independence, if you specify the **EXPECTED** option
- Deviation of the cell frequency from the expected value, if you specify the **DEVIATION** option
- Cell Chi-Square, which is the cell's contribution to the total chi-square statistic, if you specify the **CELLCHI2** option
- Tot Pct, which is the cell's percentage of the total multiway table frequency, for n -way tables when $n > 2$, if you specify the **TOTPCT** option
- Percent, which is the cell's percentage of the total (two-way table) frequency. (The **NOPERCENT** option suppresses this information.)
- Row Pct, or the row percentage, which is the cell's percentage of the total frequency for its row. (The **NOROW** option suppresses this information.)
- Col Pct, or column percentage, which is the cell's percentage of the total frequency for its column. (The **NOCOL** option suppresses this information.)
- Cumulative Col%, or cumulative column percentage, if you specify the **CUMCOL** option

The table also displays the Frequency Missing, which is the number of observations with missing values.

CROSSLIST Tables

If you specify the **CROSSLIST** option, PROC FREQ displays two-way crosstabulation tables in ODS column format. The **CROSSLIST** column format is different from the default crosstabulation table cell format, but the **CROSSLIST** table provides the same information (frequencies, percentages, and other statistics) as the default crosstabulation table.

In the **CROSSLIST** table format, the rows of the display correspond to the crosstabulation table cells, and the columns of the display correspond to descriptive statistics such as frequencies and percentages. Each table cell is identified by the values of its **TABLES** row and column variable levels, with all column variable levels listed within each row variable level. The **CROSSLIST** table also provides row totals, column totals, and overall table totals.

For a crosstabulation table in **CROSSLIST** format, PROC FREQ displays the following information:

- the row variable name and values
- the column variable name and values
- Frequency, which is the number of observations in the table cell. (The **NOFREQ** option suppresses this information.)
- Expected cell frequency under the hypothesis of independence, if you specify the **EXPECTED** option
- Deviation of the cell frequency from the expected value, if you specify the **DEVIATION** option
- Cell Chi-Square, which is the cell's contribution to the total chi-square statistic, if you specify the **CELLCHI2** option
- Total Percent, which is the cell's percentage of the total multiway table frequency, for n -way tables when $n > 2$, if you specify the **TOTPCT** option

- Percent, which is the cell's percentage of the total (two-way table) frequency. (The **NOPERCENT** option suppresses this information.)
- Row Percent, which is the cell's percentage of the total frequency for its row. (The **NOROW** option suppresses this information.)
- Column Percent, the cell's percentage of the total frequency for its column. (The **NOCOL** option suppresses this information.)

The table also displays the Frequency Missing, which is the number of observations with missing values.

LIST Tables

If you specify the **LIST** option in the **TABLES** statement, **PROC FREQ** displays multiway tables in a list format rather than as crosstabulation tables. The **LIST** option displays the entire multiway table in one table, instead of displaying a separate two-way table for each stratum. The **LIST** option is not available when you also request statistical options. Unlike the default crosstabulation output, the **LIST** output does not display row percentages, column percentages, and optional information such as expected frequencies and cell chi-squares.

For a multiway table in list format, **PROC FREQ** displays the following information:

- the variable names and values
- Frequency, which is the number of observations in the level (with the indicated variable values)
- Percent, which is the level's percentage of the total number of observations. (The **NOPERCENT** option suppresses this information.)
- Cumulative Frequency, which is the accumulated frequency of the level and all other levels listed above it in the table. The last cumulative frequency in the table is the total number of nonmissing observations. (The **NOCUM** option suppresses this information.)
- Cumulative Percent, which is the accumulated percentage of the level and all other levels listed above it in the table. (The **NOCUM** or the **NOPERCENT** option suppresses this information.)

The table also displays the Frequency Missing, which is the number of observations with missing values.

Statistics for Multiway Tables

PROC FREQ computes statistical tests and measures for crosstabulation tables, depending on which statements and options you specify. You can suppress the display of these results by specifying the **NOPRINT** option in the **PROC FREQ** statement. With any of the following information, **PROC FREQ** also displays the Sample Size and the Frequency Missing.

- If you specify the **SCOROUT** option in the **TABLES** statement, **PROC FREQ** displays the Row Scores and Column Scores that it uses for statistical computations. The Row Scores table displays the row variable values and the Score corresponding to each value. The Column Scores table displays the column variable values and the corresponding Scores. **PROC FREQ** also identifies the score type used to compute the row and column scores. You can specify the score type with the **SCORES=** option in the **TABLES** statement.

- If you specify the **CHISQ** option, PROC FREQ displays the following statistics for each two-way table: Pearson Chi-Square, Likelihood Ratio Chi-Square, Continuity-Adjusted Chi-Square (for 2×2 tables), Mantel-Haenszel Chi-Square, the Phi Coefficient, the Contingency Coefficient, and Cramér's V. For each test statistic, PROC FREQ also displays the degrees of freedom (DF) and the probability value (Prob).
- If you specify the **CHISQ** option for 2×2 tables, PROC FREQ also displays Fisher's exact test. The test output includes the cell (1,1) frequency (F), the exact left-sided and right-sided probability values, the table probability (P), and the exact two-sided probability value.
- If you specify the **FISHER** option in the TABLES statement (or, equivalently, the **FISHER** option in the **EXACT** statement), PROC FREQ displays Fisher's exact test for tables larger than 2×2 . The test output includes the table probability (P) and the probability value. In addition, PROC FREQ displays the CHISQ output listed earlier, even if you do not also specify the CHISQ option.
- If you specify the **PCHI**, **LRCHI**, or **MHCHI** option in the **EXACT** statement, PROC FREQ displays the corresponding exact test: Pearson Chi-Square, Likelihood Ratio Chi-Square, or Mantel-Haenszel Chi-Square, respectively. The test output includes the test statistic, the degrees of freedom (DF), and the asymptotic and exact probability values. If you also specify the **POINT** option in the **EXACT** statement, PROC FREQ displays the point probability for each exact test requested. If you specify the **CHISQ** option in the **EXACT** statement, PROC FREQ displays exact probability values for all three of these chi-square tests.
- If you specify the **MEASURES** option, PROC FREQ displays the following statistics and their asymptotic standard errors (ASE) for each two-way table: Gamma, Kendall's Tau-b, Stuart's Tau-c, Somers' $D(C|R)$, Somers' $D(R|C)$, Pearson Correlation, Spearman Correlation, Lambda Asymmetric ($C|R$), Lambda Asymmetric ($R|C$), Lambda Symmetric, Uncertainty Coefficient ($C|R$), Uncertainty Coefficient ($R|C$), and Uncertainty Coefficient Symmetric. If you specify the **CL** option, PROC FREQ also displays confidence limits for these measures.
- If you specify the **PLCORR** option, PROC FREQ displays the tetrachoric correlation for 2×2 tables or the polychoric correlation for larger tables. In addition, PROC FREQ displays the MEASURES output listed earlier, even if you do not also specify the MEASURES option.
- If you specify the **GAMMA**, **KENTB**, **STUTC**, **SMDCR**, **SMDRC**, **PCORR**, or **SCORR** option in the **TEST** statement, PROC FREQ displays asymptotic tests for Gamma, Kendall's Tau-b, Stuart's Tau-c, Somers' $D(C|R)$, Somers' $D(R|C)$, the Pearson Correlation, or the Spearman Correlation, respectively. If you specify the **MEASURES** option in the **TEST** statement, PROC FREQ displays all these asymptotic tests. The test output includes the statistic, its asymptotic standard error (ASE), Confidence Limits, the ASE under the null hypothesis H_0 , the standardized test statistic (Z), and the one-sided and two-sided probability values.
- If you specify the **KENTB**, **STUTC**, **SMDCR**, **SMDRC**, **PCORR**, or **SCORR** option in the **EXACT** statement, PROC FREQ displays asymptotic and exact tests for the corresponding measure of association: Kendall's Tau-b, Stuart's Tau-c, Somers' $D(C|R)$, Somers' $D(R|C)$, the Pearson Correlation, or the Spearman correlation, respectively. The test output includes the correlation, its asymptotic standard error (ASE), Confidence Limits, the ASE under the null hypothesis H_0 , the standardized test statistic (Z), and the asymptotic and exact one-sided and two-sided probability values. If you also specify the **POINT** option in the **EXACT** statement, PROC FREQ displays the point probability for each exact test requested.

- If you specify the **RISKDIFF** option for 2×2 tables, PROC FREQ displays the Column 1 and Column 2 Risk Estimates. For each column, PROC FREQ displays the Row 1 Risk, Row 2 Risk, Total Risk, and Risk Difference, together with their asymptotic standard errors (ASE) and Asymptotic Confidence Limits. PROC FREQ also displays Exact Confidence Limits for the Row 1 Risk, Row 2 Risk, and Total Risk. If you specify the **RISKDIFF** option in the **EXACT** statement, PROC FREQ provides unconditional Exact Confidence Limits for the Risk Difference.
- If you specify the **RISKDIFF(CL=)** option for 2×2 tables, PROC FREQ displays the Proportion Difference Confidence Limits. For each confidence limit Type that you request (Exact, Farrington-Manning, Hauck-Anderson, Newcombe Score, or Wald), PROC FREQ displays the Lower and Upper Confidence Limits.
- If you request a noninferiority or superiority test for the proportion difference (**RISKDIFF**) by specifying the **NONINF** or **SUP** *riskdiff-option*, and if you specify **METHOD=HA** (Hauck-Anderson), **METHOD=FM** (Farrington-Manning), or **METHOD=WALD** (Wald), PROC FREQ displays the following information: the Proportion Difference, the test ASE (H0, Sample, Sample H-A, or FM, depending on the method you specify), the test statistic Z, the probability value, the Noninferiority or Superiority Limit, and the test-based Confidence Limits. If you specify **METHOD=NEWCOMBE** (Newcombe score), PROC FREQ displays the Proportion Difference, the Noninferiority or Superiority Limit, and the Newcombe Confidence Limits.
- If you request an equivalence test for the proportion difference (**RISKDIFF**) by specifying the **EQUIV** *riskdiff-option*, and if you specify **METHOD=HA** (Hauck-Anderson), **METHOD=FM** (Farrington-Manning), or **METHOD=WALD** (Wald), PROC FREQ displays the following information: the Proportion Difference and the test ASE (H0, Sample, Sample H-A, or FM, depending on the method you specify). PROC FREQ displays a two one-sided test (TOST) for equivalence, which includes test statistics (Z) and probability values for the Lower and Upper tests, together with the Overall probability value. PROC FREQ also displays the Equivalence Limits and the test-based Confidence Limits. If you specify **METHOD=NEWCOMBE** (Newcombe), PROC FREQ displays the Proportion Difference, the Equivalence Limits, and the score Confidence Limits.
- If you request an equality test for the proportion difference (**RISKDIFF**) by specifying the **EQUAL** *riskdiff-option*, PROC FREQ displays the following information: the Proportion Difference and the test ASE (H0 or Sample), the test statistic Z, the One-Sided probability value ($\Pr > Z$ or $\Pr < Z$), and the Two-Sided probability value, $\Pr > |Z|$.
- If you specify the **MEASURES** option or the **RELRISK** option for 2×2 tables, PROC FREQ displays Estimates of the Relative Risk for Case-Control and Cohort studies, together with their Confidence Limits. These measures are also known as the Odds Ratio and the Column 1 and 2 Relative Risks. If you specify the **OR** option in the **EXACT** statement, PROC FREQ also displays Exact Confidence Limits for the Odds Ratio. If you specify the **RELRISK** option in the **EXACT** statement, PROC FREQ displays unconditional Exact Confidence Limits for the Relative Risk.
- If you specify the **TREND** option, PROC FREQ displays the Cochran-Armitage Trend Test for tables that are $2 \times C$ or $R \times 2$. For this test, PROC FREQ gives the Statistic (Z) and the one-sided and two-sided probability values. If you specify the **TREND** option in the **EXACT** statement, PROC FREQ also displays the exact one-sided and two-sided probability values for this test. If you specify the **POINT** option with the **TREND** option in the **EXACT** statement, PROC FREQ displays the exact point probability for the test statistic.

- If you specify the **JT** option, PROC FREQ displays the Jonckheere-Terpstra Test, showing the Statistic (JT), the standardized test statistic (Z), and the one-sided and two-sided probability values. If you specify the JT option in the **EXACT** statement, PROC FREQ also displays the exact one-sided and two-sided probability values for this test. If you specify the **POINT** option with the JT option in the EXACT statement, PROC FREQ displays the exact point probability for the test statistic.
- If you specify the **AGREE** option and the **PRINTKWT** option, PROC FREQ displays the Kappa Coefficient Weights for square tables larger than 2×2 .
- If you specify the **AGREE** option, for two-way tables PROC FREQ displays McNemar's Test and the Simple Kappa Coefficient for 2×2 tables. For square tables larger than 2×2 , PROC FREQ displays Bowker's Test of Symmetry, the Simple Kappa Coefficient, and the Weighted Kappa Coefficient. For McNemar's Test and Bowker's Test of Symmetry, PROC FREQ displays the Statistic (S), the degrees of freedom (DF), and the probability value ($\text{Pr} > S$). If you specify the **MCNEM** option in the **EXACT** statement, PROC FREQ also displays the exact probability value for McNemar's test. If you specify the **POINT** option with the **MCNEM** option in the EXACT statement, PROC FREQ displays the exact point probability for the test statistic. For the simple and weighted kappa coefficients, PROC FREQ displays the kappa values, asymptotic standard errors (ASE), and Confidence Limits.
- If you specify the **KAPPA** or **WTKAP** option in the **TEST** statement, PROC FREQ displays asymptotic tests for the simple kappa coefficient or the weighted kappa coefficient, respectively. If you specify the **AGREE** option in the TEST statement, PROC FREQ displays both these asymptotic tests. The test output includes the kappa coefficient, its asymptotic standard error (ASE), Confidence Limits, the ASE under the null hypothesis H_0 , the standardized test statistic (Z), and the one-sided and two-sided probability values.
- If you specify the **KAPPA** or **WTKAP** option in the **EXACT** statement, PROC FREQ displays asymptotic and exact tests for the simple kappa coefficient or the weighted kappa coefficient, respectively. The test output includes the kappa coefficient, its asymptotic standard error (ASE), Confidence Limits, the ASE under the null hypothesis H_0 , the standardized test statistic (Z), and the asymptotic and exact one-sided and two-sided probability values. If you specify the **POINT** option in the EXACT statement, PROC FREQ displays the point probability for each exact test requested.
- If you specify the **MC** option in the **EXACT** statement, PROC FREQ displays Monte Carlo estimates for all exact p -values requested by *statistic-options* in the EXACT statement. The Monte Carlo output includes the p -value Estimate, its Confidence Limits, the Number of Samples used to compute the Monte Carlo estimate, and the Initial Seed for random number generation.
- If you specify the **AGREE** option, for multiple strata PROC FREQ displays Overall Simple and Weighted Kappa Coefficients, with their asymptotic standard errors (ASE) and Confidence Limits. PROC FREQ also displays Tests for Equal Kappa Coefficients, giving the Chi-Squares, degrees of freedom (DF), and probability values ($\text{Pr} > \text{ChiSq}$) for the Simple Kappa and Weighted Kappa. For multiple strata of 2×2 tables, PROC FREQ displays Cochran's Q , giving the Statistic (Q), the degrees of freedom (DF), and the probability value ($\text{Pr} > Q$).
- If you specify the **CMH** option, PROC FREQ displays Cochran-Mantel-Haenszel Statistics for the following three alternative hypotheses: Nonzero Correlation, Row Mean Scores Differ (ANOVA Statistic), and General Association. For each of these statistics, PROC FREQ gives the degrees of freedom (DF) and the probability value (Prob). If you specify the **MANTELFLEISS** option, PROC FREQ displays the Mantel-Fleiss Criterion for 2×2 tables. For 2×2 tables, PROC FREQ also

displays Estimates of the Common Relative Risk for Case-Control and Cohort studies, together with their confidence limits. These include both Mantel-Haenszel and Logit stratum-adjusted estimates of the common Odds Ratio, Column 1 Relative Risk, and Column 2 Relative Risk. Also for 2×2 tables, PROC FREQ displays the Breslow-Day Test for Homogeneity of the Odds Ratios. For this test, PROC FREQ gives the Chi-Square, the degrees of freedom (DF), and the probability value ($\text{Pr} > \text{ChiSq}$).

- If you specify the **CMH** option in the TABLES statement and also specify the COMOR option in the **EXACT** statement, PROC FREQ displays exact confidence limits for the Common Odds Ratio for multiple strata of 2×2 tables. PROC FREQ also displays the Exact Test of H_0 : Common Odds Ratio = 1. The test output includes the Cell (1,1) Sum (S), Mean of S Under H_0 , One-sided $\text{Pr} \leq S$, and Point $\text{Pr} = S$. PROC FREQ also provides exact two-sided probability values for the test, computed according to the following three methods: $2 * \text{One-sided}$, Sum of probabilities $\leq \text{Point probability}$, and $\text{Pr} \geq |S - \text{Mean}|$.
- If you specify the **CMH** option in the TABLES statement and also specify the EQOR option in the **EXACT** statement, PROC FREQ computes Zelen's exact test for equal odds ratios for $h \times 2 \times 2$ tables. PROC FREQ displays Zelen's test along with the asymptotic Breslow-Day test produced by the CMH option. PROC FREQ displays the test statistic, Zelen's Exact Test (P), and the probability value, Exact $\text{Pr} \leq P$.
- If you specify the **GAILSIMON** option in the TABLES statement for a multiway 2×2 tables, PROC FREQ displays the Gail-Simon test for qualitative interactions. The display include the following statistics and their p -values: Q+ (Positive Risk Differences), Q- (Negative Risk Differences), and Q (Two-Sided).

ODS Table Names

PROC FREQ assigns a name to each table that it creates. You can use these names to refer to tables when you use the Output Delivery System (ODS) to select tables and create output data sets. For more information about ODS, see Chapter 20, "Using the Output Delivery System."

Table 38.21 lists the ODS table names together with their descriptions and the options required to produce the tables. Note that the ALL option in the TABLES statement invokes the CHISQ, MEASURES, and CMH options.

Table 38.21 ODS Tables Produced by PROC FREQ

ODS Table Name	Description	Statement	Option
BarnardsTest	Barnard's exact test	EXACT	BARNARD
BinomialCLs	Binomial confidence limits	TABLES	BINOMIAL(AC J W)
BinomialEquiv	Binomial equivalence analysis	TABLES	BINOMIAL(EQUIV)
BinomialEquivLimits	Binomial equivalence limits	TABLES	BINOMIAL(EQUIV)
BinomialEquivTest	Binomial equivalence test	TABLES	BINOMIAL(EQUIV)
BinomialNoninf	Binomial noninferiority test	TABLES	BINOMIAL(NONINF)
BinomialProp	Binomial proportion	TABLES	BINOMIAL
BinomialPropTest	Binomial proportion test	TABLES	BINOMIAL
BinomialSup	Binomial superiority test	TABLES	BINOMIAL(SUP)

Table 38.21 continued

ODS Table Name	Description	Statement	Option
BreslowDayTest	Breslow-Day test	TABLES	CMH ($h \times 2 \times 2$ table)
CMH	Cochran-Mantel-Haenszel statistics	TABLES	CMH
ChiSq	Chi-square tests	TABLES	CHISQ
CochransQ	Cochran's Q	TABLES	AGREE ($h \times 2 \times 2$ table)
ColScores	Column scores	TABLES	SCOROUT

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

When ODS Graphics is enabled, you can request specific plots with the **PLOTS=** option in the **TABLES** statement. To produce a frequency plot or cumulative frequency plot, you must specify the **FREQPLOT** or **CUMFREQPLOT** *plot-request*, respectively, in the **PLOTS=** option. To produce a mosaic plot, you must specify the **MOSAICPLOT** *plot-request* in the **PLOTS=** option. You can also produce frequency, cumulative frequency, and mosaic plots by specifying the **PLOTS=ALL** option. By default, PROC FREQ produces all other plots that are associated with the analyses that you request in the **TABLES** statement. You can suppress the default plots and request specific plots by using the **PLOTS(ONLY)=** option. See the description of the **PLOTS=** option for details.

PROC FREQ assigns a name to each graph that it creates with ODS Graphics. You can use these names to refer to the graphs. [Table 38.22](#) lists the names of the graphs that PROC FREQ generates together with their descriptions, their **PLOTS=** options (*plot-requests*), and the **TABLES** statement options that are required to produce the graphs.

Table 38.22 Graphs Produced by PROC FREQ

ODS Graph Name	Description	PLOTS= Option	TABLES Statement Option
AgreePlot	Agreement plot	AGREEPLOT	AGREE ($r \times r$ table)
CumFreqPlot	Cumulative frequency plot	CUMFREQPLOT	One-way table request
DeviationPlot	Deviation plot	DEVIATIONPLOT	CHISQ (one-way table)
FreqPlot	Frequency plot	FREQPLOT	Any table request
KappaPlot	Kappa plot	KAPPAPLOT	AGREE ($h \times r \times r$ table)
MosaicPlot	Mosaic plot	MOSAICPLOT	Two-way or multiway table request
ORPlot	Odds ratio plot	ODDSRATIOPLOT	MEASURES or RELRISK ($h \times 2 \times 2$ table)
RelRiskPlot	Relative risk plot	RELRIKSPLOT	MEASURES or RELRISK ($h \times 2 \times 2$ table)
RiskDiffPlot	Risk difference plot	RISKDIFFPLOT	RISKDIFF ($h \times 2 \times 2$ table)
WtKappaPlot	Weighted kappa plot	WTKAPPAPLOT	AGREE ($h \times r \times r$ table, $r > 2$)

Examples: FREQ Procedure

Example 38.1: Output Data Set of Frequencies

The eye and hair color of children from two different regions of Europe are recorded in the data set Color. Instead of recording one observation per child, the data are recorded as cell counts, where the variable Count contains the number of children exhibiting each of the 15 eye and hair color combinations. The data set does not include missing combinations.

The following DATA step statements create the SAS data set Color:

```
data Color;
  input Region Eyes $ Hair $ Count @@;
  label Eyes  = 'Eye Color'
        Hair  = 'Hair Color'
        Region= 'Geographic Region';
  datalines;
1 blue fair 23 1 blue red 7 1 blue medium 24
1 blue dark 11 1 green fair 19 1 green red 7
1 green medium 18 1 green dark 14 1 brown fair 34
1 brown red 5 1 brown medium 41 1 brown dark 40
1 brown black 3 2 blue fair 46 2 blue red 21
2 blue medium 44 2 blue dark 40 2 blue black 6
2 green fair 50 2 green red 31 2 green medium 37
2 green dark 23 2 brown fair 56 2 brown red 42
2 brown medium 53 2 brown dark 54 2 brown black 13
;
```

The following PROC FREQ statements read the Color data set and create an output data set that contains the frequencies, percentages, and expected cell frequencies of the two-way table of Eyes by Hair. The TABLES

statement requests three tables: a frequency table for Eyes, a frequency table for Hair, and a crosstabulation table for Eyes by Hair. The OUT= option creates the FreqCount data set, which contains the crosstabulation table frequencies. The OUTEXPECT option outputs the expected table cell frequencies to FreqCount, and the SPARSE option includes zero cell frequencies in the output data set. The WEIGHT statement specifies that the variable Count contains the observation weights. These statements create [Output 38.1.1](#) through [Output 38.1.3](#).

```
proc freq data=Color;
  tables Eyes Hair Eyes*Hair / out=FreqCount outexpect sparse;
  weight Count;
  title 'Eye and Hair Color of European Children';
run;

proc print data=FreqCount noobs;
  title2 'Output Data Set from PROC FREQ';
run;
```

[Output 38.1.1](#) displays the two frequency tables produced by PROC FREQ: one showing the distribution of eye color, and one showing the distribution of hair color. By default, PROC FREQ lists the variables values in alphabetical order. The 'Eyes*Hair' specification produces a crosstabulation table, shown in [Output 38.1.2](#), with eye color defining the table rows and hair color defining the table columns. A zero cell frequency for green eyes and black hair indicates that this eye and hair color combination does not occur in the data.

The output data set FreqCount ([Output 38.1.3](#)) contains frequency counts and percentages for the last table requested in the TABLES statement, Eyes by Hair. Because the SPARSE option is specified, the data set includes the observation with a zero frequency. The variable Expected contains the expected frequencies, as requested by the OUTEXPECT option.

Output 38.1.1 Frequency Tables

Eye and Hair Color of European Children				
The FREQ Procedure				
Eye Color				
Eyes	Frequency	Percent	Cumulative Frequency	Cumulative Percent
blue	222	29.13	222	29.13

Example 38.2: Frequency Dot Plots

This example produces frequency dot plots for the children's eye and hair color data from [Example 38.1](#).

PROC FREQ produces plots by using ODS Graphics to create graphs as part of the procedure output. Frequency plots are available for any frequency or crosstabulation table request. You can display frequency plots as bar charts or dot plots. You can use *plot-options* to specify the orientation (vertical or horizontal), scale, and layout of the plots.

The following PROC FREQ statements request frequency tables and dot plots. The first TABLES statement requests a one-way frequency table of Hair and a crosstabulation table of Eyes by Hair. The PLOTS= option requests frequency plots for the tables, and the TYPE=DOTPLOT *plot-option* specifies dot plots. By default, frequency plots are produced as bar charts. ODS Graphics must be enabled before producing plots.

The second TABLES statement requests a crosstabulation table of Region by Hair and a frequency dot plot for this table. The SCALE=PERCENT *plot-option* plots percentages instead of frequency counts. SCALE=LOG and SCALE=SQRT *plot-options* are also available to plot log frequencies and square roots of frequencies, respectively.

The ORDER=FREQ option in the PROC FREQ statement orders the variable levels by frequency. This order applies to the frequency and crosstabulation table displays and also to the corresponding frequency plots.

```
ods graphics on;
proc freq data=Color order=freq;
    tables Hair Hair*Eyes / plots=freqplot(type=dotplot);
    tables Hair*Region / plots=freqplot(type=dotplot scale=percent);
    weight Count;
    title 'Eye and Hair Color of European Children';
run;
ods graphics off;
```

[Output 38.2.1](#), [Output 38.2.2](#), and [Output 38.2.3](#) display the dot plots produced by PROC FREQ. By default, the orientation of dot plots is horizontal, which places the variable levels on the Y axis. You can specify the ORIENT=VERTICAL *plot-option* to request a vertical orientation. For two-way plots, you can use the TWOWAY= *plot-option* to specify the plot layout. The default layout (shown in [Output 38.2.2](#) and [Output 38.2.3](#)) is GROUPVERTICAL. Two-way layouts STACKED and GROUPTHORIZONTAL are also available.

Output 38.2.1 One-Way Frequency Dot Plot

Output 38.2.2 Two-Way Frequency Dot Plot

Output 38.2.3 Two-Way Percent Dot Plot

Example 38.3: Chi-Square Goodness-of-Fit Tests

This example examines whether the children’s hair color (from [Example 38.1](#)) has a specified multinomial distribution for the two geographical regions. The hypothesized distribution of hair color is 30% fair, 12% red, 30% medium, 25% dark, and 3% black.

In order to test the hypothesis for each region, the data are first sorted by Region. Then the FREQ procedure uses a BY statement to produce a separate table for each BY group (Region). The option ORDER=DATA orders the variable values (hair color) in the frequency table by their order in the input data set. The TABLES statement requests a frequency table for hair color, and the option NOCUM suppresses the display of the cumulative frequencies and percentages.

The CHISQ option requests a chi-square goodness-of-fit test for the frequency table of Hair. The TESTP= option specifies the hypothesized (or test) percentages for the chi-square test; the number of percentages listed equals the number of table levels, and the percentages sum to 100%. The TESTP= percentages are listed in the same order as the corresponding variable levels appear in frequency table.

The PLOTS= option requests a deviation plot, which is associated with the CHISQ option and displays the relative deviations from the test frequencies. The TYPE=DOTPLOT *plot-option* requests a dot plot instead

of the default type, which is a bar chart. ODS Graphics must be enabled before producing plots. These statements produce [Output 38.3.1](#) through [Output 38.3.4](#).

```
proc sort data=Color;
  by Region;
run;

ods graphics on;
proc freq data=Color order=data;
  tables Hair / nocum chisq testp=(30 12 30 25 3)
           plots(only)=deviationplot(type=dotplot);
  weight Count;
  by Region;
  title 'Hair Color of European Children';
run;
ods graphics off;
```

Output 38.3.1 Frequency Table and Chi-Square Test for Region 1

Hair Color of European Children			
----- Geographic Region=1 -----			
The FREQ Procedure			
Hair Color			
Hair	Frequency	Percent	Test Percent
-----	-----	-----	-----
fair	76	30.89	30.00
red	19	7.72	12.00
medium	83	33.74	30.00
dark	65	26.42	25.00
black	3	1.22	3.00
----- Geographic Region=1 -----			
Chi-Square Test for Specified Proportions			
Chi-Square	7.7602		
DF	4		
Pr > ChiSq	0.1008		

[Output 38.3.1](#) shows the frequency table and chi-square test for Region 1. The frequency table lists the variable values (hair color) in the order in which they appear in the data set. The “Test Percent” column lists the hypothesized percentages for the chi-square test. Always check that you have ordered the TESTP= percentages to correctly match the order of the variable levels.

Output 38.3.2 shows the deviation plot for Region 1, which displays the relative deviations from the hypothesized values. The relative deviation for a level is the difference between the observed and hypothesized (test) percentage divided by the test percentage. You can suppress the chi-square p -value that is displayed by default in the deviation plot by specifying the NOSTATS *plot-option*.

Output 38.3.2 Deviation Plot for Region 1

Output 38.3.3 and Output 38.3.4 show the results for Region 2. PROC FREQ computes a chi-square statistic for each region. The chi-square statistic is significant at the 0.05 level for Region 2 ($p=0.0003$) but not for Region 1. This indicates a significant departure from the hypothesized percentages in Region 2.

Output 38.3.3 Frequency Table and Chi-Square Test for Region 2

Hair Color of European Children			
----- Geographic Region=2 -----			
The FREQ Procedure			
Hair Color			
Hair	Frequency	Percent	Test Percent
fair	152	29.46	30.00
red	94	18.22	12.00
medium	134	25.97	30.00
dark	117	22.67	25.00
black	19	3.68	3.00
----- Geographic Region=2 -----			
Chi-Square Test for Specified Proportions			
Chi-Square	21.3824		
DF	4		
Pr > ChiSq	0.0003		

Output 38.3.4 Deviation Plot for Region 2

Example 38.4: Binomial Proportions

In this example, PROC FREQ computes binomial proportions, confidence limits, and tests. The example uses the eye and hair color data from [Example 38.1](#). By default, PROC FREQ computes the binomial proportion as the proportion of observations in the first level of the one-way table. You can designate a different level by using the `LEVEL= binomial-option`.

The following PROC FREQ statements compute the proportion of children with brown eyes (from the data set in [Example 38.1](#)) and test the null hypothesis that the population proportion equals 50%. These statements also compute an equivalence for the proportion of children with fair hair.

The first TABLES statement requests a one-way frequency table for the variable Eyes. The BINOMIAL option requests the binomial proportion, confidence limits, and test. PROC FREQ computes the proportion with Eyes = 'brown', which is the first level displayed in the table. The AC, WILSON, and EXACT *binomial-options* request the following confidence limits types: Agresti-Coull, Wilson (score), and exact (Clopper-Pearson). By default, PROC FREQ provides Wald and exact (Clopper-Pearson) confidence limits for the binomial proportion. The BINOMIAL option also produces an asymptotic Wald test that the proportion equals 0.5. You can specify a different test proportion with the `P= binomial-option`. The ALPHA=0.1 option specifies that $\alpha = 10\%$, which produces 90% confidence limits.

The second TABLES statement requests a one-way frequency table for the variable Hair. The BINOMIAL option requests the proportion for the first level, Hair = 'fair'. The EQUIV *binomial-option* requests an equivalence test for the binomial proportion. The P=.28 option specifies 0.28 as the null hypothesis proportion, and the MARGIN=.1 option specifies 0.1 as the equivalence test margin.

```
proc freq data=Color order=freq;
  tables Eyes / binomial(ac wilson exact) alpha=.1;
  tables Hair / binomial(equiv p=.28 margin=.1);
  weight Count;
  title 'Hair and Eye Color of European Children';
run;
```

Output 38.4.1 displays the results for eye color, and Output 38.4.2 displays the results for hair color.

Output 38.4.1 Binomial Proportion for Eye Color

Hair and Eye Color of European Children				
The FREQ Procedure				
Eye Color				
Eyes	Frequency	Percent	Cumulative Frequency	Cumulative Percent
brown	341	44.75	341	44.75
blue	222	29.13	563	73.88
green	199	26.12	762	100.00
Binomial Proportion				
Eyes = brown				
Proportion		0.4475		
ASE		0.0180		
Type		90% Confidence Limits		
Wilson		0.4181	0.4773	
Agresti-Coull		0.4181	0.4773	
Clopper-Pearson (Exact)		0.4174	0.4779	
Test of H0: Proportion = 0.5				
ASE under H0		0.0181		
Z		-2.8981		
One-sided Pr < Z		0.0019		
Two-sided Pr > Z		0.0038		

The frequency table in Output 38.4.1 displays the values of Eyes in order of descending frequency count. PROC FREQ computes the proportion of children in the first level displayed in the frequency table, Eyes = 'brown'. Output 38.4.1 displays the binomial proportion confidence limits and test. The confidence

limits are 90% confidence limits. If you do not specify the ALPHA= option, PROC FREQ computes 95% confidence limits by default. Because the value of Z is less than zero, PROC FREQ displays the a left-sided p -value (0.0019). This small p -value supports the alternative hypothesis that the true value of the proportion of children with brown eyes is less than 50%.

Output 38.4.2 displays the equivalence test results produced by the second TABLES statement. The null hypothesis proportion is 0.28 and the equivalence margins are -0.1 and 0.1 , which yield equivalence limits of 0.18 and 0.38 . PROC FREQ provides two one-sided tests (TOST) for equivalence. The small p -value indicates rejection of the null hypothesis in favor of the alternative that the proportion is equivalent to the null value.

Output 38.4.2 Binomial Proportion for Hair Color

Hair Color				
Hair	Frequency	Percent	Cumulative Frequency	Cumulative Percent
fair	228	29.92	228	29.92
medium	217	28.48	445	58.40
dark	182	23.88	627	82.28
red	113	14.83	740	97.11
black	22	2.89	762	100.00

Equivalence Analysis				
H0: $P - p_0 \leq \text{Lower Margin or } \geq \text{Upper Margin}$				
Ha: $\text{Lower Margin} < P - p_0 < \text{Upper Margin}$				
$p_0 = 0.28$ Lower Margin = -0.1 Upper Margin = 0.1				
Proportion		ASE (Sample)		
0.2992		0.0166		
Two One-Sided Tests (TOST)				
Test	Z	P-Value		
Lower Margin	7.1865	Pr > Z	<.0001	
Upper Margin	-4.8701	Pr < Z	<.0001	
Overall			<.0001	
Equivalence Limits		90% Confidence Limits		
0.1800	0.3800	0.2719	0.3265	

Example 38.5: Analysis of a 2x2 Contingency Table

This example computes chi-square tests and Fisher's exact test to compare the probability of coronary heart disease for two types of diet. It also estimates the relative risks and computes exact confidence limits for the odds ratio.

The data set `FatComp` contains hypothetical data for a case-control study of high fat diet and the risk of coronary heart disease. The data are recorded as cell counts, where the variable `Count` contains the frequencies for each exposure and response combination. The data set is sorted in descending order by the variables `Exposure` and `Response`, so that the first cell of the 2×2 table contains the frequency of positive exposure and positive response. The `FORMAT` procedure creates formats to identify the type of exposure and response with character values.

```
proc format;
    value ExpFmt 1='High Cholesterol Diet'
                0='Low Cholesterol Diet';
    value RspFmt 1='Yes'
                0='No';
run;

data FatComp;
    input Exposure Response Count;
    label Response='Heart Disease';
    datalines;
0 0 6
0 1 2
1 0 4
1 1 11
;

proc sort data=FatComp;
    by descending Exposure descending Response;
run;
```

In the following `PROC FREQ` statements, `ORDER=DATA` option orders the contingency table values by their order in the input data set. The `TABLES` statement requests a two-way table of `Exposure` by `Response`. The `CHISQ` option produces several chi-square tests, while the `RELRISK` option produces relative risk measures. The `EXACT` statement requests the exact Pearson chi-square test and exact confidence limits for the odds ratio.

```
proc freq data=FatComp order=data;
    format Exposure ExpFmt. Response RspFmt.;
    tables Exposure*Response / chisq relrisk;
    exact pchi or;
    weight Count;
    title 'Case-Control Study of High Fat/Cholesterol Diet';
run;
```

The contingency table in [Output 38.5.1](#) displays the variable values so that the first table cell contains the frequency for the first cell in the data set (the frequency of positive exposure and positive response).

Output 38.5.1 Contingency Table

Case-Control Study of High Fat/Cholesterol Diet				
The FREQ Procedure				
Table of Exposure by Response				
Exposure	Response(Heart Disease)			
Frequency				
Percent				
Row Pct				
Col Pct		Yes	No	Total
-----+-----+-----+				
High Cholesterol		11	4	15
Diet		47.83	17.39	65.22
		73.33	26.67	
		84.62	40.00	
-----+-----+-----+				
Low Cholesterol		2	6	8
Diet		8.70	26.09	34.78
		25.00	75.00	
		15.38	60.00	
-----+-----+-----+				
Total		13	10	23
		56.52	43.48	100.00

[Output 38.5.2](#) displays the chi-square statistics. Because the expected counts in some of the table cells are small, PROC FREQ gives a warning that the asymptotic chi-square tests might not be appropriate. In this case, the exact tests are appropriate. The alternative hypothesis for this analysis states that coronary heart disease is more likely to be associated with a high fat diet, so a one-sided test is desired. Fisher's exact right-sided test analyzes whether the probability of heart disease in the high fat group exceeds the probability of heart disease in the low fat group; because this p -value is small, the alternative hypothesis is supported.

The odds ratio, displayed in [Output 38.5.3](#), provides an estimate of the relative risk when an event is rare. This estimate indicates that the odds of heart disease is 8.25 times higher in the high fat diet group; however, the wide confidence limits indicate that this estimate has low precision.

Output 38.5.2 Chi-Square Statistics

Statistic	DF	Value	Prob
Chi-Square	1	4.9597	0.0259

Example 38.6: Output Data Set of Chi-Square Statistics

This example uses the Color data from [Example 38.1](#) to output the Pearson chi-square and the likelihood ratio chi-square statistics to a SAS data set. The following PROC FREQ statements create a two-way table of eye color versus hair color.

```
proc freq data=Color order=data;
  tables Eyes*Hair / expected cellchi2 norow nocol chisq;
  output out=ChiSqData n nmiss pchi lrchi;
  weight Count;
  title 'Chi-Square Tests for 3 by 5 Table of Eye and Hair Color';
run;

proc print data=ChiSqData noobs;
  title1 'Chi-Square Statistics for Eye and Hair Color';
  title2 'Output Data Set from the FREQ Procedure';
run;
```

The EXPECTED option displays expected cell frequencies in the crosstabulation table, and the CELLCHI2 option displays the cell contribution to the overall chi-square. The NOROW and NOCOL options suppress the display of row and column percents in the crosstabulation table. The CHISQ option produces chi-square tests.

The OUTPUT statement creates the ChiSqData output data set and specifies the statistics to include. The N option requests the number of nonmissing observations, the NMISS option stores the number of missing observations, and the PCHI and LRCHI options request Pearson and likelihood ratio chi-square statistics, respectively, together with their degrees of freedom and p -values.

The preceding statements produce [Output 38.6.1](#) and [Output 38.6.2](#). The contingency table in [Output 38.6.1](#) displays eye and hair color in the order in which they appear in the Color data set. The Pearson chi-square statistic in [Output 38.6.2](#) provides evidence of an association between eye and hair color ($p=0.0073$). The cell chi-square values show that most of the association is due to more green-eyed children with fair or red hair and fewer with dark or black hair. The opposite occurs with the brown-eyed children.

[Output 38.6.3](#) displays the output data set created by the OUTPUT statement. It includes one observation that contains the sample size, the number of missing values, and the chi-square statistics and corresponding degrees of freedom and p -values as in [Output 38.6.2](#).

Output 38.6.1 Contingency Table

Example 38.7: Cochran-Mantel-Haenszel Statistics

The data set *Migraine* contains hypothetical data for a clinical trial of migraine treatment. Subjects of both genders receive either a new drug therapy or a placebo. Their response to treatment is coded as ‘Better’ or ‘Same’. The data are recorded as cell counts, and the number of subjects for each treatment and response combination is recorded in the variable *Count*.

```
data Migraine;
  input Gender $ Treatment $ Response $ Count @@;
  datalines;
female Active Better 16   female Active Same 11
female Placebo Better 5   female Placebo Same 20
male Active Better 12     male Active Same 16
male Placebo Better 7     male Placebo Same 19
;
```

The following PROC FREQ statements create a multiway table stratified by Gender, where Treatment forms the rows and Response forms the columns. The RELRISK option in the TABLES statement requests the odds ratio and relative risks for the two-way tables of Treatment by Response. The PLOTS= option requests a relative risk plot, which shows the relative risk and its confidence limits for each level of Gender and overall. The CMH option requests Cochran-Mantel-Haenszel statistics for the multiway table. For this stratified 2×2 table, the CMH option also produces estimates of the common relative risk and the Breslow-Day test for homogeneity of the odds ratios. The NOPRINT option suppresses the display of the crosstabulation tables.

```
ods graphics on;
proc freq data=Migraine;
  tables Gender*Treatment*Response /
         relrisk plots(only)=relriskplot(stats) cmh noprint;
  weight Count;
  title 'Clinical Trial for Treatment of Migraine Headaches';
run;
ods graphics off;
```

Output 38.7.1 through Output 38.7.4 show the results of the analysis. The relative risk plot (Output 38.7.1) displays the relative risks and confidence limits for the two levels of Gender and for the overall (common) relative risk. Output 38.7.2 displays the CMH statistics. For a stratified 2×2 table, the three CMH statistics test the same hypothesis. The significant *p*-value (0.004) indicates that the association between treatment and response remains strong after adjusting for gender.

The CMH option also produces a table of overall relative risks, as shown in Output 38.7.3. Because this is a prospective study, the relative risk estimate assesses the effectiveness of the new drug; the “Cohort (Coll Risk)” values are the appropriate estimates for the first column (the risk of improvement). The probability of migraine improvement with the new drug is just over two times the probability of improvement with the placebo.

The large *p*-value for the Breslow-Day test (0.2218) in Output 38.7.4 indicates no significant gender difference in the odds ratios.

Output 38.7.1 Relative Risk Plot

Output 38.7.2 Cochran-Mantel-Haenszel Statistics

Cochran-Mantel-Haenszel Statistics (Based on Table Scores)				
Statistic	Alternative Hypothesis	DF	Value	Prob
1	Nonzero Correlation	1	8.3052	0.0040

Output 38.7.4 CMH Option: Breslow-Day Test

Breslow-Day Test for Homogeneity of the Odds Ratios	
Chi-Square	1.4929
DF	1
Pr > ChiSq	0.2218

Example 38.8: Cochran-Armitage Trend Test

The data set `Pain` contains hypothetical data for a clinical trial of a drug therapy to control pain. The clinical trial investigates whether adverse responses increase with larger drug doses. Subjects receive either a placebo or one of four drug doses. An adverse response is recorded as `Adverse='Yes'`; otherwise, it is recorded as `Adverse='No'`. The number of subjects for each drug dose and response combination is contained in the variable `Count`.

```
data pain;
  input Dose Adverse $ Count @@;
  datalines;
0 No 26    0 Yes  6
1 No 26    1 Yes  7
2 No 23    2 Yes  9
3 No 18    3 Yes 14
4 No  9    4 Yes 23
;
```

The following PROC FREQ statements provide a trend analysis. The TABLES statement requests a table of Adverse by Dose. The MEASURES option produces measures of association, and the CL option produces confidence limits for these measures. The TREND option tests for a trend across the ordinal values of the variable Dose with the Cochran-Armitage test. The PLOTS= option requests a mosaic plot of Adverse by Dose.

The EXACT statement produces exact p -values for this test, and the MAXTIME= option terminates the exact computations if they do not complete within 60 seconds. The TEST statement computes an asymptotic test for Somers' $D(R|C)$.

```
ods graphics on;
proc freq data=Pain;
  tables Adverse*Dose / trend measures cl
    plots=mosaicplot;
  test smdrc;
  exact trend / maxtime=60;
  weight Count;
  title 'Clinical Trial for Treatment of Pain';
run;
ods graphics off;
```

Output 38.8.1 through Output 38.8.4 display the results of the analysis. The “Col Pct” values in Output 38.8.1 show the expected increasing trend in the proportion of adverse effects with the increasing dosage (from 18.75% to 71.88%). The corresponding mosaic plot (Output 38.8.2) also shows this increasing trend.

Output 38.8.1 Contingency Table

Clinical Trial for Treatment of Pain						
The FREQ Procedure						
Table of Adverse by Dose						
Adverse	Dose					
Frequency						
Percent						
Row Pct						
Col Pct	0	1	2	3	4	Total

	18.75	21.21	28.13	43.75	71.88	
-----+-----+-----+-----+-----+						
Total	32	33	32	32	32	161
	19.88	20.50	19.88	19.88	19.88	100.00

Output 38.8.2 Mosaic Plot

Output 38.8.3 displays the measures of association produced by the MEASURES option. Somers' $D(R|C)$ measures the association treating the row variable (Adverse) as the response and the column variable (Dose) as a predictor. Because the asymptotic 95% confidence limits do not contain zero, this indicates a strong positive association. Similarly, the Pearson and Spearman correlation coefficients show evidence of a strong positive association, as hypothesized.

The Cochran-Armitage test (**Output 38.8.4**) supports the trend hypothesis. The small left-sided p -values for the Cochran-Armitage test indicate that the probability of the Row 1 level (Adverse='No') decreases as Dose increases or, equivalently, that the probability of the Row 2 level (Adverse='Yes') increases as Dose increases. The two-sided p -value tests against either an increasing or decreasing alternative. This is an appropriate hypothesis when you want to determine whether the drug has progressive effects on the probability of adverse effects but the direction is unknown.

Example 38.9: Friedman's Chi-Square Test

Friedman's test is a nonparametric test for treatment differences in a randomized complete block design. Each block of the design might be a subject or a homogeneous group of subjects. If blocks are groups of subjects, the number of subjects in each block must equal the number of treatments. Treatments are randomly assigned to subjects within each block. If there is one subject per block, then the subjects are repeatedly measured once under each treatment. The order of treatments is randomized for each subject.

In this setting, Friedman's test is identical to the ANOVA (row means scores) CMH statistic when the analysis uses rank scores (SCORES=RANK). The three-way table uses subject (or subject group) as the stratifying variable, treatment as the row variable, and response as the column variable. PROC FREQ handles ties by assigning midranks to tied response values. If there are multiple subjects per treatment in each block, the ANOVA CMH statistic is a generalization of Friedman's test.

The data set Hypnosis contains data from a study investigating whether hypnosis has the same effect on skin potential (measured in millivolts) for four emotions (Lehmann 2006, p. 264). Eight subjects are asked to display fear, joy, sadness, and calmness under hypnosis. The data are recorded as one observation per subject for each emotion.

```
data Hypnosis;
  length Emotion $ 10;
  input Subject Emotion $ SkinResponse @@;
  datalines;
1 fear 23.1 1 joy 22.7 1 sadness 22.5 1 calmness 22.6
2 fear 57.6 2 joy 53.2 2 sadness 53.7 2 calmness 53.1
3 fear 10.5 3 joy 9.7 3 sadness 10.8 3 calmness 8.3
4 fear 23.6 4 joy 19.6 4 sadness 21.1 4 calmness 21.6
5 fear 11.9 5 joy 13.8 5 sadness 13.7 5 calmness 13.3
6 fear 54.6 6 joy 47.1 6 sadness 39.2 6 calmness 37.0
7 fear 21.0 7 joy 13.6 7 sadness 13.7 7 calmness 14.8
8 fear 20.3 8 joy 23.6 8 sadness 16.3 8 calmness 14.8
;
```

In the following PROC FREQ statements, the TABLES statement creates a three-way table stratified by Subject and a two-way table; the variables Emotion and SkinResponse form the rows and columns of each table. The CMH2 option produces the first two Cochran-Mantel-Haenszel statistics, the option SCORES=RANK specifies that rank scores are used to compute these statistics, and the NOPRINT option suppresses the contingency tables. These statements produce [Output 38.9.1](#) and [Output 38.9.2](#).

```
proc freq data=Hypnosis;
  tables Subject*Emotion*SkinResponse /
    cmh2 scores=rank noprint;
run;

proc freq data=Hypnosis;
  tables Emotion*SkinResponse /
    cmh2 scores=rank noprint;
run;
```

Because the CMH statistics in [Output 38.9.1](#) are based on rank scores, the Row Mean Scores Differ statistic is identical to Friedman's chi-square ($Q = 6.45$). The p -value of 0.0917 indicates that differences in skin potential response for different emotions are significant at the 10% level but not at the 5% level.

When you do not stratify by subject, the Row Mean Scores Differ CMH statistic is identical to a Kruskal-Wallis test and is not significant ($p = 0.9038$ in [Output 38.9.2](#)). Thus, adjusting for subject is critical to reducing the background variation due to subject differences.

Output 38.9.1 CMH Statistics: Stratifying by Subject

Clinical Trial for Treatment of Pain				
The FREQ Procedure				
Summary Statistics for Emotion by SkinResponse Controlling for Subject				
Cochran-Mantel-Haenszel Statistics (Based on Rank Scores)

1	Nonzero Correlation	1	0.0001	0.9933
2	Row Mean Scores Differ	3	0.5678	0.9038

Example 38.10: Cochran's Q Test

When a binary response is measured several times or under different conditions, Cochran's Q tests that the marginal probability of a positive response is unchanged across the times or conditions. When there are more than two response categories, you can use the CATMOD procedure to fit a repeated-measures model.

The data set `Drugs` contains data for a study of three drugs to treat a chronic disease (Agresti 2002). Forty-six subjects receive drugs A, B, and C. The response to each drug is either favorable ('F') or unfavorable ('U').

```
proc format;
  value $ResponseFmt 'F'='Favorable'
                    'U'='Unfavorable';
run;
```

```

data drugs;
  input Drug_A $ Drug_B $ Drug_C $ Count @@;
  datalines;
F F F 6   U F F 2
F F U 16  U F U 4
F U F 2   U U F 6
F U U 4   U U U 6
;

```

The following statements create one-way frequency tables of the responses to each drug. The AGREE option produces Cochran's Q and other measures of agreement for the three-way table. These statements produce [Output 38.10.1](#) through [Output 38.10.5](#).

```

proc freq data=Drugs;
  tables Drug_A Drug_B Drug_C / nocum;
  tables Drug_A*Drug_B*Drug_C / agree noprint;
  format Drug_A Drug_B Drug_C $ResponseFmt.;
  weight Count;
  title 'Study of Three Drug Treatments for a Chronic Disease';
run;

```

The one-way frequency tables in [Output 38.10.1](#) provide the marginal response for each drug. For drugs A and B, 61% of the subjects reported a favorable response while 35% of the subjects reported a favorable response to drug C. [Output 38.10.2](#) and [Output 38.10.3](#) display measures of agreement for the 'Favorable' and 'Unfavorable' levels of drug A, respectively. McNemar's test shows a strong discordance between drugs B and C when the response to drug A is favorable.

Output 38.10.1 One-Way Frequency Tables

Study of Three Drug Treatments for a Chronic Disease		
The FREQ Procedure		
Drug_A	Frequency	Percent

Favorable	28	60.87

Overview: GAM Procedure

The GAM procedure fits generalized additive models as defined by Hastie and Tibshirani (1990). This procedure provides powerful tools for nonparametric regression and smoothing.

Nonparametric regression relaxes the usual assumption of linearity and enables you to uncover relationships between the independent variables and the dependent variable that might otherwise be missed. SAS provides many procedures for nonparametric regression, such as the LOESS procedure for local regression and the TPSPLINE procedure for thin-plate smoothing splines. The generalized additive models fit by the GAM procedure combine the following:

- an additivity assumption (Stone 1985) that enables relatively many nonparametric relationships to be explored simultaneously
- the distributional flexibility of generalized linear models (Nelder and Wedderburn 1972)

Thus, you can use the GAM procedure when you have multiple independent variables whose effect you want to model nonparametrically, or when the dependent variable is not normally distributed. See the section “[Nonparametric Regression](#)” on page 2672 for more details on the form of generalized additive models.

The GAM procedure does the following:

- provides nonparametric estimates for additive models
- supports the use of multidimensional data
- supports multiple SCORE statements
- fits both generalized semiparametric additive models and generalized additive models
- enables you to choose a particular model by specifying the model degrees of freedom or smoothing parameter
- produces graphs with ODS Graphics

Getting Started: GAM Procedure

The following example illustrates the use of the GAM procedure to explore in a nonparametric way how two factors affect a response. The data come from a study of the factors affecting patterns of insulin-dependent diabetes mellitus in children (Sochett et al. 1987). The objective is to investigate the dependence of the level of serum C-peptide on various other factors in order to understand the patterns of residual insulin secretion. The response measurement is the logarithm of C-peptide concentration (pmol/ml) at diagnosis, and the predictor measurements are age and base deficit (a measure of acidity).

```

title 'Patterns of Diabetes';
data diabetes;

7.9     -13.9  4.8   5.2   -4.5  4.9   0.9  -11.6  3.0
11.8     -2.1  4.6   7.9   -2.0  4.8  11.5   -9.0  5.5
10.6    -11.2  4.5   8.5   -0.2  5.3  11.1   -6.1  4.7
12.8     -1.0  6.6  11.3   -3.6  5.1   1.0   -8.2  3.9
14.5     -0.5  5.7  11.9   -2.0  5.1   8.1   -1.6  5.2
13.8    -11.9  3.7  15.5   -0.7  4.9   9.8   -1.2  4.8
11.0    -14.3  4.4  12.4   -0.8  5.2  11.1  -16.8  5.1
5.1      -5.1  4.6   4.8   -9.5  3.9   4.2  -17.0  5.1
6.9      -3.3  5.1  13.2   -0.7  6.0   9.9   -3.3  4.9
12.5    -13.6  4.1  13.2   -1.9  4.6   8.9  -10.0  4.9
10.8    -13.5  5.1
;

```

The following statements perform the desired analysis. The PROC GAM statement invokes the procedure and specifies the diabetes data set as input. The MODEL statement specifies logCP as the response variable and names Age and BaseDeficit as independent variables with univariate smoothing splines and the default of four degrees of freedom.

```

ods graphics on;
proc gam data=diabetes;
  model logCP = spline(Age) spline(BaseDeficit);
run;

```

The results are shown in [Figure 39.1](#) and [Figure 39.2](#).

Figure 39.1 Summary Statistics

Patterns of Diabetes	
The GAM Procedure	
Dependent Variable: logCP	
Smoothing Model Component(s): spline(Age) spline(BaseDeficit)	
Summary of Input Data Set	
Number of Observations	43
Number of Missing Observations	0
Distribution	Gaussian
Link Function	Identity

Figure 39.1 continued

Iteration Summary and Fit Statistics	
Final Number of Backfitting Iterations	5
Final Backfitting Criterion	5.542745E-10
The Deviance of the Final Estimate	0.4180791724

Figure 39.1 shows two tables. The first table summarizes the input data set and the distributional family used for the model; the second table summarizes the convergence criterion for backfitting.

Figure 39.2 Analysis of Model

Regression Model Analysis Parameter Estimates				
Parameter	Parameter Estimate	Standard Error	t Value	Pr > t
Intercept	1.48141	0.05120	28.93	<.0001
Linear (Age)	0.01437	0.00437	3.28	0.0024
Linear (BaseDeficit)	0.00807	0.00247	3.27	0.0025
Smoothing Model Analysis Fit Summary for Smoothing Components				
Component	Smoothing Parameter	DF	GCV	Num Unique Obs
Spline (Age)	0.995582	3.000000	0.011675	37
Spline (BaseDeficit)	0.995299	3.000000	0.012437	39
Smoothing Model Analysis Analysis of Deviance				
Source	DF	Sum of Squares	Chi-Square	Pr > ChiSq
Spline (Age)	3.00000	0.150761	12.2605	0.0065
Spline (BaseDeficit)	3.00000	0.081273	6.6095	0.0854

Figure 39.2 displays summary statistics for the model. It consists of three tables. The first is the “Parameter Estimates” table for the parametric part of the model. It indicates that the linear trends for both Age and BaseDeficit are highly significant. The second table is the summary of smoothing components of the nonparametric part of the model. This table presents the smoothing parameter and degrees of freedom (DF) for each component. By default, each smoothing component has approximately 4 DF. For univariate spline components, one DF is taken up by the (parametric) linear part of the model, so the remaining approximate DF is 3. Finally, the third table is the “Analysis of Deviance” table for the nonparametric component of the model.

With ODS Graphics enabled, PROC GAM produces by default a panel of plots of partial prediction curves of smoothing components. In these plots, the partial prediction for a predictor such as *Age* is its nonparametric contribution to the model, $s(\text{Age})$. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For specific information about the graphics available in the GAM procedure, see the section “[ODS Graphics](#)” on page 2686.

Plots for both predictors ([Figure 39.3](#)) show a strong quadratic pattern, with a possible indication of higher-order behavior. Further investigation is required to determine whether these patterns are real or not.

Figure 39.3 Partial Predictions for Each Predictor

Syntax: GAM Procedure

The following statements are available in the GAM procedure:

```
PROC GAM < options > ;
  CLASS variable < (options) > < variable < (options) > ... > < / options > ;
  MODEL dependent < (options) > = < PARAM(effects) > < smoothing-effects > < / options > ;
  SCORE DATA= SAS-data-set OUT= SAS-data-set ;
  OUTPUT OUT= SAS-data-set < keyword < =prefix > ... keyword < =prefix > > ;
  BY variables ;
  FREQ variable ;
```

The syntax of the GAM procedure is similar to that of other regression procedures in the SAS System. The PROC GAM and MODEL statements are required. The CLASS statement, if specified, must precede the MODEL statement. The CLASS and SCORE statements can appear multiple times; all other statements must appear only once.

The syntax for PROC GAM is described in the following sections in alphabetical order after the description of the PROC GAM statement.

PROC GAM Statement

PROC GAM < options > ;

The PROC GAM statement invokes the procedure. Table 39.1 summarizes the options available in the PROC GAM statement.

Table 39.1 PROC GAM Statement Options

Option	Description
DATA=	Specifies the input SAS data set
DESCENDING	Reverses the sort order of all CLASS variables
ORDER=	Specifies the sort order for CLASS variables
PLOTS	Controls plots produced through ODS Graphics

You can specify the following options.

DATA=SAS-data-set

specifies the SAS data set to be read by PROC GAM. The default value is the most recently created data set.

DESCENDING

DESC

reverses the sort order of all classification variables (specified in the **CLASS** statement). If both the **DESCENDING** and **ORDER=** options are specified, PROC GAM orders the categories according to the **ORDER=** option and then reverses that order. This option has the same effect as the classification variable option **DESCENDING** in the **CLASS** statement and the response variable option **DESCENDING** in the **MODEL** statement.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of all classification variables (specified in the **CLASS** statement). This ordering determines which parameters in the model correspond to each level in the data. Note that the **ORDER=** option in the **CLASS** statement and the **ORDER=** response variable option in the **MODEL** statement override the **ORDER=** option in the PROC GAM statement.

PLOTS < (global-plot-options) > < = plot-request < (options) > >

PLOTS < (global-plot-options) > < =(plot-request < (options) > < ... plot-request < (options) > > >

controls the plots produced through ODS Graphics. When you specify only one *plot-request*, you can omit the parentheses around the *plot-request*. Here are some examples:

```

plots=all

plots=components(commonaxes)

plots(unpack)=components(commonaxes clm)

```

ODS Graphics must be enabled before plots can be requested. For example:

```

ods graphics on;

proc gam data=test plots(unpack)=components(commonaxes clm);
  model z=spline(x) spline(y);
run;

ods graphics off;

```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

With ODS Graphics enabled, PROC GAM produces by default a panel of plots of partial prediction curves of smoothing components.

Global Plot Options

The *global-plot-options* apply to all plots generated by the GAM procedure, unless altered by a *specific-plot-option*.

UNPACK

separately displays the smoothing component plots that are by default presented in panels. Use this option if you want to access individual smoothing component plots within the panel.

Specific Plot Options

The following listing describes the specific plots and their options.

ALL

requests that all plots be produced.

NONE

suppresses all plots.

COMPONENTS | COMPONENT <(components-options)>

displays a panel of smoothing component plots. The following *components-options* are available:

ADDITIVE

produces the additive component plots for spline and loess effects. The additive component plots combine the linear trend and the nonparametric prediction for each spline or loess effect.

CLM

includes confidence limits in the smoothing component plots. By default, 95% confidence limits are produced, but you can change the significance level by specifying the `ALPHA=` option in the `MODEL` statement. Note that producing these limits can be computationally intensive for large data sets.

COMMONAXES

specifies that smoothing component plots use a common vertical axis. This enables you to visually judge relative effect size.

UNPACK

displays the smoothing components individually.

BY Statement

BY *variables* ;

You can specify a `BY` statement with `PROC GAM` to obtain separate analyses of observations in groups that are defined by the `BY` variables. When a `BY` statement appears, the procedure expects the input data set to be sorted in order of the `BY` variables. If you specify more than one `BY` statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the `SORT` procedure with a similar `BY` statement.
- Specify the `NOTSORTED` or `DESCENDING` option in the `BY` statement for the `GAM` procedure. The `NOTSORTED` option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the `BY` variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the `BY` variables by using the `DATASETS` procedure (in Base SAS software).

For more information about `BY`-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the `DATASETS` procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* <(options)> <*variable* <(options)> ... > </options> ;

The `CLASS` statement names the classification variables to be used in the analysis. The `CLASS` statement must precede the `MODEL` statement. You can specify various *options* for each variable by enclosing them in parentheses after the variable name. You can also specify global *options* for the `CLASS` statement by placing them after a slash (/). Global *options* are applied to all the variables specified in the `CLASS` statement. If you specify more than one `CLASS` statement, the global *options* specified on any one `CLASS` statement apply to all `CLASS` statements. However, individual `CLASS` variable *options* override the global *options*.

DESCENDING**DESC**

reverses the sort order of the classification variable. If both the **DESCENDING** and **ORDER=** options are specified, PROC GAM orders the categories according to the **ORDER=** option and then reverses that order.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the categories of categorical variables. This ordering determines which parameters in the model correspond to each level in the data. When the default **ORDER=FORMATTED** is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. The following table shows how PROC GAM interprets values of the **ORDER=** option.

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, **ORDER=FORMATTED**. For **FORMATTED** and **INTERNAL**, the sort order is machine-dependent. For more information on sort order, see the chapter on the **SORT** procedure in the *Base SAS Procedures Guide* and the discussion of **BY**-group processing in *SAS Language Reference: Concepts*.

TRUNCATE<=n>

specifies the length n of **CLASS** variable values to use in determining **CLASS** variable levels. If you specify **TRUNCATE** without the length n , the first 16 characters of the formatted values are used. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases previous to SAS 9. The default is to use the full formatted length of the **CLASS** variable. The **TRUNCATE** option is available only as a global option.

FREQ Statement

FREQ *variable* ;

The **FREQ** statement names a variable that provides frequencies for each observation in the **DATA=** data set. Specifically, if n is the value of the **FREQ** variable for a given observation, then that observation is used n times.

The analysis produced by using a **FREQ** statement reflects the expanded number of observations. You can produce the same analysis (without the **FREQ** statement) by first creating a new data set that contains the expanded number of observations. For example, if the value of the **FREQ** variable is 5 for the first

observation, the first five observations in the new data set are identical. Each observation in the old data set is replicated n_i times in the new data set, where n_i is the value of the FREQ variable for that observation.

If the value of the FREQ variable is missing or is less than 1, the observation is not used in the analysis. If the value is not an integer, only the integer portion is used.

The FREQ statement is not available when a loess smoother is included in the model.

MODEL Statement

MODEL *dependent* < (*options*) > = < **PARAM**(*effects*) > < *smoothing-effects* > < / *options* > ;

MODEL *event/trials* = < **PARAM**(*effects*) > < *smoothing-effects* > < / *options* > ;

The MODEL statement specifies the dependent variable and the independent effects you want to use in the model. Specify the independent parametric variables inside the parentheses of PARAM(). The parametric variables can be either classification variables or continuous variables. Classification variables must be declared in a CLASS statement. Interactions between variables can also be included as parametric effects. Multiple PARAM() specifications are allowed in the MODEL statement. The syntax for the specification of effects is the same as for the GLM procedure (Chapter 42, “[The GLM Procedure](#)”).

Only continuous variables can be specified in smoothing effects. Any number of smoothing effects can be specified, as follows:

Smoothing Effect	Meaning
SPLINE(<i>variable</i> < , DF= <i>number</i> >)	Fits a smoothing spline with the variable and with DF= <i>number</i>
LOESS(<i>variable</i> < , DF= <i>number</i> >)	Fits a local regression with the variable and with DF= <i>number</i>
SPLINE2(<i>variable1</i> , <i>variable2</i> < ,DF= <i>number</i> >)	Fits a bivariate thin-plate smoothing spline with <i>variable1</i> and <i>variable2</i> and with DF= <i>number</i>

The number specified in the DF= option must be positive. If you specify neither the DF= option nor the **METHOD=GCV** in the MODEL statement, then the default is DF=4. Note that for univariate spline and loess components, a degree of freedom is used by default to account for the linear portion of the model, so the value displayed in the “Fit Summary” and “Analysis of Deviance” tables will be one less than the value you specify.

Both parametric effects and smoothing effects are optional. If none are specified, a model that contains only an intercept is fitted.

If only parametric variables are present, PROC GAM fits a parametric linear model by using the terms inside the parentheses of PARAM(). If only smoothing effects are present, PROC GAM fits a nonparametric additive model. If both types of effect are present, PROC GAM fits a semiparametric model by using the parametric effects as the linear part of the model.

Table 39.2 shows how to specify various models for a dependent variable y and independent variables x , x_1 , and x_2 . $s_i(\cdot)$, $i = 1, 2$ are nonparametric smooth functions.

Table 39.2 Syntax for Common GAM Models

Type of Model	Syntax for model	Mathematical Form
Parametric	<code>y=param(x1 x2)</code>	$E(Y X = x) = \beta_0 + \beta_1 x_1 + \beta_2 x_2$
Nonparametric	<code>y=spline(x)</code>	$E(Y X = x) = \beta_0 + \beta_1 x + s(x)$
Nonparametric	<code>y=loess(x)</code>	$E(Y X = x) = \beta_0 + \beta_1 x + s(x)$
Semiparametric	<code>y=spline(x1) param(x2)</code>	$E(Y X = x) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + s(x_1)$
Additive	<code>y=spline(x1) spline(x2)</code>	$E(Y X = x) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + s_1(x_1) + s_2(x_2)$
Thin-plate spline	<code>y=spline2(x1, x2)</code>	$E(Y X = x) = \beta_0 + s(x_1, x_2)$

Table 39.3 summarizes the options available in the MODEL statement.

Table 39.3 MODEL Statement Options

Option	Description
Response Variable Options	
DESCENDING	Reverses the order of the response categories
EVENT=	Specifies the event category for the binary response model
ORDER=	Specifies the sort order for the response variable
Model Options	
ALPHA=	Specifies the significance level
ANODEV=	Specifies the method used to analyze smoothing effects
DIST=	Specifies the distribution family
EPSILON=	Specifies the convergence criterion for the backfitting algorithm
EPSSCORE=	Specifies the convergence criterion for the local scoring algorithm
ITPRINT	Produces an iteration summary table for the smoothing effects
MAXITER=	Specifies the maximum number of iterations for the backfitting algorithm
MAXITSCORE=	Specifies the maximum number of iterations for the local scoring algorithm
METHOD=	Specifies the method for selecting the value of the smoothing parameter
OFFSET=	Specifies an offset for the linear predictor

Response Variable Options

Response variable options determine how the GAM procedure models probabilities for binary data.

You can specify the following options by enclosing them in parentheses after the response variable. See the section “[CLASS Statement](#)” on page 2664 for more detail.

DESCENDING

DESC

reverses the order of the response categories. If both the DESCENDING and ORDER= options are specified, PROC GAM orders the response categories according to the ORDER= option and then reverses that order.

EVENT=*'category' | keyword*

specifies the event category for the binary response model. PROC GAM models the probability of the event category. You can specify the value (formatted, if a format is applied) of the event category in quotes, or you can specify one of the following keywords. The default is EVENT=FIRST.

FIRST

designates the first ordered category as the event.

LAST

designates the last ordered category as the event.

One of the most common sets of response levels is $\{0, 1\}$, with 1 representing the event for which the probability is to be modeled. Consider the example where Y takes the value 1 and 0 for event and nonevent, respectively, and X is the explanatory variable. By default, PROC GAM models the probability that $Y = 0$. To model the probability that $Y = 1$, specify the following MODEL statement:

```
model Y (event='1') = X;
```

ORDER=*DATA | FORMATTED | FREQ | INTERNAL*

specifies the sort order for the levels of the response variable. By default, ORDER=FORMATTED. When ORDER=FORMATTED, the values of numeric variables for which you have supplied no explicit format (that is, for which there is no corresponding FORMAT statement in the current PROC GAM run or in the DATA step that created the data set), are ordered by their internal (numeric) value. If you specify the ORDER= option in the MODEL statement and the ORDER= option in the CLASS statement, the former takes precedence. The following table shows the interpretation of the ORDER= values:

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

For the FORMATTED and INTERNAL values, the sort order is machine-dependent.

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

Model Options

ALPHA=*number*

specifies the significance level α of the confidence limits on the final nonparametric component estimates when you request confidence limits to be included in the output data set. Specify *number* as a value between 0 and 1. The default value is 0.05. See the section “[OUTPUT Statement](#)” on page 2670 for more information about the OUTPUT statement.

ANODEV=type

specifies the *type* of method to be used to produce the “Analysis of Deviance” table for smoothing effects. The available choices are as follows:

REFIT	specifies that PROC GAM perform χ^2 tests by fitting nested GAM models. This is the default choice if you do not specify the ANODEV= option. This choice requires fitting separate GAM models where one smoothing term is omitted from each model.
NOREFIT	specifies that PROC GAM perform approximate tests of smoothing effects. To test each smoothing effect, a weighted least squares model is fitted to the remaining parametric part of the model while keeping other nonlinear smoothers fixed. For details, see Hastie (1991). This choice requires only a single GAM fitting to be performed, which reduces the time of the procedure.
NONE	requests that the procedure not produce the “Analysis of Deviance” table for smoothing effects.

DIST=distribution-id**LINK=distribution-id**

specifies the distribution family used in the model. The choices for *distribution-id* are displayed in Table 39.4. See “Distribution Family and Canonical Link” on page 2682 for more information.

Table 39.4 Distribution Families for GAM Models

DIST=	Distribution	Link Function	Response Data Type
GAUSSIAN GAUS NORM	Normal (Gaussian)	Identity	Continuous variables
BINOMIAL LOGI BIN	Binomial	Logit	Binary variables
POISSON POIS LOGL	Poisson	Log	Nonnegative discrete variables
GAMMA GAMM	Gamma	Negative reciprocal	Positive continuous variables
IGAUSSIAN IGAU INVG	Inverse Gaussian	Squared reciprocal	Positive continuous variables

Canonical link functions are used with those distributions. Although alternative links are possible theoretically, the final fit of nonparametric regression models is relatively insensitive to the precise choice of link functions. Therefore, only the canonical link for each distribution family is implemented in PROC GAM. The loess smoother is not available for DIST=BINOMIAL when the number of trials is greater than 1.

EPSILON=number

specifies the convergence criterion for the backfitting algorithm. The default value is 1E–8.

EPSSCORE=number

specifies the convergence criterion for the local scoring algorithm. The default value is 1E–8.

ITPRINT

produces an iteration summary table for the smoothing effects when doing backfitting and local scoring.

MAXITER=number

specifies the maximum number of iterations for the backfitting algorithm. The default value is 50.

MAXITSCORE=number

specifies the maximum number of iterations for the local scoring algorithm. The default value is 100.

METHOD=GCV

specifies that the value of the smoothing parameter should be selected by generalized cross validation. If you specify both METHOD=GCV and the DF= option for the smoothing effects, the user-specified DF is used, and the METHOD=GCV option is ignored. See the section “[Selection of Smoothing Parameters](#)” on page 2679 for more details on the GCV method.

OFFSET=variable

specifies an offset for the linear predictor. An offset plays the role of a predictor whose coefficient is known to be 1. For example, you can use an offset in a Poisson model when counts have been obtained in time intervals of different lengths. With a log link function, you can model the counts as Poisson variables with the logarithm of the time interval as the offset variable. The offset variable cannot appear in the CLASS statement or elsewhere in the MODEL statement.

OUTPUT Statement

OUTPUT OUT= SAS-data-set < keyword< =prefix> ... keyword< =prefix> > ;

The OUTPUT statement creates a new SAS data set that contains diagnostic measures calculated after fitting the model.

All the variables in the original data set are included in the new data set, along with new variables that are created with *keywords* specified in the OUTPUT statement. These new variables contain the values of a variety of statistics and diagnostic measures that are calculated for each observation in the data set. If no *keywords* are present, the OUT= data set contains only the original data set and predicted values. The predicted values include the linear predictor for the response and the prediction for each smoothing term in the model. When you specify a distribution family with the DIST= or LINK= option in the MODEL statement, predicted response values after applying the inverse link function are also included. Predicted values are computed for observations that have missing response values, nonmissing values in the explanatory variables, and values of the smoothing variables that are within the smoothing ranges of the fitted model.

You can specify the following options in the OUTPUT statement:

OUT=SAS-data-set

specifies the name of the new data set to contain the diagnostic measures. This option is required.

keyword < =prefix>

specifies the statistics to include in the output data set. The keywords and the statistics they represent are as follows:

PREDICTED	predicted values for each smoothing component and overall predicted values on the response scale at design points. The prediction for each spline or loess term is only for the nonlinear component of each smoother.
------------------	---

LINP	linear prediction values on the link scale at design points
UCLM	upper confidence limits for each predicted smoothing component
LCLM	lower confidence limits for each predicted smoothing component
ADIAG	diagonal element of the hat matrix associated with the observation for each smoothing spline component
RESIDUAL	residual standardized by its weights
STD	standard deviation of the prediction for each smoothing component
ALL	all statistics in this list

The names of the new variables that contain the statistics are formed by concatenating a *prefix* and the corresponding variable names. If you do not specify a *prefix*, the names are formed by using default prefixes listed in the following table:

Keyword	Prefix
PRED	P_
LINP	LINP_
UCLM	UCLM_
LCLM	LCLM_
ADIAG	ADIAG_
RESID	R_
STD	STD_ (for spline) STDP_ (for loess)

For example, suppose that you have a dependent variable *y* and an independent smoothing variable *x*. If you specify the keywords `PRED=MyP_` and `ADIAG=MyA_`, the new variables in the output SAS data set are `MyP_y`, `MyP_x`, and `MyA_x`. If you specify the keywords `PRED` and `ADIAG` without prefixes, the new variables are `P_y`, `P_x`, and `ADIAG_x`.

SCORE Statement

SCORE DATA= *SAS-data-set* **OUT=** *SAS-data-set* ;

The SCORE statement calculates predicted values for a new data set. All the variables in the DATA= data set are included in the OUT= data set, along with the predicted values. The predicted values consist of predicted responses after the inverse link function transformation, predicted values of all smoothing terms, and predicted values on the link scale. Predicted values are computed for observations with missing response values whose values of the specified explanatory variables are nonmissing, and whose values of the specified smoothing variables are within the smoothing ranges of the fitted model. The predicted variables use the same naming convention as the OUTPUT statement. If you have multiple data sets to score, you can specify multiple SCORE statements.

The following options must be specified in the SCORE statement:

DATA=SAS-data-set

specifies an input SAS data set containing all the variables included in independent effects in the MODEL statement. The predicted response is computed for each observation in the SCORE DATA= data set.

OUT=SAS-data-set

specifies the name of the SAS data set to contain the predictions.

Details: GAM Procedure

Missing Values

When fitting a model, PROC GAM excludes any observation with missing values for an explanatory variable, offset variable, or dependent variable. However, if only the response is missing, predicted values can be computed and output to a data set by using the OUTPUT or SCORE statement.

Nonparametric Regression

Nonparametric regression relaxes the usual assumption of linearity and enables you to explore the data more flexibly, uncovering structure in the data that might otherwise be missed.

However, many forms of nonparametric regression do not perform well when the number of independent variables in the model is large. The sparseness of data in this setting causes the variances of the estimates to be unacceptably large unless the sample size is extremely large. The problem of rapidly increasing variance for increasing dimensionality is sometimes referred to as the “curse of dimensionality.” Interpretability is another problem with nonparametric regression based on kernel and smoothing spline estimates. These estimates contain information about the relationship between the dependent and independent variables, and the information is often difficult to comprehend.

To overcome these difficulties, additive models were proposed by some researchers, for example, Stone (1985). These models estimate an additive approximation to the multivariate regression function. The benefits of an additive approximation are at least twofold. First, since each of the individual additive terms is estimated by using a univariate smoother, the curse of dimensionality is avoided, at the cost of not being able to approximate universally. Second, estimates of the individual terms explain how the dependent variable changes with the corresponding independent variables.

To extend the additive model to a wide range of distribution families, Hastie and Tibshirani (1990) proposed generalized additive models. These models enable the mean of the dependent variable to depend on an additive predictor through a nonlinear link function. The models permit the response probability distribution to be any member of the exponential family of distributions. Many widely used statistical models belong to this general class; they include additive models for Gaussian data, nonparametric logistic models for binary data, and nonparametric log-linear models for Poisson data.

Additive Models and Generalized Additive Models

This section describes the methodology and the fitting procedure behind generalized additive models.

Let Y be a response random variable and X_1, X_2, \dots, X_p be a set of predictor variables. A regression procedure can be viewed as a method for estimating the expected value of Y given the values of X_1, X_2, \dots, X_p . The standard linear regression model assumes a linear form for the dependency of Y on X :

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_p X_p + \epsilon$$

where $E(\epsilon) = 0$ and $\text{Var}(\epsilon) = \sigma^2$. Given a sample, estimates of $\beta_0, \beta_1, \dots, \beta_p$ are usually obtained by the least squares method.

The additive model generalizes the linear model by modeling the dependency as

$$Y = s_0 + s_1(X_1) + s_2(X_2) + \dots + s_p(X_p) + \epsilon$$

where $s_j(X)$, $j = 1, 2, \dots, p$, are smooth functions, $E(\epsilon) = 0$ and $\text{Var}(\epsilon) = \sigma^2$.

In order to be estimable, the smooth functions s_i have to satisfy standardized conditions such as $E(s_j(X_j)) = 0$. These functions are not given a parametric form but instead are estimated in a non-parametric fashion.

While traditional linear models and additive models can be used in most statistical data analysis, there are types of problems for which they are not appropriate. For example, the normal distribution might not be adequate for modeling discrete responses such as counts or bounded responses such as proportions.

Generalized additive models address these difficulties, extending additive models to many other distributions besides just the normal. Thus, generalized additive models can be applied to a much wider range of data analysis problems.

Like generalized linear models, generalized additive models consist of a random component, an additive component, and a link function relating the two components. The response Y , the random component, is assumed to have exponential family density

$$f_Y(y; \theta, \phi) = \exp \left\{ \frac{y\theta - b(\theta)}{a(\phi)} + c(y, \phi) \right\}$$

where θ is called the natural parameter and ϕ is the scale parameter. The mean of the response variable μ is related to the set of covariates X_1, X_2, \dots, X_p by a link function g . The quantity

$$\eta = s_0 + \sum_{j=1}^p s_j(X_j)$$

defines the additive component, where $s_1(\cdot), \dots, s_p(\cdot)$ are smooth functions, and the relationship between μ and η is defined by $g(\mu) = \eta$. The most commonly used link function is the canonical link, for which $\eta = \theta$.

Generalized additive models and generalized linear models can be applied in similar situations, but they serve different analytic purposes. Generalized linear models emphasize estimation and inference for the parameters of the model, while generalized additive models focus on exploring data nonparametrically. Generalized additive models are more suitable for exploring the data and visualizing the relationship between the dependent variable and the independent variables.

Forms of Additive Models

Suppose that y is a continuous variable and x_1 and x_2 are two explanatory variables of interest. To fit an additive model, you can use a MODEL statement similar to that used in many regression procedures in the SAS System:

```
model y = spline(x1) spline(x2);
```

This model statement requires the procedure to fit the following model:

$$\eta(x_1, x_2) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + s_1(x_1) + s_2(x_2)$$

where the $s_i(\cdot)$ terms denote nonparametric spline functions of the respective explanatory variables.

The GAM procedure can fit semiparametric models. The following MODEL statement assumes a linear relation with x_1 and an unknown functional relation with x_2 :

```
model y = param(x1) spline(x2);
```

If you want to fit a model containing a functional two-way interaction between x_1 and x_2 , you can use the following MODEL statement:

```
model y = spline2(x1, x2);
```

In this case, the GAM procedure fits a model equivalent to that of PROC TPSPLINE.

Estimates from PROC GAM

PROC GAM provides the capability to fit both nonparametric and semiparametric models. So that you can better understand the underlying trend of any given factor, PROC GAM separates the linear trend from any general nonparametric trend during the fitting as well as in the final report. This makes it easy to determine whether the significance of a smoothing variable is associated with a simple linear trend or a more complicated pattern.

For example, suppose you want to fit a semiparametric model as

$$y = \alpha_0 + \alpha_1 z + f_1(x_1) + f_2(x_2)$$

The GAM estimate for this model is

$$y = \hat{\alpha}_0 + \hat{\alpha}_1 z + \hat{\beta}_1 x_1 + \hat{\beta}_2 x_2 + \hat{s}_1(x_1) + \hat{s}_2(x_2)$$

where \hat{s}_1 and \hat{s}_2 are linear-adjusted nonparametric estimates of the f_1 and f_2 effects. The p -values for $\hat{\alpha}_0$, $\hat{\alpha}_1$, $\hat{\beta}_1$, and $\hat{\beta}_2$ are reported in the parameter estimates table. $\hat{\beta}_1$ and $\hat{\beta}_2$ are the estimates labeled Linear(x1) and Linear(x2) in the table. The p -values for \hat{s}_1 and \hat{s}_2 are reported in the analysis of deviance table.

Only \hat{s}_1 , \hat{s}_2 , and \hat{y} are output to the output data set, with the corresponding variable names P_x1, P_x2, and P_y. For Gaussian data, the complete marginal prediction for variable x_1 is:

$$\hat{\beta}_1 x_1 + P_x1$$

If the additive component plots are requested by the ADDITIVE suboption, the additive component for variable x_2 is computed as:

$$\widehat{\beta}_2(x_2 - \bar{x}_2) + P_{-}x_2$$

where \bar{x}_2 is the mean for variable x_2 .

Backfitting and Local Scoring Algorithms

Much of the development and notation in this section follows Hastie and Tibshirani (1986).

Additive Models

Consider the estimation of the smoothing terms $s_0, s_1(\cdot), \dots, s_p(\cdot)$ in the additive model

$$\eta(X) = s_0 + \sum_{j=1}^p s_j(X_j)$$

where $E(s_j(X_j)) = 0$ for every j . Since the algorithm for additive models is the basis for fitting generalized additive models, the algorithm for additive models is discussed first.

Many ways are available to approach the formulation and estimation of additive models. The backfitting algorithm is a general algorithm that can fit an additive model with any regression-type fitting mechanisms.

Define the k th set of partial residuals as

$$R_k = Y - s_0 - \sum_{j \neq k} s_j(X_j)$$

then $E(R_k|X_k) = s_k(X_k)$. This observation provides a way to estimate each smoothing function $s_k(\cdot)$ given estimates $\{\hat{s}_j(\cdot), j \neq k\}$ for all the others. The resulting iterative procedure is known as the backfitting algorithm (Friedman and Stuetzle 1981). The following formulation is taken from Hastie and Tibshirani (1986).

The Backfitting Algorithm

The unweighted form of the backfitting algorithm is as follows:

1. Initialization:

$$s_0 = E(Y), s_1^{(1)} = s_2^{(1)} = \dots = s_p^{(1)} = 0, m = 0$$

2. Iterate:

$$m = m + 1;$$

for $j = 1$ to p do:

$$R_j = Y - s_0 - \sum_{k=1}^{j-1} s_k^{(m)}(X_k) - \sum_{k=j+1}^p s_k^{(m-1)}(X_k);$$

$$s_j^{(m)} = E(R_j|X_j);$$

3. Until:

$$\text{RSS} = \frac{1}{n} \left\| Y - s_0 - \sum_{j=1}^p s_j^{(m)}(X_j) \right\|^2 \text{ fails to decrease, or satisfies the convergence criterion.}$$

In the preceding notation, $s_j^{(m)}()$ denotes the estimate of $s_j()$ at the m th iteration. It can be shown that with many smoothers (including linear regression, univariate and bivariate splines, and combinations of these), RSS never increases at any step. This implies that the algorithm always converges (Hastie and Tibshirani 1986). Note, however, that for distributions other than Gaussian, numerical instabilities with weights can cause convergence problems. Even when the algorithm converges, the individual functions need not be unique, since dependence among the covariates can lead to more than one representation for the same fitted surface.

A weighted backfitting algorithm has the same form as for the unweighted case, except that the smoothers are weighted. In PROC GAM, weights are used with non-Gaussian data in the local scoring procedure described later in this section.

The GAM procedure uses the following condition as the convergence criterion for the backfitting algorithm:

$$\frac{\sum_{i=1}^n \sum_{j=1}^p \left(s_j^{(m-1)}(\mathbf{X}_{ij}) - s_j^{(m)}(\mathbf{X}_{ij}) \right)^2}{1 + \sum_{i=1}^n \sum_{j=1}^p \left(s_j^{(m-1)}(\mathbf{X}_{ij}) \right)^2} \leq \epsilon$$

where $\epsilon = 10^{-8}$ by default; you can change this with the EPSILON= option in the MODEL statement.

Generalized Additive Models

The algorithm described so far fits only additive models. The algorithm for generalized additive models is a little more complicated. Generalized additive models extend generalized linear models in the same manner that additive models extend linear regression models—that is, by replacing the form $\alpha + \sum_j \beta_j \mathbf{x}_j$ with the additive form $\alpha + \sum_j f_j(\mathbf{x}_j)$. See “Generalized Linear Models Theory” on page 2799 in Chapter 40, “The GENMOD Procedure,” for more information.

PROC GAM fits generalized additive models by using a modified form of adjusted dependent variable regression, as described for generalized linear models in McCullagh and Nelder (1989), with the additive predictor taking the role of the linear predictor. Hastie and Tibshirani (1986) call this the *local scoring algorithm*. Important components of this algorithm depend on the link function for each distribution, as shown in the following table.

Distribution	Link	Adjusted Dependent (z)	Weights (w)
Normal	μ	y	1
Binomial	$\log\left(\frac{\mu}{n-\mu}\right)$	$\eta + (y - \mu)/n\mu(1 - \mu)$	$n\mu(1 - \mu)$
Gamma	$-1/\mu$	$\eta + (y - \mu)/\mu^2$	μ^2
Poisson	$\log(\mu)$	$\eta + (y - \mu)/\mu$	μ
Inverse Gaussian	$1/\mu^2$	$\eta - 2(y - \mu)/\mu^3$	$\mu^3/4$

Once the distribution and hence these quantities are defined, the local scoring algorithm proceeds as follows.

The General Local Scoring Algorithm

1. Initialization:

$$s_i = g(E(y)), s_1^0 = s_2^0 = \cdots = s_p^0 = 0, m = 0$$

2. Iterate:

$$m = m + 1;$$

Form the predictor η , mean μ , weights \mathbf{w} , and adjusted dependent variable \mathbf{z} based on their corresponding values from the previous iteration:

$$\begin{aligned}\eta_i^{(m-1)} &= s_0 + \sum_{j=1}^p s_j^{(m-1)}(x_{ij}) \\ \mu_i^{(m-1)} &= g^{-1}(\eta_i^{(m-1)}) \\ w_i &= \left(V_i^{(m-1)}\right)^{-1} \cdot \left[\left(\frac{\partial \mu}{\partial \eta}\right)_i^{(m-1)}\right]^2 \\ z_i &= \eta_i^{(m-1)} + \left(y_i - \mu_i^{(m-1)}\right) \cdot \left(\frac{\partial \mu}{\partial \eta}\right)_i^{(m-1)}\end{aligned}$$

where $V_i^{(m-1)}$ is the variance of Y at $\mu_i^{(m-1)}$. Fit an additive model to \mathbf{z} by using the backfitting algorithm with weights \mathbf{w} to obtain estimated functions $s_j^{(m)}(\cdot)$, $j = 1, \dots, p$;

3. Until:

The convergence criterion is satisfied or the deviance fails to decrease. The deviance is an extension to generalized linear models of the RSS; see “[Goodness of Fit](#)” on page 2806 in Chapter 40, “[The GENMOD Procedure](#),” for a definition.

The GAM procedure uses the following condition as the convergence criterion for local scoring:

$$\frac{\sum_{i=1}^n w_i \sum_{j=1}^p \left(s_j^{(m-1)}(\mathbf{X}_{ij}) - s_j^{(m)}(\mathbf{X}_{ij})\right)^2}{\sum_{i=1}^n w_i \left(1 + \sum_{j=1}^p \left(s_j^{(m-1)}(\mathbf{X}_{ij})\right)^2\right)} \leq \epsilon^s$$

where $\epsilon^s = 10^{-8}$ by default; you can change this with the EPSSCORE= option in the MODEL statement.

The estimating procedure for generalized additive models consists of two loops. Inside each step of the local scoring algorithm (outer loop), a weighted backfitting algorithm (inner loop) is used until convergence or until the RSS fails to decrease. Then, based on the estimates from this weighted backfitting algorithm, a new set of weights is calculated and the next iteration of the scoring algorithm starts. The scoring algorithm stops when the convergence criterion is satisfied or the deviance of the estimates stops decreasing.

Smoother

You can specify three types of smoothers in the MODEL statement:

- **SPLINE(x)** specifies a cubic smoothing spline term for variable x
- **LOESS(x)** specifies a loess term for variable x
- **SPLINE2(x1, x2)** specifies a thin-plate smoothing spline term for variables x_1 and x_2

A smoother is a tool for summarizing the trend of a response measurement Y as a function of one or more predictor measurements X_1, \dots, X_p . It produces an estimate of the trend that is less variable than Y itself. An important property of a smoother is its nonparametric nature. It does not assume a rigid form for the dependence of Y on X_1, \dots, X_p . This section gives a brief overview of the smoothers that can be used with the GAM procedure.

Cubic Smoothing Spline

A smoothing spline is the solution to the following optimization problem: among all functions $\eta(x)$ with two continuous derivatives, find one that minimizes the penalized least square

$$\sum_{i=1}^n (y_i - \eta(x_i))^2 + \lambda \int_a^b (\eta''(t))^2 dt$$

where λ is a fixed constant and $a \leq x_1 \leq \dots \leq x_n \leq b$. The first term measures closeness to the data while the second term penalizes curvature in the function. It can be shown that there exists an explicit, unique minimizer, and that minimizer is a natural cubic spline with knots at the unique values of x_i .

The value $\lambda/(1 + \lambda)$ is the *smoothing parameter*. When λ is large, the smoothing parameter is close to 1, producing a smoother curve; small values of λ , corresponding to smoothing parameters near 0, are apt to produce rougher curves, more nearly interpolating the data.

Local Regression

Local regression was proposed by Cleveland, Devlin, and Grosse (1988). The idea of local regression is that at a predictor x , the regression function $\eta(x)$ can be locally approximated by the value of a function in some specified parametric class. Such a local approximation is obtained by fitting a regression surface to the data points within a chosen neighborhood of the point x . A weighted least squares algorithm is used to fit linear functions of the predictors at the centers of neighborhoods. The radius of each neighborhood is chosen so that the neighborhood contains a specified percentage of the data points. The smoothing parameter for the local regression procedure, which controls the smoothness of the estimated curve, is the fraction of the data in each local neighborhood. Data points in a given local neighborhood are weighted by a smooth decreasing function of their distance from the center of the neighborhood. See Chapter 53, “[The LOESS Procedure](#),” for more details.

Thin-Plate Smoothing Spline

The thin-plate smoothing spline is a multivariate version of the cubic smoothing spline. The theoretical foundations for the thin-plate smoothing spline are described in Duchon (1976, 1977); Meinguet (1979). The smoothing parameter for the thin-plate smoothing spline smoother is the parameter that controls the smoothness penalty. When the smoothing parameter is close to 0, the fit is close to an interpolation. When the smoothing parameter is very large, the fit is a smooth surface. Further results and applications are given in Wahba and Wendelberger (1980). See Chapter 96, “[The TPSPLINE Procedure](#),” for more details.

Selection of Smoothing Parameters

CV and GCV

The smoothers discussed here have a single smoothing parameter. In choosing the smoothing parameter, cross validation can be used. Cross validation works by leaving points (x_i, y_i) out one at a time, estimating the squared residual for smooth function at x_i based on the remaining $n - 1$ data points, and choosing the smoother to minimize the sum of those squared residuals. This mimics the use of training and test samples for prediction. The cross validation function is defined as

$$CV(\lambda) = \frac{1}{n} \sum_{i=1}^n \left(y_i - \hat{\eta}_{\lambda}^{(-i)}(x_i) \right)^2$$

where $\hat{\eta}_{\lambda}^{(-i)}(x_i)$ indicates the fit at x_i , computed by leaving out the i th data point. The quantity $nCV(\lambda)$ is sometimes called the prediction sum of squares, or PRESS (Allen 1974).

All of the smoothers fit by the GAM procedure can be formulated as a linear combination of the sample responses

$$\hat{\eta}(x) = \mathbf{A}(\lambda)\mathbf{y}$$

for some matrix $\mathbf{A}(\lambda)$, which depends on λ . (The matrix $\mathbf{A}(\lambda)$ depends on x and the sample data as well, but this dependence is suppressed in the preceding equation.) Let a_{ii} be the i th diagonal element of $\mathbf{A}(\lambda)$. Then the CV function can be expressed as

$$CV(\lambda) = \frac{1}{n} \sum_{i=1}^n \left(\frac{y_i - \hat{\eta}_{\lambda}(x_i)}{1 - a_{ii}} \right)^2$$

In most cases, it is very time-consuming to compute the quantity a_{ii} individually. To solve this computational problem, Wahba (1990) has proposed the generalized cross validation function (GCV) that can be used to solve a wide variety of problems involving selection of a parameter to minimize the prediction risk.

The GCV function is defined as

$$GCV(\lambda) = \frac{n \sum_{i=1}^n (y_i - \hat{\eta}_{\lambda}(x_i))^2}{(n - \text{Trace}(\mathbf{A}(\lambda)))^2}$$

The GCV formula simply replaces the a_{ii} with $\text{Trace}(\mathbf{A}(\lambda))/n$. Therefore, it can be viewed as a weighted version of CV. In most of the cases of interest, GCV is closely related to CV but much easier to compute. Specify the **METHOD=GCV** option in the MODEL statement in order to use the GCV function to choose the smoothing parameters.

Degrees of Freedom

The estimated GAM model can be expressed as

$$\hat{\eta}(X) = \hat{s}_0 + \sum_{j=1}^p \mathbf{A}_j(\lambda_j)Y$$

Because the weights are calculated based on previous iteration during the local scoring iteration, the matrices \mathbf{A}_j might depend on Y for non-Gaussian data. However, for the final iteration, the \mathbf{A}_j matrix for the spline smoothers has the same role as the projection matrix in linear regression; therefore, nonparametric degrees of freedom (DF) for the j th spline smoother can be defined as

$$\text{DF}(j\text{th spline smoother}) = \text{Trace}(\mathbf{A}_j(\lambda_j))$$

For loess smoothers \mathbf{A}_j is not symmetric and so is not a projection matrix. In this case PROC GAM uses

$$\text{DF}(j\text{th loess smoother}) = \text{Trace}(\mathbf{A}_j(\lambda_j)' \mathbf{A}_j(\lambda_j))$$

The GAM procedure gives you the option of specifying the degrees of freedom for each individual smoothing component. If you choose a particular value for the degrees of freedom, then during every local scoring iteration the procedure will search for a corresponding smoothing parameter lambda that yields the specified value or comes as close as possible. The final estimate for the smoother during this local scoring iteration will be based on this lambda. Note that for univariate spline and loess components, an additional degree of freedom is used by default to account for the linear portion of the model, so the value displayed in the “Fit Summary” and “Analysis of Deviance” tables will be one less than the value you specify.

Confidence Intervals for Smoothers

Buja, Hastie, and Tibshirani (1989) showed that each smoothing function estimate from the backfitting algorithm is the result of a linear mapping applied to the working response, if the backfitting algorithm converges.

The smoothing function estimate can be expressed as

$$\hat{s}_j(\mathbf{x}_j) = \mathbf{H}_j \mathbf{z}$$

where \mathbf{x}_j is the j th covariate and \mathbf{z} is the adjusted dependent variable that is formed in the local scoring algorithm. If the errors are independent and identically distributed, then

$$\text{Cov}(\hat{s}_j) = \sigma^2 \mathbf{H}_j \mathbf{H}_j'$$

where $\sigma^2 = \text{Var}(\mathbf{z})$.

However, direct computation of \mathbf{H}_j is formidable within the backfitting framework. Hastie and Tibshirani (1990) proposed using each individual smoothing matrix $\mathbf{A}_j(\lambda_j)$ as a substitute for the linear operator \mathbf{H}_j when computing confidence intervals. In the GAM procedure, curvewise confidence intervals for smoothing splines and pointwise confidence intervals for loess are provided in the output data set.

Curvewise Confidence Interval for Smoothing Spline Smoothers

Viewing the spline model as a Bayesian model, Wahba (1983) proposes Bayesian confidence intervals for smoothing spline estimates as:

$$\hat{s}_\lambda(x_i) \pm z_{\alpha/2} \sqrt{\hat{\mathbf{V}}_{ii}(\lambda)}$$

where $\hat{\mathbf{V}}_{ii}(\lambda)$ is the i th diagonal element of the Bayesian posterior covariance matrix $\hat{\mathbf{V}}$ and $z_{\alpha/2}$ is the $1 - \alpha/2$ quantile of the standard normal distribution. The confidence intervals are interpreted as intervals “across the function” as opposed to pointwise intervals.

Suppose that you fit a spline estimate to experimental data that consist of a true function f and a random error term ϵ_i . In repeated experiments, it is likely that about $100(1 - \alpha)\%$ of the confidence intervals cover the corresponding true values, although some values are covered every time and other values are not covered by the confidence intervals most of the time. This effect is more pronounced when the true response curve or surface has small regions of particularly rapid change.

In the GAM procedure, let the smoothing matrix for the nonlinear part of the j th spline term be $\tilde{\mathbf{A}}_j$ after the linear part is separated out from $\mathbf{A}_j(\lambda)$. The Bayesian posterior variance for the nonlinear part is computed as

$$\hat{\mathbf{V}}_j = \hat{\phi} \tilde{\mathbf{A}}_j \mathbf{W}^{-1}$$

where $\hat{\phi}$ is the dispersion parameter estimate and \mathbf{W} is the weight matrix from the final local scoring iteration. If you specify UCLM, LCLM, ADIAG, and STD options in the OUTPUT statement, the statistics are derived based on $\hat{\mathbf{V}}_j$.

When you request both the ADDITIVE and CLM suboptions in the PLOTS=COMPONENTS option, each of the smoothing component plots displays a confidence band for the total contribution of each smoothing spline smoother. The confidence band is derived from the total variance that is contributed by both linear and nonlinear parts by the j th term

$$\hat{\phi} \left(\mathbf{x}'_j (\mathbf{X}'\mathbf{W}\mathbf{X})^{-1} \mathbf{x}_j + \tilde{\mathbf{A}}_j \mathbf{W}^{-1} \right)$$

Pointwise Confidence Interval for Loess Smoothers

As shown in Cleveland, Devlin, and Grosse (1988), the smoothing matrix $\mathbf{A}(\lambda)$ for a loess smoother is asymmetric. The confidence intervals are computed as follows:

$$\hat{s}_\lambda(x_i) \pm z_{\alpha/2} \sqrt{\hat{\mathbf{V}}_{ii}(\lambda)}$$

where $\hat{\mathbf{V}}_{ii}(\lambda)$ is the i th diagonal element of the covariance matrix $\hat{\mathbf{V}}$ and $z_{\alpha/2}$ is the $1 - \alpha/2$ quantile of the standard normal distribution.

In the GAM procedure, let the smoothing matrix for the nonlinear part of the j th loess term be $\tilde{\mathbf{A}}_j$ after the linear part is separated out from $\mathbf{A}_j(\lambda)$. The covariance matrix for the nonlinear part is then

$$\hat{\mathbf{V}}_j = \hat{\phi} \tilde{\mathbf{A}}_j \mathbf{W}^{-1} \tilde{\mathbf{A}}'_j$$

where $\hat{\phi}$ is the dispersion parameter estimate and \mathbf{W} is the weight matrix from the final local scoring iteration. If you specify UCLM, LCLM, and STD options in the OUTPUT statement, the statistics are derived based on $\hat{\mathbf{V}}_j$.

When you request both the ADDITIVE and CLM suboptions in the PLOTS=COMPONENTS option, each of the smoothing component plots displays confidence intervals for total prediction of each loess smoother. The confidence intervals are derived from the total variance that is contributed by both the linear and nonlinear parts by the j th term

$$\hat{\phi} \left(\mathbf{x}'_j (\mathbf{X}'\mathbf{W}\mathbf{X})^{-1} \mathbf{x}_j + \tilde{\mathbf{A}}_j \mathbf{W}^{-1} \tilde{\mathbf{A}}'_j \right)$$

Distribution Family and Canonical Link

In general, there is not just one reasonable link function for a given response variable distribution. For parametric models, the choice of link function can lead to substantively different estimates and tests. However, the inherent flexibility of nonparametric models makes them less likely to be sensitive to the precise choice of link function. Thus, for simplicity and computational efficiency, the GAM procedure uses only the canonical link for each distribution, as discussed in the following sections.

The Gaussian Model

For a Gaussian model, the link function is the identity function, and the generalized additive model is the same as the additive model. The Gaussian model is selected by default or when you specify the `DIST=GAUSSIAN` option in the `MODEL` statement.

The Binomial Model

The binomial model is selected by specifying the `DIST=BINOMIAL` option in the `MODEL` statement. A binomial response model assumes that the proportion of successes Y is such that Y has a $\text{Bi}(n, p(x))$ distribution. $\text{Bi}(n, p(x))$ refers to the binomial distribution with the parameters n and $p(x)$. Often the data are binary, in which case $n = 1$. The canonical link is

$$g(p) = \log \frac{p}{n - p} = \eta$$

By default, PROC GAM models the probability of the response level with the *lower ordered value*. Ordered values are assigned to response levels in ascending sorted order and are displayed in the “Response Profiles” table. For binary data, if your event category has a higher Ordered Value, then by default the nonevent is modeled. The effect of modeling the nonevent is to change the signs of the estimated coefficients for linear terms in the model for the event. You can change which probability is modeled by specifying the `EVENT=`, `DESCENDING`, or `ORDER=` response variable options in the `MODEL` statement.

The Poisson Model

The Poisson model is selected by specifying the `DIST=POISSON` option in the `MODEL` statement. The link function for the Poisson model is the log function. Assuming that the mean of the Poisson distribution is $\mu(x)$, the dependence of $\mu(x)$ and independent variables x_1, \dots, x_k is

$$g(\mu) = \log(\mu) = \eta$$

The Gamma Model

The gamma model is selected by specifying the `DIST=GAMMA` option in the `MODEL` statement. Let the mean of the gamma distribution be $\mu(x)$. The canonical link function for the gamma distribution is $-1/\mu(x)$. Note that this link function is the negative of the default link function in PROC GENMOD for a gamma model. The relationship between $\mu(x)$ and the independent variables x_1, \dots, x_k is

$$g(\mu) = -\frac{1}{\mu} = \eta$$

The Inverse Gaussian Model

The inverse Gaussian model is selected by specifying the DIST=IGAUSSIAN option in the MODEL statement. Let the mean of the inverse Gaussian distribution be $\mu(x)$. The canonical link function for inverse Gaussian distribution is $1/\mu^2$. Therefore, the relationship between $\mu(x)$ and the independent variables x_1, \dots, x_k is

$$g(\mu) = \frac{1}{\mu^2} = \eta$$

Dispersion Parameter

Continuous distributions in the exponential family (Gaussian, gamma, and inverse Gaussian) have a dispersion parameter that can be estimated by the scaled deviance. For these continuous response distributions, PROC GAM incorporates this dispersion parameter estimate into standard errors of the parameter estimates, prediction standard errors of spline and loess components, and chi-square statistics. The discrete distributions used in GAM (binomial and Poisson) do not have a dispersion parameter. For more details on the distributions, dispersion parameter, and deviance, see “[Generalized Linear Models Theory](#)” on page 2799 in Chapter 40, “[The GENMOD Procedure](#).”

Computational Resources

Since PROC GAM implements a doubly iterative method (inner backfitting iterations within each local scoring iteration), data are accessed multiple times in performing a fit. To expedite the data access, PROC GAM keeps the data used in the analysis in memory.

Let

- n = number of observations used in the analysis
- p_r = number of parametric variables
- p_s = number of univariate spline smoothers
- p_l = number of loess smoothers
- p_b = number of bivariate thin-plate spline smoothers
- p = $p_r + p_s + p_l + p_b$
- p_n = $p_s + p_l + p_b$
- m = maximum number of iterations for the backfitting algorithm

In addition to the space to store the data ($8np$ bytes), the minimum working space (in bytes) needed for fitting a model using PROC GAM is

$$(16 + 8p_r)(n + 2p_r) + (160 + 48p + 16p_s + 8p_b + 8p_l)n + 8p + 32p_b + 32p_s + 8m + 8n + (4n + 4)p_s + 4.$$

For fitting bivariate thin-plate smoothing spline variables, an extra $80 + 120n + 8n^2 + 8p_b$ bytes of memory are needed. For fitting loess variables, an extra $48n + 16p_l$ bytes of memory are needed. If model inference or confidence limits are requested, additional memory is required.

It is difficult to provide accurate estimates of the time required to fit a GAM model. Both the backfitting algorithm and the local scoring algorithm are iterative techniques whose convergence rates depend on the particular data being analyzed. Furthermore, the time required depends on the types of smoothers that you specify, as well as on the inferential information you request.

You can estimate the time required for problems with a larger number of observations by observing the time required for smaller problems and then using the following growth rules (obtained using by simulations) that show that the time required grows proportionally with the following:

- n^3 when at least one bivariate thin-plate spline is used
- $n^{3/2}$ when only loess smoothers are used
- n when only univariate smoothing splines are used

For additive models (models with Gaussian response distribution) with a fixed number of observations, the time required is roughly proportional to $p_n^{3/2}$. For generalized additive models (models with non-Gaussian distributions), the computation time grows more rapidly as p_n increases. This is harder to quantify as it depends on the distribution family and the number of iterations required for the local scoring algorithm to converge.

Figure 39.4 Feasible Problem Sizes for Different Smoothers

Figure 39.4 shows a rough estimation of feasible sizes for the smoothers that you can use, as a function of the number of observations and number of smoothing components. This figure depicts the regions where you can expect a single fit of an additive model to finish within a few minutes on a typical Pentium 4 system.

Note that the times reflected in Figure 39.4 are based on fitting additive models (no local scoring iterations) when no analysis of deviance or confidence limits are computed. The time required for fitting generalized additive models grows proportionally with the number of the local scoring iterations. Furthermore, analysis of deviance (if you do not request the fast approximations with the ANODEV option) requires fitting multiple GAM models as each smoothing component is omitted sequentially, and so the time estimates need to be multiplied by the number of smoothing components when analysis of deviance is performed. Finally computation of confidence limits for each individual smoother increases the time required, especially when loess smoothers are utilized.

For univariate spline smoothers, subject to the aforementioned caveats, problems that correspond to all shaded regions in Figure 39.4 can be completed within a few minutes. For univariate loess smoothers, the two darkest regions are feasible. For bivariate spline smoothers, problems that correspond to only the darkest shading can be completed in the order of a few minutes. The problems that correspond to the upper right unshaded region might be possible, but they require long computation times.

ODS Table Names

PROC GAM assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 39.5 ODS Tables Produced by PROC GAM

ODS Table Name	Description	Statement	Option
ANODEV	Analysis of deviance table for smoothing variables	PROC	Default
ClassSummary	Summary of classification variables	PROC	Default
ConvergenceStatus	Convergence status of the local scoring algorithm	PROC	Default
InputSummary	Input data summary	PROC	Default
IterHistory	Iteration history table	MODEL	ITPRINT
IterSummary	Iteration summary	PROC	Default
FitSummary	Fit parameters and fit summary	PROC	Default
ParameterEstimates	Parameter estimation for regression variables	PROC	Default
ResponseProfile	Frequency counts for binary models	MODEL	DIST=BINOMIAL

By referring to the names of such tables, you can use the ODS OUTPUT statement to place one or more of these tables in output data sets.

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

When ODS Graphics is enabled, the GAM procedure by default produces plots of the partial predictions for each nonparametric predictor in the model. Use the PLOTS option in the PROC GAM statement to control aspects of these plots.

ODS Graph Names

PROC GAM assigns a name to each graph it creates by using ODS. You can use these names to reference the graphs when using ODS. The names are listed in [Table 39.6](#).

Table 39.6 Graphs Produced by PROC GAM

ODS Graph Name	Plot Description	PLOTS= Option
SmoothingComponentPlot	Panel of multiple partial prediction curves	COMPONENTS
SmoothingComponentPlot	Unpacked partial prediction curves	COMPONENTS(UNPACK)

By default, partial prediction plots for each component are displayed in panels containing at most six plots. If you specify more than six smoothing components, multiple panels are used. Use the PLOTS(UNPACK) option in the PROC GAM statement to display these plots individually.

Examples: GAM Procedure

Example 39.1: Generalized Additive Model with Binary Data

This example illustrates the capabilities of the GAM procedure and compares it to the GENMOD procedure. From this example, you can see that PROC GAM is very useful in visualizing the data and detecting the nonlinearity among the variables.

The data used in this example are based on a study by Bell et al. (1994). Bell and his associates studied the result of multiple-level thoracic and lumbar laminectomy, a corrective spinal surgery commonly performed on children. The data in the study consist of retrospective measurements on 83 patients. The specific outcome of interest is the presence (1) or absence (0) of kyphosis, defined as a forward flexion of the

spine of at least 40 degrees from vertical. The available predictor variables are age in months at time of the operation (Age), the starting of vertebrae levels involved in the operation (StartVert), and the number of levels involved (NumVert). The goal of this analysis is to identify risk factors for kyphosis. PROC GENMOD can be used to investigate the relationship among kyphosis and the predictors. The following statements create the data kyphosis and fit a logistic model specifying linear effects for the three predictors:

```

NOTE: The scale parameter was held fixed.

The GENMOD procedure assumes a strict linear relationship between the predictors and the response function, which is the logit (log odds) in this model. The following SAS statements use PROC GAM to investigate a less restrictive model, with moderately flexible spline terms for each of the predictors:

```

title 'Comparing PROC GAM with PROC GENMOD';
proc gam data=kyphosis;
  model Kyphosis (event='1') = spline(Age      ,df=3)
                               spline(StartVert,df=3)
                               spline(NumVert  ,df=3) / dist=binomial;
run;

```

The MODEL statement requests an additive model with a univariate smoothing spline for each term. The response variable option `EVENT=` chooses `Kyphosis= 1` (presence) as the event so that the probability of presence of kyphosis is modeled. The option `DIST=BINOMIAL` with binary responses specifies a logistic model. Each term is fit by using a univariate smoothing spline with three degrees of freedom. Of these three degrees of freedom, one is taken up by the linear portion of the fit and two are left for the nonlinear spline portion. Although this might seem to be an unduly modest amount of flexibility, it is better to be conservative with a data set this small.

[Output 39.1.2](#) and [Output 39.1.3](#) list the output from PROC GAM.

Smoothing Model Analysis				
Analysis of Deviance				
Source	DF	Sum of Squares	Chi-Square	Pr > ChiSq
Spline(Age)	2.00000	10.494369	10.4944	0.0053
Spline(StartVert)	2.00000	5.494968	5.4950	0.0641
Spline(NumVert)	2.00000	2.184518	2.1845	0.3355

The critical part of the GAM results is the “Analysis of Deviance” table, shown in [Output 39.1.3](#). For each smoothing effect in the model, this table gives a χ^2 test comparing the deviance between the full model and the model without the nonparametric component of this variable. The analysis of deviance results indicate that the nonparametric effect of **Age** is highly significant, the nonparametric effect of **StartVert** is nearly significant, and the nonparametric effect of **NumVert** is insignificant at the 5% level.

PROC GAM can also perform approximate analysis of deviance for smoothing effects by using the ANODEV=NOREFIT option, as in the following statements:

```
title 'PROC GAM with Approximate Analysis of Deviance';  
proc gam data=kyphosis;  
    model Kyphosis (event='1') = spline(Age          ,df=3)  
                                spline(StartVert,df=3)  
                                spline(NumVert   ,df=3) /  
                                dist=binomial anodev=norefit;  
run;
```

Output 39.1.4 Approximate Analysis of Deviance Table

PROC GAM with Approximate Analysis of Deviance			
The GAM Procedure			
Dependent Variable: Kyphosis			
Smoothing Model Component(s): spline(Age) spline(StartVert) spline(NumVert)			
Smoothing Model Analysis			
Approximate Analysis of Deviance			
Source	DF	Chi-Square	Pr > ChiSq
Spline(Age)	2.00000	7.0888	0.0289
Spline(StartVert)	2.00000	5.0431	0.0803
Spline(NumVert)	2.00000	2.2471	0.3251

The “Approximate Analysis of Deviance” table shown in [Output 39.1.4](#) yields similar conclusions to those of the “Analysis of Deviance” table ([Output 39.1.3](#)). In addition to fitting the model using all the specified smoothing effects, the default ANODEV=REFIT option requires fitting p additional subset models to p smoothing effects. Each submodel is fit by omitting one smoothing term from the model. By contrast, the ANODEV=NOREFIT option keeps the nonparametric terms fixed and requires a weighted least squares fit for only the parametric part of the model. Hence, GAM with the ANODEV=NOREFIT option is computationally inexpensive and is useful for obtaining approximate analysis of deviance results for models with many smoothing effects. This option assumes that the remaining nonparametric terms do not change much with the deletion of one nonparametric component. It should be used with caution when a model contains highly correlated predictors.

Plots of the partial predictions for each predictor can be used to investigate why PROC GAM and PROC GENMOD produce different results. The following statements use ODS Graphics to produce plots of the individual smoothing components. The CLM suboption in the PLOTS=COMPONENTS option adds a curvewise Bayesian confidence band to each smoothing component, while the COMMONAXES suboption forces all three smoothing component plots to share the same vertical axis limits, allowing a visual judgment of the relative nonparametric effect sizes.

```
ods graphics on;

proc gam data=kyphosis plots=components(clm commonaxes);
  model Kyphosis (event='1') = spline(Age      ,df=3)
                               spline(StartVert,df=3)
                               spline(NumVert  ,df=3) / dist=binomial;
run;

ods graphics off;
```

For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For specific information about the graphics available in the GAM procedure, see the section “[ODS Graphics](#)” on page 2686. The smoothing component plots are displayed in [Output 39.1.5](#).

Output 39.1.5 Partial Prediction for Each Predictor

The plots show that the partial predictions corresponding to both **Age** and **StartVert** have a quadratic pattern, while **NumVert** has a more complicated but ultimately nonsignificant pattern.

An important difference between the first analysis of these data with PROC GENMOD and the subsequent analysis with PROC GAM is that PROC GAM indicates that **Age** has a significant but nonlinear association with kyphosis. The difference is due to the fact that the generalized linear model includes only the linear effect of **Age** whereas the generalized additive model allows a more complex relationship, which the plots indicate is nearly quadratic. Having used the GAM procedure to discover an appropriate form of the dependence of Kyphosis on each of the three independent variables, you can use the GENMOD procedure to fit and assess the corresponding parametric model. The following statements fit a generalized linear model with quadratic terms for all three variables. The parameter estimates are shown in [Output 39.1.6](#).

```

title 'Comparing PROC GAM with PROC GENMOD';
proc genmod data=kyphosis descending;
  model kyphosis = Age      Age      *Age
                  StartVert StartVert*StartVert
                  NumVert   NumVert  *NumVert /
                  link=logit dist=binomial;
run;

```

Output 39.1.6 Logistic Model with Quadratic Terms

Comparing PROC GAM with PROC GENMOD

StartVert*StartVert	0.0495					
NumVert	0.5259					
NumVert*NumVert	0.9621					
Scale						
NOTE: The scale parameter was held fixed.						

The p -value for the χ^2 test is 0.0376 for dropping the quadratic term of Age, 0.0495 for dropping the quadratic term of StartVert, and 0.9621 for dropping this quadratic term of NumVert. The results for the quadratic GENMOD model are consistent with the GAM results.

Example 39.2: Poisson Regression Analysis of Component Reliability

In this example, the number of maintenance repairs on a complex system are modeled as realizations of Poisson random variables. The system under investigation has a large number of components, which occasionally break down and are replaced or repaired. During a four-year period, the system was observed to be in a state of steady operation, meaning that the rate of operation remained approximately constant. A monthly maintenance record is available for that period, which tracks the number of components removed for maintenance each month. The data are listed in the following statements, which create a SAS data set:

```

title 'Analysis of Component Reliability';
data equip;
    input year month removals @@;
    datalines;
1987   1   2 1987   2   4 1987   3   3
1987   4   3 1987   5   3 1987   6   8

1987  10   9 1987  11   4 1987  12  10
1988   1   4 1988   2   6 1988   3   4
1988   4   4 1988   5   3 1988   6   5
1988   7   3 1988   8   4 1988   9   5
1988  10   3 1988  11   6 1988  12   3
1989   1   2 1989   2   6 1989   3   1
1989   4   5 1989   5   5 1989   6   4
1989   7   2 1989   8   2 1989   9   2
1989  10   5 1989  11   1 1989  12  10
1990   1   3 1990   2   8 1990   3  12
1990   4   7 1990   5   3 1990   6   2
1990   7   4 1990   8   3 1990   9   0
1990  10   6 1990  11   6 1990  12   6
    ;

```

For planning purposes, it is of interest to understand the long- and short-term trends in the maintenance needs of the system. Over the long term, it is suspected that the quality of new components and repair work improves over time, so the number of component removals would tend to decrease from year to year. It is not known whether the robustness of the system is affected by seasonal variations in the operating environment, but this possibility is also of interest.

Because the maintenance record is in the form of counts, the number of removals are modeled as realizations of Poisson random variables. Denote by λ_{ij} the unobserved component removal rate for year i and month j . Since the data were recorded at regular intervals (from a system operating at a constant rate), each λ_{ij} is assumed to be a function of year and month only.

A preliminary two-way analysis is performed by using PROC GENMOD to make broad inferences on repair trends. A log-link is specified for the model

$$\log \lambda_{ij} = \mu + \alpha_i^Y + \alpha_j^M$$

where μ is a grand mean, α_i^Y is the effect of the i th year, and α_j^M is the effect of the j th month.

In the following statements, the CLASS statement declares the variables year and month as categorical. Type III sum of squares are requested to test whether there is an overall effect of year and/or month.

```

title2 'Two-way model';
proc genmod data=equip;
    class year month;
    model removals=year month / dist=Poisson link=log type3;
run;

```

Output 39.2.1 displays the listed Type III statistics for the fitted model. With the test for year effects yielding a p -value of 0.4527, there is no evidence of a long-term trend in maintenance rates. Apparently, the quality of new or repaired components did not change between 1987 and 1990. However, the test for monthly trends does yield a small p -value of 0.0321, indicating that seasonal trends are significant at the $\alpha = 0.05$ level.

Output 39.2.1 PROC GENMOD Listing for Type III Analysis

Analysis of Component Reliability			
Two-way model			
The GENMOD Procedure			
LR Statistics For Type 3 Analysis			
Source	DF	Chi-Square	Pr > ChiSq
year	3	2.63	0.4527
month	11	21.12	0.0321

If year is dropped from the model, the focus of the analysis is now on identifying the form of the underlying seasonal trend, which is a task that PROC GAM is especially suited for. PROC GAM will be used to fit both a reduced categorical model, with year eliminated, and a nonparametric spline model. Although PROC GENMOD also has the capability to fit categorical models, as demonstrated earlier, PROC GAM will be used here to fit both models for a better comparison.

The following PROC GAM statements specify the reduced categorical model and write predicted values to a data set. For this part of the analysis, a CLASS statement is again used to specify that month is a categorical variable. In the follow-up, the seasonal effect will be treated as a nonparametric function of month.

```

title2 'One-way model';
proc gam data=equip;
  class month;
  model removals=param(month) / dist=Poisson;
  output out=est p;
run;

```

The following statements use the SGPLOT procedure to generate a plot of the estimated seasonal trend. The plot is displayed in [Output 39.2.2](#).

```

proc sort data=est; by month; run;
proc sgplot data=est;
  title "Predicted Seasonal Trend";
  yaxis label="Number of Removals";
  xaxis integer values=(1 to 12);
  scatter x=Month y=Removals / name="points"
          legendLabel="Removals";
  series x=Month y=p_Removals / name="line"
        legendLabel="Predicted Removals"
        lineattrs = GRAPHFIT;
  discretelegend "points" "line";
run;

```

Output 39.2.2 Predicted Seasonal Trend from a Parametric Model Fit Using a CLASS Statement

The predicted repair rates shown in [Output 39.2.2](#) form a jagged seasonal pattern. Ignoring the month-to-month fluctuations, which are difficult to explain and can be artifacts of random noise, the general removal rate trend is high in winter and low in summer.

One advantage of nonparametric regression is its ability to highlight general trends in the data, such as those described earlier, and to attribute local fluctuations to unexplained random noise. The nonparametric regression model used by PROC GAM specifies that the underlying removal rates λ_j are of the form

$$\log \lambda_j = \beta_0 + \beta_1 \text{Month}_j + s(\text{Month}_j)$$

where β_1 is a linear coefficient and $s(\cdot)$ is a nonparametric regression function. β_1 and $s(\cdot)$ define the linear and nonparametric parts, respectively, of the seasonal trend.

The following statements request that PROC GAM fit a cubic spline model to the monthly repair data. The output listing is displayed in [Output 39.2.3](#) and [Output 39.2.4](#).

```
title 'Analysis of Component Reliability';
title2 'Spline model';
proc gam data=equip;
  model removals=spline(month) / dist=Poisson method=gcv;
run;
```

The **METHOD=GCV** option is used to determine an appropriate level of smoothing.

Output 39.2.3 PROC GAM Listing for Cubic Spline Regression Using the **METHOD=GCV** Option

Smoothing Model Analysis				
Fit Summary for Smoothing Components				
Component	Smoothing Parameter	DF	GCV	Num Unique Obs
Spline(month)	0.901512	1.879980	0.115848	12
Smoothing Model Analysis				
Analysis of Deviance				
Source	DF	Sum of Squares	Chi-Square	Pr > ChiSq
Spline(month)	1.87998	8.877764	8.8778	0.0103

Notice in the listing in [Output 39.2.4](#) that the DF value chosen for the nonlinear portion of the spline by minimizing GCV is about 1.88, which is smaller than the default value of 3. This indicates that the spline model of the seasonal trend is relatively simple. As indicated by the “Analysis of Deviance” table, it is a significant feature of the data. The table lists a p -value of 0.0103 for the hypothesis of no seasonal trend. Note also that the “Parameter Estimates” table lists a p -value of 0.2362 for the hypothesis of no linear factor in the seasonal trend indicating no significant linear trend.

The following statements use ODS Graphics to plot the smoothing component for the effect of Month on predicted repair rates. The CLM suboption for the PLOTS=COMPONENTS option adds a 95% confidence band to the fit.

```
ods graphics on;

proc gam data=equip plots=components(clm);
  model removals=spline(month) / dist=Poisson method=gcv;
run;

ods graphics off;
```

For general information about ODS graphics, see Chapter 21, “Statistical Graphics Using ODS.” For specific information about the graphics available in the GAM procedure, see the section “ODS Graphics” on page 2686. The smoothing component plot is displayed in [Output 39.2.5](#).

In [Output 39.2.5](#), it is apparent that the pattern of repair rates follows the general pattern observed in [Output 39.2.2](#). However, the plot in [Output 39.2.5](#) is much cleaner because the month-to-month fluctuations are smoothed out to reveal the broader seasonal trend.

Output 39.2.5 Estimated Nonparametric Factor of Seasonal Trend, Along with 95% Confidence Bounds

In [Output 39.2.1](#) the small p -value ($p = 0.0321$) for the hypothesis of no seasonal trend indicates that the data exhibit significant seasonal structure. [Output 39.2.5](#) is a graphical illustration of the seasonality of the number of removals.

Example 39.3: Comparing PROC GAM with PROC LOESS

In an analysis of simulated data from a hypothetical chemistry experiment, additive nonparametric regression performed by PROC GAM is compared to the unrestricted multidimensional procedure of PROC LOESS.

In each repetition of the experiment, a catalyst is added to a chemical solution, thereby inducing synthesis of a new material. The data are measurements of the temperature of the solution, the amount of catalyst added, and the yield of the chemical reaction. The following statements read and plots the raw data.

```

;

proc sort data=ExperimentA;
  by Temperature Catalyst;
run;

proc template;
  define statgraph surface;
    dynamic _X _Y _Z _T;
    begingraph;
    entrytitle _T;
    layout overlay3d/
      xaxisopts=(linearopts=(tickvaluesequence=
        (start=85 end=135 increment=25)))
      yaxisopts=(linearopts=(tickvaluesequence=
        (start=0 end=0.08 increment=0.04)))
      rotate=30 cube=false;
    surfaceplotparm x=_X y=_Y z=_Z;
    endlayout;
  endgraph;
end;
run;

ods graphics on;
proc sgrender data=ExperimentA template=surface;
  dynamic _X='Temperature' _Y='Catalyst' _Z='Yield' _T='Raw Data';
run;

```

The plot is displayed in [Output 39.3.1](#). A surface fitted to the plot of [Output 39.3.1](#) by PROC LOESS will be of a very general (and flexible) type, since the procedure requires only weak assumptions about the structure of the dependencies among the data. PROC GAM, on the other hand, makes stronger structural assumptions by restricting the fitted surface to an additive form. These differences will be demonstrated in this example.

Output 39.3.1 Surface Plot of Yield by Temperature and Amount of Catalyst

The following statements request that both PROC LOESS and PROC GAM fit surfaces to the data:

```
ods output ScoreResults=PredLOESS;
proc loess data=ExperimentA;
  model Yield = Temperature Catalyst
           / scale=sd select=gcv degree=2;
  score;
run;

proc gam data=PredLoess;
  model Yield = loess(Temperature) loess(Catalyst) / method=gcv;
  output out=PredGAM p=Gam_p_;
run;
```

In both cases the smoothing parameter was chosen as the value that minimizes GCV. This is performed automatically by PROC LOESS and PROC GAM.

The following statements generate plots of the predicted yields, which are displayed in [Output 39.3.2](#):

```
proc template;
  define statgraph surfacel;
    beginngraph;
      entrytitle "Fitted Surface";
      layout lattice/columns=2;
      layout
        overlay3d/xaxisopts=(linearopts=(tickvaluesequence=
          (start=85 end=135 increment=25)))
          yaxisopts=(linearopts=(tickvaluesequence=
            (start=0 end=0.08 increment=0.04)))
          zaxisopts=(label="P_Yield")
          rotate=30 cube=0;
      entry "PROC LOESS"/location=outside valign=top
        textattrs=graphlabeltext;
      surfaceplotparm x=Temperature y=Catalyst z=p_Yield;
    endlayout;
    layout
      overlay3d/xaxisopts=(linearopts=(tickvaluesequence=
        (start=85 end=135 increment=25)))
        yaxisopts=(linearopts=(tickvaluesequence=
          (start=0 end=0.08 increment=0.04)))
        rotate=30 cube=0
        zaxisopts=(label="P_Yield")
        rotate=30 cube=0;
      entry "PROC GAM"/location=outside valign=top
        textattrs=graphlabeltext;
      surfaceplotparm x=Temperature y=Catalyst z=Gam_p_Yield;
    endlayout;
  endlayout;
endngraph;
end;
run;

proc sgrender data=PredGAM template=surfacel;
run;
```

Output 39.3.2 Fitted Regression Surfaces

Though both PROC LOESS and PROC GAM use the statistical technique loess, it is apparent from [Output 39.3.2](#) that the manner in which it is applied is very different. By smoothing out the data in local neighborhoods, PROC LOESS essentially fits a surface to the data in pieces, one neighborhood at a time. The local regions are treated independently, so separate areas of the fitted surface are only weakly related. PROC GAM imposes additive structure, requiring that cross sections of the fitted surface always have the same shape and thereby relating regions that have a common value of the same individual regressor variable. Under that restriction, the loess technique need not be applied to the entire multidimensional scatter plot, but only to one-dimensional cross sections of the data.

The advantage of using additive model fitting is that its statistical power is directed toward univariate smoothing, and so it is able to discern the finer details of any underlying structure in the data. Regression data can be very sparse when viewed in the context of multidimensional space, even when every individual set of regressor values densely covers its range. This is the familiar curse of dimensionality. Sparse data greatly restrict the effectiveness of nonparametric procedures, but additive model fitting, when appropriate, is one way to overcome this limitation.

To examine these properties, you can use ODS Graphics to generate plots of cross sections of the unrestricted (PROC LOESS) and additive (PROC GAM) fitted surfaces for the variable Catalyst, as shown in the following statements:

```
proc template;
  define statgraph projection;
    beginingraph;
      entrytitle "Cross Sections of Fitted Surfaces";
      layout lattice/rows=2 columndatarange=unionall
        columngutter=10;
      columnAxes;
        columnAxis / display=all griddisplay=auto_on;
      endColumnAxes;

      layout overlay/
        xaxisopts=(display=none)
        yaxisopts=(label="LOESS Prediction"
          linearopts=(viewmin=2 viewmax=10));
        seriesplot x=Catalyst y=p_Yield /
          group=temperature
          name="Temperature";
      endlayout;

      layout overlay/
        xaxisopts=(display=none)
        yaxisopts=(label="GAM Prediction"
          linearopts=(viewmin=2 viewmax=10));
        seriesplot x=Catalyst y=Gam_p_Yield /
          group=temperature
          name="Temperature";
      endlayout;

      columnheaders;
        discreteLegend "Temperature" / title = "Temperature";
      endcolumnheaders;

    endlayout;
  endgraph;
end;
run;

proc sgrender data=PredGAM template=projection;
run;
```

The plots are displayed in [Output 39.3.3](#).

Output 39.3.3 Cross Sections of Fitted Regression Surfaces

Notice that the cross sections in the top panel (PROC LOESS) of [Output 39.3.3](#) have varying shapes, while every cross section in the bottom panel (PROC GAM) is the same curve shifted vertically. This illustrates precisely the kind of structural differences that distinguish additive models. A second important comparison to make between [Output 39.3.2](#) and [Output 39.3.3](#) is the level of detail in the fitted regression surfaces. Cross sections of the PROC LOESS surface are rather flat, but those of the additive surface have a clear shape. In particular, the ridge near Catalyst=0.055 is only vaguely evident in the PROC LOESS surface, but it is plainly revealed by the additive procedure.

For an example of a situation where unrestricted multidimensional fitting is preferred over additive regression, consider the following simulated data from a similar experiment. The following statements create another SAS data set and plot.

```

;

proc sort data=ExperimentB;
    by Temperature Catalyst;
run;

proc sgrender data=ExperimentB template=surface;
    dynamic _X='Temperature' _Y='Catalyst' _Z='Yield' _T='Raw Data';
run;

```

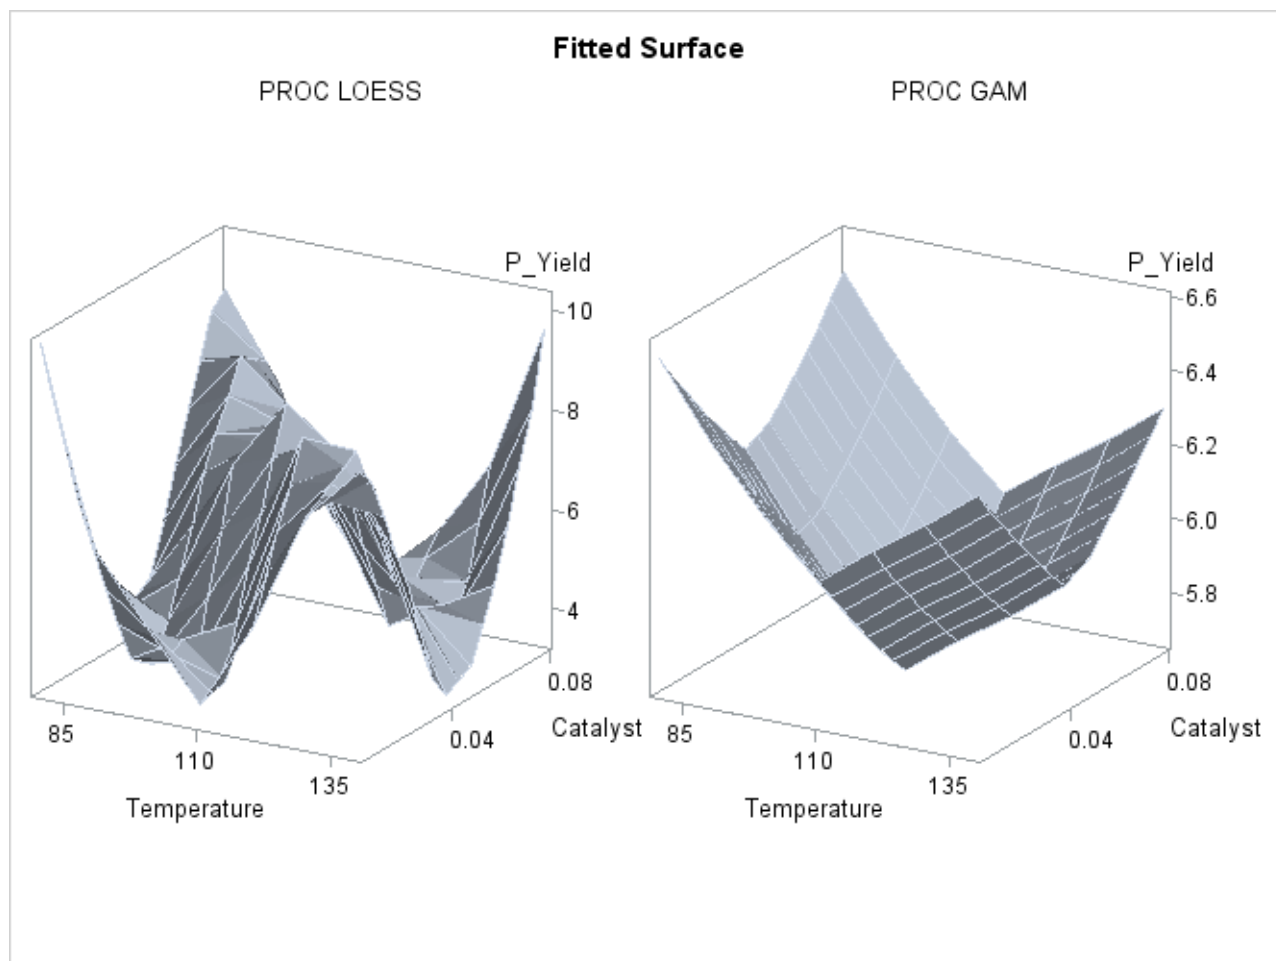

A plot of the raw data is displayed in [Output 39.3.4](#).

Output 39.3.4 Raw Data from Experiment B

Though the surface displayed in [Output 39.3.4](#) is quite jagged, a distinct feature of the plot is a large ridge that runs diagonally across its surface. One would expect that the ridge would appear in the fitted regression surface of an appropriate nonparametric procedure. Nevertheless, between PROC LOESS and PROC GAM, only PROC LOESS is able to capture this significant feature.

The SAS program for fitting the new data is essentially the same as that for the data set from the first experiment and produces output data set `PredGAMb` for this experiment. As in [Output 39.3.2](#), multivariate and additive fitted surfaces for these data are displayed in [Output 39.3.5](#).

Output 39.3.5 Fitted Regression Surfaces

It is clear from [Output 39.3.5](#) that the results of PROC LOESS and PROC GAM are completely different. While the plot in the left panel resembles the raw data plot in [Output 39.3.4](#), the plot in the right panel is essentially featureless.

To understand what is happening, compare the scatter plots of Yield by Catalyst for the two data sets in this example. These are generated by the following statements and displayed in [Output 39.3.6](#).

```
data PredGAM;
  set PredGAM;
  rename Yield=Yield_a;
run;

data PredGAMb;
  set PredGAMb;
  set PredGAM(keep=Yield_a);
run;
```

```

proc template;
  define statgraph scatter2;
    dynamic _X _Y1 _Y2;
    begingraph;
      entrytitle "Scatter Plots of Yield by Catalyst";
      layout lattice/rows=2 columndatarange=unionall
        rowdatarange=unionall
        columngutter=15;
      columnAxes;
        columnAxis / display=all griddisplay=auto_on;
      endColumnAxes;

      layout overlay/
        xaxisopts=(display=none)
        yaxisopts=(label="Yield of Experiment A"
          linearopts=(viewmin=2 viewmax=10));
        scatterplot x=_X y=_Y1;
      endlayout;

      layout overlay/
        xaxisopts=(display=none)
        yaxisopts=(label="Yield of Experiment B"
          linearopts=(viewmin=2 viewmax=10));
        scatterplot x=_X y=_Y2;
      endlayout;

    endlayout;
  endgraph;
end;
run;

proc sgrender data=PredGAMb template=scatter2;
  dynamic _X='Catalyst' _Y1='Yield_a' _Y2='Yield';
run;

ods graphics off;

```

The top panel of [Output 39.3.6](#) hints at the same kind of structure exhibited in the fitted cross sections of [Output 39.3.3](#). In PROC GAM, the additive model component corresponding to Catalyst is fit to a similar scatter plot, with the partial residuals computed in the backfitting algorithm, so it is able to capture the trend seen here. In contrast, when the second data set is viewed from the perspective of [Output 39.3.6](#), the diagonal ridge apparent in [Output 39.3.4](#) is washed out, and no clear structure shows up in the scatter plot. As a result, the additive model fit produced by PROC GAM is relatively featureless.

Overview: GENMOD Procedure

The GENMOD procedure fits generalized linear models, as defined by Nelder and Wedderburn (1972). The class of generalized linear models is an extension of traditional linear models that allows the mean of a population to depend on a *linear predictor* through a nonlinear *link function* and allows the response probability distribution to be any member of an exponential family of distributions. Many widely used statistical models are generalized linear models. These include classical linear models with normal errors, logistic and probit models for binary data, and log-linear models for multinomial data. Many other useful statistical models can be formulated as generalized linear models by the selection of an appropriate link function and response probability distribution.

See McCullagh and Nelder (1989) for a discussion of statistical modeling using generalized linear models. The books by Aitkin et al. (1989) and Dobson (1990) are also excellent references with many examples of applications of generalized linear models. Firth (1991) provides an overview of generalized linear models. Myers, Montgomery, and Vining (2002) provide applications of generalized linear models in the engineering and physical sciences. Collett (2003) and Hilbe (2009) provide comprehensive accounts of generalized linear models when the responses are binary.

The analysis of correlated data arising from repeated measurements when the measurements are assumed to be multivariate normal has been studied extensively. However, the normality assumption might not always be reasonable; for example, different methodology must be used in the data analysis when the responses are discrete and correlated. Generalized estimating equations (GEEs) provide a practical method with reasonable statistical efficiency to analyze such data.

Liang and Zeger (1986) introduced GEEs as a method of dealing with correlated data when, except for the correlation among responses, the data can be modeled as a generalized linear model. For example, correlated binary and count data in many cases can be modeled in this way.

The GENMOD procedure can fit models to correlated responses by the GEE method. You can use PROC GENMOD to fit models with most of the correlation structures from Liang and Zeger (1986) by using GEEs. For more details on GEEs, see Hardin and Hilbe (2003); Diggle, Liang, and Zeger (1994); Lipsitz et al. (1994).

Bayesian analysis of generalized linear models can be requested by using the BAYES statement in the GENMOD procedure. In Bayesian analysis, the model parameters are treated as random variables, and inference about parameters is based on the posterior distribution of the parameters, given the data. The posterior distribution is obtained using Bayes' theorem as the likelihood function of the data weighted with a prior distribution. The prior distribution enables you to incorporate knowledge or experience of the likely range of values of the parameters of interest into the analysis. If you have no prior knowledge of the parameter values, you can use a noninformative prior distribution, and the results of the Bayesian analysis will be very similar to a classical analysis based on maximum likelihood. A closed form of the posterior distribution is often not feasible, and a Markov chain Monte Carlo method by Gibbs sampling is used to simulate samples from the posterior distribution. See Chapter 7, "[Introduction to Bayesian Analysis Procedures](#)," for an introduction to the basic concepts of Bayesian statistics. Also see the section "[Bayesian Analysis: Advantages and Disadvantages](#)" on page 132 for a discussion of the advantages and disadvantages of Bayesian analysis. See Ibrahim, Chen, and Sinha (2001) for a detailed description of Bayesian analysis.

In a Bayesian analysis, a Gibbs chain of samples from the posterior distribution is generated for the model parameters. Summary statistics (mean, standard deviation, quartiles, HPD and credible intervals, correlation matrix) and convergence diagnostics (autocorrelations; Gelman-Rubin, Geweke, Raftery-Lewis, and

Heidelberger and Welch tests; the effective sample size; and Monte Carlo standard errors) are computed for each parameter, as well as the correlation matrix and the covariance matrix of the posterior sample. Trace plots, posterior density plots, and autocorrelation function plots that are created using ODS Graphics are also provided for each parameter.

The GENMOD procedure enables you to perform exact logistic regression, also called exact conditional binary logistic regression, and exact Poisson regression, also called exact conditional Poisson regression, by specifying one or more **EXACT** statements. You can test individual parameters or conduct a joint test for several parameters. The procedure computes two exact tests: the exact conditional score test and the exact conditional probability test. You can request exact estimation of specific parameters and corresponding odds ratios where appropriate. Point estimates, standard errors, and confidence intervals are provided.

The GENMOD procedure uses ODS Graphics to create graphs as part of its output. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).”

What Is a Generalized Linear Model?

A traditional linear model is of the form

$$y_i = \mathbf{x}_i' \boldsymbol{\beta} + \varepsilon_i$$

where y_i is the response variable for the i th observation. The quantity \mathbf{x}_i is a column vector of covariates, or explanatory variables, for observation i that is known from the experimental setting and is considered to be fixed, or nonrandom. The vector of unknown coefficients $\boldsymbol{\beta}$ is estimated by a least squares fit to the data y . The ε_i are assumed to be independent, normal random variables with zero mean and constant variance. The expected value of y_i , denoted by μ_i , is

$$\mu_i = \mathbf{x}_i' \boldsymbol{\beta}$$

While traditional linear models are used extensively in statistical data analysis, there are types of problems such as the following for which they are not appropriate.

- It might not be reasonable to assume that data are normally distributed. For example, the normal distribution (which is continuous) might not be adequate for modeling counts or measured proportions that are considered to be discrete.
- If the mean of the data is naturally restricted to a range of values, the traditional linear model might not be appropriate, since the linear predictor $\mathbf{x}_i' \boldsymbol{\beta}$ can take on any value. For example, the mean of a measured proportion is between 0 and 1, but the linear predictor of the mean in a traditional linear model is not restricted to this range.
- It might not be realistic to assume that the variance of the data is constant for all observations. For example, it is not unusual to observe data where the variance increases with the mean of the data.

A generalized linear model extends the traditional linear model and is therefore applicable to a wider range of data analysis problems. A generalized linear model consists of the following components:

- The linear component is defined just as it is for traditional linear models:

$$\eta_i = \mathbf{x}_i' \boldsymbol{\beta}$$

- A monotonic differentiable link function g describes how the expected value of y_i is related to the linear predictor η_i :

$$g(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}$$

- The response variables y_i are independent for $i = 1, 2, \dots$ and have a probability distribution from an exponential family. This implies that the variance of the response depends on the mean μ through a *variance function* V :

$$\text{Var}(y_i) = \frac{\phi V(\mu_i)}{w_i}$$

where ϕ is a constant and w_i is a known weight for each observation. The *dispersion parameter* ϕ is either known (for example, for the binomial or Poisson distribution, $\phi = 1$) or must be estimated.

See the section “[Response Probability Distributions](#)” on page 2799 for the form of a probability distribution from the exponential family of distributions.

As in the case of traditional linear models, fitted generalized linear models can be summarized through statistics such as parameter estimates, their standard errors, and goodness-of-fit statistics. You can also make statistical inference about the parameters by using confidence intervals and hypothesis tests. However, specific inference procedures are usually based on asymptotic considerations, since exact distribution theory is not available or is not practical for all generalized linear models.

Examples of Generalized Linear Models

You construct a generalized linear model by deciding on response and explanatory variables for your data and choosing an appropriate link function and response probability distribution. Some examples of generalized linear models follow. Explanatory variables can be any combination of continuous variables, classification variables, and interactions.

Traditional Linear Model

- response variable: a continuous variable
- distribution: normal
- link function: identity, $g(\mu) = \mu$

Logistic Regression

- response variable: a proportion
- distribution: binomial
- link function: logit, $g(\mu) = \log\left(\frac{\mu}{1 - \mu}\right)$

Poisson Regression in Log-Linear Model

- response variable: a count
- distribution: Poisson
- link function: $\log, g(\mu) = \log(\mu)$

Gamma Model with Log Link

- response variable: a positive, continuous variable
- distribution: gamma
- link function: $\log, g(\mu) = \log(\mu)$

The GENMOD Procedure

The GENMOD procedure fits a generalized linear model to the data by maximum likelihood estimation of the parameter vector β . There is, in general, no closed form solution for the maximum likelihood estimates of the parameters. The GENMOD procedure estimates the parameters of the model numerically through an iterative fitting process. The dispersion parameter ϕ is also estimated by maximum likelihood or, optionally, by the residual deviance or by Pearson's chi-square divided by the degrees of freedom. Covariances, standard errors, and p -values are computed for the estimated parameters based on the asymptotic normality of maximum likelihood estimators. A number of popular link functions and probability distributions are available in the GENMOD procedure. The built-in link functions are as follows:

- identity: $g(\mu) = \mu$
- logit: $g(\mu) = \log(\mu/(1 - \mu))$
- probit: $g(\mu) = \Phi^{-1}(\mu)$, where Φ is the standard normal cumulative distribution function
- power: $g(\mu) = \begin{cases} \mu^\lambda & \text{if } \lambda \neq 0 \\ \log(\mu) & \text{if } \lambda = 0 \end{cases}$
- log: $g(\mu) = \log(\mu)$
- complementary log-log: $g(\mu) = \log(-\log(1 - \mu))$

The available distributions and associated variance functions are as follows:

- normal: $V(\mu) = 1$
- binomial (proportion): $V(\mu) = \mu(1 - \mu)$
- Poisson: $V(\mu) = \mu$
- gamma: $V(\mu) = \mu^2$

- inverse Gaussian: $V(\mu) = \mu^3$
- negative binomial: $V(\mu) = \mu + k\mu^2$
- geometric: $V(\mu) = \mu + \mu^2$
- multinomial
- zero-inflated Poisson
- zero-inflated negative binomial

The negative binomial and zero-inflated negative binomial are distributions with an additional parameter k in the variance function. PROC GENMOD estimates k by maximum likelihood, or you can optionally set it to a constant value. For discussions of the negative binomial distribution, see McCullagh and Nelder (1989); Hilbe (1994, 2007); Long (1997); Cameron and Trivedi (1998); Lawless (1987).

The multinomial distribution is sometimes used to model a response that can take values from a number of categories. The binomial is a special case of the multinomial with two categories. See the section “[Multinomial Models](#)” on page 2817 and McCullagh and Nelder (1989, Chapter 5) for a description of the multinomial distribution.

The zero-inflated Poisson and zero-inflated negative binomial are included in PROC GENMOD even though they are not generalized linear models. They are useful extensions of generalized linear models. See the section “[Zero-Inflated Models](#)” on page 2818 for information about the zero-inflated distributions. Models for data with correlated responses fit by the GEE method are not available for zero-inflated distributions.

In addition, you can easily define your own link functions or distributions through DATA step programming statements used within the procedure.

An important aspect of generalized linear modeling is the selection of explanatory variables in the model. Changes in goodness-of-fit statistics are often used to evaluate the contribution of subsets of explanatory variables to a particular model. The deviance, defined to be twice the difference between the maximum attainable log likelihood and the log likelihood of the model under consideration, is often used as a measure of goodness of fit. The maximum attainable log likelihood is achieved with a model that has a parameter for every observation. See the section “[Goodness of Fit](#)” on page 2806 for formulas for the deviance.

One strategy for variable selection is to fit a sequence of models, beginning with a simple model with only an intercept term, and then to include one additional explanatory variable in each successive model. You can measure the importance of the additional explanatory variable by the difference in deviances or fitted log likelihoods between successive models. Asymptotic tests computed by the GENMOD procedure enable you to assess the statistical significance of the additional term.

The GENMOD procedure enables you to fit a sequence of models, up through a maximum number of terms specified in a MODEL statement. A table summarizes twice the difference in log likelihoods between each successive pair of models. This is called a *Type I* analysis in the GENMOD procedure, because it is analogous to Type I (sequential) sums of squares in the GLM procedure. As with the PROC GLM Type I sums of squares, the results from this process depend on the order in which the model terms are fit.

The GENMOD procedure also generates a *Type 3* analysis analogous to Type III sums of squares in the GLM procedure. A Type 3 analysis does not depend on the order in which the terms for the model are specified. A GENMOD procedure Type 3 analysis consists of specifying a model and computing likelihood ratio statistics for Type III contrasts for each term in the model. The contrasts are defined in the same way

as they are in the GLM procedure. The GENMOD procedure optionally computes Wald statistics for Type III contrasts. This is computationally less expensive than likelihood ratio statistics, but it is thought to be less accurate because the specified significance level of hypothesis tests based on the Wald statistic might not be as close to the actual significance level as it is for likelihood ratio tests.

A Type 3 analysis generalizes the use of Type III estimable functions in linear models. Briefly, a Type III estimable function (contrast) for an effect is a linear function of the model parameters that involves the parameters of the effect and any interactions with that effect. A test of the hypothesis that the Type III contrast for a main effect is equal to 0 is intended to test the significance of the main effect in the presence of interactions. See Chapter 42, “[The GLM Procedure](#),” and Chapter 15, “[The Four Types of Estimable Functions](#),” for more information about Type III estimable functions. Also see Littell, Freund, and Spector (1991).

Additional features of the GENMOD procedure include the following:

- likelihood ratio statistics for user-defined contrasts—that is, linear functions of the parameters and p -values based on their asymptotic chi-square distributions
- estimated values, standard errors, and confidence limits for user-defined contrasts and least squares means
- ability to create a SAS data set corresponding to most tables displayed by the procedure (see [Table 40.12](#) and [Table 40.13](#))
- confidence intervals for model parameters based on either the profile likelihood function or asymptotic normality
- syntax similar to that of PROC GLM for the specification of the response and model effects, including interaction terms and automatic coding of classification variables
- ability to fit GEE models for clustered response data
- ability to perform Bayesian analysis by Gibbs sampling

Getting Started: GENMOD Procedure

Poisson Regression

You can use the GENMOD procedure to fit a variety of statistical models. A typical use of PROC GENMOD is to perform Poisson regression.

You can use the Poisson distribution to model the distribution of cell counts in a multiway contingency table. Aitkin et al. (1989) have used this method to model insurance claims data. Suppose the following hypothetical insurance claims data are classified by two factors: age group (with two levels) and car type (with three levels).

```

data insure;
  input n c car$ age;
  ln = log(n);
  datalines;
500  42  small  1
1200 37  medium 1
100   1  large  1
400 101  small  2
500  73  medium 2
300  14  large  2
;

```

In the preceding data set, the variable *n* represents the number of insurance policyholders and the variable *c* represents the number of insurance claims. The variable *car* is the type of car involved (classified into three groups) and the variable *age* is the age group of a policyholder (classified into two groups).

You can use PROC GENMOD to perform a Poisson regression analysis of these data with a log link function. This type of model is sometimes called a *log-linear model*.

Assume that the number of claims *c* has a Poisson probability distribution and that its mean, μ_i , is related to the factors *car* and *age* for observation *i* by

$$\begin{aligned}
 \log(\mu_i) &= \log(n_i) + \mathbf{x}_i' \boldsymbol{\beta} \\
 &= \log(n_i) + \beta_0 + \\
 &\quad \text{car}_i(1)\beta_1 + \text{car}_i(2)\beta_2 + \text{car}_i(3)\beta_3 + \\
 &\quad \text{age}_i(1)\beta_4 + \text{age}_i(2)\beta_5
 \end{aligned}$$

The indicator variables $\text{car}_i(j)$ and $\text{age}_i(j)$ are associated with the *j*th level of the variables *car* and *age* for observation *i*

$$\text{car}_i(j) = \begin{cases} 1 & \text{if } \text{car} = j \\ 0 & \text{if } \text{car} \neq j \end{cases}$$

The β s are unknown parameters to be estimated by the procedure. The logarithm of the variable *n* is used as an *offset*—that is, a regression variable with a constant coefficient of 1 for each observation. A log-linear relationship between the mean and the factors *car* and *age* is specified by the log link function. The log link function ensures that the mean number of insurance claims for each car and age group predicted from the fitted model is positive.

The following statements invoke the GENMOD procedure to perform this analysis:

```

proc genmod data=insure;
  class car age;
  model c = car age / dist    = poisson
                        link   = log
                        offset = ln;
run;

```

The variables `car` and `age` are specified as CLASS variables so that PROC GENMOD automatically generates the indicator variables associated with `car` and `age`.

The MODEL statement specifies `c` as the response variable and `car` and `age` as explanatory variables. An intercept term is included by default. Thus, the model matrix **X** (the matrix that has as its *i*th row the transpose of the covariate vector for the *i*th observation) consists of a column of 1s representing the intercept term and columns of 0s and 1s derived from indicator variables representing the levels of the `car` and `age` variables.

That is, the model matrix is

$$\mathbf{X} = \begin{bmatrix} 1 & 1 & 0 & 0 & 1 & 0 \\ 1 & 0 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 1 \end{bmatrix}$$

where the first column corresponds to the intercept, the next three columns correspond to the variable `car`, and the last two columns correspond to the variable `age`.

The response distribution is specified as Poisson, and the link function is chosen to be log. That is, the Poisson mean parameter μ is related to the linear predictor by

$$\log(\mu) = \mathbf{x}_i' \boldsymbol{\beta}$$

The logarithm of `n` is specified as an offset variable, as is common in this type of analysis. In this case, the offset variable serves to normalize the fitted cell means to a per-policyholder basis, since the total number of claims, not individual policyholder claims, is observed. PROC GENMOD produces the following default output from the preceding statements.

Figure 40.1 Model Information

The GENMOD Procedure	
Model Information	
Data Set	WORK.INSURE
Distribution	Poisson
Link Function	Log
Dependent Variable	c
Offset Variable	ln

The “Model Information” table displayed in Figure 40.1 provides information about the specified model and the input data set.

Figure 40.2 Class Level Information

Class Level Information			
Class	Levels	Values	
car	3	large	medium small
age	2	1	2

Figure 40.2 displays the “Class Level Information” table, which identifies the levels of the classification variables that are used in the model. Note that car is a character variable, and the values are sorted in alphabetical order. This is the default sort order, but you can select different sort orders with the **ORDER=** option in the PROC GENMOD statement.

Figure 40.3 Goodness of Fit

Criteria For Assessing Goodness Of Fit			
Criterion	DF	Value	Value/DF
Deviance	2	2.8207	1.4103
Scaled Deviance	2	2.8207	1.4103
Pearson Chi-Square	2	2.8416	1.4208
Scaled Pearson X2	2	2.8416	1.4208
Log Likelihood		837.4533	
Full Log Likelihood		-16.4638	
AIC (smaller is better)		40.9276	
AICC (smaller is better)		80.9276	
BIC (smaller is better)		40.0946	

The “Criteria For Assessing Goodness Of Fit” table displayed in Figure 40.3 contains statistics that summarize the fit of the specified model. These statistics are helpful in judging the adequacy of a model and in comparing it with other models under consideration. If you compare the deviance of 2.8207 with its asymptotic chi-square with 2 degrees of freedom distribution, you find that the p -value is 0.24. This indicates that the specified model fits the data reasonably well.

Figure 40.4 Analysis of Parameter Estimates

Analysis Of Maximum Likelihood Parameter Estimates						
Parameter		DF	Estimate	Standard Error	Wald 95% Confidence Limits	Wald Chi-Square
Intercept		1	-1.3168	0.0903	-1.4937 -1.1398	212.73
car	large	1	-1.7643	0.2724	-2.2981 -1.2304	41.96
car	medium	1	-0.6928	0.1282	-0.9441 -0.4414	29.18
car	small	0	0.0000	0.0000	0.0000 0.0000	.
age	1	1	-1.3199	0.1359	-1.5863 -1.0536	94.34
age	2	0	0.0000	0.0000	0.0000 0.0000	.
Scale		0	1.0000	0.0000	1.0000 1.0000	

Analysis Of Maximum Likelihood Parameter Estimates		
Parameter		Pr > ChiSq
Intercept		<.0001
car	large	<.0001
car	medium	<.0001
car	small	.
age	1	<.0001
age	2	.
Scale		

NOTE: The scale parameter was held fixed.

Figure 40.4 displays the “Analysis Of Parameter Estimates” table, which summarizes the results of the iterative parameter estimation process. For each parameter in the model, PROC GENMOD displays columns with the parameter name, the degrees of freedom associated with the parameter, the estimated parameter value, the standard error of the parameter estimate, the confidence intervals, and the Wald chi-square statistic and associated *p*-value for testing the significance of the parameter to the model. If a column of the model matrix corresponding to a parameter is found to be linearly dependent, or *aliased*, with columns corresponding to parameters preceding it in the model, PROC GENMOD assigns it zero degrees of freedom and displays a value of zero for both the parameter estimate and its standard error.

This table includes a row for a scale parameter, even though there is no free scale parameter in the Poisson distribution. See the section “[Response Probability Distributions](#)” on page 2799 for the form of the Poisson probability distribution. PROC GENMOD allows the specification of a scale parameter to fit overdispersed Poisson and binomial distributions. In such cases, the SCALE row indicates the value of the overdispersion scale parameter used in adjusting output statistics. See the section “[Overdispersion](#)” on page 2809 for more about overdispersion and the meaning of the SCALE parameter output by the GENMOD procedure. PROC GENMOD displays a note indicating that the scale parameter is fixed—that is, not estimated by the iterative fitting process.

It is usually of interest to assess the importance of the main effects in the model. Type 1 and Type 3 analyses generate statistical tests for the significance of these effects.

You can request these analyses with the TYPE1 and TYPE3 options in the MODEL statement, as follows:

```

proc genmod data=insure;
  class car age;
  model c = car age / dist    = poisson
                    link     = log
                    offset   = ln
                    type1
                    type3;
run;

```

The results of these analyses are summarized in the figures that follow.

Figure 40.5 Type 1 Analysis

The GENMOD Procedure				
LR Statistics For Type 1 Analysis				
Source	Deviance	DF	Chi-Square	Pr > ChiSq
Intercept	175.1536			
car	107.4620	2	67.69	<.0001
age	2.8207	1	104.64	<.0001

In the table for Type 1 analysis displayed in [Figure 40.5](#), each entry in the deviance column represents the deviance for the model containing the effect for that row and all effects preceding it in the table. For example, the deviance corresponding to car in the table is the deviance of the model containing an intercept and car. As more terms are included in the model, the deviance decreases.

Entries in the chi-square column are likelihood ratio statistics for testing the significance of the effect added to the model containing all the preceding effects. The chi-square value of 67.69 for car represents twice the difference in log likelihoods between fitting a model with only an intercept term and a model with an intercept and car. Since the scale parameter is set to 1 in this analysis, this is equal to the difference in deviances. Since two additional parameters are involved, this statistic can be compared with a chi-square distribution with two degrees of freedom. The resulting *p*-value (labeled Pr>Chi) of less than 0.0001 indicates that this variable is highly significant. Similarly, the chi-square value of 104.64 for age represents the difference in log likelihoods between the model with the intercept and car and the model with the intercept, car, and age. This effect is also highly significant, as indicated by the small *p*-value.

Figure 40.6 Type 3 Analysis

LR Statistics For Type 3 Analysis				
Source	DF	Chi-Square	Pr > ChiSq	
car	2	72.82	<.0001	
age	1	104.64	<.0001	

The Type 3 analysis results in the same conclusions as the Type 1 analysis. The Type 3 chi-square value for the car variable, for example, is twice the difference between the log likelihood for the model with the variables Intercept, car, and age included and the log likelihood for the model with the car variable excluded. The hypothesis tested in this case is the significance of the variable car given that the variable age is in the model. In other words, it tests the additional contribution of car in the model.

The values of the Type 3 likelihood ratio statistics for the car and age variables indicate that both of these factors are highly significant in determining the claims performance of the insurance policyholders.

Bayesian Analysis of a Linear Regression Model

Neter et al. (1996) describe a study of 54 patients undergoing a certain kind of liver operation in a surgical unit. The data set Surg contains survival time and certain covariates for each patient. Observations for the first 20 patients in the data set Surg are shown in Figure 40.7.

Figure 40.7 Surgical Unit Data

Obs	x1	x2	x3	x4	y	logy	Logx1
1	6.7	62	81	2.59	200	2.3010	1.90211

11	6.3	84	83	4.13	329	2.5172	1.84055
12	6.7	51	43	1.86	65	1.8129	1.90211
13	5.8	96	114	3.95	830	2.9191	1.75786
14	5.8	83	88	3.95	330	2.5185	1.75786
15	7.7	62	67	3.40	168	2.2253	2.04122
16	7.4	74	68	2.40	217	2.3365	2.00148
17	6.0	85	28	2.98	87	1.9395	1.79176
18	3.7	51	41	1.55	34	1.5315	1.30833
19	7.3	68	74	3.56	215	2.3324	1.98787
20	5.6	57	87	3.02	172	2.2355	1.72277

Consider the model

$$Y = \beta_0 + \beta_1 \text{LogX1} + \beta_2 X2 + \beta_3 X3 + \beta_4 X4 + \epsilon$$

where Y is the survival time, LogX1 is log(blood-clotting score), X2 is a prognostic index, X3 is an enzyme function test score, X4 is a liver function test score, and ϵ is an $N(0, \sigma^2)$ error term.

A question of scientific interest is whether blood clotting score has a positive effect on survival time. Using PROC GENMOD, you can obtain a maximum likelihood estimate of the coefficient and construct a null point hypothesis to test whether β_1 is equal to 0. However, if you are interested in finding the probability that the coefficient is positive, Bayesian analysis offers a convenient alternative. You can use Bayesian analysis to directly estimate the conditional probability, $\Pr(\beta_1 > 0|Y)$, using the posterior distribution samples, which are produced as part of the output by PROC GENMOD.

The example that follows shows how to use PROC GENMOD to carry out a Bayesian analysis of the linear model with a normal error term. The SEED= option is specified to maintain reproducibility; no other options are specified in the BAYES statement. By default, a uniform prior distribution is assumed on the regression coefficients. The uniform prior is a flat prior on the real line with a distribution that reflects ignorance of the location of the parameter, placing equal likelihood on all possible values the regression coefficient can take. Using the uniform prior in the following example, you would expect the Bayesian estimates to resemble the classical results of maximizing the likelihood. If you can elicit an informative prior distribution for the regression coefficients, you should use the COEFFPRIOR= option to specify it. A default noninformative gamma prior is used for the scale parameter σ .

You should make sure that the posterior distribution samples have achieved convergence before using them for Bayesian inference. PROC GENMOD produces three convergence diagnostics by default. If ODS Graphics is enabled as specified in the following SAS statements, diagnostic plots are also displayed. See the section “[Assessing Markov Chain Convergence](#)” on page 139 for more information about convergence diagnostics and their interpretation.

Summary statistics of the posterior distribution samples are produced by default. However, these statistics might not be sufficient for carrying out your Bayesian inference, and further processing of the posterior samples might be necessary. The following SAS statements request the Bayesian analysis, and the OUTPOST= option saves the samples in the SAS data set PostSurg for further processing:

```
proc genmod data=Surg;
  model y = Logx1 X2 X3 X4 / dist=normal;
  bayes seed=1 OutPost=PostSurg;
run;
```

The results of this analysis are shown in the following figures.

The “Model Information” table in [Figure 40.8](#) summarizes information about the model you fit and the size of the simulation.

Intercept	1	-730.559	85.4333	-898.005	-563.112
Logx1	1	171.8758	38.2250	96.9561	246.7954
x2	1	4.3019	0.5566	3.2109	5.3929
x3	1	4.0309	0.4996	3.0517	5.0100
x4	1	18.1377	12.0721	-5.5232	41.7986
Scale	1	59.8591	5.7599	49.5705	72.2832

NOTE: The scale parameter was estimated by maximum likelihood.

Since no prior distributions for the regression coefficients were specified, the default noninformative uniform distributions shown in the “Uniform Prior for Regression Coefficients” table in [Figure 40.10](#) are used. Noninformative priors are appropriate if you have no prior knowledge of the likely range of values of the parameters, and if you want to make probability statements about the parameters or functions of the parameters. See, for example, Ibrahim, Chen, and Sinha (2001) for more information about choosing prior distributions.

Figure 40.10 Regression Coefficient Priors

The GENMOD Procedure

Bayesian Analysis

Uniform Prior for Regression Coefficients

Parameter	Prior
Intercept	Constant
Logx1	Constant
x2	Constant
x3	Constant
x4	Constant

The default noninformative improper prior distribution for the normal dispersion parameter is shown in the “Independent Prior Distributions for Model Parameters” table in [Figure 40.11](#).

Figure 40.11 Scale Parameter Prior

Independent Prior Distributions for Model Parameters	
Parameter	Prior Distribution
Dispersion	Improper

By default, the maximum likelihood estimates of the regression parameters are used as the starting values for the simulation when noninformative prior distributions are used. These are listed in the “Initial Values and Seeds” table in [Figure 40.12](#).

Figure 40.12 MCMC Initial Values and Seeds

Initial Values of the Chain						
Chain	Seed	Intercept	Logx1	x2	x3	x4

Since noninformative prior distributions were used, the posterior sample means, standard deviations, and interval statistics shown in [Figure 40.13](#) and [Figure 40.14](#) are consistent with the maximum likelihood estimates shown in [Figure 40.9](#).

By default, PROC GENMOD computes three convergence diagnostics: the lag1, lag5, lag10, and lag50 autocorrelations ([Figure 40.17](#)); Geweke diagnostic statistics ([Figure 40.18](#)); and effective sample sizes ([Figure 40.19](#)). There is no indication that the Markov chain has not converged. See the section “Assessing Markov Chain Convergence” on page 139 for more information about convergence diagnostics and their interpretation.

Trace, autocorrelation, and density plots for the seven model parameters, shown in [Figure 40.20](#) through [Figure 40.25](#), are useful in diagnosing whether the Markov chain of posterior samples has converged. These plots show no evidence that the chain has not converged. See the section “[Visual Analysis via Trace Plots](#)” on page 139 for help with interpreting these diagnostic plots.

Figure 40.24 Diagnostic Plots for X4

Figure 40.25 Diagnostic Plots for X5

Suppose, for illustration, a question of scientific interest is whether blood clotting score has a positive effect on survival time. Since the model parameters are regarded as random quantities in a Bayesian analysis, you can answer this question by estimating the conditional probability of β_1 being positive, given the data, $\Pr(\beta_1 > 0 | \mathbf{Y})$, from the posterior distribution samples. The following SAS statements compute the estimate of the probability of β_1 being positive:

```
data Prob;
  set PostSurg;
  Indicator = (logX1 > 0);
  label Indicator= 'log(Blood Clotting Score) > 0';
run;

proc Means data = Prob(keep=Indicator) n mean;
run;
```

As shown in Figure 40.26, there is a 1.00 probability of a positive relationship between the logarithm of a blood clotting score and survival time, adjusted for the other covariates.

Figure 40.26 Probability That $\beta_1 > 0$

The MEANS Procedure	
Analysis Variable : Indicator log(Blood Clotting Score) > 0	
N	Mean
10000	0.9999000

Generalized Estimating Equations

This section illustrates the use of the REPEATED statement to fit a GEE model, using repeated measures data from the “Six Cities” study of the health effects of air pollution (Ware et al. 1984). The data analyzed are the 16 selected cases in Lipsitz et al. (1994). The binary response is the wheezing status of 16 children at ages 9, 10, 11, and 12 years. The mean response is modeled as a logistic regression model by using the explanatory variables city of residence, age, and maternal smoking status at the particular age. The binary responses for individual children are assumed to be equally correlated, implying an exchangeable correlation structure.

The data set and SAS statements that fit the model by the GEE method are as follows:

```
data six;
  input case city$ @@;
  do i=1 to 4;
    input age smoke wheeze @@;
    output;
  end;
  datalines;
1 portage 9 0 1 10 0 1 11 0 1 12 0 0
2 kingston 9 1 1 10 2 1 11 2 0 12 2 0
3 kingston 9 0 1 10 0 0 11 1 0 12 1 0
4 portage 9 0 0 10 0 1 11 0 1 12 1 0
5 kingston 9 0 0 10 1 0 11 1 0 12 1 0
6 portage 9 0 0 10 1 0 11 1 0 12 1 0
7 kingston 9 1 0 10 1 0 11 0 0 12 0 0
8 portage 9 1 0 10 1 0 11 1 0 12 2 0
9 portage 9 2 1 10 2 0 11 1 0 12 1 0
10 kingston 9 0 0 10 0 0 11 0 0 12 1 0
11 kingston 9 1 1 10 0 0 11 0 1 12 0 1
12 portage 9 1 0 10 0 0 11 0 0 12 0 0
13 kingston 9 1 0 10 0 1 11 1 1 12 1 1
14 portage 9 1 0 10 2 0 11 1 0 12 2 1
15 kingston 9 1 0 10 1 0 11 1 0 12 2 1
16 portage 9 1 1 10 1 1 11 2 0 12 1 0
;
```

```
proc genmod data=six;  
  class case city;  
  model wheeze = city age smoke / dist=bin;  
  repeated subject=case / type=exch covb corrw;  
run;
```

The CLASS statement and the MODEL statement specify the model for the mean of the wheeze variable response as a logistic regression with city, age, and smoke as independent variables, just as for an ordinary logistic regression.

The REPEATED statement invokes the GEE method, specifies the correlation structure, and controls the displayed output from the GEE model. The option SUBJECT=CASE specifies that individual subjects be identified in the input data set by the variable case. The SUBJECT= variable case must be listed in the CLASS statement. Measurements on individual subjects at ages 9, 10, 11, and 12 are in the proper order in the data set, so the WITHINSUBJECT= option is not required. The TYPE=EXCH option specifies an exchangeable working correlation structure, the COVB option specifies that the parameter estimate covariance matrix be displayed, and the CORRW option specifies that the final working correlation be displayed.

Initial parameter estimates for iterative fitting of the GEE model are computed as in an ordinary generalized linear model, as described previously. Results of the initial model fit displayed as part of the generated output are not shown here. Statistics for the initial model fit such as parameter estimates, standard errors, deviances, and Pearson chi-squares do not apply to the GEE model and are valid only for the initial model fit. The following figures display information that applies to the GEE model fit.

Figure 40.27 displays general information about the GEE model fit.

Figure 40.27 GEE Model Information

The GENMOD Procedure	
GEE Model Information	
Correlation Structure	Exchangeable
Subject Effect	case (16 levels)
Number of Clusters	16
Correlation Matrix Dimension	4
Maximum Cluster Size	4
Minimum Cluster Size	4

Figure 40.28 displays the parameter estimate covariance matrices specified by the COVB option. Both model-based and empirical covariances are produced.

Figure 40.28 GEE Parameter Estimate Covariance Matrices

Covariance Matrix (Model-Based)				
	Prm1	Prm2	Prm4	Prm5
Prm1	5.74947	-0.22257	-0.53472	0.01655
Prm2	-0.22257	0.45478	-0.002410	0.01876

  WEIGHT | SCWGT variable ;
  VARIANCE variable = expression ;
  ZEROMODEL < effects > < / options > ;

```

The **ASSESS**, **BAYES**, **BY**, **CLASS**, **CODE**, **CONTRAST**, **DEVIANCE**, **ESTIMATE**, **FREQUENCY**, **FWDLINK**, **INVLINK**, **MODEL**, **OUTPUT**, programming statements, **REPEATED**, **VARIANCE**, **WEIGHT**, and **ZEROMODEL** statements are described in full after the **PROC GENMOD** statement in alphabetical order. The **EFFECTPLOT**, **LSMEANS**, **LSMESTIMATE**, **SLICE**, and **STORE** statements are common to many procedures. Summary descriptions of functionality and syntax for these statements are also given after the **PROC GENMOD** statement in alphabetical order, and full documentation about them is available in Chapter 19, “Shared Concepts and Topics.”

The **PROC GENMOD** statement invokes the **GENMOD** procedure. All statements other than the **MODEL** statement are optional. The **CLASS** statement, if present, must precede the **MODEL** statement, and the **CONTRAST** and **EXACT** statements must come after the **MODEL** statement.

PROC GENMOD Statement

PROC GENMOD < options > ;

The **PROC GENMOD** statement invokes the **GENMOD** procedure. Table 40.1 summarizes the options available in the **PROC GENMOD** statement.

Table 40.1 PROC GENMOD Statement Options

Option	Description
DATA=	Specifies the input data set
DESCENDING	Sorts response variable in the reverse of the default order
EXACTONLY	Requests only the exact analyses
NAMELEN=	Specifies the length of effect names
ORDER=	Specifies the sort order of CLASS variable
PLOTS	Controls the plots produced through ODS Graphics
RORDER=	Specifies the sort order for the levels of the response variable

You can specify the following options.

DATA=SAS-data-set

specifies the SAS data set containing the data to be analyzed. If you omit the **DATA=** option, the procedure uses the most recently created SAS data set.

DESCENDING

DESCEND

DESC

specifies that the levels of the response variable for the ordinal multinomial model and the binomial model with single variable response syntax be sorted in the reverse of the default order. For example, if **RORDER=FORMATTED** (the default), the **DESCENDING** option causes the levels to be sorted from highest to lowest instead of from lowest to highest. If **RORDER=FREQ**, the **DESCENDING** option causes the levels to be sorted from lowest frequency count to highest instead of from highest to lowest.

EXACTONLY

requests only the exact analyses. The asymptotic analysis that PROC GENMOD usually performs is suppressed.

NAMELEN=*n*

specifies the length of effect names in tables and output data sets to be *n* characters long, where *n* is a value between 20 and 200 characters. The default length is 20 characters.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of the classification variables (which are specified in the [CLASS](#) statement). The ORDER= option can be useful when you use the CONTRAST or ESTIMATE statement because it determines which parameters in the model correspond to each level in the data.

This option applies to the levels for all classification variables, except when you use the (default) ORDER=FORMATTED option with numeric classification variables that have no explicit format. With this option, the levels of such variables are ordered by their internal value.

The ORDER= option can take the following values:

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent. For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PLOTS <(global-plot-option)>= plot-request <(options)>**PLOTS <(global-plot-options)> <= (plot-request <(options)> <...plot-request <(options)>>)>**

specifies plots to be created using ODS Graphics. Many of the observational statistics in the output data set can be plotted using this option. You are not required to create an output data set in order to produce a plot. When you specify only one plot request, you can omit the parentheses around the plot request. Here are some examples:

```
plots=all
plots=predicted
plots=(predicted reschi)
plots(unpack)=dfbeta
```

ODS Graphics must be enabled before plots can be requested. For example:

```
proc genmod plots=all;
  model y = x;
run;
```

For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

Any specified global plot options apply to all plots that are specified with plot requests. The following global plot options are available.

CLUSTERLABEL

displays formatted levels of the SUBJECT= effect instead of plot symbols. This option applies only to diagnostic statistics for models fit by GEEs that are plotted against cluster number, and provides a way to identify cluster level names with corresponding ordered cluster numbers.

UNPACK

displays multiple plots individually. The default is to display related multiple plots in a panel.

See the section “[OUTPUT Statement](#)” on page 2787 for definitions of the statistics specified with the plot requests. The plot requests include the following:

ALL

produces all available plots.

COOKSD

DOBS

plots the Cook’s distance statistic as a function of observation number.

DFBETA

plots the β deletion statistic as a function of observation number for each regression parameter in the model.

DFBETAS

plots the standardized β deletion statistic as a function of observation number for each regression parameter in the model.

LEVERAGE

plots the leverage as a function of observation number.

PREDICTED<(option)>

plots predicted values with confidence limits as a function of observation number. The PREDICTED plot request has the following *option*:

CLM

includes confidence limits in the predicted value plot.

PZERO

plots the zero inflation probability for zero-inflated Poisson and negative binomial models as a function of observation number.

RESCHI<(options)>

The RESCHI plot request has the following *options*:

INDEX

plots as a function of observation number.

XBETA

plots as a function of linear predictor.

If you do not specify an option, Pearson residuals are plotted as a function of observation number.

RESDEV<(options)>

plots deviance residuals. The RESDEV plot request has the following *options*:

INDEX

plots as a function of observation number.

XBETA

plots as a function of linear predictor.

If you do not specify an option, deviance residuals are plotted as a function of observation number.

RESLIK<(options)>

plots likelihood residuals. The RESLIK plot request has the following *options*:

INDEX

plots as a function of observation number.

XBETA

plots as a function of linear predictor.

If you do not specify an option, likelihood residuals are plotted as a function of observation number.

RESRAW<(options)>

plots raw residuals. The RESRAW plot request has the following *options*:

INDEX

plots as a function of observation number.

XBETA

plots as a function of linear predictor.

If you do not specify an option, raw residuals are plotted as a function of observation number.

STDRESCHI<(options)>

plots standardized Pearson residuals. The STDRESCHI plot request has the following *options*:

INDEX

plots as a function of observation number.

XBETA

plots as a function of linear predictor.

If you do not specify an option, standardized Pearson residuals are plotted as a function of observation number.

STDRESDEV<(options)>

plots standardized deviance residuals. The STDRESDEV plot request has the following *options*:

INDEX

plots as a function of observation number.

XBETA

plots as a function of linear predictor.

If you do not specify an option, standardized deviance residuals are plotted as a function of observation number.

If you fit a model by using generalized estimating equations (GEEs), the following additional plot requests are available:

CLEVERAGE

plots the cluster leverage as a function of ordered cluster.

CLUSTERCOOKSD**DCLS**

plots the cluster Cook's distance statistic as a function of ordered cluster.

CLUSTERDFIT**MCLS**

plots the studentized cluster Cook's distance statistic as a function of ordered cluster.

DFBETAC

plots the cluster deletion statistic as a function of ordered cluster for each regression parameter in the model.

DFBETACS

plots the standardized cluster deletion statistic as a function of ordered cluster for each regression parameter in the model.

RORDER=keyword

specifies the sort order for the levels of the response variable. This order determines which intercept parameter in the model corresponds to each level in the data. If RORDER=FORMATTED for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. The following table displays the valid *keywords* and describes how PROC GENMOD interprets them.

RORDER=keyword	Levels Sorted by
DATA	Order of appearance in the input data set
FORMATTED	External formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	Descending frequency count; levels with the most observations come first in the order
INTERNAL	Unformatted value

By default, RORDER=FORMATTED. For RORDER=FORMATTED and RORDER=INTERNAL, the sort order is machine dependent. The DESCENDING option in the PROC GENMOD statement causes the response variable to be sorted in the reverse of the order displayed in the previous table. For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide*.

The NOPRINT option, which suppresses displayed output in other SAS procedures, is not available in the PROC GENMOD statement. However, you can use the Output Delivery System (ODS) to suppress all displayed output, store all output on disk for further analysis, or create SAS data sets from selected output. You can suppress all displayed output with the statement **ODS SELECT NONE;** and turn displayed output back on with the statement **ODS SELECT ALL;**. See [Table 40.12](#) and [Table 40.13](#) for the names of output tables available from PROC GENMOD. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

ASSESS Statement

ASSESS VAR=(effect)| LINK </ options> ;

ASSESSMENT VAR=(effect)| LINK </ options> ;

The ASSESS statement computes and plots, using ODS Graphics, model-checking statistics based on aggregates of residuals. See the section “[Assessment of Models Based on Aggregates of Residuals](#)” on page 2827 for details about the model assessment methods available in GENMOD.

The types of aggregates available are cumulative residuals, moving sums of residuals, and loess smoothed residuals. If you do not specify which aggregate to use, the assessments are based on cumulative sums. PROC GENMOD uses ODS Graphics for graphical displays. For specific information about the graphics available in PROC GENMOD, see the section “[ODS Graphics](#)” on page 2856.

You must specify either LINK or VAR= in order to create an analysis.

LINK requests the assessment of the link function by performing the analysis with respect to the linear predictor.

VAR=(effect) specifies that the functional form of a covariate be checked by performing the analysis with respect to the variable identified by the effect. The effect must be specified in the MODEL statement and must contain only continuous variables (variables not listed in a CLASS statement).

You can specify the following options after the slash (/).

CRPANEL

requests that a plot with four panels showing just a few of the paths from the default aggregate plot to make it easier to compare simulated and observed paths. The plot in each panel contains aggregates of the observed residuals and two simulated curves (fewer if `NPATHS=` is less than 8).

LOESS< (*number*) >**LOWESS**< (*number*) >

requests model assessment based on loess smoothed residuals with optional *number* the fraction of data used; *number* must be between zero and one. If *number* is not specified, the default value one-third is used.

NPATHS=*number***NPATH**=*number***PATHS**=*number***PATH**=*number*

specifies the number of simulated paths to plot in the default aggregate residuals plot. The default value of *number* is twenty.

RESAMPLE< =*number* >**RESAMPLES**< =*number* >

specifies that a *p*-value be computed based on 1,000 simulated paths, or *number* paths, if *number* is specified.

SEED=*number*

specifies a seed for the normal random number generator used in creating simulated realizations of aggregates of residuals for plots and estimating *p*-values. Specifying a seed enables you to produce identical graphs and *p*-values from one run of the procedure to the next run. If a seed is not specified, or if *number* is negative or zero, a random number seed is derived from the time of day.

WINDOW< (*number*) >

requests assessment based on a moving sum window of width *number*. If *number* is not specified, a value of one-half of the range of the *x*-coordinate is used.

BAYES Statement

BAYES < *options* > ;

The BAYES statement requests a Bayesian analysis of the regression model by using Gibbs sampling. The Bayesian posterior samples (also known as the chain) for the regression parameters are not tabulated. The Bayesian posterior samples (also known as the chain) for the regression parameters can be output to a SAS data set. [Table 40.2](#) summarizes the options available in the BAYES statement.

Table 40.2 BAYES Statement Options

Option	Description
Monte Carlo Options	
INITIAL=	Specifies the initial values of the chain

Table 40.2 (continued)

Option	Description
INITIALMLE	Specifies that maximum likelihood estimates be used as initial values of the chain
METROPOLIS=	Specifies the use of a Metropolis step in the ARMS algorithm
NBI=	Specifies the number of burn-in iterations
NMC=	Specifies the number of iterations after burn-in
SAMPLING=	Specifies the algorithm used to sample the posterior distribution
SEED=	Specifies the random number generator seed
THINNING=	Controls the thinning of the Markov chain
Model and Prior Options	
COEFFPRIOR=	Specifies the prior of the regression coefficients
DISPERSIONPRIOR=	Specifies the prior of the dispersion parameter
PRECISIONPRIOR=	Specifies the prior of the precision parameter
SCALEPRIOR=	Specifies the prior of the scale parameter
Summary Statistics and Convergence Diagnostics	
DIAGNOSTICS=	Displays convergence diagnostics
PLOTS=	Displays diagnostic plots
STATISTICS=	Displays summary statistics of the posterior samples
Posterior Samples	
OUTPOST=	Names a SAS data set for the posterior samples

The following list describes these options and their suboptions.

COEFFPRIOR=JEFFREYS< (option) > | **NORMAL**< (options) > | **UNIFORM**

COEFF=JEFFREYS< (options) > | **NORMAL**< (options) > | **UNIFORM**

CPRIOR=JEFFREYS< (options) > | **NORMAL**< (options) > | **UNIFORM**

specifies the prior distribution for the regression coefficients. The default is COEFFPRIOR=UNIFORM, which specifies the noninformative and improper prior of a constant.

Jeffreys' prior is specified by COEFFPRIOR=JEFFREYS, which can be followed by the following option in parentheses. Jeffreys' prior is proportional to $|I(\boldsymbol{\beta})|^{-\frac{1}{2}}$, where $I(\boldsymbol{\beta})$ is the Fisher information matrix. See the section “Jeffreys' Prior” on page 2837 and Ibrahim and Laud (1991) for more details.

CONDITIONAL

specifies that the Jeffreys' prior, conditional on the current Markov chain value of the generalized linear model precision parameter τ , is proportional to $|\tau I(\boldsymbol{\beta})|^{-\frac{1}{2}}$.

The normal prior is specified by COEFFPRIOR=NORMAL, which can be followed by one of the following options enclosed in parentheses. However, if you do not specify an option, the normal prior $N(\mathbf{0}, 10^6 \mathbf{I})$, where \mathbf{I} is the identity matrix, is used. See the section “Normal Prior” on page 2837 for more details.

CONDITIONAL

specifies that the normal prior, conditional on the current Markov chain value of the generalized linear model precision parameter τ , is $N(\boldsymbol{\mu}, \tau^{-1} \boldsymbol{\Sigma})$, where $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are the mean and covariance of the normal prior specified by other normal options.

INPUT=SAS-data-set

specifies a SAS data set containing the mean and covariance information of the normal prior. The data set must have a `_TYPE_` variable to represent the type of each observation and a variable for each regression coefficient. If the data set also contains a `_NAME_` variable, the values of this variable are used to identify the covariances for the `_TYPE_='COV'` observations; otherwise, the `_TYPE_='COV'` observations are assumed to be in the same order as the explanatory variables in the MODEL statement. PROC GENMOD reads the mean vector from the observation with `_TYPE_='MEAN'` and reads the covariance matrix from observations with `_TYPE_='COV'`. For an independent normal prior, the variances can be specified with `_TYPE_='VAR'`; alternatively, the precisions (inverse of the variances) can be specified with `_TYPE_='PRECISION'`.

RELVAR<=c>

specifies the normal prior $N(\mathbf{0}, c\mathbf{J})$, where \mathbf{J} is a diagonal matrix with diagonal elements equal to the variances of the corresponding ML estimator. By default, $c = 10^6$.

VAR<=c>

specifies the normal prior $N(\mathbf{0}, c\mathbf{I})$, where \mathbf{I} is the identity matrix.

DIAGNOSTICS=ALL | NONE | (keyword-list)**DIAG=ALL | NONE | (keyword-list)**

controls the number of diagnostics produced. You can request all the following diagnostics by specifying `DIAGNOSTICS=ALL`. If you do not want any of these diagnostics, specify `DIAGNOSTICS=NONE`. If you want some but not all of the diagnostics, or if you want to change certain settings of these diagnostics, specify a subset of the following keywords. The default is `DIAGNOSTICS=(AUTOCORR ESS GEWEKE)`.

AUTOCORR <(LAGS= numeric-list)>

computes the autocorrelations of lags given by `LAGS=` list for each parameter. Elements in the list are truncated to integers and repeated values are removed. If the `LAGS=` option is not specified, autocorrelations of lags 1, 5, 10, and 50 are computed for each variable. See the section “[Autocorrelations](#)” on page 152 for details.

ESS

computes Carlin’s estimate of the effective sample size, the correlation time, and the efficiency of the chain for each parameter. See the section “[Effective Sample Size](#)” on page 152 for details.

GELMAN <(gelman-options)>

computes the Gelman and Rubin convergence diagnostics. You can specify one or more of the following *gelman-options*:

NCHAIN | N=number

specifies the number of parallel chains used to compute the diagnostic, and must be 2 or larger. The default is `NCHAIN=3`. If an `INITIAL=` data set is used, `NCHAIN` defaults to the number of rows in the `INITIAL=` data set. If any number other than this is specified with the `NCHAIN=` option, the `NCHAIN=` value is ignored.

ALPHA=value

specifies the significance level for the upper bound. The default is ALPHA=0.05, resulting in a 97.5% bound.

See the section “[Gelman and Rubin Diagnostics](#)” on page 145 for details.

GEWEKE < (geweke-options) >

computes the Geweke spectral density diagnostics, which are essentially a two-sample t test between the first f_1 portion and the last f_2 portion of the chain. The default is $f_1 = 0.1$ and $f_2 = 0.5$, but you can choose other fractions by using the following *geweke-options*:

FRAC1=value

specifies the fraction f_1 for the first window.

FRAC2=value

specifies the fraction f_2 for the second window.

See the section “[Geweke Diagnostics](#)” on page 146 for details.

HEIDELBERGER < (heidel-options) >

computes the Heidelberg and Welch diagnostic for each variable, which consists of a stationarity test of the null hypothesis that the sample values form a stationary process. If the stationarity test is not rejected, a halfwidth test is then carried out. Optionally, you can specify one or more of the following *heidel-options*:

SALPHA=value

specifies the α level ($0 < \alpha < 1$) for the stationarity test.

HALPHA=value

specifies the α level ($0 < \alpha < 1$) for the halfwidth test.

EPS=value

specifies a positive number ϵ such that if the halfwidth is less than ϵ times the sample mean of the retained iterates, the halfwidth test is passed.

See the section “[Heidelberg and Welch Diagnostics](#)” on page 148 for details.

MCSE**MCERROR**

computes the Monte Carlo standard error for each parameter. The Monte Carlo standard error, which measures the simulation accuracy, is the standard error of the posterior mean estimate and is calculated as the posterior standard deviation divided by the square root of the effective sample size. See the section “[Standard Error of the Mean Estimate](#)” on page 153 for details.

RAFTERY < (raftery-options) >

computes the Raftery and Lewis diagnostics that evaluate the accuracy of the estimated quantile ($\hat{\theta}_Q$ for a given $Q \in (0, 1)$) of a chain. $\hat{\theta}_Q$ can achieve any degree of accuracy when the chain is allowed to run for a long time. A stopping criterion is when the estimated probability $\hat{P}_Q = \Pr(\theta \leq \hat{\theta}_Q)$ reaches within $\pm R$ of the value Q with probability S ; that is, $\Pr(Q - R \leq \hat{P}_Q \leq Q + R) = S$. The following *raftery-options* enable you to specify Q , R , S , and a precision level ϵ for the test:

QUANTILE | Q=value

specifies the order (a value between 0 and 1) of the quantile of interest. The default is 0.025.

ACCURACY | R=value

specifies a small positive number as the margin of error for measuring the accuracy of estimation of the quantile. The default is 0.005.

PROBABILITY | S=value

specifies the probability of attaining the accuracy of the estimation of the quantile. The default is 0.95.

EPSILON | EPS=value

specifies the tolerance level (a small positive number) for the stationary test. The default is 0.001.

See the section “[Raftery and Lewis Diagnostics](#)” on page 149 for details.

DISPERSIONPRIOR=GAMMA< (options)> | IGAMMA< (options)> | IMPROPER**DPRIOR=GAMMA< (options)> | IGAMMA< (options)> | IMPROPER**

specifies that Gibbs sampling be performed on the generalized linear model dispersion parameter and the prior distribution for the dispersion parameter, if there is a dispersion parameter in the model. For models that do not have a dispersion parameter (the Poisson and binomial), this option is ignored. Note that you can specify Gibbs sampling on either the dispersion parameter ϕ , the scale parameter $\sigma = \phi^{\frac{1}{2}}$, or the precision parameter $\tau = \phi^{-1}$, with the DPRIOR=, SPRIOR=, and PPRIOR= options, respectively. These three parameters are transformations of one another, and you should specify Gibbs sampling for only one of them.

A gamma prior $G(a, b)$ with density $f(t) = \frac{b(b t)^{a-1} e^{-b t}}{\Gamma(a)}$ is specified by DISPERSIONPRIOR=GAMMA, which can be followed by one of the following *gamma-options* enclosed in parentheses. The hyperparameters a and b are the shape and inverse-scale parameters of the gamma distribution, respectively. See the section “[Gamma Prior](#)” on page 2836 for details. The default is $G(10^{-4}, 10^{-4})$.

RELSHAPE<=c>

specifies independent $G(c\hat{\phi}, c)$ distribution, where $\hat{\phi}$ is the MLE of the dispersion parameter. With this choice of hyperparameters, the mean of the prior distribution is $\hat{\phi}$ and the variance is $\frac{\hat{\phi}}{c}$. By default, $c=10^{-4}$.

SHAPE=a**ISCALE=b**

when both specified, results in a $G(a, b)$ prior.

SHAPE=c

when specified alone, results in a $G(c, c)$ prior.

ISCALE=c

when specified alone, results in a $G(c, c)$ prior.

An inverse gamma prior $IG(a, b)$ with density $f(t) = \frac{b^a}{\Gamma(a)} t^{-(a+1)} e^{-b/t}$ is specified by DISPERSIONPRIOR=IGAMMA, which can be followed by one of the following *inverse gamma-options*

enclosed in parentheses. The hyperparameters a and b are the shape and scale parameters of the inverse gamma distribution, respectively. See the section “[Inverse Gamma Prior](#)” on page 2837 for details. The default is $\text{IG}(2.001, 0.001)$.

RELSHAPE=<c>

specifies independent $\text{IG}(\frac{c+\hat{\phi}}{\hat{\phi}}, c)$ distribution, where $\hat{\phi}$ is the MLE of the dispersion parameter.

With this choice of hyperparameters, the mean of the prior distribution is $\hat{\phi}$. By default, $c=10^{-4}$.

SHAPE=a

SCALE=b

when both specified, results in a $\text{IG}(a, b)$ prior.

SHAPE=c

when specified alone, results in an $\text{IG}(c, c)$ prior.

SCALE=c

when specified alone, results in an $\text{IG}(c, c)$ prior.

An improper prior with density $f(t)$ proportional to t^{-1} is specified with `DISPERSION-PRIOR=IMPROPER`.

INITIAL=SAS-data-set

specifies the SAS data set that contains the initial values of the Markov chains. The INITIAL= data set must contain all the variables of the model. You can specify multiple rows as the initial values of the parallel chains for the Gelman-Rubin statistics, but posterior summaries, diagnostics, and plots are computed only for the first chain. If the data set also contains the variable `_SEED_`, the value of the `_SEED_` variable is used as the seed of the random number generator for the corresponding chain.

INITIALMLE

specifies that maximum likelihood estimates of the model parameters be used as initial values of the Markov chain. If this option is not specified, estimates of the mode of the posterior distribution obtained by optimization are used as initial values.

METROPOLIS=YES

METROPOLIS=NO

specifies the use of a Metropolis step to generate Gibbs samples for posterior distributions that are not log concave. The default value is `METROPOLIS=YES`.

NBI=number

specifies the number of burn-in iterations before the chains are saved. The default is 2000.

NMC=number

specifies the number of iterations after the burn-in. The default is 10000.

OUTPOST=SAS-data-set

OUT=SAS-data-set

names the SAS data set that contains the posterior samples. See the sections “[OUTPOST= Output Data Set](#)” on page 2839 and “[Posterior Samples Output Data Set](#)” on page 2836 for more information. Alternatively, you can create the output data set by specifying an `ODS OUTPUT` statement as follows:

ODS OUTPUT POSTERIORSAMPLE=SAS-data-set

PRECISIONPRIOR=GAMMA< (options)> | IMPROPER**PPRIOR=GAMMA< (options)> | IMPROPER**

specifies that Gibbs sampling be performed on the generalized linear model precision parameter and the prior distribution for the precision parameter, if there is a precision parameter in the model. For models that do not have a precision parameter (the Poisson and binomial), this option is ignored. Note that you can specify Gibbs sampling on either the dispersion parameter ϕ , the scale parameter $\sigma = \phi^{\frac{1}{2}}$, or the precision parameter $\tau = \phi^{-1}$, with the DPRIOR=, SPRIOR=, and PPRIOR= options, respectively. These three parameters are transformations of one another, and you should specify Gibbs sampling for only one of them.

A gamma prior $G(a, b)$ with density $f(t) = \frac{b(bt)^{a-1}e^{-bt}}{\Gamma(a)}$ is specified by PRECISIONPRIOR=GAMMA, which can be followed by one of the following *gamma-options* enclosed in parentheses. The hyperparameters a and b are the shape and inverse-scale parameters of the gamma distribution, respectively. See the section “Gamma Prior” on page 2836 for details. The default is $G(10^{-4}, 10^{-4})$.

RELSHAPE=<c>

specifies independent $G(c\hat{\tau}, c)$ distribution, where $\hat{\tau}$ is the MLE of the dispersion parameter. With this choice of hyperparameters, the mean of the prior distribution is $\hat{\tau}$ and the variance is $\frac{\hat{\tau}}{c}$. By default, $c = 10^{-4}$.

SHAPE=a**ISCALE=b**

when both specified, results in a $G(a, b)$ prior.

SHAPE=c

when specified alone, results in an $G(c, c)$ prior.

ISCALE=c

when specified alone, results in an $G(c, c)$ prior.

An improper prior with density $f(t)$ proportional to t^{-1} is specified with PRECISIONPRIOR=IMPROPER.

PLOTS< (global-plot-options)>= plot-request**PLOTS< (global-plot-options)>= (plot-request < ... plot-request>)**

controls the display of diagnostic plots. Three types of plots can be requested: trace plots, autocorrelation function plots, and kernel density plots. By default, the plots are displayed in panels unless the global plot option UNPACK is specified. Also, when you are specifying more than one type of plots, the plots are displayed by parameters unless the global plot option GROUPBY is specified. When you specify only one plot request, you can omit the parentheses around the plot request. For example:

```
plots=none
plots(unpack)=trace
plots=(trace autocorr)
```

ODS Graphics must be enabled before requesting plots. For example, the following SAS statements enable ODS Graphics:

```
ods graphics on;
proc genmod;
  model y=x;
  bayes plots=trace;
run;
ods graphics off;
```

The global plot options are as follows:

FRINGE

creates a fringe plot on the X axis of the density plot.

GROUPBY=PARAMETER

GROUPBY=TYPE

specifies how the plots are grouped when there is more than one type of plot.

GROUPBY=TYPE

specifies that the plots be grouped by type.

GROUPBY=PARAMETER

specifies that the plots be grouped by parameter.

GROUPBY=PARAMETER is the default.

LAGS= n

specifies that autocorrelations be plotted up to lag n . If this option is not specified, autocorrelations are plotted up to lag 50.

SMOOTH

displays a fitted penalized B-spline curve for each trace plot.

UNPACKPANEL

UNPACK

specifies that all paneled plots be unpacked, meaning that each plot in a panel is displayed separately.

The plot requests include the following:

ALL

specifies all types of plots. PLOTS=ALL is equivalent to specifying PLOTS=(TRACE AUTO-CORR DENSITY).

AUTOCORR

displays the autocorrelation function plots for the parameters.

DENSITY

displays the kernel density plots for the parameters.

NONE

suppresses all diagnostic plots.

TRACE

displays the trace plots for the parameters. See the section “[Visual Analysis via Trace Plots](#)” on page 139 for details.

SAMPLING=option

specifies an algorithm used to sample the posterior distribution. The following options are available:

ARMS**GIBBS**

use the ARMS algorithm. This is the default method except for the normal distribution with a conjugate prior. In this case a closed form for the posterior distribution is available, and samples are obtained directly from the posterior distribution.

GAMERMAN**GAM**

use the Gamerman algorithm.

IM

Use the independent Metropolis algorithm.

SCALEPRIOR=GAMMA< options > | IMPROPER**SPRIOR=GAMMA< options > | IMPROPER**

specifies that Gibbs sampling be performed on the generalized linear model scale parameter and the prior distribution for the scale parameter, if there is a scale parameter in the model. For models that do not have a scale parameter (the Poisson and binomial), this option is ignored. Note that you can specify Gibbs sampling on either the dispersion parameter ϕ , the scale parameter $\sigma = \phi^{\frac{1}{2}}$, or the precision parameter $\tau = \phi^{-1}$, with the DPRIOR=, SPRIOR=, and PPRIOR= options, respectively. These three parameters are transformations of one another, and you should specify Gibbs sampling for only one of them.

A gamma prior $G(a, b)$ with density $f(t) = \frac{b(bt)^{a-1}e^{-bt}}{\Gamma(a)}$ is specified by SCALEPRIOR=GAMMA, which can be followed by one of the following *gamma-options* enclosed in parentheses. The hyperparameters a and b are the shape and inverse-scale parameters of the gamma distribution, respectively. See the section “[Gamma Prior](#)” on page 2836 for details. The default is $G(10^{-4}, 10^{-4})$.

RELSHAPE<=c>

specifies independent $G(c\hat{\sigma}, c)$ distribution, where $\hat{\sigma}$ is the MLE of the dispersion parameter. With this choice of hyperparameters, the mean of the prior distribution is $\hat{\sigma}$ and the variance is $\frac{\hat{\sigma}}{c}$. By default, $c = 10^{-4}$.

SHAPE=a**ISCALE=b**

when both specified, results in a $G(a, b)$ prior.

SHAPE=*c*

when specified alone, results in an $G(c, c)$ prior.

ISCALE=*c*

when specified alone, results in an $G(c, c)$ prior.

An improper prior with density $f(t)$ proportional to t^{-1} is specified with SCALEPRIOR=IMPROPER.

SEED=*number*

specifies an integer seed in the range 1 to $2^{31} - 1$ for the random number generator in the simulation. Specifying a seed enables you to reproduce identical Markov chains for the same specification. If the SEED= option is not specified, or if you specify a nonpositive seed, a random seed is derived from the time of day.

STATISTICS < (*global-options*) > = ALL | NONE | *keyword* | (*keyword-list*)**STATS < (*global-options*) > = ALL | NONE | *keyword* | (*keyword-list*)**

controls the number of posterior statistics produced. Specifying STATISTICS=ALL is equivalent to specifying STATISTICS= (SUMMARY INTERVAL COV CORR). If you do not want any posterior statistics, you specify STATISTICS=NONE. The default is STATISTICS=(SUMMARY INTERVAL). See the section “[Summary Statistics](#)” on page 153 for details. The *global-options* include the following:

ALPHA=*numeric-list*

controls the probabilities of the credible intervals. The ALPHA= values must be between 0 and 1. Each ALPHA= value produces a pair of $100(1-\text{ALPHA})\%$ equal-tail and HPD intervals for each parameters. The default is the value of the ALPHA= option in the MODEL statement, or 0.05 if that option is not specified (yielding the 95% credible intervals for each parameter).

PERCENT=*numeric-list*

requests the percentile points of the posterior samples. The PERCENT= values must be between 0 and 100. The default is PERCENT=25, 50, 75, which yield the 25th, 50th, and 75th percentile points, respectively, for each parameter.

The list of *keywords* includes the following:

CORR

produces the posterior correlation matrix.

COV

produces the posterior covariance matrix.

SUMMARY

produces the means, standard deviations, and percentile points for the posterior samples. The default is to produce the 25th, 50th, and 75th percentile points, but you can use the global PERCENT= option to request specific percentile points.

INTERVAL

produces equal-tail credible intervals and HPD intervals. The default is to produce the 95% equal-tail credible intervals and 95% HPD intervals, but you can use the global ALPHA= option to request intervals of any probabilities.

THINNING=*number*

THIN=*number*

controls the thinning of the Markov chain. Only one in every k samples is used when **THINNING**= k , and if **NBI**= n_0 and **NMC**= n , the number of samples kept is

$$\left[\frac{n_0 + n}{k} \right] - \left[\frac{n_0}{k} \right]$$

where $[a]$ represents the integer part of the number a . The default is **THINNING**=1.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC GENMOD to obtain separate analyses of observations in groups that are defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If you specify more than one BY statement, only the last one specified is used.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data by using the SORT procedure with a similar BY statement.
- Specify the NOTSORTED or DESCENDING option in the BY statement for the GENMOD procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables by using the DATASETS procedure (in Base SAS software).

For more information about BY-group processing, see the discussion in *SAS Language Reference: Concepts*. For more information about the DATASETS procedure, see the discussion in the *Base SAS Procedures Guide*.

CLASS Statement

CLASS *variable* <(*options*)> ... <*variable* <(*options*)>> </*global-options*> ;

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. Response variables do not need to be specified in the CLASS statement.

The CLASS statement must precede the **MODEL** statement. Most options can be specified either as individual variable *options* or as *global-options*. You can specify *options* for each variable by enclosing the options in parentheses after the variable name. You can also specify *global-options* for the CLASS statement by placing them after a slash (/). *Global-options* are applied to all the variables specified in the CLASS

statement. If you specify more than one CLASS statement, the *global-options* specified in any one CLASS statement apply to all CLASS statements. However, individual CLASS variable *options* override the *global-options*. You can specify the following values for either an *option* or a *global-option*:

CPREFIX=*n*

specifies that, at most, the first *n* characters of a CLASS variable name be used in creating names for the corresponding design variables. The default is $32 - \min(32, \max(2, f))$, where *f* is the formatted length of the CLASS variable.

DESCENDING

DESC

reverses the sort order of the classification variable. If both the DESCENDING and **ORDER=** options are specified, PROC GENMOD orders the categories according to the ORDER= option and then reverses that order.

LPREFIX=*n*

specifies that, at most, the first *n* characters of a CLASS variable label be used in creating labels for the corresponding design variables. The default is $256 - \min(256, \max(2, f))$, where *f* is the formatted length of the CLASS variable.

MISSING

treats missing values ('.', '_', 'A', ..., 'Z' for numeric variables and blanks for character variables) as valid values for the CLASS variable.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of classification variables. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option can be useful when you use the CONTRAST statement. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine-dependent. When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values.

The following table shows how PROC GENMOD interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	Order of appearance in the input data set
FORMATTED	External formatted values, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) values
FREQ	Descending frequency count; levels with more observations come earlier in the order
INTERNAL	Unformatted value

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PARAM=keyword

specifies the parameterization method for the classification variable or variables. You can specify any of the *keywords* shown in the following table; Design matrix columns are created from CLASS variables according to the corresponding coding schemes:

Value of PARAM=	Coding
EFFECT	Effect coding
GLM	Less-than-full-rank reference cell coding (this <i>keyword</i> can be used only in a global option)
ORDINAL THERMOMETER	Cumulative parameterization for an ordinal CLASS variable
POLYNOMIAL POLY	Polynomial coding
REFERENCE REF	Reference cell coding
ORTHEFFECT	Orthogonalizes PARAM=EFFECT coding
ORTHORDINAL ORTHOTHERM	Orthogonalizes PARAM=ORDINAL coding
ORTHPOLY	Orthogonalizes PARAM=POLYNOMIAL coding
ORTHREF	Orthogonalizes PARAM=REFERENCE coding

All parameterizations are full rank, except for the GLM parameterization. The **REF=** option in the CLASS statement determines the reference level for EFFECT and REFERENCE coding and for their orthogonal parameterizations. It also indirectly determines the reference level for a singular GLM parameterization through the order of levels.

If PARAM=ORTHPOLY or PARAM=POLY and the classification variable is numeric, then the **ORDER=** option in the CLASS statement is ignored, and the internal unformatted values are used. See the section “Other Parameterizations” on page 387 of Chapter 19, “Shared Concepts and Topics,” for further details.

REF= 'level' | *keyword*

specifies the reference level for **PARAM=EFFECT**, **PARAM=REFERENCE**, and their orthogonalizations. For **PARAM=GLM**, the REF= option specifies a level of the classification variable to be put at the end of the list of levels. This level thus corresponds to the reference level in the usual interpretation of the linear estimates with a singular parameterization.

For an individual variable REF= option (but not for a global REF= option), you can specify the *level* of the variable to use as the reference level. Specify the formatted value of the variable if a format is assigned. For a global or individual variable REF= option, you can use one of the following *keywords*. The default is REF=LAST.

FIRST designates the first ordered level as reference.

LAST designates the last ordered level as reference.

TRUNCATE $\langle =n \rangle$

specifies the length n of CLASS variable values to use in determining CLASS variable levels. The default is to use the full formatted length of the CLASS variable. If you specify TRUNCATE without the length n , the first 16 characters of the formatted values are used. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases before SAS 9. The TRUNCATE option is available only as a global option.

Class Variable Default Parameterization

If you do not specify the PARAM= option, the default PARAM=GLM parameterization is used.

Class Variable Naming Convention

Parameter names for a CLASS predictor variable are constructed by concatenating the CLASS variable name with the CLASS levels. However, for the POLYNOMIAL and orthogonal parameterizations, parameter names are formed by concatenating the CLASS variable name and keywords that reflect the parameterization. See the section “Other Parameterizations” on page 387 in Chapter 19, “Shared Concepts and Topics,” for examples and further details.

Class Variable Parameterization with Unbalanced Designs

PROC GENMOD initially parameterizes the CLASS variables by looking at the levels of the variables across the complete data set. If you have an *unbalanced* replication of levels across variables or BY groups, then the design matrix and the parameter interpretation might be different from what you expect. For instance, suppose you have a model with one CLASS variable A with three levels (1, 2, and 3), and another CLASS variable B with two levels (1 and 2). If the third level of A occurs only with the first level of B, if you use the EFFECT parameterization, and if your model contains the effect A(B) and an intercept, then the design for A within the second level of B is not a differential effect. In particular, the design looks like the following:

		Design Matrix			
		A(B=1)		A(B=2)	
B	A	A1	A2	A1	A2
1	1	1	0	0	0
1	2	0	1	0	0
1	3	-1	-1	0	0
2	1	0	0	1	0
2	2	0	0	0	1

PROC GENMOD detects linear dependency among the last two design variables and sets the parameter for A2(B=2) to zero, resulting in an interpretation of these parameters as if they were reference- or dummy-coded. The REFERENCE or GLM parameterization might be more appropriate for such problems.

CODE Statement

CODE $\langle options \rangle$;

The CODE statement enables you to write SAS DATA step code for computing predicted values of the fitted model either to a file or to a catalog entry. This code can then be included in a DATA step to score new data.

Table 40.3 summarizes the *options* available in the CODE statement.

Table 40.3 CODE Statement Options

Option	Description
CATALOG=	Names the catalog entry where the generated code is saved
DUMMIES	Retains the dummy variables in the data set
ERROR	Computes the error function
FILE=	Names the file where the generated code is saved
FORMAT=	Specifies the numeric format for the regression coefficients
GROUP=	Specifies the group identifier for array names and statement labels
IMPUTE	Imputes predicted values for observations with missing or invalid covariates
LINESIZE=	Specifies the line size of the generated code
LOOKUP=	Specifies the algorithm for looking up CLASS levels
RESIDUAL	Computes residuals

For details about the syntax of the CODE statement, see the section “[CODE Statement](#)” on page 390 in Chapter 19, “[Shared Concepts and Topics](#).”

CONTRAST Statement

CONTRAST *'label' contrast-specification* *</ options>* ;

The CONTRAST statement provides a means of obtaining a test of a specified hypothesis concerning the model parameters. This is accomplished by specifying a matrix **L** for testing the hypothesis $L'\beta = 0$. You must be familiar with the details of the model parameterization that PROC GENMOD uses. For more information, see the section “[Parameterization Used in PROC GENMOD](#)” on page 2811 and the section “[CLASS Statement](#)” on page 2759. Computed statistics are based on the asymptotic chi-square distribution of the likelihood ratio statistic, or the generalized score statistic for GEE models, with degrees of freedom determined by the number of linearly independent rows in the **L** matrix. You can request Wald chi-square statistics with the Wald option in the CONTRAST statement.

There is no limit to the number of CONTRAST statements that you can specify, but they must appear after the MODEL statement and after the ZEROMODEL statement for zero-inflated models. Statistics for multiple CONTRAST statements are displayed in a single table.

The elements of the CONTRAST statement are as follows:

label identifies the contrast on the output. A label is required for every contrast specified. Labels can be up to 20 characters and must be enclosed in single quotes.

contrast-specification identifies the effects and their coefficients from which the **L** matrix is formed. The *contrast-specification* can be specified in two different ways. The first method applies to all models except the zero-inflated (ZI) distributions (zero-inflated Poisson and zero-inflated negative binomial), and the syntax is:

effect values <,... *effect values*>

The second method of specifying a contrast applies only to ZI models, and the syntax is:

effect values <,... *effect values*> **@ZERO** *effect values* <,... *effect values*>

where

effect identifies an effect that appears in the MODEL statement. The value INTERCEPT or intercept can be used as an effect when an intercept is included in the model. You do not need to include all effects that are included in the MODEL statement.

values are constants that are elements of the **L** vector associated with the effect.

options specifies CONTRAST statement options.

Specification of sets of *effect values* before the @ZERO separator results in a row of the **L'** matrix with coefficients for *effects* in the regression part of the model set to *values* and with the coefficients for the zero-inflation part of the model set to zero. Specification of sets of *effect values* after the @ZERO separator results in a row of the **L** matrix with the coefficients for the regression part of the model set to zero and with the coefficients of *effects* in the zero-inflation part of the model set to *values*.

For example, the statements

```
class a;
model y=a;
contrast 'Label1' A 1 -1;
```

specify an **L'** matrix with one row with coefficients 1 for the first level of A and -1 for the second level of A.

The statements

```
class a b;
model y=a / dist=zip;
zeromodel b;
contrast 'Label2' A 1 -1 @zero B 1 -1;
```

specify an **L'** matrix with two rows: the first row has coefficients 1 for the first level of A, -1 for the second level of A, and zeros for all levels of B; the second row has coefficients 0 for all levels of A, 1 for the first level of B, and -1 for the second level of B.

The rows of **L'** are specified in order and are separated by commas.

If you use the default less-than-full-rank PROC GLM CLASS variable parameterization, each row of the **L'** matrix is checked for estimability. If PROC GENMOD finds a contrast to be nonestimable, it displays missing values in corresponding rows in the results. See Searle (1971) for a discussion of estimable functions. If the elements of **L'** are not specified for an effect that contains a specified effect, then the elements of the specified effect are distributed over the levels of the higher-order effect just as the GLM procedure does for its CONTRAST and ESTIMATE statements. For example, suppose that the model contains effects A and B and their interaction A*B. If you specify a CONTRAST statement involving A alone, the **L'** matrix contains nonzero terms for both A and A*B, since A*B contains A.

When you use any of the full-rank PARAM= CLASS variable options, all parameters are directly estimable, and rows of **L'** are not checked for estimability.

If an effect is not specified in the CONTRAST statement, all of its coefficients in the L' matrix are set to 0. If too many values are specified for an effect, the extra ones are ignored. If too few values are specified, the remaining ones are set to 0.

PROC GENMOD handles missing level combinations of classification variables in the same manner as the GLM and MIXED procedures. Parameters corresponding to missing level combinations are not included in the model. This convention can affect the way in which you specify the L matrix in your CONTRAST statement.

If you specify the WALD option, the test of hypothesis is based on a Wald chi-square statistic. If you omit the WALD option, the test statistic computed depends on whether an ordinary generalized linear model or a GEE-type model is specified.

For an ordinary generalized linear model, the CONTRAST statement computes the likelihood ratio statistic. This is defined to be twice the difference between the log likelihood of the model unconstrained by the contrast and the log likelihood with the model fitted under the constraint that the linear function of the parameters defined by the contrast is equal to 0. A p -value is computed based on the asymptotic chi-square distribution of the chi-square statistic.

If you specify a GEE model with the REPEATED statement, the test is based on a score statistic. The GEE model is fit under the constraint that the linear function of the parameters defined by the contrast is equal to 0. The score chi-square statistic is computed based on the generalized score function. See the section “[Generalized Score Statistics](#)” on page 2827 for more information.

The degrees of freedom is the number of linearly independent constraints implied by the CONTRAST statement—that is, the rank of L .

You can specify the following options after a slash (/).

E

requests that the L matrix be displayed.

SINGULAR=*number*

EPSILON=*number*

tunes the estimability checking. If \mathbf{v} is a vector, define $ABS(\mathbf{v})$ to be the absolute value of the element of \mathbf{v} with the largest absolute value. Let \mathbf{K}' be any row in the contrast matrix L . Define C to be equal to $ABS(\mathbf{K}')$ if $ABS(\mathbf{K}')$ is greater than 0; otherwise, C equals 1. If $ABS(\mathbf{K}' - \mathbf{K}'\mathbf{T})$ is greater than $C * \textit{number}$, then \mathbf{K} is declared nonestimable. \mathbf{T} is the Hermite form matrix $(\mathbf{X}'\mathbf{X})^-(\mathbf{X}'\mathbf{X})$, and $(\mathbf{X}'\mathbf{X})^-$ represents a generalized inverse of the matrix $\mathbf{X}'\mathbf{X}$. The value for *number* must be between 0 and 1; the default value is 1E-4. The SINGULAR= option in the MODEL statement affects the computation of the generalized inverse of the matrix $\mathbf{X}'\mathbf{X}$. It might also be necessary to adjust this value for some data.

WALD

requests that a Wald chi-square statistic be computed for the contrast rather than the default likelihood ratio or score statistic. The Wald statistic for testing $L'\beta = 0$ is defined by

$$S = (L'\hat{\beta})'(L'\Sigma L)^-(L'\hat{\beta})$$

where $\hat{\beta}$ is the maximum likelihood estimate and Σ is its estimated covariance matrix. The asymptotic distribution of S is χ_r^2 , where r is the rank of L . Computed p -values are based on this distribution.

If you specify a GEE model with the REPEATED statement, Σ is the empirical covariance matrix estimate.

DEVIANCE Statement

DEVIANCE *variable=expression* ;

You can specify a probability distribution other than those available in PROC GENMOD by using the DEVIANCE and VARIANCE statements. You do not need to specify the DEVIANCE or VARIANCE statement if you use the DIST= MODEL statement option to specify a probability distribution. The *variable* identifies the deviance contribution from a single observation to the procedure, and it must be a valid SAS variable name that does not appear in the input data set. The *expression* can be any arithmetic expression supported by the DATA step language, and it is used to define the functional dependence of the deviance on the mean and the response. You use the automatic variables `_MEAN_` and `_RESP_` to represent the mean and response in the *expression*.

Alternatively, the deviance function can be defined using programming statements (see the section “[Programming Statements](#)” on page 2790) and assigned to a variable, which is then listed as the *expression*. This form is convenient for using complex statements such as IF-THEN/ELSE clauses.

The DEVIANCE statement is ignored unless the VARIANCE statement is also specified.

EFFECTPLOT Statement

EFFECTPLOT *<plot-type <(plot-definition-options)>> </options>* ;

The EFFECTPLOT statement produces a display of the fitted model and provides options for changing and enhancing the displays. [Table 40.4](#) describes the available *plot-types* and their *plot-definition-options*.

Table 40.4 *Plot-Types and Plot-Definition-Options*

Plot-Type and Description	Plot-Definition-Options
BOX Displays a box plot of continuous response data at each level of a CLASS effect, with predicted values superimposed and connected by a line. This is an alternative to the INTERACTION <i>plot-type</i> .	PLOTBY= variable or CLASS effect X= CLASS variable or effect
CONTOUR Displays a contour plot of predicted values against two continuous covariates.	PLOTBY= variable or CLASS effect X= continuous variable Y= continuous variable
FIT Displays a curve of predicted values versus a continuous variable.	PLOTBY= variable or CLASS effect X= continuous variable
INTERACTION Displays a plot of predicted values (possibly with error bars) versus the levels of a CLASS effect. The predicted values are connected with lines and can be grouped by the levels of another CLASS effect.	PLOTBY= variable or CLASS effect SLICEBY= variable or CLASS effect X= CLASS variable or effect

Table 40.4 continued

Plot-Type and Description	Plot-Definition-Options
SLICEFIT Displays a curve of predicted values versus a continuous variable grouped by the levels of a CLASS effect.	PLOTBY= variable or CLASS effect SLICEBY= variable or CLASS effect X= continuous variable

For full details about the syntax and options of the EFFECTPLOT statement, see the section “[EFFECTPLOT Statement](#)” on page 411 in Chapter 19, “[Shared Concepts and Topics](#).”

ESTIMATE Statement

ESTIMATE *'label' contrast-specification* *</ options>* ;

The ESTIMATE statement is similar to a CONTRAST statement, except only one-row L' matrices are permitted.

The elements of the ESTIMATE statement are as follows:

label identifies the contrast on the output. A label is required for every contrast specified. Labels can be up to 20 characters and must be enclosed in single quotes.

contrast-specification identifies the effects and their coefficients from which the L matrix is formed. The *contrast-specification* can be specified in two different ways. The first method applies to all models except the zero-inflated (ZI) distributions (zero-inflated Poisson and zero-inflated negative binomial), and the syntax is:

effect values *<... effect values>*

The second method of specifying a contrast applies only to ZI models, and the syntax is:

effect values *<... effect values>* **@ZERO** *effect values* *<... effect values>*

where

effect identifies an effect that appears in the MODEL statement. The value INTERCEPT or intercept can be used as an effect when an intercept is included in the model. You do not need to include all effects that are included in the MODEL statement.

values are constants that are elements of the L vector associated with the effect.

options specifies options for the ESTIMATE statement.

For ZI models, sets of *effects values* before the @ZERO separator correspond to the regression part of the model with regression parameters β , and *effects values* after the @ZERO separator correspond to the zero-inflation part of the model with regression parameters γ . In the case of ZI models, a one-row L' matrix is created for the regression part of the model, another one-row L' matrix is created for the zero-inflation part of the model, and separate estimates for the two L matrices are computed and displayed.

If you use the default less-than-full-rank GLM CLASS variable parameterization, each row is checked for estimability. If PROC GENMOD finds a contrast to be nonestimable, it displays missing values in corresponding rows in the results. See Searle (1971) for a discussion of estimable functions.

The actual estimate, $L'\beta$ (and $L'\gamma$ for ZI models), its approximate standard error, and confidence limits are displayed. Additionally, the corresponding estimate on the mean scale (defined as the inverse link function applied to $L'\beta$), and confidence limits are displayed. Wald chi-square tests that $L'\beta = 0$ and $L'\gamma = 0$ are also displayed.

The approximate standard error of the estimate is computed as the square root of $L'\hat{\Sigma}L$, where $\hat{\Sigma}$ is the estimated covariance matrix of the parameter estimates. If you specify a GEE model in the REPEATED statement, $\hat{\Sigma}$ is the empirical covariance matrix estimate.

If you specify the EXP option, then $\exp(L'\beta)$, its standard error, and its confidence limits are also displayed.

The construction of the L vector and the checking for estimability for an ESTIMATE statement follow the same rules as listed under the CONTRAST statement.

You can specify the following options in the ESTIMATE statement after a slash (/).

ALPHA=number

requests that a confidence interval be constructed with confidence level $1 - \text{number}$. The value of *number* must be between 0 and 1; the default value is 0.05.

DIVISOR=number

specifies a value by which to divide all coefficients so that fractional coefficients can be entered as integer numerators. For example, you can use

```
estimate '1/3(A1+A2) - 2/3A3' a 1 1 -2 / divisor=3;
```

instead of

```
estimate '1/3(A1+A2) - 2/3A3' a 0.33333 0.33333 -0.66667;
```

E

requests that the L matrix coefficients be displayed.

EXP

requests that $\exp(L'\beta)$, its standard error, and its confidence limits be computed. If you specify the EXP option, standard errors are computed using the delta method. Confidence limits are computed by exponentiating the confidence limits for $L'\beta$.

SINGULAR=number

EPSILON=number

tunes the estimability checking as described for the CONTRAST statement.

EXACT Statement

```
EXACT <'label'> <INTERCEPT> <effects> </options>;
```

The EXACT statement performs exact tests of the parameters for the specified *effects* and optionally estimates the parameters and outputs the exact conditional distributions. You can specify the keyword INTERCEPT and any effects in the MODEL statement. Inference on the parameters of the specified effects is

performed by conditioning on the sufficient statistics of all the other model parameters (possibly including the intercept).

You can specify several EXACT statements, but they must follow the **MODEL** statement. Each statement can optionally include an identifying *label*. If several EXACT statements are specified, any statement without a label is assigned a label of the form “Exact n ,” where n indicates the n th EXACT statement. The label is included in the headers of the displayed exact analysis tables.

If a **STRATA** statement is also specified, then a stratified exact logistic regression or a stratified exact Poisson regression is performed. The model contains a different intercept for each stratum, and these intercepts are conditioned out of the model along with any other nuisance parameters (parameters for effects specified in the **MODEL** statement that are not in the EXACT statement).

The **ASSESSMENT**, **BAYES**, **CONTRAST**, **EFFECTPLOT**, **ESTIMATE**, **LSMEANS**, **LSMESTIMATE**, **OUTPUT**, **SLICE**, and **STORE** statements are not available with an exact analysis. Exact analyses are not performed when you specify a **WEIGHT** statement, or a model other than **LINK=LOGIT** with **DIST=BIN** or **LINK=LOG** with **DIST=POISSON**. An **OFFSET=** variable is not available with exact logistic regression. Exact estimation is not available for ordinal response models.

For classification variables, use of the reference parameterization is recommended.

The following options can be specified in each EXACT statement after a slash (/):

ALPHA=number

specifies the level of significance α for $100(1 - \alpha)\%$ confidence limits for the parameters or odds ratios. The value of *number* must be between 0 and 1. By default, *number* is equal to the value of the **ALPHA=** option in the **MODEL** statement, or 0.05 if that option is not specified.

CLTYPE=EXACT | MIDP

requests either the exact or mid- p confidence intervals for the parameter estimates. By default, the exact intervals are produced. The confidence coefficient can be specified with the **ALPHA=** option. The mid- p interval can be modified with the **MIDPFACTOR=** option. See the section “Exact Logistic and Exact Poisson Regression” on page 2839 for details.

ESTIMATE <=keyword>

estimates the individual parameters (conditioned on all other parameters) for the effects specified in the EXACT statement. For each parameter, a point estimate, a standard error, a confidence interval, and a p -value for a two-sided test that the parameter is zero are displayed. Note that the two-sided p -value is twice the one-sided p -value. You can optionally specify one of the following keywords:

- PARM** specifies that the parameters be estimated. This is the default.
- ODDS** specifies that the odds ratios be estimated. If you have classification variables, then you must also specify the **PARAM=REF** option in the **CLASS** statement.
- BOTH** specifies that both the parameters and odds ratios be estimated.

JOINT

performs the joint test that all of the parameters are simultaneously equal to zero, performs individual hypothesis tests for the parameter of each continuous variable, and performs joint tests for the parameters of each classification variable. The joint test is indicated in the “Conditional Exact Tests” table by the label “Joint.”

JOINTONLY

performs only the joint test of the parameters. The test is indicated in the “Conditional Exact Tests” table by the label “Joint.” When this option is specified, individual tests for the parameters of each continuous variable and joint tests for the parameters of the classification variables are not performed.

MIDPFACTOR= δ_1 | (δ_1, δ_2)

sets the tie factors used to produce the mid- p hypothesis statistics and the mid- p confidence intervals. δ_1 modifies both the hypothesis tests and confidence intervals, while δ_2 affects only the hypothesis tests. By default, $\delta_1 = 0.5$ and $\delta_2 = 1.0$. See the section “[Exact Logistic and Exact Poisson Regression](#)” on page 2839 for details.

ONESIDED

requests one-sided confidence intervals and p -values for the individual parameter estimates and odds ratios. The one-sided p -value is the smaller of the left- and right-tail probabilities for the observed sufficient statistic of the parameter under the null hypothesis that the parameter is zero. The two-sided p -values (default) are twice the one-sided p -values. See the section “[Exact Logistic and Exact Poisson Regression](#)” on page 2839 for more details.

OUTDIST=*SAS-data-set*

names the SAS data set that contains the exact conditional distributions. This data set contains all of the exact conditional distributions that are required to process the corresponding EXACT statement. This data set contains the possible sufficient statistics for the parameters of the effects specified in the EXACT statement, the counts, and, when hypothesis tests are performed on the parameters, the probability of occurrence and the score value for each sufficient statistic. When you request an OUTDIST= data set, the observed sufficient statistics are displayed in the “Sufficient Statistics” table. See the section “[OUTDIST= Output Data Set](#)” on page 2840 for more information.

EXACT Statement Examples

In the following example, two exact tests are computed: one for x_1 and the other for x_2 . The test for x_1 is based on the exact conditional distribution of the sufficient statistic for the x_1 parameter given the observed values of the sufficient statistics for the intercept, x_2 , and x_3 parameters; likewise, the test for x_2 is conditional on the observed sufficient statistics for the intercept, x_1 , and x_3 .

```
proc genmod;
  model y= x1 x2 x3/d=b;
  exact x1 x2;
run;
```

PROC GENMOD determines, from all the specified EXACT statements, the distinct conditional distributions that need to be evaluated. For example, there is only one exact conditional distribution for the following two EXACT statements:

```
exact 'One' x1 / estimate=parm;
exact 'Two' x1 / estimate=parm onesided;
```

For each EXACT statement, individual tests for the parameters of the specified effects are computed unless the **JOINTONLY** option is specified. Consider the following EXACT statements:

```

exact 'E12' x1 x2 / estimate;
exact 'E1'  x1      / estimate;
exact 'E2'  x2      / estimate;
exact 'J12' x1 x2 / joint;

```

In the E12 statement, the parameters for x1 and x2 are estimated and tested separately. Specifying the E12 statement is equivalent to specifying both the E1 and E2 statements. In the J12 statement, the joint test for the parameters of x1 and x2 is computed in addition to the individual tests for x1 and x2.

EXACTOPTIONS Statement

EXACTOPTIONS *options* ;

The EXACTOPTIONS statement specifies options that apply to every **EXACT** statement in the program. The following *options* are available:

ABSFCNV=*value*

specifies the absolute function convergence criterion. Convergence requires a small change in the log-likelihood function in subsequent iterations,

$$|l_i - l_{i-1}| < \text{value}$$

where l_i is the value of the log-likelihood function at iteration i .

By default, ABSFCNV=1E-12. You can also specify the **FCONV=** and **XCONV=** criteria; optimizations are terminated as soon as one criterion is satisfied.

ADDTOBS

adds the observed sufficient statistic to the sampled exact distribution if the statistic was not sampled. This option has no effect unless the **METHOD=NETWORKMC** option is specified and the **ESTIMATE** option is specified in the **EXACT** statement. If the observed statistic has not been sampled, then the parameter estimate does not exist; by specifying this option, you can produce (biased) estimates.

BUILDSUBSETS

builds every distribution for sampling. By default, some exact distributions are created by taking a subset of a previously generated exact distribution. When the **METHOD=NETWORKMC** option is invoked, this subsetting behavior has the effect of using fewer than the desired n samples; see the **N=** option for more details. Use the **BUILDSUBSETS** option to suppress this subsetting.

EPSILON=*value*

controls how the partial sums $\sum_{i=1}^j y_i x_i$ are compared. *value* must be between 0 and 1; by default, *value*=1E-8.

FCONV=*value*

specifies the relative function convergence criterion. Convergence requires a small relative change in the log-likelihood function in subsequent iterations,

$$\frac{|l_i - l_{i-1}|}{|l_{i-1}| + 1\text{E-}6} < \text{value}$$

where l_i is the value of the log likelihood at iteration i .

By default, FCONV=1E-8. You can also specify the **ABSFCNV=** and **XCONV=** criteria; if more than one criterion is specified, then optimizations are terminated as soon as one criterion is satisfied.

MAXTIME=seconds

specifies the maximum clock time (in seconds) that PROC GENMOD can use to calculate the exact distributions. If the limit is exceeded, the procedure halts all computations and prints a note to the LOG. The default maximum clock time is seven days.

METHOD=keyword

specifies which exact conditional algorithm to use for every **EXACT** statement specified. You can specify one of the following *keywords*:

DIRECT invokes the multivariate shift algorithm of Hirji, Mehta, and Patel (1987). This method directly builds the exact distribution, but it can require an excessive amount of memory in its intermediate stages. **METHOD=DIRECT** is invoked by default when you are conditioning out at most the intercept.

NETWORK invokes an algorithm described in Mehta, Patel, and Senchaudhuri (1992). This method builds a network for each parameter that you are conditioning out, combines the networks, then uses the multivariate shift algorithm to create the exact distribution. The **NETWORK** method can be faster and require less memory than the **DIRECT** method. The **NETWORK** method is invoked by default for most analyses.

NETWORKMC invokes the hybrid network and Monte Carlo algorithm of Mehta, Patel, and Senchaudhuri (1992). This method creates a network, then samples from that network; this method does not reject any of the samples at the cost of using a large amount of memory to create the network. **METHOD=NETWORKMC** is most useful for producing parameter estimates for problems that are too large for the **DIRECT** and **NETWORK** methods to handle and for which asymptotic methods are invalid—for example, for sparse data on a large grid.

N=n

specifies the number of Monte Carlo samples to take when the **METHOD=NETWORKMC** option is specified. By default, $n = 10,000$. If the procedure cannot obtain n samples due to a lack of memory, then a note is printed in the SAS log (the number of valid samples is also reported in the listing) and the analysis continues.

The number of samples used to produce any particular statistic might be smaller than n . For example, let $X1$ and $X2$ be continuous variables, denote their joint distribution by $f(X1, X2)$, and let $f(X1 | X2 = x2)$ denote the marginal distribution of $X1$ conditioned on the observed value of $X2$. If you request the **JOINT** test of $X1$ and $X2$, then n samples are used to generate the estimate $\hat{f}(X1, X2)$ of $f(X1, X2)$, from which the test is computed. However, the parameter estimate for $X1$ is computed from the subset of $\hat{f}(X1, X2)$ that has $X2 = x2$, and this subset need not contain n samples. Similarly, the distribution for each level of a classification variable is created by extracting the appropriate subset from the joint distribution for the **CLASS** variable.

In some cases, the marginal sample size can be too small to admit accurate estimation of a particular statistic; a note is printed in the SAS log when a marginal sample size is less than 100. Increasing n increases the number of samples used in a marginal distribution; however, if you want to control the sample size exactly, you can either specify the **BUILDSUBSETS** option or do both of the following:

- Remove the **JOINT** option from the **EXACT** statement.
- Create dummy variables in a **DATA** step to represent the levels of a **CLASS** variable, and specify them as independent variables in the **MODEL** statement.

NOLOGSCALE

specifies that computations for the exact conditional models be computed by using normal scaling. Log scaling can handle numerically larger problems than normal scaling; however, computations in the log scale are slower than computations in normal scale.

ONDISK

uses disk space instead of random access memory to build the exact conditional distribution. Use this option to handle larger problems at the cost of slower processing.

SEED=*seed*

specifies the initial seed for the random number generator used to take the Monte Carlo samples when the **METHOD=NETWORKMC** option is specified. The value of the **SEED=** option must be an integer. If you do not specify a seed, or if you specify a value less than or equal to zero, then PROC GENMOD uses the time of day from the computer's clock to generate an initial seed.

STATUSN=*number*

prints a status line in the SAS log after every *number* of Monte Carlo samples when the **METHOD=NETWORKMC** option is specified. The number of samples taken and the current exact *p*-value for testing the significance of the model are displayed. You can use this status line to track the progress of the computation of the exact conditional distributions.

STATUSTIME=*seconds*

specifies the time interval (in seconds) for printing a status line in the LOG. You can use this status line to track the progress of the computation of the exact conditional distributions. The time interval you specify is approximate; the actual time interval varies. By default, no status reports are produced.

XCONV=*value*

specifies the relative parameter convergence criterion. Convergence requires a small relative parameter change in subsequent iterations,

$$\max_j |\delta_j^{(i)}| < \text{value}$$

where

$$\delta_j^{(i)} = \begin{cases} \beta_j^{(i)} - \beta_j^{(i-1)} & |\beta_j^{(i-1)}| < 0.01 \\ \frac{\beta_j^{(i)} - \beta_j^{(i-1)}}{\beta_j^{(i-1)}} & \text{otherwise} \end{cases}$$

and $\beta_j^{(i)}$ is the estimate of the *j*th parameter at iteration *i*.

By default, **XCONV=1E-4**. You can also specify the **ABSFCNV=** and **FCNV=** criteria; if more than one criterion is specified, then optimizations are terminated as soon as one criterion is satisfied.

FREQ Statement

FREQ *variable* ;

FREQUENCY *variable* ;

The *variable* in the FREQ statement identifies a variable in the input data set containing the frequency of occurrence of each observation. PROC GENMOD treats each observation as if it appears n times, where n is the value of the FREQ variable for the observation. If it is not an integer, the frequency value is truncated to an integer. If it is less than 1 or missing, the observation is not used. In the case of models fit with generalized estimating equations (GEEs), the frequencies apply to the subject/cluster and therefore must be the same for all observations within each subject.

FWDLINK Statement

FWDLINK *variable=expression* ;

You can define a link function other than a built-in link function by using the FWDLINK statement. If you use the MODEL statement option LINK= to specify a link function, you do not need to use the FWDLINK statement. The *variable* identifies the link function to the procedure. The *expression* can be any arithmetic expression supported by the DATA step language, and it is used to define the functional dependence on the mean.

Alternatively, the link function can be defined by using programming statements (see the section “[Programming Statements](#)” on page 2790) and assigned to a variable, which is then listed as the *expression*. The second form is convenient for using complex statements such as IF-THEN/ELSE clauses. The GENMOD procedure automatically computes derivatives of the link function required for iterative fitting. You must specify the inverse of the link function in the INVLINK statement when you specify the FWDLINK statement to define the link function. You use the automatic variable `_MEAN_` to represent the mean in the preceding *expression*.

INVLINK Statement

INVLINK *variable=expression* ;

If you define a link function in the FWDLINK statement, then you must define the inverse link function by using the INVLINK statement. If you use the MODEL statement option LINK= to specify a link function, you do not need to use the INVLINK statement. The *variable* identifies the inverse link function to the procedure. The *expression* can be any arithmetic expression supported by the DATA step language, and it is used to define the functional dependence on the linear predictor.

Alternatively, the inverse link function can be defined using programming statements (see the section “[Programming Statements](#)” on page 2790) and assigned to a variable, which is then listed as the *expression*. The second form is convenient for using complex statements such as IF-THEN/ELSE clauses. The automatic variable `_XBETA_` represents the linear predictor in the preceding *expression*.

LSMEANS Statement

LSMEANS < *model-effects* > < / *options* > ;

The LSMEANS statement computes and compares least squares means (LS-means) of fixed effects. LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs.

Table 40.5 summarizes the options available in the LSMEANS statement. If you specify the BAYES statement, the ADJUST=, STEPDOWN, and LINES options are ignored. The PLOTS= option is not available for a maximum likelihood analysis; it is available only for a Bayesian analysis.

If you specify a zero-inflated model (that is, a model for either the zero-inflated Poisson or the zero-inflated negative binomial distribution), then the least squares means are computed only for effects in the model for the distribution mean, and not for effects in the zero-inflation probability part of the model.

Table 40.5 LSMEANS Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies the covariate value in computing LS-means
BYLEVEL	Computes separate margins
DIFF	Requests differences of LS-means
OM=	Specifies the weighting scheme for LS-means computation as determined by the input data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and <i>p</i>-values	
ADJUST=	Determines the method for multiple-comparison adjustment of LS-means differences
ALPHA= α	Determines the confidence level ($1 - \alpha$)
STEPDOWN	Adjusts multiple-comparison <i>p</i> -values further in a step-down fashion
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the L matrix
LINES	Produces a “Lines” display for pairwise LS-means differences
MEANS	Prints the LS-means
PLOTS=	Requests graphs of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers

Table 40.5 *continued*

Option	Description
Generalized Linear Modeling	
EXP	Exponentiates and displays estimates of LS-means or LS-means differences
ILINK	Computes and displays estimates and standard errors of LS-means (but not differences) on the inverse linked scale
ODDSRATIO	Reports (simple) differences of least squares means in terms of odds ratios if permitted by the link function

For details about the syntax of the LSMEANS statement, see the section “[LSMEANS Statement](#)” on page 453 of Chapter 19, “[Shared Concepts and Topics](#).”

LSMESTIMATE Statement

```
LSMESTIMATE model-effect <'label'> values <divisor=n>
              < , ... <'label'> values <divisor=n> >
              </ options > ;
```

The LSMESTIMATE statement provides a mechanism for obtaining custom hypothesis tests among least squares means.

Table 40.6 summarizes the options available in the LSMESTIMATE statement.

Table 40.6 LSMESTIMATE Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies covariate values in computing LS-means
BYLEVEL	Computes separate margins
DIVISOR=	Specifies a list of values to divide the coefficients
OM=	Specifies the weighting scheme for LS-means computation as determined by a data set
SINGULAR=	Tunes estimability checking
Degrees of Freedom and <i>p</i>-values	
ADJUST=	Determines the method for multiple-comparison adjustment of LS-means differences
ALPHA= α	Determines the confidence level $(1 - \alpha)$
LOWER	Performs one-sided, lower-tailed inference
STEPDOWN	Adjusts multiple-comparison <i>p</i> -values further in a step-down fashion
TESTVALUE=	Specifies values under the null hypothesis for tests
UPPER	Performs one-sided, upper-tailed inference

Table 40.6 *continued*

Option	Description
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Prints the L matrix
ELSM	Prints the K matrix
JOINT	Produces a joint <i>F</i> or chi-square test for the LS-means and LS-means differences
PLOTS=	Requests graphs of means and mean comparisons
SEED=	Specifies the seed for computations that depend on random numbers
Generalized Linear Modeling	
CATEGORY=	Specifies how to construct estimable functions with multinomial data
EXP	Exponentiates and displays LS-means estimates
ILINK	Computes and displays estimates and standard errors of LS-means (but not differences) on the inverse linked scale

For details about the syntax of the LSMESTIMATE statement, see the section “[LSMESTIMATE Statement](#)” on page 470 in Chapter 19, “[Shared Concepts and Topics](#).”

MODEL Statement

MODEL *response* = < *effects* > < / *options* > ;

MODEL *events/trials* = < *effects* > < / *options* > ;

The MODEL statement specifies the response, or dependent variable, and the effects, or explanatory variables. If you omit the explanatory variables, the procedure fits an intercept-only model. An intercept term is included in the model by default. The intercept can be removed with the NOINT option.

You can specify the response in the form of a single variable or in the form of a ratio of two variables denoted *events/trials*. The first form is applicable to all responses. The second form is applicable only to summarized binomial response data. When each observation in the input data set contains the number of events (for example, successes) and the number of trials from a set of binomial trials, use the *events/trials* syntax.

In the *events/trials* model syntax, you specify two variables that contain the event and trial counts. These two variables are separated by a slash (/). The values of both *events* and (*trials*–*events*) must be nonnegative, and the value of the *trials* variable must be greater than 0 for an observation to be valid. The variable *events* or *trials* can take noninteger values.

When each observation in the input data set contains a single trial from a binomial or multinomial experiment, use the first form of the preceding MODEL statements. The response variable can be numeric or

character. The ordering of response levels is critical in these models. You can use the RORDER= option in the PROC GENMOD statement to specify the response level ordering.

Responses for the Poisson distribution must be all nonnegative, but they can be noninteger values.

The effects in the MODEL statement consist of an explanatory variable or combination of variables. Explanatory variables can be continuous or classification variables. Classification variables can be character or numeric. Explanatory variables representing nominal, or classification, data must be declared in a CLASS statement. Interactions between variables can also be included as effects. Columns of the design matrix are automatically generated for classification variables and interactions. The syntax for specification of effects is the same as for the GLM procedure. See the section “[Specification of Effects](#)” on page 2810 for more information. Also see Chapter 42, “[The GLM Procedure](#).”

Table 40.7 summarizes the options available in the MODEL statement.

Table 40.7 MODEL Statement Options

Option	Description
AGGREGATE=	Specifies the subpopulations
ALPHA=	Sets the confidence coefficient
CICONV=	Sets the convergence criterion for profile likelihood confidence intervals
CL	Displays confidence limits for predicted values
CODING=	Uses effect coding for all classification variables
CONVERGE=	Sets the convergence criterion
CONVH=	Sets the relative Hessian convergence criterion
CORRB	Displays the parameter estimate correlation matrix
COVB	Displays the parameter estimate covariance matrix
DIAGNOSTICS	Displays case deletion diagnostic statistics
DIST=	Specifies the built-in probability distribution
EXACTMAX	Names a variable used for performing an exact Poisson regression
EXPECTED	Computes covariances and associated statistics using the expected Fisher information matrix
ID=	Displays the values of <i>variable</i> in the input data set in the OBSTATS table
INITIAL=	Sets initial values for parameter estimates
INTERCEPT=	Initializes the intercept term
ITPRINT	Displays the iteration history for all iterative processes
LINK=	Specifies the link function
LOGNB	Computes the maximum likelihood estimate and confidence limits of k based $\log(k)$
LRCI	Computes two-sided confidence intervals for the partially likelihood function
MAXITER=	Sets the maximum allowable number of iterations for all iterative computation processes
NOINT	Requests that no intercept term
NOLOGNB	Computes the maximum likelihood estimate and confidence limits of k based on k
NOSCALE	Holds the scale parameter fixed
OBSTATS	Displays an additional table of statistics
OFFSET=	Specifies a variable in the input data set to be used as an offset

Table 40.7 *continued*

Option	Description
PREDICTED	Displays predicted values and associated statistics
RESIDUALS	Displays residuals and standardized residuals
SCALE=	Sets the value used for the scale
SCORING=	Computes the Hessian matrix using the Fisher scoring method
SINGULAR=	Sets the tolerance for testing singularity
TYPE1	Performs a Type 1 analysis
TYPE3	Computes statistics for Type 3 contrasts
WALD	Requests Wald statistics for Type 3 contrasts
WALDCI	Computes two-sided Wald confidence intervals
XVARS	Includes the regression variables in the OBSTATS table

You can specify the following options in the MODEL statement after a slash (/).

AGGREGATE= (*variable-list*)

AGGREGATE= *variable*

AGGREGATE

specifies the subpopulations on which the Pearson chi-square and the deviance are calculated. This option applies only to the multinomial distribution or the binomial distribution with binary (single trial syntax) response. It is ignored if specified for other cases. Observations with common values in the given list of variables are regarded as coming from the same subpopulation. This affects the computation of the deviance and Pearson chi-square statistics. Variables in the list can be any variables in the input data set. Specifying the AGGREGATE option is equivalent to specifying the AGGREGATE= option with a variable list that includes all explanatory variables in the MODEL statement. Pearson chi-square and deviance statistics are not computed for multinomial models unless this option is specified.

ALPHA=*number*

ALPH=*number*

A=*number*

sets the confidence coefficient for parameter confidence intervals to $1 - \text{number}$. The value of *number* must be between 0 and 1. The default value of *number* is 0.05.

CICONV=*number*

sets the convergence criterion for profile likelihood confidence intervals. See the section “[Confidence Intervals for Parameters](#)” on page 2813 for the definition of convergence. The value of *number* must be between 0 and 1. By default, CICONV=1E-4.

CL

requests that confidence limits for predicted values be displayed (see the OBSTATS option).

CODING=EFFECT

CODING=FULLRANK

specifies that effect coding be used for all classification variables in the model. This is the same as specifying PARAM=EFFECT as a CLASS statement option.

CONVERGE=number

sets the convergence criterion. The value of *number* must be between 0 and 1. The iterations are considered to have converged when the maximum change in the parameter estimates between iteration steps is less than the value specified. The change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change. By default, CONVERGE=1E-4. This convergence criterion is used in parameter estimation for a single model fit, Type 1 statistics, and likelihood ratio statistics for Type 3 analyses and CONTRAST statements.

CONVH=number

sets the relative Hessian convergence criterion. The value of *number* must be between 0 and 1. After convergence is determined with the change in parameter criterion specified with the CONVERGE= option, the quantity $tc = \frac{\mathbf{g}'\mathbf{H}^{-1}\mathbf{g}}{|f|}$ is computed and compared to *number*, where \mathbf{g} is the gradient vector, \mathbf{H} is the Hessian matrix for the model parameters, and f is the log-likelihood function. If tc is greater than *number*, a warning that the relative Hessian convergence criterion has been exceeded is printed. This criterion detects the occasional case where the change in parameter convergence criterion is satisfied, but a maximum in the log-likelihood function has not been attained. By default, CONVH=1E-4.

CORRB

requests that the parameter estimate correlation matrix be displayed.

COVB

requests that the parameter estimate covariance matrix be displayed.

DIAGNOSTICS**INFLUENCE**

requests that case deletion diagnostic statistics be displayed (see the OBSTATS option).

DIST=keyword**D=keyword****ERROR=keyword****ERR=keyword**

specifies the built-in probability distribution to use in the model. If you specify the DIST= option and you omit a user-defined link function, a default link function is chosen as displayed in the following table. If you specify no distribution and no link function, then the GENMOD procedure defaults to the normal distribution with the identity link function. Models for data with correlated responses fit by the GEE method are not available for the zero-inflated distributions.

DIST=	Distribution	Default Link Function
BINOMIAL BIN B	Binomial	Logit
GAMMA GAM G	Gamma	Inverse (power(-1))
GEOMETRIC GEOM	Geometric	Log
IGAUSSIAN IG	Inverse Gaussian	Inverse squared (power(-2))
MULTINOMIAL MULT	Multinomial	Cumulative logit
NEGBIN NB	Negative binomial	Log
NORMAL NOR N	Normal	Identity
POISSON POI P	Poisson	Log
ZIP	Zero-inflated Poisson	Log/logit
ZINB	Zero-inflated negative binomial	Log/logit

EXACTMAX*<=variable>*

names a variable used for performing an exact Poisson regression. For each observation, the integer part of the EXACTMAX value should be nonnegative and at least as large as the response value. If the EXACTMAX option is specified without a variable, then default values are computed. See the section “Exact Logistic and Exact Poisson Regression” on page 2839 for information about using this option.

EXPECTED

requests that the expected Fisher information matrix be used to compute parameter estimate covariances and the associated statistics. The default action is to use the observed Fisher information matrix. This option does not affect the model fitting, only the way in which the covariance matrix is computed (see the **SCORING**= option.)

ID*=variable*

causes the values of *variable* in the input data set to be displayed in the OBSTATS table. If an explicit format for *variable* has been defined, the formatted values are displayed. If the OBSTATS option is not specified, this option has no effect.

INITIAL*=numbers*

sets initial values for parameter estimates in the model. The default initial parameter values are weighted least squares estimates based on using the response data as the initial mean estimate. This option can be useful in case of convergence difficulty. The intercept parameter is initialized with the **INTERCEPT**= option and is not included here. The values are assigned to the variables in the MODEL statement in the same order in which they appear in the MODEL statement. The order of levels for CLASS variables is determined by the **ORDER**= option. Note that some levels of classification variables can be aliased; that is, they correspond to linearly dependent parameters that are not estimated by the procedure. Initial values must be assigned to all levels of classification variables, regardless of whether they are aliased or not. The procedure ignores initial values corresponding to parameters not being estimated. If you specify a BY statement, all classification variables must take on the same number of levels in each BY group. Otherwise, classification variables in some of the BY groups are assigned incorrect initial values. Types of INITIAL= specifications are illustrated in the following table.

Type of List	Specification
List separated by blanks	INITIAL = 3 4 5
List separated by commas	INITIAL = 3, 4, 5
x to y	INITIAL = 3 to 5
x to y by z	INITIAL = 3 to 5 by 1
Combination of list types	INITIAL = 1, 3 to 5, 9

INTERCEPT*=number***INTERCEPT***=number-list*

initializes the intercept term to *number* for parameter estimation. If you specify both the **INTERCEPT**= and the **NOINT** options, the intercept term is not estimated, but an intercept term of *number* is included in the model. If you specify a multinomial model for ordinal data, you can specify a *number-list* for the multiple intercepts in the model.

ITPRINT

displays the iteration history for all iterative processes: parameter estimation, fitting constrained models for contrasts and Type 3 analyses, and profile likelihood confidence intervals. The last evaluation of the gradient and the negative of the Hessian (second derivative) matrix are also displayed for parameter estimation. If you perform a Bayesian analysis by specifying the BAYES statement, the iteration history for computing the mode of the posterior distribution is also displayed.

This option might result in a large amount of displayed output, especially if some of the optional iterative processes are selected.

LINK=keyword

specifies the link function to use in the model. The keywords and their associated built-in link functions are as follows.

LINK=	Link Function
CUMCLL	
CCLL	Cumulative complementary log-log
CUMLOGIT	
CLOGIT	Cumulative logit
CUMPROBIT	
CPROBIT	Cumulative probit
CLOGLOG	
CLL	Complementary log-log
IDENTITY	
ID	Identity
LOG	Log
LOGIT	Logit
PROBIT	Probit
POWER(<i>number</i>) POW(<i>number</i>)	Power with $\lambda = \text{number}$

If no LINK= option is supplied and there is a user-defined link function, the user-defined link function is used. If you specify neither the LINK= option nor a user-defined link function, then the default canonical link function is used if you specify the DIST= option. Otherwise, if you omit the DIST= option, the identity link function is used.

The cumulative link functions are appropriate only for the multinomial distribution.

LOGNB

specifies that the maximum likelihood estimate and confidence limits of the negative binomial dispersion parameter k be computed based $\log(k)$. This is the default method used for the negative binomial dispersion parameter, so that specifying no option or specifying the LOGNB option have the same effect. The GENMOD procedure computes the maximum likelihood estimate of $\log(k)$ and computes confidence limits based on the asymptotic normality of $\log(k)$ rather than of k . The results are always reported in terms of k rather than of $\log(k)$. This method ensures that the estimate and confidence limits for k are positive. See Meeker and Escobar (1998, p. 163) for details about this method of computing confidence limits.

LRCI

requests that two-sided confidence intervals for all model parameters be computed based on the profile likelihood function. This is sometimes called the partially maximized likelihood function. See the section “[Confidence Intervals for Parameters](#)” on page 2813 for more information about the profile likelihood function. This computation is iterative and can consume a relatively large amount of CPU time. The confidence coefficient can be selected with the `ALPHA=number` option. The resulting confidence coefficient is $1 - \text{number}$. The default confidence coefficient is 0.95.

MAXITER=number**MAXIT=number**

sets the maximum allowable number of iterations for all iterative computation processes in PROC GENMOD. By default, MAXITER=50.

NOINT

requests that no intercept term be included in the model. An intercept is included unless this option is specified.

NOLOGNB

specifies that the maximum likelihood estimate and confidence limits of the negative binomial dispersion parameter k be computed based on k rather than $\log(k)$. If this option is not specified, then the GENMOD procedure computes the maximum likelihood estimate of $\log(k)$ and computes confidence limits based on the asymptotic normality of $\log(k)$ rather than of k . The results are always reported in terms of k rather than of $\log(k)$. This method ensures that the estimate and confidence limits for k are positive. See Meeker and Escobar (1998, p. 163) for details about this method of computing confidence limits.

NOSCALE

holds the scale parameter fixed. Otherwise, for the normal, inverse Gaussian, and gamma distributions, the scale parameter is estimated by maximum likelihood. If you omit the `SCALE=` option, the scale parameter is fixed at the value 1.

OBSTATS

specifies that an additional table of statistics be displayed. Formulas for the statistics are given in the section “[Predicted Values of the Mean](#)” on page 2815, the section “[Residuals](#)” on page 2816, and the section “[Case Deletion Diagnostic Statistics](#)” on page 2831. Residuals and fit diagnostics are not computed for multinomial models.

For each observation, the following items are displayed:

- the value of the response variable (variables if the data are binomial), frequency, and weight variables
- the values of the regression variables
- predicted mean, $\hat{\mu} = g^{-1}(\eta)$, where $\eta = \mathbf{x}_i' \hat{\boldsymbol{\beta}}$ is the linear predictor and g is the link function. If there is an offset, it is included in $\mathbf{x}_i' \hat{\boldsymbol{\beta}}$.
- estimate of the linear predictor $\mathbf{x}_i' \hat{\boldsymbol{\beta}}$. If there is an offset, it is included in $\mathbf{x}_i' \hat{\boldsymbol{\beta}}$.
- standard error of the linear predictor $\mathbf{x}_i' \hat{\boldsymbol{\beta}}$
- the value of the Hessian weight at the final iteration

- lower confidence limit of the predicted value of the mean. The confidence coefficient is specified with the ALPHA= option. See the section “[Confidence Intervals on Predicted Values](#)” on page 2815 for the computational method.
- upper confidence limit of the predicted value of the mean
- raw residual, defined as $Y - \mu$
- Pearson, or chi residual, defined as the square root of the contribution for the observation to the Pearson chi-square—that is,

$$\frac{Y - \mu}{\sqrt{V(\mu)/w}}$$

where Y is the response, μ is the predicted mean, w is the value of the prior weight variable specified in a WEIGHT statement, and $V(\mu)$ is the variance function evaluated at μ .

- the standardized Pearson residual
- deviance residual, defined as the square root of the deviance contribution for the observation, with sign equal to the sign of the raw residual
- the standardized deviance residual
- the likelihood residual
- a Cook distance type statistic for assessing the influence of individual observations on overall model fit
- observation leverage
- DFBETA, defined as an approximation to $\hat{\beta} - \hat{\beta}_{[i]}$ for each parameter estimate $\hat{\beta}$, where $\hat{\beta}_{[i]}$ is the parameter estimate with the i th observation deleted
- standardized DFBETA, defined as DFBETA, normalized by its standard deviation
- [zero inflation probability](#) for zero-inflated models
- the [mean of a zero-inflated response](#)

The following additional cluster deletion diagnostic statistics are created and displayed for each cluster if a REPEATED statement is specified:

- a Cook distance type statistic for assessing the influence of entire clusters on overall model fit
- a studentized Cook distance for assessing influence of clusters
- cluster leverage
- cluster DFBETA for assessing the influence of entire clusters on individual parameter estimates
- cluster DFBETA normalized by its standard deviation

If you specify the multinomial distribution, only regression variable values, response values, predicted values, confidence limits for the predicted values, and the linear predictor are displayed in the table. Residuals and other diagnostic statistics are not available for the multinomial distribution.

The RESIDUALS, DIAGNOSTICS | INFLUENCE, PREDICTED, XVARS, and CL options cause only subgroups of the observation statistics to be displayed. You can specify more than one of these options to include different subgroups of statistics.

The `ID=variable` option causes the values of *variable* in the input data set to be displayed in the table. If an explicit format for *variable* has been defined, the formatted values are displayed.

If a `REPEATED` statement is present, a table is displayed for the GEE model specified in the `REPEATED` statement. Regression variables, response values, predicted values, confidence limits for the predicted values, linear predictor, raw residuals, Pearson residuals for each observation in the input data set are available. Case deletion diagnostic statistics are available for each observation and for each cluster.

OFFSET=variable

specifies a variable in the input data set to be used as an offset variable. This variable cannot be a `CLASS` variable, and it cannot be the response variable or one of the explanatory variables.

When you perform an exact Poisson regression with an `OFFSET=` variable but the `EXACTMAX=` option is not specified, then if o_i is the offset for the i th observation, $\text{floor}(\exp(o_i))$ should be greater than or equal to the response value. See the section “[Exact Logistic and Exact Poisson Regression](#)” on page 2839 for information about the use of the offset in the exact Poisson model.

PREDICTED

PRED

P

requests that predicted values, the linear predictor, its standard error, and the Hessian weight be displayed (see the `OBSTATS` option).

RESIDUALS

R

requests that residuals and standardized residuals be displayed. Residuals and other diagnostic statistics are not available for the multinomial distribution (see the `OBSTATS` option).

SCALE=number

SCALE=PEARSON

SCALE=P

PSCALE

SCALE=DEVIANCE

SCALE=D

DSCALE

sets the value used for the scale parameter where the `NOSCALE` option is used. For the binomial and Poisson distributions, which have no free scale parameter, this can be used to specify an *overdispersed* model. In this case, the parameter covariance matrix and the likelihood function are adjusted by the scale parameter. See the section “[Dispersion Parameter](#)” on page 2808 and the section “[Overdispersion](#)” on page 2809 for more information. If the `NOSCALE` option is not specified, then *number* is used as an initial estimate of the scale parameter.

Specifying `SCALE=PEARSON` or `SCALE=P` is the same as specifying the `PSCALE` option. This fixes the scale parameter at the value 1 in the estimation procedure. After the parameter estimates are determined, the exponential family dispersion parameter is assumed to be given by Pearson’s chi-square statistic divided by the degrees of freedom, and all statistics such as standard errors and likelihood ratio statistics are adjusted appropriately.

Specifying SCALE=DEVIANCE or SCALE=D is the same as specifying the DSCALE option. This fixes the scale parameter at a value of 1 in the estimation procedure.

After the parameter estimates are determined, the exponential family dispersion parameter is assumed to be given by the deviance divided by the degrees of freedom. All statistics such as standard errors and likelihood ratio statistics are adjusted appropriately.

SCORING=number

requests that on iterations up to *number*, the Hessian matrix be computed using the Fisher scoring method. For further iterations, the full Hessian matrix is computed. The default value is 1. A value of 0 causes all iterations to use the full Hessian matrix, and a value greater than or equal to the value of the MAXITER option causes all iterations to use Fisher scoring. The value of the SCORING= option must be 0 or a positive integer.

SINGULAR=number

sets the tolerance for testing singularity of the information matrix and the crossproducts matrix. Roughly, the test requires that a pivot be at least this number times the original diagonal value. By default, *number* is 10^7 times the machine epsilon. The default *number* is approximately 10^{-9} on most machines. This value also controls the check on estimability for ESTIMATE and CONTRAST statements.

TYPE1

requests that a Type 1, or sequential, analysis be performed. This consists of sequentially fitting models, beginning with the null (intercept term only) model and continuing up to the model specified in the MODEL statement. The likelihood ratio statistic between each successive pair of models is computed and displayed in a table.

A Type 1 analysis is not available for GEE models, since there is no associated likelihood.

TYPE3

requests that statistics for Type 3 contrasts be computed for each effect specified in the MODEL statement. The default analysis is to compute likelihood ratio statistics for the contrasts or score statistics for GEEs. Wald statistics are computed if the WALD option is also specified.

WALD

requests Wald statistics for Type 3 contrasts. You must also specify the TYPE3 option in order to compute Type 3 Wald statistics.

WALDCI

requests that two-sided Wald confidence intervals for all model parameters be computed based on the asymptotic normality of the parameter estimators. This computation is not as time-consuming as the LRCI method, since it does not involve an iterative procedure. However, it is thought to be less accurate, especially for small sample sizes. The confidence coefficient can be selected with the ALPHA= option in the same way as for the LRCI option.

XVARS

requests that the regression variables be included in the OBSTATS table.

OUTPUT Statement

OUTPUT < **OUT**=*SAS-data-set* > < *keyword=name* ... *keyword=name* > ;

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimated linear predictors (XBETA) and their standard error estimates, the weights for the Hessian matrix, predicted values of the mean, confidence limits for predicted values, residuals, and case deletion diagnostics. Residuals and diagnostic statistics are not computed for multinomial models.

You can also request these statistics with the OBSTATS, PREDICTED, RESIDUALS, DIAGNOSTICS | INFLUENCE, CL, or XVARS option in the MODEL statement. You can then create a SAS data set containing them with ODS OUTPUT commands.

You might prefer to specify the OUTPUT statement for requesting these statistics since the following are true:

- The OUTPUT statement produces no tabular output.
- The OUTPUT statement creates a SAS data set more efficiently than ODS. This can be an advantage for large data sets.
- You can specify the individual statistics to be included in the SAS data set.

If you use the multinomial distribution with one of the cumulative link functions for ordinal data, the data set also contains variables named `_ORDER_` and `_LEVEL_` that indicate the levels of the ordinal response variable and the values of the variable in the input data set corresponding to the sorted levels. These variables indicate that the predicted value for a given observation is the probability that the response variable is as large as the value of the `_LEVEL_` variable. Residuals and other diagnostic statistics are not available for the multinomial distribution.

The estimated linear predictor, its standard error estimate, and the predicted values and their confidence intervals are computed for all observations in which the explanatory variables are all nonmissing, even if the response is missing. By adding observations with missing response values to the input data set, you can compute these statistics for new observations or for settings of the explanatory variables not present in the data without affecting the model fit.

The following list explains specifications in the OUTPUT statement.

OUT=*SAS-data-set*

specifies the output data set. If you omit the OUT=option, the output data set is created and given a default name that uses the *DATA**n* convention.

keyword=name

specifies the statistics to be included in the output data set and names the new variables that contain the statistics. Specify a keyword for each desired statistic (see the following list of keywords), an equal sign, and the name of the new variable or variables to contain the statistic. You can list only one variable after the equal sign for all the statistics, except for the case deletion diagnostics for individual parameter estimates, DFBETA, DFBETAS, DFBETAC, and DFBETACS. You can list variables enclosed in parentheses to correspond to the variables in the model, or you can specify the keyword `_all_`, without parentheses, to include deletion diagnostics for all of the parameters in the model.

Although you can use the OUTPUT statement without any *keyword=name* specifications, the output data set then contains only the original variables and, possibly, the variables Level and Value (if you use the multinomial model with ordinal data). Note that the residuals and deletion diagnostics are not available for the multinomial model with ordinal data. Some of the case deletion diagnostic statistics apply only to models for correlated data specified with a REPEATED statement. If you request these statistics for ordinary generalized linear models, the values of the corresponding variables are set to missing in the output data set. Formulas for the statistics are given in the section “[Predicted Values of the Mean](#)” on page 2815, the section “[Residuals](#)” on page 2816, and the section “[Case Deletion Diagnostic Statistics](#)” on page 2831.

The keywords allowed and the statistics they represent are as follows:

DFBETA DBETA	represents the effect of deleting an observation on parameter estimates. If you specify the keyword <i>_all_</i> after the equal sign, variables named DFBETA_ <i>ParameterName</i> will be included in the output data set to contain the values of the diagnostic statistic to measure the influence of deleting a single observation on the individual parameter estimates. <i>ParameterName</i> is the name of the regression model parameter formed from the input variable names concatenated with the appropriate levels, if classification variables are involved.
DFBETAS DBETAS	represents the effect of deleting an observation on standardized parameter estimates. If you specify the keyword <i>_all_</i> after the equal sign, variables named DFBETAS_ <i>ParameterName</i> will be included in the output data set to contain the values of the diagnostic statistic to measure the influence of deleting a single observation on the individual parameter estimates. <i>ParameterName</i> is the name of the regression model parameter formed from the input variable names concatenated with the appropriate levels, if classification variables are involved.
DOBS COOKD COOKSD	represents the Cook distance type statistic to measure the influence of deleting a single observation on the overall model fit.
HESSWGT	represents the diagonal element of the weight matrix used in computing the Hessian matrix.
H LEVERAGE	represents the leverage of a single observation.
LOWER L	represents the lower confidence limit for the predicted value of the mean, or the lower confidence limit for the probability that the response is less than or equal to the value of Level or Value. The confidence coefficient is determined by the ALPHA= <i>number</i> option in the MODEL statement as $(1 - \textit{number}) \times 100\%$. The default confidence coefficient is 95%.
PREDICTED PRED PROB P	represents the predicted value of the mean of the response or the predicted probability that the response variable is less than or equal to the value of <i>_LEVEL_</i> if the multinomial model for ordinal data is used (in other words, $\Pr(Y \leq \textit{_LEVEL_})$, where Y is the response variable).
PZERO	represents the zero-inflation probability for zero-inflated models.
RESCHI	represents the Pearson (chi) residual for identifying observations that are poorly accounted for by the model.
RESDEV	represents the deviance residual for identifying poorly fitted observations.
RESLIK	represents the likelihood residual for identifying poorly fitted observations.

RESRAW	represents the raw residual for identifying poorly fitted observations.
STDRESCHI	represents the standardized Pearson (chi) residual for identifying observations that are poorly accounted for by the model.
STDRESDEV	represents the standardized deviance residual for identifying poorly fitted observations.
STDXBETA	represents the standard error estimate of XBETA (see the XBETA keyword).
UPPER U	represents the upper confidence limit for the predicted value of the mean, or the upper confidence limit for the probability that the response is less than or equal to the value of Level or Value. The confidence coefficient is determined by the ALPHA= <i>number</i> option in the MODEL statement as $(1 - \textit{number}) \times 100\%$. The default confidence coefficient is 95%.
XBETA	represents the estimate of the linear predictor $\mathbf{x}_i' \boldsymbol{\beta}$ for observation <i>i</i> , or $\alpha_j + \mathbf{x}_i' \boldsymbol{\beta}$, where <i>j</i> is the corresponding ordered value of the response variable for the multinomial model with ordinal data. If there is an offset, it is included in $\mathbf{x}_i' \boldsymbol{\beta}$.

The keywords in the following list apply only to models specified with a REPEATED statement, fit by generalized estimating equations (GEEs).

CH CLUSTERH CLEVERAGE	represents the leverage of a cluster.
CLUSTER	represents the numerical cluster index, in order of sorted clusters.
DCLS CLUSTERCOOKD CLUSTERCOOKSD	represents the Cook distance type statistic to measure the influence of deleting an entire cluster on the overall model fit.
DFBETAC DBETAC	represents the effect of deleting an entire cluster on parameter estimates. If you specify the keyword <i>_all_</i> after the equal sign, variables named DFBETAC_ <i>ParameterName</i> will be included in the output data set to contain the values of the diagnostic statistic to measure the influence of deleting the cluster on the individual parameter estimates. <i>ParameterName</i> is the name of the regression model parameter formed from the input variable names concatenated with the appropriate levels, if classification variables are involved.
DFBETACS DBETACS	represents the effect of deleting an entire cluster on normalized parameter estimates. If you specify the keyword <i>_all_</i> after the equal sign, variables named DFBETACS_ <i>ParameterName</i> will be included in the output data set to contain the values of the diagnostic statistic to measure the influence of deleting the cluster on the individual parameter estimates, normalized by their standard errors. <i>ParameterName</i> is the name of the regression model parameter formed from the input variable names concatenated with the appropriate levels, if classification variables are involved.
MCLS CLUSTERDFIT	represents the studentized Cook distance type statistic to measure the influence of deleting an entire cluster on the overall model fit.

Programming Statements

Although the most commonly used link and probability distributions are available as built-in functions, the GENMOD procedure enables you to define your own link functions and response probability distributions by using the FWDLINK, INVLINK, VARIANCE, and DEVIANCE statements. The variables assigned in these statements can have values computed in programming statements.

These programming statements can occur anywhere between the PROC GENMOD statement and the RUN statement. Variable names used in programming statements must be unique. Variables from the input data set can be referenced in programming statements. The mean, linear predictor, and response are represented by the automatic variables `_MEAN_`, `_XBETA_`, and `_RESP_`, respectively, which can be referenced in your programming statements. Programming statements are used to define the functional dependencies of the link function, the inverse link function, the variance function, and the deviance function on the mean, linear predictor, and response variable.

The following statements illustrate the use of programming statements. Even though you usually request the Poisson distribution by specifying `DIST=POISSON` as a MODEL statement option, you can define the variance and deviance functions for the Poisson distribution by using the VARIANCE and DEVIANCE statements. For example, the following statements perform the same analysis as the Poisson regression example in the section “[Getting Started: GENMOD Procedure](#)” on page 2720.

The statements must be in logical order for computation, just as in a DATA step.

```
proc genmod;
  class car age;
  a = _MEAN_;
  y = _RESP_;
  d = 2 * ( y * log( y / a ) - ( y - a ) );
  variance var = a;
  deviance dev = d;
  model c = car age / link = log offset = ln;
run;
```

The variables `var` and `dev` are dummy variables used internally by the procedure to identify the variance and deviance functions. Any valid SAS variable names can be used.

Similarly, the log link function and its inverse could be defined with the FWDLINK and INVLINK statements, as follows:

```
fwmlink link = log(_MEAN_);
invlink ilink = exp(_XBETA_);
```

These statements are for illustration, and they work well for most Poisson regression problems. If, however, in the iterative fitting process, the mean parameter becomes too close to 0, or a 0 response value occurs, an error condition occurs when the procedure attempts to evaluate the log function. You can circumvent this kind of problem by using IF-THEN/ELSE clauses or other conditional statements to check for possible error conditions and appropriately define the functions for these cases.

Data set variables can be referenced in user definitions of the link function and response distributions by using programming statements and the FWDLINK, INVLINK, DEVIANCE, and VARIANCE statements.

See the DEVIANCE, VARIANCE, FWDLINK, and INVLINK statements for more information.

The syntax of programming statements used in PROC GENMOD is identical to that used in the NLMIXED procedure and the GLIMMIX procedure (see Chapter 64, “[The NLMIXED Procedure](#),” and Chapter 41, “[The GLIMMIX Procedure](#),”) and the MODEL procedure (see the *SAS/ETS User’s Guide*). Most of the programming statements that can be used in the DATA step can also be used in the GENMOD procedure. See *SAS Statements: Reference* for a description of SAS programming statements. The following are some commonly used programming statements.

```

ABORT;
ARRAY arrayname <[ dimensions ]> <$> <variables-and-constants>;
CALL name <(expression <,> expression ... )>;
DELETE;
DO <variable = expression <TO expression> <BY expression> >
    <,> expression <TO expression> <BY expression> > ...
    <WHILE expression> <UNTIL expression>;
END;
GOTO statement-label;
IF expression;
IF expression THEN program-statement;
    ELSE program-statement;
variable = expression;
variable + expression;
LINK statement-label;
PUT <variable> <=> ...;
RETURN;
SELECT <(expression)>;
STOP;
SUBSTR(variable, index, length)= expression;
WHEN (expression)program-statement;
    OTHERWISE program-statement;

```

REPEATED Statement

REPEATED SUBJECT=subject-effect </ options> ;

The REPEATED statement specifies the covariance structure of multivariate responses for GEE model fitting in the GENMOD procedure. In addition, the REPEATED statement controls the iterative fitting algorithm used in GEEs and specifies optional output. Other GENMOD procedure statements, such as the MODEL and CLASS statements, are used in the same way as they are for ordinary generalized linear models to specify the regression model for the mean of the responses.

Table 40.8 summarizes the options available in the REPEATED statement.

Table 40.8 REPEATED Statement Options

Option	Description
ALPHAINIT=	Specifies initial values for log odds ratio regression parameters
CONVERGE=	Specifies the convergence criterion for GEE parameter estimation
CORRB	Displays the estimated correlation matrix
CORRW	Displays the estimated working correlation matrix

Table 40.8 *continued*

Option	Description
COVB	Displays the estimated covariance matrix
ECORRB	Displays the estimated empirical correlation matrix
ECOV	Displays the estimated empirical covariance matrix
INITIAL=	Specifies initial values of the regression parameters estimation
INTERCEPT=	Specifies either an initial or a fixed value of the intercept
LOGOR=	Specifies the regression structure of the log odds ratio
MAXITER=	Specifies the maximum number of iterations
MCORRB	Displays the estimated model-based correlation matrix
MCOVB	Displays the estimated model-based covariance matrix
MODELSE	Displays an analysis of parameter estimates table
PRINTMLE	Displays an analysis of maximum likelihood parameter estimates table
RUPDATE=	Specifies the number of iterations between updates of the working correlation matrix
SORTED	Groups by subject and sorts within subject
SUBCLUSTER=	Specifies a variable defining subclusters
SUBJECT=	Identifies a different subject, or cluster
TYPE=	Specifies the working correlation matrix structure
V6CORR	Uses the SAS 'Version 6' method of computing normalized Pearson chi-square
WITHIN=	Specifies the order of measurements within subjects
YPAIR=	Specifies the pairs of responses
ZDATA=	Specifies the full z matrix
ZROW=	Specifies the rows of the z matrix

SUBJECT=*subject-effect*

identifies subjects in the input data set. The *subject-effect* can be a single variable, an interaction effect, a nested effect, or a combination. Each distinct value, or level, of the effect identifies a different subject, or cluster. Responses from different subjects are assumed to be statistically independent, and responses within subjects are assumed to be correlated. A *subject-effect* must be specified, and variables used in defining the *subject-effect* must be listed in the CLASS statement. The input data set does not need to be sorted by subject (see the SORTED option).

The *options* control how the model is fit and what output is produced. You can specify the following options after a slash (/).

ALPHAINIT=*numbers*

specifies initial values for log odds ratio regression parameters if the LOGOR= option is specified for binary data. If this option is not specified, an initial value of 0.01 is used for all the parameters.

CONVERGE=*number*

specifies the convergence criterion for GEE parameter estimation. If the maximum absolute difference between regression parameter estimates is less than the value of *number* on two successive iterations, convergence is declared. If the absolute value of a regression parameter estimate is greater than 0.08, then the absolute difference normalized by the regression parameter value is used instead of the absolute difference. The default value of *number* is 0.0001.

CORRW

displays the estimated working correlation matrix. If you specify an exchangeable working correlation structure with the `CORR=EXCH` option, the `CORRW` option is not needed to view the estimated correlation, since a table is printed by default that contains the single estimated correlation.

CORRB

displays the estimated regression parameter correlation matrix. Both model-based and empirical correlations are displayed.

COVB

displays the estimated regression parameter covariance matrix. Both model-based and empirical covariances are displayed.

ECORRB

displays the estimated regression parameter empirical correlation matrix.

ECOV

displays the estimated regression parameter empirical covariance matrix.

INTERCEPT=number

specifies either an initial or a fixed value of the intercept regression parameter in the GEE model. If you specify the `NOINT` option in the `MODEL` statement, then the intercept is fixed at the value of *number*.

INITIAL=numbers

specifies initial values of the regression parameters estimation, other than the intercept parameter, for GEE estimation. If this option is not specified, the estimated regression parameters assuming independence for all responses are used for the initial values.

LOGOR=log-odds-ratio-structure-keyword

specifies the regression structure of the log odds ratio used to model the association of the responses from subjects for binary data. The response syntax must be of the single variable type, the distribution must be binomial, and the data must be binary. [Table 40.9](#) displays the log odds ratio structure keywords and the corresponding log odds ratio regression structures. See the section “[Alternating Logistic Regressions](#)” on page 2823 for definitions of the log odds ratio types and examples of specifying log odds ratio models. You should specify either the `LOGOR=` or the `TYPE=` option, but not both.

Table 40.9 Log Odds Ratio Regression Structures

Keyword	Log Odds Ratio Regression Structure
EXCH	Exchangeable
FULLCLUST	Fully parameterized clusters
LOGORVAR(<i>variable</i>)	Indicator variable for specifying block effects
NESTK	<i>k</i> -nested
NEST1	1-nested
ZFULL	Fully specified <i>z</i> matrix specified in <code>ZDATA=</code> data set
ZREP	Single cluster specification for replicated <i>z</i> matrix specified in <code>ZDATA=</code> data set
ZREP(matrix)	Single cluster specification for replicated <i>z</i> matrix

MAXITER=*number***MAXIT=***number*

specifies the maximum number of iterations allowed in the iterative GEE estimation process. The default number is 50.

MCORRB

displays the estimated regression parameter model-based correlation matrix.

MCOVB

displays the estimated regression parameter model-based covariance matrix.

MODELSE

displays an analysis of parameter estimates table that uses model-based standard errors for inference. By default, an “Analysis of Parameter Estimates” table based on empirical standard errors is displayed.

PRINTMLE

displays an analysis of maximum likelihood parameter estimates table. The maximum likelihood estimates are not displayed unless this option is specified.

RUPDATE=*number*

specifies the number of iterations between updates of the working correlation matrix. For example, RUPDATE=5 specifies that the working correlation is updated once for every five regression parameter updates. The default value of *number* is 1; that is, the working correlation is updated every time the regression parameters are updated.

SORTED

specifies that the input data are grouped by subject and sorted within subject. If this option is not specified, then the procedure internally sorts by *subject-effect* and *within subject-effect*, if a *within subject-effect* is specified.

SUBCLUSTER=*variable***SUBCLUST=***variable*

specifies a variable defining subclusters for the 1-nested or *k*-nested log odds ratio association modeling structures. This variable must be listed in the CLASS statement.

TYPE=*correlation-structure keyword***CORR=***correlation-structure keyword*

specifies the structure of the working correlation matrix used to model the correlation of the responses from subjects. [Table 40.10](#) displays the correlation structure keywords and the corresponding correlation structures. The default working correlation type is the independent (CORR=IND). See the section “[Details: GENMOD Procedure](#)” on page 2799 for definitions of the correlation matrix types. You should specify LOGOR= or TYPE= but not both.

Table 40.10 Correlation Structure Types

Keyword	Correlation Matrix Type
AR	
AR(1)	Autoregressive(1)
EXCH	
CS	Exchangeable
IND	Independent
MDEP(number)	<i>m</i> -dependent with <i>m</i> =number
UNSTR	
UN	Unstructured
USER	
FIXED (matrix)	Fixed, user-specified correlation matrix

For example, you can specify a fixed 4×4 correlation matrix with the following option:

```
type=user( 1.0  0.9  0.8  0.6
           0.9  1.0  0.9  0.8
           0.8  0.9  1.0  0.9
           0.6  0.8  0.9  1.0 )
```

V6CORR

specifies that the SAS ‘Version 6’ method of computing the normalized Pearson chi-square be used for working correlation estimation and for model-based covariance matrix scale factor.

WITHINSUBJECT | **WITHIN**=*within subject-effect*

defines an effect specifying the order of measurements within subjects. Each distinct level of the *within subject-effect* defines a different response from the same subject. If the data are in proper order within each subject, you do not need to specify this option.

If some measurements do not appear in the data for some subjects, this option properly orders the existing measurements and treats the omitted measurements as missing values. If the WITHINSUBJECT= option is not used in this situation, measurements might be improperly ordered and missing values assumed for the last measurements in a cluster.

Variables used in defining the *within subject-effect* must be listed in the CLASS statement.

YPAIR=*variable-list*

specifies the variables in the ZDATA= data set corresponding to pairs of responses for log odds ratio association modeling.

ZDATA=*SAS-data-set*

specifies a SAS data set containing either the full **z** matrix for log odds ratio association modeling or the **z** matrix for a single complete cluster to be replicated for all clusters.

ZROW=*variable-list*

specifies the variables in the ZDATA= data set corresponding to rows of the z matrix for log odds ratio association modeling.

SLICE Statement

SLICE *model-effect* < / *options* > ;

The SLICE statement provides a general mechanism for performing a partitioned analysis of the LS-means for an interaction. This analysis is also known as an analysis of simple effects.

The SLICE statement uses the same options as the LSMEANS statement, which are summarized in Table 19.21. For details about the syntax of the SLICE statement, see the section “SLICE Statement” on page 498 in Chapter 19, “Shared Concepts and Topics.”

STORE Statement

STORE < **OUT=** *item-store-name* < / **LABEL=** *'label'* > ;

The STORE statement requests that the procedure save the context and results of the statistical analysis. The resulting item store has a binary file format that cannot be modified. The contents of the item store can be processed with the PLM procedure.

For details about the syntax of the STORE statement, see the section “STORE Statement” on page 501 in Chapter 19, “Shared Concepts and Topics.”

STRATA Statement

STRATA *variable* < (*option*) > . . . < *variable* < (*option*) > > < / *options* > ;

The STRATA statement names the *variables* that define *strata* or *matched sets* to use in *stratified exact* logistic regression of binary response data, or a *stratified exact* Poisson regression of count data. An **EXACT** statement must also be specified.

Observations that have the same *variable* values are in the same matched set. For a stratified logistic model, you can analyze 1: 1, 1: *n*, *m*: *n*, and general *m*_{*i*}: *n*_{*i*} matched sets where the number of cases and controls varies across strata. For a stratified Poisson model, you can have any number of observations in each stratum. At least one variable must be specified to invoke the stratified analysis, and the usual unconditional asymptotic analysis is not performed. The stratified logistic model has the form

$$\text{logit}(\pi_{hi}) = \alpha_h + \mathbf{x}_{hi}'\boldsymbol{\beta}$$

where π_{hi} is the event probability for the *i*th observation in stratum *h* with covariates \mathbf{x}_{hi} and where the stratum-specific intercepts α_h are the nuisance parameters that are to be conditioned out.

STRATA variables can also be specified in the **MODEL** statement as classification or continuous covariates; however, the effects are nondegenerate only when crossed with a nonstratification variable. Specifying

several STRATA statements is the same as specifying one STRATA statement that contains all the strata variables. The STRATA variables can be either character or numeric, and the formatted values of the STRATA variables determine the levels. Thus, you can also use formats to group values into levels; see the discussion of the FORMAT procedure in the *Base SAS Procedures Guide*.

The “Strata Summary” table is displayed by default. For an exact logistic regression, it displays the number of strata that have a specific number of events and non-events. For example, if you are analyzing a 1: 5 matched study, this table enables you to verify that every stratum in the analysis has exactly one event and five non-events. Strata that contain only events or only non-events are reported in this table, but such strata are uninformative and are not used in the analysis. For an exact Poisson regression, the “Strata Summary” table displays the number of strata that contain a specific number of observations, which enables you to check whether every stratum in the analysis has the same number of observations.

The ASSESSMENT, BAYES, CONTRAST, EFFECTPLOT, ESTIMATE, LSMEANS, LSMESTIMATE, OUTPUT, REPEATED, SLICE, and STORE statements are not available with a STRATA statement. Exact analyses are not performed when you specify a WEIGHT statement, or a model other than LINK=LOGIT with DIST=BIN or LINK=LOG with DIST=POISSON. An OFFSET= variable is not available with exact logistic regression.

The following *option* can be specified for a stratification variable by enclosing the option in parentheses after the variable name, or it can be specified globally for all STRATA variables after a slash (/).

MISSING

treats missing values (‘.’, ‘._’, ‘.A’, ..., ‘.Z’ for numeric variables and blanks for character variables) as valid STRATA variable values.

The following strata *options* are also available after the slash:

CHECKDEPENDENCY | CHECK=keyword

specifies which variables are to be tested for dependency before the analysis is performed. The available *keywords* are as follows:

NONE performs no dependence checking. Typically, a message about a singular information matrix is displayed if you have dependent variables. Dependent variables can be identified after the analysis by noting any missing parameter estimates.

COVARIATES checks dependence between covariates and an added intercept. Dependent covariates are removed from the analysis. However, covariates that are linear functions of the strata variable might not be removed, which results in a singular information matrix message being displayed in the SAS log. This is the default.

ALL checks dependence between all the strata and covariates. This option can adversely affect performance if you have a large number of strata.

NOSUMMARY

suppresses the display of the “Strata Summary” table.

INFO

displays the “Strata Information” table, which includes the stratum number, levels of the STRATA variables that define the stratum, and the total frequency for each stratum. Since the number of strata can be very large, this table is displayed only by request.

VARIANCE Statement

VARIANCE *variable* = *expression* ;

You can specify a probability distribution other than the built-in distributions by using the VARIANCE and DEVIANCE statements. The variable name *variable* identifies the variance function to the procedure. The *expression* is used to define the functional dependence on the mean, and it can be any arithmetic expression supported by the DATA step language. You use the automatic variable `_MEAN_` to represent the mean in the expression.

Alternatively, you can define the variance function with programming statements, as detailed in the section “Programming Statements” on page 2790. This form is convenient for using complex statements such as IF-THEN/ELSE clauses. Derivatives of the variance function for use during optimization are computed automatically. The DEVIANCE statement must also appear when the VARIANCE statement is used to define the variance function.

WEIGHT Statement

WEIGHT | **SCWGT** *variable* ;

The WEIGHT statement identifies a *variable* in the input data set to be used as the exponential family dispersion parameter weight for each observation. The exponential family dispersion parameter is divided by the WEIGHT variable value for each observation. This is true regardless of whether the parameter is estimated by the procedure or specified in the MODEL statement with the SCALE= option. It is also true for distributions such as the Poisson and binomial that are not usually defined to have a dispersion parameter. For these distributions, a WEIGHT variable weights the overdispersion parameter, which has the default value of 1.

The WEIGHT variable does not have to be an integer; if it is less than or equal to 0 or if it is missing, the corresponding observation is not used.

ZEROMODEL Statement

ZEROMODEL *effects* < / *options* > ;

The ZEROMODEL statement enables you to perform zero-inflated Poisson regression or zero-inflated negative binomial regression when those respective distributions are specified by the DIST= option in the MODEL statement. The effects in the ZEROMODEL statement consist of explanatory variables or combinations of variables for the zero-inflation probability regression model in a zero-inflated model. The same effects can be used in both the ZEROMODEL statement and the MODEL statement, or effects can be used in one statement or the other separately. Explanatory variables can be continuous or classification variables. Classification variables can be character or numeric. Explanatory variables representing nominal, or classification, data must be declared in a CLASS statement. Interactions between variables can also be included as effects. Columns of the design matrix are automatically generated for classification variables and interactions. The syntax for specification of effects is the same as for the GLM procedure. See the section “Specification of Effects” on page 2810 for more information. Also see Chapter 42, “The GLM Procedure.”

You can specify the following option in the ZEROMODEL statement after a slash (/).

LINK=keyword

specifies the link function to use in the model. The keywords and their associated link functions are as follows.

LINK=	Link Function
CLOGLOG	
CLL	Complementary log-log
LOGIT	Logit
PROBIT	Probit

If no LINK= option is supplied, the LOGIT link is used. User-defined link functions are not allowed.

Details: GENMOD Procedure

Generalized Linear Models Theory

This is a brief introduction to the theory of generalized linear models.

Response Probability Distributions

In generalized linear models, the response is assumed to possess a probability distribution of the exponential form. That is, the probability density of the response Y for continuous response variables, or the probability function for discrete responses, can be expressed as

$$f(y) = \exp \left\{ \frac{y\theta - b(\theta)}{a(\phi)} + c(y, \phi) \right\}$$

for some functions a , b , and c that determine the specific distribution. For fixed ϕ , this is a one-parameter exponential family of distributions. The functions a and c are such that $a(\phi) = \phi/w$ and $c = c(y, \phi/w)$, where w is a known weight for each observation. A variable representing w in the input data set can be specified in the WEIGHT statement. If no WEIGHT statement is specified, $w_i = 1$ for all observations.

Standard theory for this type of distribution gives expressions for the mean and variance of Y :

$$\begin{aligned} E(Y) &= b'(\theta) \\ \text{Var}(Y) &= \frac{b''(\theta)\phi}{w} \end{aligned}$$

where the primes denote derivatives with respect to θ . If μ represents the mean of Y , then the variance expressed as a function of the mean is

$$\text{Var}(Y) = \frac{V(\mu)\phi}{w}$$

where V is the *variance function*.

Probability distributions of the response Y in generalized linear models are usually parameterized in terms of the mean μ and dispersion parameter ϕ instead of the *natural parameter* θ . The probability distributions that are available in the GENMOD procedure are shown in the following list. The zero-inflated Poisson and zero-inflated negative binomial distributions are not generalized linear models. However, the zero-inflated distributions are included in PROC GENMOD since they are useful extensions of generalized linear models. See Long (1997) for a discussion of the zero-inflated Poisson and zero-inflated negative binomial distributions. The PROC GENMOD scale parameter and the variance of Y are also shown.

- Normal:

$$\begin{aligned} f(y) &= \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{1}{2}\left(\frac{y-\mu}{\sigma}\right)^2\right] \quad \text{for } -\infty < y < \infty \\ \phi &= \sigma^2 \\ \text{scale} &= \sigma \\ \text{Var}(Y) &= \sigma^2 \end{aligned}$$

- Inverse Gaussian:

$$\begin{aligned} f(y) &= \frac{1}{\sqrt{2\pi y^3}\sigma} \exp\left[-\frac{1}{2y}\left(\frac{y-\mu}{\mu\sigma}\right)^2\right] \quad \text{for } 0 < y < \infty \\ \phi &= \sigma^2 \\ \text{scale} &= \sigma \\ \text{Var}(Y) &= \sigma^2 \mu^3 \end{aligned}$$

- Gamma:

$$\begin{aligned} f(y) &= \frac{1}{\Gamma(v)y} \left(\frac{yv}{\mu}\right)^v \exp\left(-\frac{yv}{\mu}\right) \quad \text{for } 0 < y < \infty \\ \phi &= v^{-1} \\ \text{scale} &= v \\ \text{Var}(Y) &= \frac{\mu^2}{v} \end{aligned}$$

- Geometric: This is a special case of the negative binomial with $k = 1$.

$$\begin{aligned} f(y) &= \frac{(\mu)^y}{(1+\mu)^{y+1}} \quad \text{for } y = 0, 1, 2, \dots \\ \phi &= 1 \\ \text{Var}(Y) &= \mu(1+\mu) \end{aligned}$$

- Negative binomial:

$$\begin{aligned}
 f(y) &= \frac{\Gamma(y+1/k)}{\Gamma(y+1)\Gamma(1/k)} \frac{(k\mu)^y}{(1+k\mu)^{y+1/k}} \quad \text{for } y = 0, 1, 2, \dots \\
 \phi &= 1 \\
 \text{dispersion} &= k \\
 \text{Var}(Y) &= \mu + k\mu^2
 \end{aligned}$$

- Poisson:

$$\begin{aligned}
 f(y) &= \frac{\mu^y e^{-\mu}}{y!} \quad \text{for } y = 0, 1, 2, \dots \\
 \phi &= 1 \\
 \text{Var}(Y) &= \mu
 \end{aligned}$$

- Binomial:

$$\begin{aligned}
 f(y) &= \binom{n}{r} \mu^r (1-\mu)^{n-r} \quad \text{for } y = \frac{r}{n}, \quad r = 0, 1, 2, \dots, n \\
 \phi &= 1 \\
 \text{Var}(Y) &= \frac{\mu(1-\mu)}{n}
 \end{aligned}$$

- Multinomial:

$$\begin{aligned}
 f(y_1, y_2, \dots, y_k) &= \frac{m!}{y_1! y_2! \dots y_k!} p_1^{y_1} p_2^{y_2} \dots p_k^{y_k} \\
 \phi &= 1
 \end{aligned}$$

- Zero-inflated Poisson:

$$\begin{aligned}
 f(y) &= \begin{cases} \omega + (1-\omega)e^{-\lambda} & \text{for } y = 0 \\ (1-\omega)\frac{\lambda^y e^{-\lambda}}{y!} & \text{for } y = 1, 2, \dots \end{cases} \\
 \phi &= 1 \\
 \mu = E(Y) &= (1-\omega)\lambda \\
 \text{Var}(Y) &= (1-\omega)\lambda(1+\omega\lambda) \\
 &= \mu + \frac{\omega}{1-\omega}\mu^2
 \end{aligned}$$

- Zero-inflated negative binomial:

$$\begin{aligned}
 f(y) &= \begin{cases} \omega + (1 - \omega)(1 + k\lambda)^{-\frac{1}{k}} & \text{for } y = 0 \\ (1 - \omega) \frac{\Gamma(y+1/k)}{\Gamma(y+1)\Gamma(1/k)} \frac{(k\lambda)^y}{(1+k\lambda)^{y+1/k}} & \text{for } y = 1, 2, \dots \end{cases} \\
 \phi &= 1 \\
 \text{dispersion} &= k \\
 \mu = E(Y) &= (1 - \omega)\lambda \\
 \text{Var}(Y) &= (1 - \omega)\lambda(1 + \omega\lambda + k\lambda) \\
 &= \mu + \left(\frac{\omega}{1 - \omega} + \frac{k}{1 - \omega} \right) \mu^2
 \end{aligned}$$

The negative binomial and the zero-inflated negative binomial distributions contain a parameter k , called the negative binomial dispersion parameter. This is not the same as the generalized linear model dispersion ϕ , but it is an additional distribution parameter that must be estimated or set to a fixed value.

For the binomial distribution, the response is the binomial proportion $Y = \text{events}/\text{trials}$. The variance function is $V(\mu) = \mu(1 - \mu)$, and the binomial trials parameter n is regarded as a weight w .

If a weight variable is present, ϕ is replaced with ϕ/w , where w is the weight variable.

PROC GENMOD works with a scale parameter that is related to the exponential family dispersion parameter ϕ instead of working with ϕ itself. The scale parameters are related to the dispersion parameter as shown previously with the probability distribution definitions. Thus, the scale parameter output in the “Analysis of Parameter Estimates” table is related to the exponential family dispersion parameter. If you specify a constant scale parameter with the SCALE= option in the MODEL statement, it is also related to the exponential family dispersion parameter in the same way.

Link Function

For distributions other than the zero-inflated Poisson or zero-inflated negative binomial, the mean μ_i of the response in the i th observation is related to a linear predictor through a monotonic differentiable link function g .

$$g(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}$$

Here, \mathbf{x}_i is a fixed known vector of explanatory variables, and $\boldsymbol{\beta}$ is a vector of unknown parameters.

There are two link functions and linear predictors associated with zero-inflated distributions: one for the zero inflation probability ω , and another for the mean parameter λ . See the section “Zero-Inflated Models” on page 2818 for more details about zero-inflated distributions.

Log-Likelihood Functions

Log-likelihood functions for the distributions that are available in the procedure are parameterized in terms of the means μ_i and the dispersion parameter ϕ . Zero-inflated log likelihoods are parameterized in terms two parameters, λ and ω . The parameter ω is the zero-inflation probability, and λ is a function of the distribution mean. The relationship between the mean of the zero-inflated Poisson and zero-inflated negative binomial distributions and the parameter λ is defined in the section “Response Probability Distributions”

on page 2799. The term y_i represents the response for the i th observation, and w_i represents the known dispersion weight. The log-likelihood functions are of the form

$$L(\mathbf{y}, \boldsymbol{\mu}, \phi) = \sum_i \log(f(y_i, \mu_i, \phi))$$

where the sum is over the observations. The forms of the individual contributions

$$l_i = \log(f(y_i, \mu_i, \phi))$$

are shown in the following list; the parameterizations are expressed in terms of the mean and dispersion parameters.

For the discrete distributions (binomial, multinomial, negative binomial, and Poisson), the functions computed as the sum of the l_i terms are not proper log-likelihood functions, since terms involving binomial coefficients or factorials of the observed counts are dropped from the computation of the log likelihood, and a dispersion parameter ϕ is included in the computation. Deletion of factorial terms and inclusion of a dispersion parameter do not affect parameter estimates or their estimated covariances for these distributions, and this is the function used in maximum likelihood estimation. The value of ϕ used in computing the reported log-likelihood function is either the final estimated value, or the fixed value, if the dispersion parameter is fixed. Even though it is not a proper log-likelihood function in all cases, the function computed as the sum of the l_i terms is reported in the output as the *log likelihood*. The proper log-likelihood function is also computed as the sum of the ll_i terms in the following list, and it is reported as the *full log likelihood* in the output.

- Normal:

$$ll_i = l_i = -\frac{1}{2} \left[\frac{w_i (y_i - \mu_i)^2}{\phi} + \log\left(\frac{\phi}{w_i}\right) + \log(2\pi) \right]$$

- Inverse Gaussian:

$$ll_i = l_i = -\frac{1}{2} \left[\frac{w_i (y_i - \mu_i)^2}{y_i \mu^2 \phi} + \log\left(\frac{\phi y_i^3}{w_i}\right) + \log(2\pi) \right]$$

- Gamma:

$$ll_i = l_i = \frac{w_i}{\phi} \log\left(\frac{w_i y_i}{\phi \mu_i}\right) - \frac{w_i y_i}{\phi \mu_i} - \log(y_i) - \log\left(\Gamma\left(\frac{w_i}{\phi}\right)\right)$$

- Negative binomial:

$$l_i = y_i \log\left(\frac{k\mu}{w_i}\right) - (y_i + w_i/k) \log\left(1 + \frac{k\mu}{w_i}\right) + \log\left(\frac{\Gamma(y_i + w_i/k)}{\Gamma(w_i/k)}\right)$$

$$ll_i = y_i \log\left(\frac{k\mu}{w_i}\right) - (y_i + w_i/k) \log\left(1 + \frac{k\mu}{w_i}\right) + \log\left(\frac{\Gamma(y_i + w_i/k)}{\Gamma(y_i + 1)\Gamma(w_i/k)}\right)$$

- Poisson:

$$l_i = \frac{w_i}{\phi} [y_i \log(\mu_i) - \mu_i]$$

$$ll_i = w_i [y_i \log(\mu_i) - \mu_i - \log(y_i!)]$$

- Binomial:

$$l_i = \frac{w_i}{\phi} [r_i \log(p_i) + (n_i - r_i) \log(1 - p_i)]$$

$$ll_i = w_i [\log \binom{n_i}{r_i} + r_i \log(p_i) + (n_i - r_i) \log(1 - p_i)]$$

- Multinomial (k categories):

$$l_i = \frac{w_i}{\phi} \sum_{j=1}^k y_{ij} \log(\mu_{ij})$$

$$ll_i = w_i [\log(m_i!) + \sum_{j=1}^k (y_{ij} \log(\mu_{ij}) - \log(y_{ij}!))]$$

- Zero-inflated Poisson:

$$l_i = ll_i = \begin{cases} w_i \log[\omega_i + (1 - \omega_i) \exp(-\lambda_i)] & y_i = 0 \\ w_i [\log(1 - \omega_i) + y_i \log(\lambda_i) - \lambda_i - \log(y_i!)] & y_i > 0 \end{cases}$$

- Zero-inflated negative binomial:

$$l_i = ll_i = \begin{cases} \log[\omega_i + (1 - \omega_i)(1 + \frac{k}{w_i} \lambda)^{-\frac{1}{k}}] & y_i = 0 \\ \log(1 - \omega_i) + y_i \log\left(\frac{k\lambda}{w_i}\right) \\ - (y_i + \frac{w_i}{k}) \log\left(1 + \frac{k\lambda}{w_i}\right) \\ + \log\left(\frac{\Gamma(y_i + \frac{w_i}{k})}{\Gamma(y_i + 1) \Gamma(\frac{w_i}{k})}\right) & y_i > 0 \end{cases}$$

Maximum Likelihood Fitting

The GENMOD procedure uses a ridge-stabilized Newton-Raphson algorithm to maximize the log-likelihood function $L(\mathbf{y}, \boldsymbol{\mu}, \phi)$ with respect to the regression parameters. By default, the procedure also produces maximum likelihood estimates of the scale parameter as defined in the section “[Response Probability Distributions](#)” on page 2799 for the normal, inverse Gaussian, negative binomial, and gamma distributions.

On the r th iteration, the algorithm updates the parameter vector $\boldsymbol{\beta}_r$ with

$$\boldsymbol{\beta}_{r+1} = \boldsymbol{\beta}_r - \mathbf{H}^{-1}\mathbf{s}$$

where \mathbf{H} is the Hessian (second derivative) matrix, and \mathbf{s} is the gradient (first derivative) vector of the log-likelihood function, both evaluated at the current value of the parameter vector. That is,

$$\mathbf{s} = [s_j] = \left[\frac{\partial L}{\partial \beta_j} \right]$$

and

$$\mathbf{H} = [h_{ij}] = \left[\frac{\partial^2 L}{\partial \beta_i \partial \beta_j} \right]$$

In some cases, the scale parameter is estimated by maximum likelihood. In these cases, elements corresponding to the scale parameter are computed and included in \mathbf{s} and \mathbf{H} .

If $\eta_i = \mathbf{x}_i' \boldsymbol{\beta}$ is the linear predictor for observation i and g is the link function, then $\eta_i = g(\mu_i)$, so that $\mu_i = g^{-1}(\mathbf{x}_i' \boldsymbol{\beta})$ is an estimate of the mean of the i th observation, obtained from an estimate of the parameter vector $\boldsymbol{\beta}$.

The gradient vector and Hessian matrix for the regression parameters are given by

$$\begin{aligned} \mathbf{s} &= \sum_i \frac{w_i(y_i - \mu_i)\mathbf{x}_i}{V(\mu_i)g'(\mu_i)\phi} \\ \mathbf{H} &= -\mathbf{X}'\mathbf{W}_o\mathbf{X} \end{aligned}$$

where \mathbf{X} is the design matrix, \mathbf{x}_i is the transpose of the i th row of \mathbf{X} , and V is the variance function. The matrix \mathbf{W}_o is diagonal with its i th diagonal element

$$w_{oi} = w_{ei} + w_i(y_i - \mu_i) \frac{V(\mu_i)g''(\mu_i) + V'(\mu_i)g'(\mu_i)}{(V(\mu_i))^2(g'(\mu_i))^3\phi}$$

where

$$w_{ei} = \frac{w_i}{\phi V(\mu_i)(g'(\mu_i))^2}$$

The primes denote derivatives of g and V with respect to μ . The negative of \mathbf{H} is called the observed information matrix. The expected value of \mathbf{W}_o is a diagonal matrix \mathbf{W}_e with diagonal values w_{ei} . If you replace \mathbf{W}_o with \mathbf{W}_e , then the negative of \mathbf{H} is called the expected information matrix. \mathbf{W}_e is the weight matrix for the Fisher scoring method of fitting. Either \mathbf{W}_o or \mathbf{W}_e can be used in the update equation. The GENMOD procedure uses Fisher scoring for iterations up to the number specified by the SCORING option in the MODEL statement, and it uses the observed information matrix on additional iterations.

Covariance and Correlation Matrix

The estimated covariance matrix of the parameter estimator is given by

$$\Sigma = -\mathbf{H}^{-1}$$

where \mathbf{H} is the Hessian matrix evaluated using the parameter estimates on the last iteration. Note that the dispersion parameter, whether estimated or specified, is incorporated into \mathbf{H} . Rows and columns corresponding to aliased parameters are not included in Σ .

The correlation matrix is the normalized covariance matrix. That is, if σ_{ij} is an element of Σ , then the corresponding element of the correlation matrix is $\sigma_{ij}/\sigma_i\sigma_j$, where $\sigma_i = \sqrt{\sigma_{ii}}$.

Goodness of Fit

Two statistics that are helpful in assessing the goodness of fit of a given generalized linear model are the scaled deviance and Pearson's chi-square statistic. For a fixed value of the dispersion parameter ϕ , the scaled deviance is defined to be twice the difference between the maximum achievable log likelihood and the log likelihood at the maximum likelihood estimates of the regression parameters.

Note that these statistics are not valid for GEE models.

If $l(\mathbf{y}, \boldsymbol{\mu})$ is the log-likelihood function expressed as a function of the predicted mean values $\boldsymbol{\mu}$ and the vector \mathbf{y} of response values, then the scaled deviance is defined by

$$D^*(\mathbf{y}, \boldsymbol{\mu}) = 2(l(\mathbf{y}, \mathbf{y}) - l(\mathbf{y}, \boldsymbol{\mu}))$$

For specific distributions, this can be expressed as

$$D^*(\mathbf{y}, \boldsymbol{\mu}) = \frac{D(\mathbf{y}, \boldsymbol{\mu})}{\phi}$$

where D is the deviance. The following table displays the deviance for each of the probability distributions available in PROC GENMOD. The deviance cannot be directly calculated for zero-inflated models. Twice the negative of the log likelihood is reported instead of the proper deviance for the zero-inflated Poisson and zero-inflated negative binomial.

Distribution	Deviance
Normal	$\sum_i w_i (y_i - \mu_i)^2$
Poisson	$2 \sum_i w_i \left[y_i \log \left(\frac{y_i}{\mu_i} \right) - (y_i - \mu_i) \right]$
Binomial	$2 \sum_i w_i m_i \left[y_i \log \left(\frac{y_i}{\mu_i} \right) + (1 - y_i) \log \left(\frac{1 - y_i}{1 - \mu_i} \right) \right]$
Gamma	$2 \sum_i w_i \left[-\log \left(\frac{y_i}{\mu_i} \right) + \frac{y_i - \mu_i}{\mu_i} \right]$
Inverse Gaussian	$\sum_i \frac{w_i (y_i - \mu_i)^2}{\mu_i^2 y_i}$
Multinomial	$\sum_i \sum_j w_i y_{ij} \log \left(\frac{y_{ij}}{p_{ij} m_i} \right)$
Negative binomial	$2 \sum_i \left[y \log(y/\mu) - (y + w_i/k) \log \left(\frac{y + w_i/k}{\mu + w_i/k} \right) \right]$
Zero-inflated Poisson	$-2 \sum_i \begin{cases} w_i \log[\omega_i + (1 - \omega_i) \exp(-\mu_i)] & y_i = 0 \\ w_i [\log(1 - \omega_i) + y_i \log(\mu_i) - \mu_i - \log(y_i!)] & y_i > 0 \end{cases}$
Zero-inflated negative binomial	$-2 \sum_i \begin{cases} \log[\omega_i + (1 - \omega_i)(1 + \frac{k}{w_i} \lambda)] & y_i = 0 \\ \log(1 - \omega_i) + y_i \log \left(\frac{k\lambda}{w_i} \right) - (y_i + \frac{w_i}{k}) \log \left(1 + \frac{k\lambda}{w_i} \right) + \log \left(\frac{\Gamma(y_i + \frac{w_i}{k})}{\Gamma(y_i + 1) \Gamma(\frac{w_i}{k})} \right) & y_i > 0 \end{cases}$

In the binomial case, $y_i = r_i/m_i$, where r_i is a binomial count and m_i is the binomial number of trials parameter.

In the multinomial case, y_{ij} refers to the observed number of occurrences of the j th category for the i th subpopulation defined by the AGGREGATE= variable, m_i is the total number in the i th subpopulation, and p_{ij} is the category probability.

Pearson's chi-square statistic is defined as

$$X^2 = \sum_i \frac{w_i (y_i - \mu_i)^2}{V(\mu_i)}$$

and the scaled Pearson's chi-square is X^2/ϕ .

The scaled version of both of these statistics, under certain regularity conditions, has a limiting chi-square distribution, with degrees of freedom equal to the number of observations minus the number of parameters estimated. The scaled version can be used as an approximate guide to the goodness of fit of a given model. Use caution before applying these statistics to ensure that all the conditions for the asymptotic distributions hold. McCullagh and Nelder (1989) advise that differences in deviances for nested models can be better approximated by chi-square distributions than the deviances can themselves.

In cases where the dispersion parameter is not known, an estimate can be used to obtain an approximation to the scaled deviance and Pearson's chi-square statistic. One strategy is to fit a model that contains a sufficient

number of parameters so that all systematic variation is removed, estimate ϕ from this model, and then use this estimate in computing the scaled deviance of submodels. The deviance or Pearson's chi-square divided by its degrees of freedom is sometimes used as an estimate of the dispersion parameter ϕ . For example, since the limiting chi-square distribution of the scaled deviance $D^* = D/\phi$ has $n - p$ degrees of freedom, where n is the number of observations and p is the number of parameters, equating D^* to its mean and solving for ϕ yields $\hat{\phi} = D/(n - p)$. Similarly, an estimate of ϕ based on Pearson's chi-square X^2 is $\hat{\phi} = X^2/(n - p)$. Alternatively, a maximum likelihood estimate of ϕ can be computed by the procedure, if desired. See the discussion in the section “[Type 1 Analysis](#)” on page 2811 for more about the estimation of the dispersion parameter.

Other Fit Statistics

The Akaike information criterion (AIC) is a measure of goodness of model fit that balances model fit against model simplicity. AIC has the form

$$\text{AIC} = -2\text{LL} + 2p$$

where p is the number of parameters estimated in the model, and LL is the log likelihood evaluated at the value of the estimated parameters. An alternative form is the corrected AIC given by

$$\text{AICC} = -2\text{LL} + 2p \frac{n}{n - p - 1}$$

where n is the total number of observations used.

The Bayesian information criterion (BIC) is a similar measure. BIC is defined by

$$\text{BIC} = -2\text{LL} + p \log(n)$$

See Akaike (1981, 1979) for details of AIC and BIC. See Simonoff (2003) for a discussion of using AIC, AICC, and BIC with generalized linear models. These criteria are useful in selecting among regression models, with smaller values representing better model fit. PROC GENMOD uses the full log likelihoods defined in the section “[Log-Likelihood Functions](#)” on page 2802, with all terms included, for computing all of the criteria.

Dispersion Parameter

There are several options available in PROC GENMOD for handling the exponential distribution dispersion parameter. The NOSCALE and SCALE options in the MODEL statement affect the way in which the dispersion parameter is treated. If you specify the SCALE=DEVIANCE option, the dispersion parameter is estimated by the deviance divided by its degrees of freedom. If you specify the SCALE=PEARSON option, the dispersion parameter is estimated by Pearson's chi-square statistic divided by its degrees of freedom.

Otherwise, values of the SCALE and NOSCALE options and the resultant actions are displayed in the following table.

NOSCALE	SCALE=value	Action
Present	Present	Scale fixed at <i>value</i>
Present	Not present	Scale fixed at 1
Not present	Not present	Scale estimated by ML
Not present	Present	Scale estimated by ML, starting point at <i>value</i>
Present (negative binomial)	Not present	k fixed at 0

The meaning of the scale parameter displayed in the “Analysis Of Parameter Estimates” table is different for the gamma distribution than for the other distributions. The relation of the scale parameter as used by PROC GENMOD to the exponential family dispersion parameter ϕ is displayed in the following table. For the binomial and Poisson distributions, ϕ is the overdispersion parameter, as defined in the “Overdispersion” section, which follows.

Distribution	Scale
Normal	$\sqrt{\phi}$
Inverse Gaussian	$\sqrt{\phi}$
Gamma	$1/\phi$
Binomial	$\sqrt{\phi}$
Poisson	$\sqrt{\phi}$

In the case of the negative binomial distribution, PROC GENMOD reports the “dispersion” parameter estimated by maximum likelihood. This is the negative binomial parameter k defined in the section “[Response Probability Distributions](#)” on page 2799.

Overdispersion

Overdispersion is a phenomenon that sometimes occurs in data that are modeled with the binomial or Poisson distributions. If the estimate of dispersion after fitting, as measured by the deviance or Pearson’s chi-square, divided by the degrees of freedom, is not near 1, then the data might be *overdispersed* if the dispersion estimate is greater than 1 or *underdispersed* if the dispersion estimate is less than 1. A simple way to model this situation is to allow the variance functions of these distributions to have a multiplicative overdispersion factor ϕ :

- Binomial: $V(\mu) = \phi\mu(1 - \mu)$
- Poisson: $V(\mu) = \phi\mu$

An alternative method to allow for overdispersion in the Poisson distribution is to fit a negative binomial distribution, where $V(\mu) = \mu + k\mu^2$, instead of the Poisson. The parameter k can be estimated by maximum likelihood, thus allowing for overdispersion of a specific form. This is different from the multiplicative overdispersion factor ϕ , which can accommodate many forms of overdispersion.

The models are fit in the usual way, and the parameter estimates are not affected by the value of ϕ . The covariance matrix, however, is multiplied by ϕ , and the scaled deviance and log likelihoods used in likelihood ratio tests are divided by ϕ . The profile likelihood function used in computing confidence intervals is also divided by ϕ . If you specify a WEIGHT statement, ϕ is divided by the value of the WEIGHT variable for each observation. This has the effect of multiplying the contributions of the log-likelihood function, the gradient, and the Hessian by the value of the WEIGHT variable for each observation.

The SCALE= option in the MODEL statement enables you to specify a value of $\sigma = \sqrt{\phi}$ for the binomial and Poisson distributions. If you specify the SCALE=DEVIANCE option in the MODEL statement, the procedure uses the deviance divided by degrees of freedom as an estimate of ϕ , and all statistics are adjusted appropriately. You can use Pearson’s chi-square instead of the deviance by specifying the SCALE=PEARSON option.

The function obtained by dividing a log-likelihood function for the binomial or Poisson distribution by a dispersion parameter is not a legitimate log-likelihood function. It is an example of a *quasi-likelihood*

function. Most of the asymptotic theory for log likelihoods also applies to quasi-likelihoods, which justifies computing standard errors and likelihood ratio statistics by using quasi-likelihoods instead of proper log likelihoods. For details on quasi-likelihood functions, see McCullagh and Nelder (1989, Chapter 9), McCullagh (1983); Hardin and Hilbe (2003).

Although the estimate of the dispersion parameter is often used to indicate overdispersion or underdispersion, this estimate might also indicate other problems such as an incorrectly specified model or outliers in the data. You should carefully assess whether this type of model is appropriate for your data.

Specification of Effects

Each term in a model is called an effect. Effects are specified in the MODEL statement. You specify effects with a special notation that uses variable names and operators. There are two types of variables, *classification* (or CLASS) variables and *continuous* variables. There are two primary types of operators, *crossing* and *nesting*. A third type, the *bar* operator, is used to simplify effect specification. Crossing is the type of operator most commonly used in generalized linear models.

Variables that identify classification levels are called CLASS variables in SAS and are identified in a CLASS statement. These might also be called *categorical*, *qualitative*, *discrete*, or *nominal* variables. CLASS variables can be either character or numeric. The values of CLASS variables are called *levels*. For example, the CLASS variable Sex could have the levels ‘male’ and ‘female’.

In a model, an explanatory variable that is not declared in a CLASS statement is assumed to be continuous. Continuous variables must be numeric. For example, the heights and weights of subjects in an experiment are continuous variables.

The types of effects most useful in generalized linear models are shown in the following list. Assume that A, B, and C are classification variables and that X1 and X2 are continuous variables.

- Regressor effects are specified by writing continuous variables by themselves: X1, X2.
- Polynomial effects are specified by joining two or more continuous variables with asterisks: X1*X2.
- Main effects are specified by writing classification variables by themselves: A, B, C.
- Crossed effects (interactions) are specified by joining two or more classification variables with asterisks: A*B, B*C, A*B*C.
- Nested effects are specified by following a main effect or crossed effect with a classification variable or list of classification variables enclosed in parentheses: B(A), C(B A), A*B(C). In the preceding example, B(A) is “B nested within A.”
- Combinations of continuous and classification variables can be specified in the same way by using the crossing and nesting operators.

The bar operator consists of two effects joined with a vertical bar (|). It is shorthand notation for including the left-hand side, the right-hand side, and the cross between them as effects in the model. For example, A | B is equivalent to A B A*B. The effects in the bar operator can be classification variables, continuous variables, or combinations of effects defined using operators. Multiple bars are permitted. For example, A | B | C means A B C A*B A*C B*C A*B*C.

You can specify the maximum number of variables in any effect that results from bar evaluation by specifying the maximum number, preceded by an @ sign. For example, `A | B | C@2` results in effects that involve two or fewer variables: `A B C A*B A*C B*C`.

Parameterization Used in PROC GENMOD

Design Matrix

The linear predictor part of a generalized linear model is

$$\eta = \mathbf{X}\boldsymbol{\beta}$$

where $\boldsymbol{\beta}$ is an unknown parameter vector and \mathbf{X} is a known design matrix. By default, all models automatically contain an intercept term; that is, the first column of \mathbf{X} contains all 1s. Additional columns of \mathbf{X} are generated for classification variables, regression variables, and any interaction terms included in the model. It is important to understand the ordering of classification variable parameters when you use the ESTIMATE or CONTRAST statement. The ordering of these parameters is displayed in the “[CLASS Level Information](#)” table and in tables displaying the parameter estimates of the fitted model.

When you specify an overparameterized model with the `PARAM=GLM` option in the CLASS statement, some columns of \mathbf{X} can be linearly dependent on other columns. For example, when you specify a model consisting of an intercept term and a classification variable, the column corresponding to any one of the levels of the classification variable is linearly dependent on the other columns of \mathbf{X} . The columns of $\mathbf{X}'\mathbf{X}$ are checked in the order in which the model is specified for dependence on preceding columns. If a dependency is found, the parameter corresponding to the dependent column is set to 0 along with its standard error to indicate that it is not estimated. The order in which the levels of a classification variable are checked for dependencies can be set by the `ORDER=` option in the PROC GENMOD statement or by the `ORDER=` option in the CLASS statement. For full-rank parameterizations, the columns of the \mathbf{X} matrix are designed to be linearly independent.

You can exclude the intercept term from the model by specifying the `NOINT` option in the MODEL statement.

Missing Level Combinations

All levels of interaction terms involving classification variables might not be represented in the data. In that case, PROC GENMOD does not include parameters in the model for the missing levels.

Type 1 Analysis

A Type 1 analysis consists of fitting a sequence of models, beginning with a simple model with only an intercept term, and continuing through a model of specified complexity, fitting one additional effect on each step. Likelihood ratio statistics—that is, twice the difference of the log likelihoods—are computed between successive models. This type of analysis is sometimes called an analysis of deviance since, if the dispersion parameter is held fixed for all models, it is equivalent to computing differences of scaled deviances. The asymptotic distribution of the likelihood ratio statistics, under the hypothesis that the additional parameters included in the model are equal to 0, is a chi-square with degrees of freedom equal to the difference in the

number of parameters estimated in the successive models. Thus, these statistics can be used in a test of hypothesis of the significance of each additional term fit.

This type of analysis is not available for GEE models, since the deviance is not computed for this type of model.

If the dispersion parameter ϕ is known, it can be included in the models; if it is unknown, there are two strategies allowed by PROC GENMOD. The dispersion parameter can be estimated from a maximal model by the deviance or Pearson's chi-square divided by degrees of freedom, as discussed in the section “[Goodness of Fit](#)” on page 2806, and this value can be used in all models. An alternative is to consider the dispersion to be an additional unknown parameter for each model and estimate it by maximum likelihood on each step. By default, PROC GENMOD estimates scale by maximum likelihood at each step.

A table of likelihood ratio statistics is produced, along with associated p -values based on the asymptotic chi-square distributions.

If you specify either the SCALE=DEVIANCE or the SCALE=PEARSON option in the MODEL statement, the dispersion parameter is estimated using the deviance or Pearson's chi-square statistic, and F statistics are computed in addition to the chi-square statistics for assessing the significance of each additional term in the Type 1 analysis. See the section “[F Statistics](#)” on page 2814 for a definition of F statistics.

This Type 1 analysis has the general property that the results depend on the order in which the terms of the model are fitted. The terms are fitted in the order in which they are specified in the MODEL statement.

Type 3 Analysis

A Type 3 analysis is similar to the Type III sums of squares used in PROC GLM, except that likelihood ratios are used instead of sums of squares. First, a Type III estimable function is defined for an effect of interest in exactly the same way as in PROC GLM. Then maximum likelihood estimates are computed under the constraint that the Type III function of the parameters is equal to 0, by using constrained optimization. Let the resulting constrained parameter estimates be $\tilde{\beta}$ and the log likelihood be $l(\tilde{\beta})$. Then the likelihood ratio statistic

$$S = 2(l(\hat{\beta}) - l(\tilde{\beta}))$$

where $\hat{\beta}$ is the unconstrained estimate, has an asymptotic chi-square distribution under the hypothesis that the Type III contrast is equal to 0, with degrees of freedom equal to the number of parameters associated with the effect.

When a Type 3 analysis is requested, PROC GENMOD produces a table that contains the likelihood ratio statistics, degrees of freedom, and p -values based on the limiting chi-square distributions for each effect in the model. If you specify either the DSCALE or PSCALE option in the MODEL statement, F statistics are also computed for each effect.

Options for handling the dispersion parameter are the same as for a Type 1 analysis. The dispersion parameter can be specified to be a known value, estimated from the deviance or Pearson's chi-square divided by degrees of freedom, or estimated by maximum likelihood individually for the unconstrained and constrained models. By default, PROC GENMOD estimates scale by maximum likelihood for each model fit.

The results of this type of analysis do not depend on the order in which the terms are specified in the MODEL statement.

A Type 3 analysis can consume considerable computation time since a constrained model is fitted for each effect. Wald statistics for Type 3 contrasts are computed if you specify the WALT option. Wald statistics for contrasts use less computation time than likelihood ratio statistics but might be less accurate indicators of the significance of the effect of interest. The Wald statistic for testing $\mathbf{L}'\boldsymbol{\beta} = \mathbf{0}$, where \mathbf{L} is the contrast matrix, is defined by

$$S = (\mathbf{L}'\hat{\boldsymbol{\beta}})'(\mathbf{L}'\hat{\boldsymbol{\Sigma}}\mathbf{L})^{-1}(\mathbf{L}'\hat{\boldsymbol{\beta}})$$

where $\boldsymbol{\beta}$ is the maximum likelihood estimate and $\boldsymbol{\Sigma}$ is its estimated covariance matrix. The asymptotic distribution of S is chi-square with r degrees of freedom, where r is the rank of \mathbf{L} .

See Chapter 42, “The GLM Procedure,” and Chapter 15, “The Four Types of Estimable Functions,” for more information about Type III estimable functions. Also see Littell, Freund, and Spector (1991).

Generalized score tests for Type III contrasts are computed for GEE models if you specify the TYPE3 option in the MODEL statement when a REPEATED statement is also used. See the section “Generalized Score Statistics” on page 2827 for more information about generalized score statistics. Wald tests are also available with the Wald option in the CONTRAST statement. In this case, the robust covariance matrix estimate is used for $\boldsymbol{\Sigma}$ in the Wald statistic.

Confidence Intervals for Parameters

Likelihood Ratio-Based Confidence Intervals

PROC GENMOD produces likelihood ratio-based confidence intervals, also known as profile likelihood confidence intervals, for parameter estimates for generalized linear models. These are not computed for GEE models, since there is no likelihood for this type of model. Suppose that the parameter vector is $\boldsymbol{\beta} = [\beta_0, \beta_1, \dots, \beta_p]'$ and that you want a confidence interval for β_j . The profile likelihood function for β_j is defined as

$$l^*(\beta_j) = \max_{\tilde{\boldsymbol{\beta}}} l(\boldsymbol{\beta})$$

where $\tilde{\boldsymbol{\beta}}$ is the vector $\boldsymbol{\beta}$ with the j th element fixed at β_j and l is the log-likelihood function. If $l = l(\hat{\boldsymbol{\beta}})$ is the log likelihood evaluated at the maximum likelihood estimate $\hat{\boldsymbol{\beta}}$, then $2(l - l^*(\beta_j))$ has a limiting chi-square distribution with one degree of freedom if β_j is the true parameter value. A $(1 - \alpha)100\%$ confidence interval for β_j is

$$\{\beta_j : l^*(\beta_j) \geq l_0 = l - 0.5\chi_{1-\alpha,1}^2\}$$

where $\chi_{1-\alpha,1}^2$ is the $100(1 - \alpha)$ th percentile of the chi-square distribution with one degree of freedom. The endpoints of the confidence interval can be found by solving numerically for values of β_j that satisfy equality in the preceding relation. PROC GENMOD solves this by starting at the maximum likelihood estimate of $\boldsymbol{\beta}$. The log-likelihood function is approximated with a quadratic surface, for which an exact solution is possible. The process is iterated until convergence to an endpoint is attained. The process is repeated for the other endpoint.

Convergence is controlled by the CICONV= option in the MODEL statement. Suppose ϵ is the number specified in the CICONV= option. The default value of ϵ is 10^{-4} . Let the parameter of interest be β_j ,

and define $\mathbf{r} = \mathbf{u}_j$, the unit vector with a 1 in position j and 0s elsewhere. Convergence is declared on the current iteration if the following two conditions are satisfied:

$$|l^*(\beta_j) - l_0| \leq \epsilon$$

$$(\mathbf{s} + \lambda \mathbf{r})' \mathbf{H}^{-1} (\mathbf{s} + \lambda \mathbf{r}) \leq \epsilon$$

where $l^*(\beta_j)$, \mathbf{s} , and \mathbf{H} are the log likelihood, the gradient, and the Hessian evaluated at the current parameter vector and λ is a constant computed by the procedure. The first condition for convergence means that the log-likelihood function must be within ϵ of the correct value, and the second condition means that the gradient vector must be proportional to the restriction vector \mathbf{r} .

When you specify the LRCI option in the MODEL statement, PROC GENMOD computes profile likelihood confidence intervals for all parameters in the model, including the scale parameter, if there is one. The interval endpoints are displayed in a table as well as the values of the remaining parameters at the solution.

Wald Confidence Intervals

You can request that PROC GENMOD produce Wald confidence intervals for the parameters. The $(1 - \alpha)100\%$ Wald confidence interval for a parameter β is defined as

$$\hat{\beta} \pm z_{1-\alpha/2} \hat{\sigma}$$

where z_p is the 100 p percentile of the standard normal distribution, $\hat{\beta}$ is the parameter estimate, and $\hat{\sigma}$ is the estimate of its standard error.

F Statistics

Suppose that D_0 is the deviance resulting from fitting a generalized linear model and that D_1 is the deviance from fitting a submodel. Then, under appropriate regularity conditions, the asymptotic distribution of $(D_1 - D_0)/\phi$ is chi-square with r degrees of freedom, where r is the difference in the number of parameters between the two models and ϕ is the dispersion parameter. If ϕ is unknown, and $\hat{\phi}$ is an estimate of ϕ based on the deviance or Pearson's chi-square divided by degrees of freedom, then, under regularity conditions, $(n-p)\hat{\phi}/\phi$ has an asymptotic chi-square distribution with $n-p$ degrees of freedom. Here, n is the number of observations and p is the number of parameters in the model that is used to estimate ϕ . Thus, the asymptotic distribution of

$$F = \frac{D_1 - D_0}{r\hat{\phi}}$$

is the F distribution with r and $n-p$ degrees of freedom, assuming that $(D_1 - D_0)/\phi$ and $(n-p)\hat{\phi}/\phi$ are approximately independent.

This F statistic is computed for the Type 1 analysis, Type 3 analysis, and hypothesis tests specified in CONTRAST statements when the dispersion parameter is estimated by either the deviance or Pearson's chi-square divided by degrees of freedom, as specified by the DSCALE or PSCALE option in the MODEL statement. In the case of a Type 1 analysis, model 0 is the higher-order model obtained by including one additional effect in model 1. For a Type 3 analysis and hypothesis tests, model 0 is the full specified model and model 1 is the submodel obtained from constraining the Type III contrast or the user-specified contrast to be 0.

Lagrange Multiplier Statistics

When you select the NOINT or NOSCALE option, restrictions are placed on the intercept or scale parameters. Lagrange multiplier, or score, statistics are computed in these cases. These statistics assess the validity of the restrictions, and they are computed as

$$\chi^2 = \frac{s^2}{V}$$

where s is the component of the score vector evaluated at the restricted maximum corresponding to the restricted parameter and $V = \mathbf{I}_{11} - \mathbf{I}_{12}\mathbf{I}_{22}^{-1}\mathbf{I}_{21}$. The matrix \mathbf{I} is the information matrix, 1 refers to the restricted parameter, and 2 refers to the rest of the parameters.

Under regularity conditions, this statistic has an asymptotic chi-square distribution with one degree of freedom, and p -values are computed based on this limiting distribution.

If you set $k = 0$ in a negative binomial model, s is the score statistic of Cameron and Trivedi (1998) for testing for overdispersion in a Poisson model against alternatives of the form $V(\mu) = \mu + k\mu^2$.

See Rao (1973, p. 417) for more details.

Predicted Values of the Mean

Predicted Values

A predicted value, or fitted value, of the mean μ_i corresponding to the vector of covariates \mathbf{x}_i is given by

$$\hat{\mu}_i = g^{-1}(\mathbf{x}_i' \hat{\boldsymbol{\beta}})$$

where g is the link function, regardless of whether \mathbf{x}_i corresponds to an observation or not. That is, the response variable can be missing and the predicted value is still computed for valid \mathbf{x}_i . In the case where \mathbf{x}_i does not correspond to a valid observation, \mathbf{x}_i is not checked for estimability. You should check the estimability of \mathbf{x}_i in this case in order to ensure the uniqueness of the predicted value of the mean. If there is an offset, it is included in the predicted value computation.

Confidence Intervals on Predicted Values

Approximate confidence intervals for predicted values of the mean can be computed as follows. The variance of the linear predictor $\eta_i = \mathbf{x}_i' \hat{\boldsymbol{\beta}}$ is estimated by

$$\sigma_x^2 = \mathbf{x}_i' \boldsymbol{\Sigma} \mathbf{x}_i$$

where $\boldsymbol{\Sigma}$ is the estimated covariance of $\hat{\boldsymbol{\beta}}$. The robust estimate of the covariance is used for $\boldsymbol{\Sigma}$ in the case of models fit with GEEs.

Approximate $100(1 - \alpha)\%$ confidence intervals are computed as

$$g^{-1} \left(\mathbf{x}_i' \hat{\boldsymbol{\beta}} \pm z_{1-\alpha/2} \sigma_x \right)$$

where z_p is the 100 p th percentile of the standard normal distribution and g is the link function. If either endpoint in the argument is outside the valid range of arguments for the inverse link function, the corresponding confidence interval endpoint is set to missing.

Residuals

The GENMOD procedure computes three kinds of residuals. Residuals are available for all generalized linear models except multinomial models for ordinal response data, for which residuals are not available. Raw residuals and Pearson residuals are available for models fit with generalized estimating equations (GEEs).

The raw residual is defined as

$$r_i = y_i - \mu_i$$

where y_i is the i th response and μ_i is the corresponding predicted mean. You can request raw residuals in an output data set with the keyword **RESRAW** in the OUTPUT statement.

The Pearson residual is the square root of the i th contribution to the Pearson's chi-square:

$$r_{Pi} = (y_i - \mu_i) \sqrt{\frac{w_i}{V(\mu_i)}}$$

You can request Pearson residuals in an output data set with the keyword **RESCHI** in the OUTPUT statement.

Finally, the deviance residual is defined as the square root of the contribution of the i th observation to the deviance, with the sign of the raw residual:

$$r_{Di} = \sqrt{d_i}(\text{sign}(y_i - \mu_i))$$

You can request deviance residuals in an output data set with the keyword **RESDEV** in the OUTPUT statement.

The adjusted Pearson, deviance, and likelihood residuals are defined by Agresti (2002); Williams (1987); Davison and Snell (1991). These residuals are useful for outlier detection and for assessing the influence of single observations on the fitted model.

For the generalized linear model, the variance of the i th individual observation is given by

$$v_i = \frac{\phi V(\mu_i)}{w_i}$$

where ϕ is the dispersion parameter, w_i is a user-specified prior weight (if not specified, $w_i = 1$), μ_i is the mean, and $V(\mu_i)$ is the variance function. Let

$$w_{ei} = v_i^{-1} (g'(\mu_i))^{-2}$$

for the i th observation, where $g'(\mu_i)$ is the derivative of the link function, evaluated at μ_i . Let \mathbf{W}_e be the diagonal matrix with w_{ei} denoting the i th diagonal element. The weight matrix \mathbf{W}_e is used in computing the expected information matrix.

Define h_i as the i th diagonal element of the matrix

$$\mathbf{W}_e^{\frac{1}{2}} \mathbf{X} (\mathbf{X}' \mathbf{W}_e \mathbf{X})^{-1} \mathbf{X}' \mathbf{W}_e^{\frac{1}{2}}$$

The Pearson residuals, standardized to have unit asymptotic variance, are given by

$$r_{Pi} = \frac{y_i - \mu_i}{\sqrt{v_i(1 - h_i)}}$$

You can request standardized Pearson residuals in an output data set with the keyword **STDRESCHI** in the OUTPUT statement. The deviance residuals, standardized to have unit asymptotic variance, are given by

$$r_{Di} = \frac{\text{sign}(y_i - \mu_i) \sqrt{d_i}}{\sqrt{\phi(1 - h_i)}}$$

where d_i is the contribution to the total deviance from observation i , and $\text{sign}(y_i - \mu_i)$ is 1 if $y_i - \mu_i$ is positive and -1 if $y_i - \mu_i$ is negative. You can request standardized deviance residuals in an output data set with the keyword **STDRESDEV** in the OUTPUT statement. The likelihood residuals are defined by

$$r_{Gi} = \text{sign}(y_i - \mu_i) \sqrt{(1 - h_i)r_{Di}^2 + h_i r_{Pi}^2}$$

You can request likelihood residuals in an output data set with the keyword **RESLIK** in the OUTPUT statement.

Multinomial Models

This type of model applies to cases where an observation can fall into one of k categories. Binary data occur in the special case where $k = 2$. If there are m_i observations in a subpopulation i , then the probability distribution of the number falling into the k categories $y_i = (y_{i1}, y_{i2}, \dots, y_{ik})$ can be modeled by the multinomial distribution, defined in the section “[Response Probability Distributions](#)” on page 2799, with $\sum_j y_{ij} = m_i$. The multinomial model is an *ordinal* model if the categories have a natural order.

Residuals are not available in the OBSTATS table or the output data set for multinomial models.

By default, and consistently with binomial models, the GENMOD procedure orders the response categories for ordinal multinomial models from lowest to highest and models the probabilities of the lower response levels. You can change the way PROC GENMOD orders the response levels with the RORDER= option in the PROC GENMOD statement. The order that PROC GENMOD uses is shown in the “[Response Profiles](#)” output table described in the section “[Response Profile](#)” on page 2843.

The GENMOD procedure supports only the ordinal multinomial model. If $(p_{i1}, p_{i2}, \dots, p_{ik})$ are the category probabilities, the cumulative category probabilities are modeled with the same link functions used for binomial data. Let $P_{ir} = \sum_{j=1}^r p_{ij}$, $r = 1, 2, \dots, k - 1$, be the cumulative category probabilities (note that $P_{ik} = 1$). The ordinal model is

$$g(P_{ir}) = \mu_r + \mathbf{x}'_i \boldsymbol{\beta} \quad \text{for } r = 1, 2, \dots, k - 1$$

where $\mu_1, \mu_2, \dots, \mu_{k-1}$ are intercept terms that depend only on the categories and \mathbf{x}_i is a vector of covariates that does not include an intercept term. The logit, probit, and complementary log-log link functions g are available. These are obtained by specifying the MODEL statement options DIST=MULTINOMIAL and LINK=CUMLOGIT (cumulative logit), LINK=CUMPROBIT (cumulative probit), or LINK=CUMCLL (cumulative complementary log-log). Alternatively,

$$P_{ir} = F(\mu_r + \mathbf{x}'_i \boldsymbol{\beta}) \quad \text{for } r = 1, 2, \dots, k - 1$$

where $F = g^{-1}$ is a cumulative distribution function for the logistic, normal, or extreme-value distribution.

PROC GENMOD estimates the intercept parameters $\mu_1, \mu_2, \dots, \mu_{k-1}$ and regression parameters $\boldsymbol{\beta}$ by maximum likelihood.

The subpopulations i are defined by constant values of the AGGREGATE= variable. This has no effect on the parameter estimates, but it does affect the deviance and Pearson chi-square statistics; it also affects parameter estimate standard errors if you specify the SCALE=DEVIANC or SCALE=PEARSON option.

Zero-Inflated Models

Count data that have an incidence of zeros greater than expected for the underlying probability distribution of counts can be modeled with a zero-inflated distribution. In GENMOD, the underlying distribution can be either Poisson or negative binomial. See Lambert (1992), Long (1997) and Cameron and Trivedi (1998) for more information about zero-inflated models. The population is considered to consist of two types of individuals. The first type gives Poisson or negative binomial distributed counts, which might contain zeros. The second type always gives a zero count. Let λ be the underlying distribution mean and ω be the probability of an individual being of the second type. The parameter ω is called here the *zero-inflation probability*, and is the probability of zero counts in excess of the frequency predicted by the underlying distribution. You can request that the zero inflation probability be displayed in an output data set with the **PZERO** keyword. The probability distribution of a zero-inflated Poisson random variable Y is given by

$$\Pr(Y = y) = \begin{cases} \omega + (1 - \omega)e^{-\lambda} & \text{for } y = 0 \\ (1 - \omega)\frac{\lambda^y e^{-\lambda}}{y!} & \text{for } y = 1, 2, \dots \end{cases}$$

and the probability distribution of a zero-inflated negative binomial random variable Y is given by

$$\Pr(Y = y) = \begin{cases} \omega + (1 - \omega)(1 + k\lambda)^{-\frac{1}{k}} & \text{for } y = 0 \\ (1 - \omega)\frac{\Gamma(y+1/k)}{\Gamma(y+1)\Gamma(1/k)}\frac{(k\lambda)^y}{(1+k\lambda)^{y+1/k}} & \text{for } y = 1, 2, \dots \end{cases}$$

where k is the negative binomial dispersion parameter.

You can model the parameters ω and λ in GENMOD with the regression models:

$$\begin{aligned} h(\omega_i) &= \mathbf{z}'_i \boldsymbol{\gamma} \\ g(\lambda_i) &= \mathbf{x}'_i \boldsymbol{\beta} \end{aligned}$$

where h is one of the binary link functions: logit, probit, or complementary log-log. The link function h is the logit link by default, or the link function option specified in the **ZEROMODEL** statement. The link function g is the log link function by default, or the link function specified in the **MODEL** statement, for both the Poisson and the negative binomial. The covariates \mathbf{z}_i for observation i are determined by the model specified in the **ZEROMODEL** statement, and the covariates \mathbf{x}_i are determined by the model specified in the **MODEL** statement. The regression parameters $\boldsymbol{\gamma}$ and $\boldsymbol{\beta}$ are estimated by maximum likelihood.

The mean and variance of Y for the zero-inflated Poisson are given by

$$\begin{aligned} E(Y) &= \mu = (1 - \omega)\lambda \\ \text{Var}(Y) &= \mu + \frac{\omega}{1 - \omega}\mu^2 \end{aligned}$$

and for the zero-inflated negative binomial by

$$\begin{aligned} E(Y) &= \mu = (1 - \omega)\lambda \\ \text{Var}(Y) &= \mu + \left(\frac{\omega}{1 - \omega} + \frac{k}{1 - \omega} \right) \mu^2 \end{aligned}$$

You can request that the mean of Y be displayed for each observation in an output data set with the **PRED** keyword.

Generalized Estimating Equations

Let y_{ij} , $j = 1, \dots, n_i$, $i = 1, \dots, K$, represent the j th measurement on the i th subject. There are n_i measurements on subject i and $\sum_{i=1}^K n_i$ total measurements.

Correlated data are modeled using the same link function and linear predictor setup (systematic component) as the independence case. The random component is described by the same variance functions as in the independence case, but the covariance structure of the correlated measurements must also be modeled. Let the vector of measurements on the i th subject be $\mathbf{Y}_i = [y_{i1}, \dots, y_{in_i}]'$ with corresponding vector of means $\boldsymbol{\mu}_i = [\mu_{i1}, \dots, \mu_{in_i}]'$, and let \mathbf{V}_i be the covariance matrix of \mathbf{Y}_i . Let the vector of independent, or explanatory, variables for the j th measurement on the i th subject be

$$\mathbf{x}_{ij} = [x_{ij1}, \dots, x_{ijp}]'$$

The generalized estimating equation of Liang and Zeger (1986) for estimating the $p \times 1$ vector of regression parameters $\boldsymbol{\beta}$ is an extension of the independence estimating equation to correlated data and is given by

$$\mathbf{S}(\boldsymbol{\beta}) = \sum_{i=1}^K \mathbf{D}_i' \mathbf{V}_i^{-1} (\mathbf{Y}_i - \boldsymbol{\mu}_i(\boldsymbol{\beta})) = \mathbf{0}$$

where

$$\mathbf{D}_i = \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}}$$

Since

$$g(\mu_{ij}) = \mathbf{x}_{ij}' \boldsymbol{\beta}$$

where g is the link function, the $p \times n_i$ matrix of partial derivatives of the mean with respect to the regression parameters for the i th subject is given by

$$\mathbf{D}_i' = \frac{\partial \boldsymbol{\mu}_i'}{\partial \boldsymbol{\beta}} = \begin{bmatrix} \frac{x_{i11}}{g'(\mu_{i1})} & \cdots & \frac{x_{in_i1}}{g'(\mu_{in_i})} \\ \vdots & & \vdots \\ \frac{x_{i1p}}{g'(\mu_{i1})} & \cdots & \frac{x_{in_ip}}{g'(\mu_{in_i})} \end{bmatrix}$$

Working Correlation Matrix

Let $\mathbf{R}_i(\boldsymbol{\alpha})$ be an $n_i \times n_i$ “working” correlation matrix that is fully specified by the vector of parameters $\boldsymbol{\alpha}$. The covariance matrix of \mathbf{Y}_i is modeled as

$$\mathbf{V}_i = \phi \mathbf{A}_i^{\frac{1}{2}} \mathbf{W}_i^{-\frac{1}{2}} \mathbf{R}_i(\boldsymbol{\alpha}) \mathbf{W}_i^{-\frac{1}{2}} \mathbf{A}_i^{\frac{1}{2}}$$

where \mathbf{A}_i is an $n_i \times n_i$ diagonal matrix with $v(\mu_{ij})$ as the j th diagonal element and \mathbf{W}_i is an $n_i \times n_i$ diagonal matrix with w_{ij} as the j th diagonal, where w_{ij} is a weight specified with the WEIGHT statement. If there is no WEIGHT statement, $w_{ij} = 1$ for all i and j . If $\mathbf{R}_i(\boldsymbol{\alpha})$ is the true correlation matrix of \mathbf{Y}_i , then \mathbf{V}_i is the true covariance matrix of \mathbf{Y}_i .

The working correlation matrix is usually unknown and must be estimated. It is estimated in the iterative fitting process by using the current value of the parameter vector $\boldsymbol{\beta}$ to compute appropriate functions of the Pearson residual

$$e_{ij} = \frac{y_{ij} - \mu_{ij}}{\sqrt{v(\mu_{ij})/w_{ij}}}$$

If you specify the working correlation as $\mathbf{R}_0 = \mathbf{I}$, which is the identity matrix, the GEE reduces to the independence estimating equation.

Following are the structures of the working correlation supported by the GENMOD procedure and the estimators used to estimate the working correlations.

Working Correlation Structure	Estimator
Fixed	
$\text{Corr}(Y_{ij}, Y_{ik}) = r_{jk}$ where r_{jk} is the jk th element of a constant, user-specified correlation matrix \mathbf{R}_0 .	The working correlation is not estimated in this case.
Independent	
$\text{Corr}(Y_{ij}, Y_{ik}) = \begin{cases} 1 & j = k \\ 0 & j \neq k \end{cases}$	The working correlation is not estimated in this case.
m-dependent	
$\text{Corr}(Y_{ij}, Y_{i,j+t}) = \begin{cases} 1 & t = 0 \\ \alpha_t & t = 1, 2, \dots, m \\ 0 & t > m \end{cases}$	$\hat{\alpha}_t = \frac{1}{(K_t - p)\phi} \sum_{i=1}^K \sum_{j \leq n_i - t} e_{ij} e_{i,j+t} = \frac{K_t}{\sum_{i=1}^K (n_i - t)}$
Exchangeable	
$\text{Corr}(Y_{ij}, Y_{ik}) = \begin{cases} 1 & j = k \\ \alpha & j \neq k \end{cases}$	$\hat{\alpha} = \frac{1}{(N^* - p)\phi} \sum_{i=1}^K \sum_{j < k} e_{ij} e_{ik}$ $N^* = 0.5 \sum_{i=1}^K n_i (n_i - 1)$
Unstructured	
$\text{Corr}(Y_{ij}, Y_{ik}) = \begin{cases} 1 & j = k \\ \alpha_{jk} & j \neq k \end{cases}$	$\hat{\alpha}_{jk} = \frac{1}{(K - p)\phi} \sum_{i=1}^K e_{ij} e_{ik}$
Autoregressive	
AR(1)	
$\text{Corr}(Y_{ij}, Y_{i,j+t}) = \alpha^t$ for $t = 0, 1, 2, \dots, n_i - j$	$\hat{\alpha} = \frac{1}{(K_1 - p)\phi} \sum_{i=1}^K \sum_{j \leq n_i - 1} e_{ij} e_{i,j+1} = \frac{K_1}{\sum_{i=1}^K (n_i - 1)}$

Dispersion Parameter

The dispersion parameter ϕ is estimated by

$$\hat{\phi} = \frac{1}{N - p} \sum_{i=1}^K \sum_{j=1}^{n_i} e_{ij}^2$$

where $N = \sum_{i=1}^K n_i$ is the total number of measurements and p is the number of regression parameters.

The square root of $\hat{\phi}$ is reported by PROC GENMOD as the scale parameter in the “Analysis of GEE Parameter Estimates Model-Based Standard Error Estimates” output table. If a fixed scale parameter is specified with the NOSCALE option in the MODEL statement, then the fixed value is used in estimating the model-based covariance matrix and standard errors.

Fitting Algorithm

The following is an algorithm for fitting the specified model by using GEEs. Note that this is not in general a likelihood-based method of estimation, so that inferences based on likelihoods are not possible for GEE methods.

1. Compute an initial estimate of β with an ordinary generalized linear model assuming independence.
2. Compute the working correlations \mathbf{R} based on the standardized residuals, the current β , and the assumed structure of \mathbf{R} .
3. Compute an estimate of the covariance:

$$\mathbf{V}_i = \phi \mathbf{A}_i^{\frac{1}{2}} \mathbf{W}_i^{-\frac{1}{2}} \hat{\mathbf{R}}(\alpha) \mathbf{W}_i^{-\frac{1}{2}} \mathbf{A}_i^{\frac{1}{2}}$$

4. Update β :

$$\beta_{r+1} = \beta_r + \left[\sum_{i=1}^K \frac{\partial \mu_i}{\partial \beta} \mathbf{V}_i^{-1} \frac{\partial \mu_i}{\partial \beta} \right]^{-1} \left[\sum_{i=1}^K \frac{\partial \mu_i}{\partial \beta} \mathbf{V}_i^{-1} (\mathbf{Y}_i - \mu_i) \right]$$

5. Repeat steps 2-4 until convergence.

Missing Data

See Diggle, Liang, and Zeger (1994, Chapter 11) for a discussion of missing values in longitudinal data. Suppose that you intend to take measurements Y_{i1}, \dots, Y_{in} for the i th unit. Missing values for which Y_{ij} are missing whenever Y_{ik} is missing for all $j \geq k$ are called *dropouts*. Otherwise, missing values that occur intermixed with nonmissing values are *intermittent* missing values. The GENMOD procedure can estimate the working correlation from data containing both types of missing values by using the *all available pairs* method, in which all nonmissing pairs of data are used in the moment estimators of the working correlation parameters defined previously. The resulting covariances and standard errors are valid under the missing completely at random (MCAR) assumption.

For example, for the unstructured working correlation model,

$$\hat{\alpha}_{jk} = \frac{1}{(K' - p)\phi} \sum e_{ij} e_{ik}$$

where the sum is over the units that have nonmissing measurements at times j and k , and K' is the number of units with nonmissing measurements at j and k . Estimates of the parameters for other working correlation types are computed in a similar manner, using available nonmissing pairs in the appropriate moment estimators.

The contribution of the i th unit to the parameter update equation is computed by omitting the elements of $(Y_i - \mu_i)$, the columns of $D'_i = \frac{\partial \mu_i'}{\partial \beta}$, and the rows and columns of V_i corresponding to missing measurements.

Parameter Estimate Covariances

The *model-based* estimator of $\text{Cov}(\hat{\beta})$ is given by

$$\Sigma_m(\hat{\beta}) = I_0^{-1}$$

where

$$I_0 = \sum_{i=1}^K \frac{\partial \mu_i'}{\partial \beta} V_i^{-1} \frac{\partial \mu_i}{\partial \beta}$$

This is the GEE equivalent of the inverse of the Fisher information matrix that is often used in generalized linear models as an estimator of the covariance estimate of the maximum likelihood estimator of β . It is a consistent estimator of the covariance matrix of $\hat{\beta}$ if the mean model and the working correlation matrix are correctly specified.

The estimator

$$\Sigma_e = I_0^{-1} I_1 I_0^{-1}$$

is called the *empirical*, or *robust*, estimator of the covariance matrix of $\hat{\beta}$, where

$$I_1 = \sum_{i=1}^K \frac{\partial \mu_i'}{\partial \beta} V_i^{-1} \text{Cov}(Y_i) V_i^{-1} \frac{\partial \mu_i}{\partial \beta}$$

It has the property of being a consistent estimator of the covariance matrix of $\hat{\beta}$, even if the working correlation matrix is misspecified—that is, if $\text{Cov}(Y_i) \neq V_i$. For further information about the robust variance estimate, see Zeger, Liang, and Albert (1988); Royall (1986); White (1982). In computing Σ_e , β and ϕ are replaced by estimates, and $\text{Cov}(Y_i)$ is replaced by the estimate

$$(Y_i - \mu_i(\hat{\beta}))(Y_i - \mu_i(\hat{\beta}))'$$

Multinomial GEEs

Lipsitz, Kim, and Zhao (1994) and Miller, Davis, and Landis (1993) describe how to extend GEEs to multinomial data. Currently, only the independent working correlation is available for multinomial models in PROC GENMOD.

Alternating Logistic Regressions

If the responses are binary (that is, they take only two values), then there is an alternative method to account for the association among the measurements. The alternating logistic regressions (ALR) algorithm of Carey, Zeger, and Diggle (1993) models the association between pairs of responses with log odds ratios, instead of with correlations, as ordinary GEEs do.

For binary data, the correlation between the j th and k th response is, by definition,

$$\text{Corr}(Y_{ij}, Y_{ik}) = \frac{\Pr(Y_{ij} = 1, Y_{ik} = 1) - \mu_{ij}\mu_{ik}}{\sqrt{\mu_{ij}(1 - \mu_{ij})\mu_{ik}(1 - \mu_{ik})}}$$

The joint probability in the numerator satisfies the following bounds, by elementary properties of probability, since $\mu_{ij} = \Pr(Y_{ij} = 1)$:

$$\max(0, \mu_{ij} + \mu_{ik} - 1) \leq \Pr(Y_{ij} = 1, Y_{ik} = 1) \leq \min(\mu_{ij}, \mu_{ik})$$

The correlation, therefore, is constrained to be within limits that depend in a complicated way on the means of the data.

The odds ratio, defined as

$$\text{OR}(Y_{ij}, Y_{ik}) = \frac{\Pr(Y_{ij} = 1, Y_{ik} = 1) \Pr(Y_{ij} = 0, Y_{ik} = 0)}{\Pr(Y_{ij} = 1, Y_{ik} = 0) \Pr(Y_{ij} = 0, Y_{ik} = 1)}$$

is not constrained by the means and is preferred, in some cases, to correlations for binary data.

The ALR algorithm seeks to model the logarithm of the odds ratio, $\gamma_{ijk} = \log(\text{OR}(Y_{ij}, Y_{ik}))$, as

$$\gamma_{ijk} = \mathbf{z}'_{ijk} \boldsymbol{\alpha}$$

where $\boldsymbol{\alpha}$ is a $q \times 1$ vector of regression parameters and \mathbf{z}_{ijk} is a fixed, specified vector of coefficients.

The parameter γ_{ijk} can take any value in $(-\infty, \infty)$ with $\gamma_{ijk} = 0$ corresponding to no association.

The log odds ratio, when modeled in this way with a regression model, can take different values in subgroups defined by \mathbf{z}_{ijk} . For example, \mathbf{z}_{ijk} can define subgroups within clusters, or it can define “block effects” between clusters.

You specify a GEE model for binary data that uses log odds ratios by specifying a model for the mean, as in ordinary GEEs, and a model for the log odds ratios. You can use any of the link functions appropriate for binary data in the model for the mean, such as logistic, probit, or complementary log-log. The ALR algorithm alternates between a GEE step to update the model for the mean and a logistic regression step to update the log odds ratio model. Upon convergence, the ALR algorithm provides estimates of the regression parameters for the mean, $\boldsymbol{\beta}$, the regression parameters for the log odds ratios, $\boldsymbol{\alpha}$, their standard errors, and their covariances.

Specifying Log Odds Ratio Models

Specifying a regression model for the log odds ratio requires you to specify rows of the \mathbf{z} matrix \mathbf{z}_{ijk} for each cluster i and each unique within-cluster pair (j, k) . The GENMOD procedure provides several methods of specifying \mathbf{z}_{ijk} . These are controlled by the `LOGOR=keyword` and associated options in the `REPEATED` statement. The supported keywords and the resulting log odds ratio models are described as follows.

EXCH specifies exchangeable log odds ratios. In this model, the log odds ratio is a constant for all clusters i and pairs (j, k) . The parameter α is the common log odds ratio.

$$z_{ijk} = 1 \quad \text{for all } i, j, k$$

FULLCLUST specifies fully parameterized clusters. Each cluster is parameterized in the same way, and there is a parameter for each unique pair within clusters. If a complete cluster is of size n , then there are $\frac{n(n-1)}{2}$ parameters in the vector α . For example, if a full cluster is of size 4, then there are $\frac{4 \times 3}{2} = 6$ parameters, and the \mathbf{z} matrix is of the form

$$\mathbf{Z} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

The elements of α correspond to log odds ratios for cluster pairs in the following order:

Pair	Parameter
(1,2)	Alpha1
(1,3)	Alpha2
(1,4)	Alpha3
(2,3)	Alpha4
(2,4)	Alpha5
(3,4)	Alpha6

LOGORVAR(variable) specifies log odds ratios by cluster. The argument *variable* is a variable name that defines the “block effects” between clusters. The log odds ratios are constant within clusters, but they take a different value for each different value of the *variable*. For example, if *Center* is a variable in the input data set taking a different value for k treatment centers, then specifying **LOGOR=LOGORVAR(Center)** requests a model with different log odds ratios for each of the k centers, constant within center.

NESTK specifies k -nested log odds ratios. You must also specify the **SUBCLUST=variable** option to define subclusters within clusters. Within each cluster, PROC GENMOD computes a log odds ratio parameter for pairs having the same value of *variable* for both members of the pair and one log odds ratio parameter for each unique combination of different values of *variable*.

NEST1 specifies 1-nested log odds ratios. You must also specify the **SUBCLUST=variable** option to define subclusters within clusters. There are two log odds ratio parameters for this model. Pairs having the same value of *variable* correspond to one parameter; pairs having different values of *variable* correspond to the other parameter. For example, if clusters are hospitals and subclusters are wards within hospitals, then patients within the same ward have

one log odds ratio parameter, and patients from different wards have the other parameter.

ZFULL

specifies the full \mathbf{z} matrix. You must also specify a SAS data set containing the \mathbf{z} matrix with the `ZDATA=data-set-name` option. Each observation in the data set corresponds to one row of the \mathbf{z} matrix. You must specify the ZDATA data set as if all clusters are complete—that is, as if all clusters are the same size and there are no missing observations. The ZDATA data set has $K[n_{max}(n_{max} - 1)/2]$ observations, where K is the number of clusters and n_{max} is the maximum cluster size. If the members of cluster i are ordered as $1, 2, \dots, n$, then the rows of the \mathbf{z} matrix must be specified for pairs in the order $(1, 2), (1, 3), \dots, (1, n), (2, 3), \dots, (2, n), \dots, (n - 1, n)$. The variables specified in the REPEATED statement for the SUBJECT effect must also be present in the ZDATA= data set to identify clusters. You must specify variables in the data set that define the columns of the \mathbf{z} matrix by the `ZROW=variable-list` option. If there are q columns (q variables in *variable-list*), then there are q log odds ratio parameters. You can optionally specify variables indicating the cluster pairs corresponding to each row of the \mathbf{z} matrix with the `YPAIR=(variable1, variable2)` option. If you specify this option, the data from the ZDATA data set are sorted within each cluster by *variable1* and *variable2*. See [Example 40.6](#) for an example of specifying a full \mathbf{z} matrix.

ZREP

specifies a replicated \mathbf{z} matrix. You specify \mathbf{z} matrix data exactly as you do for the ZFULL case, except that you specify only one complete cluster. The \mathbf{z} matrix for the one cluster is replicated for each cluster. The number of observations in the ZDATA data set is $\frac{n_{max}(n_{max}-1)}{2}$, where n_{max} is the size of a complete cluster (a cluster with no missing observations).

ZREP(matrix)

specifies direct input of the replicated \mathbf{z} matrix. You specify the \mathbf{z} matrix for one cluster with the syntax `LOGOR=ZREP ((y_1 y_2) z_1 $z_2 \dots z_q, \dots$), where y_1 and y_2 are numbers representing a pair of observations and the values z_1, z_2, \dots, z_q make up the corresponding row of the \mathbf{z} matrix. The number of rows specified is $\frac{n_{max}(n_{max}-1)}{2}$, where n_{max} is the size of a complete cluster (a cluster with no missing observations). For example,`

```
logor = zrep( (1 2) 1 0,
              (1 3) 1 0,
              (1 4) 1 0,
              (2 3) 1 1,
              (2 4) 1 1,
              (3 4) 1 1)
```

specifies the $\frac{4 \times 3}{2} = 6$ rows of the \mathbf{z} matrix for a cluster of size 4 with $q = 2$ log odds ratio parameters. The log odds ratio for the pairs (1 2), (1 3), (1 4) is α_1 , and the log odds ratio for the pairs (2 3), (2 4), (3 4) is $\alpha_1 + \alpha_2$.

Quasi-likelihood Information Criterion

The quasi-likelihood information criterion (QIC) was developed by Pan (2001) as a modification of the Akaike information criterion (AIC) to apply to models fit by GEEs.

Define the quasi-likelihood under the independence working correlation assumption, evaluated with the parameter estimates under the working correlation of interest as

$$Q(\hat{\beta}(R), \phi) = \sum_{i=1}^K \sum_{j=1}^{n_i} Q(\hat{\beta}(R), \phi; (Y_{ij}, \mathbf{X}_{ij}))$$

where the quasi-likelihood contribution of the j th observation in the i th cluster is defined in the section “[Quasi-likelihood Functions](#)” on page 2826 and $\hat{\beta}(R)$ are the parameter estimates obtained from GEEs with the working correlation of interest R .

QIC is defined as

$$\text{QIC}(R) = -2Q(\hat{\beta}(R), \phi) + 2\text{trace}(\hat{\Omega}_I \hat{V}_R)$$

where \hat{V}_R is the robust covariance estimate and $\hat{\Omega}_I$ is the inverse of the model-based covariance estimate under the independent working correlation assumption, evaluated at $\hat{\beta}(R)$, the parameter estimates obtained from GEEs with the working correlation of interest R .

PROC GENMOD also computes an approximation to $\text{QIC}(R)$ defined by Pan (2001) as

$$\text{QIC}_u(R) = -2Q(\hat{\beta}(R), \phi) + 2p$$

where p is the number of regression parameters.

Pan (2001) notes that QIC is appropriate for selecting regression models and working correlations, whereas QIC_u is appropriate only for selecting regression models.

Quasi-likelihood Functions

See McCullagh and Nelder (1989) and Hardin and Hilbe (2003) for discussions of quasi-likelihood functions. The contribution of observation j in cluster i to the quasi-likelihood function evaluated at the regression parameters β is given by $Q(\beta, \phi; (Y_{ij}, \mathbf{X}_{ij})) = \frac{Q_{ij}}{\phi}$, where Q_{ij} is defined in the following list. These are used in the computation of the quasi-likelihood information criteria (QIC) for goodness of fit of models fit with GEEs. The w_{ij} are prior weights, if any, specified with the WEIGHT or FREQ statements. Note that the definition of the quasi-likelihood for the negative binomial differs from that given in McCullagh and Nelder (1989). The definition used here allows the negative binomial quasi-likelihood to approach the Poisson as $k \rightarrow 0$.

- Normal:

$$Q_{ij} = -\frac{1}{2}w_{ij}(y_{ij} - \mu_{ij})^2$$

- Inverse Gaussian:

$$Q_{ij} = \frac{w_{ij}(\mu_{ij} - .5y_{ij})}{\mu_{ij}^2}$$

- Gamma:

$$Q_{ij} = -w_{ij} \left[\frac{y_{ij}}{\mu_{ij}} + \log(\mu_{ij}) \right]$$

- Negative binomial:

$$Q_{ij} = w_{ij} \left[\log \Gamma \left(y_{ij} + \frac{1}{k} \right) - \log \Gamma \left(\frac{1}{k} \right) + y_{ij} \log \left(\frac{k\mu_{ij}}{1 + k\mu_{ij}} \right) + \frac{1}{k} \log \left(\frac{1}{1 + k\mu_{ij}} \right) \right]$$

- Poisson:

$$Q_{ij} = w_{ij} (y_{ij} \log(\mu_{ij}) - \mu_{ij})$$

- Binomial:

$$Q_{ij} = w_{ij} [r_{ij} \log(p_{ij}) + (n_{ij} - r_{ij}) \log(1 - p_{ij})]$$

- Multinomial (s categories):

$$Q_{ij} = w_{ij} \sum_{k=1}^s y_{ijk} \log(\mu_{ijk})$$

Generalized Score Statistics

Boos (1992) and Rotnitzky and Jewell (1990) describe score tests applicable to testing $\mathbf{L}'\boldsymbol{\beta} = \mathbf{0}$ in GEEs, where \mathbf{L}' is a user-specified $r \times p$ contrast matrix or a contrast for a Type 3 test of hypothesis.

Let $\tilde{\boldsymbol{\beta}}$ be the regression parameters resulting from solving the GEE under the restricted model $\mathbf{L}'\boldsymbol{\beta} = \mathbf{0}$, and let $\mathbf{S}(\tilde{\boldsymbol{\beta}})$ be the generalized estimating equation values at $\tilde{\boldsymbol{\beta}}$.

The generalized score statistic is

$$T = \mathbf{S}(\tilde{\boldsymbol{\beta}})' \boldsymbol{\Sigma}_m \mathbf{L} (\mathbf{L}' \boldsymbol{\Sigma}_e \mathbf{L})^{-1} \mathbf{L}' \boldsymbol{\Sigma}_m \mathbf{S}(\tilde{\boldsymbol{\beta}})$$

where $\boldsymbol{\Sigma}_m$ is the model-based covariance estimate and $\boldsymbol{\Sigma}_e$ is the empirical covariance estimate. The p -values for T are computed based on the chi-square distribution with r degrees of freedom.

Assessment of Models Based on Aggregates of Residuals

Lin, Wei, and Ying (2002) present graphical and numerical methods for model assessment based on the cumulative sums of residuals over certain coordinates (such as covariates or linear predictors) or some related aggregates of residuals. The distributions of these stochastic processes under the assumed model can be approximated by the distributions of certain zero-mean Gaussian processes whose realizations can be generated by simulation. Each observed residual pattern can then be compared, both graphically and numerically, with a number of realizations from the null distribution. Such comparisons enable you to assess objectively whether the observed residual pattern reflects anything beyond random fluctuation. These procedures are useful in determining appropriate functional forms of covariates and link function. You use the ASSESS|ASSESSMENT statement to perform this kind of model-checking with cumulative sums of

residuals, moving sums of residuals, or LOESS smoothed residuals. See [Example 40.8](#) and [Example 40.9](#) for examples of model assessment.

Let the model for the mean be

$$g(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}$$

where μ_i is the mean of the response y_i and \mathbf{x}_i is the vector of covariates for the i th observation. Denote the raw residual resulting from fitting the model as

$$e_i = y_i - \hat{\mu}_i$$

and let x_{ij} be the value of the j th covariate in the model for observation i . Then to check the functional form of the j th covariate, consider the cumulative sum of residuals with respect to x_{ij} ,

$$W_j(x) = \frac{1}{\sqrt{n}} \sum_{i=1}^n I(x_{ij} \leq x) e_i$$

where $I()$ is the indicator function. For any x , $W_j(x)$ is the sum of the residuals with values of x_j less than or equal to x .

Denote the score, or gradient vector, by

$$U(\boldsymbol{\beta}) = \sum_{i=1}^n h(\mathbf{x}_i' \boldsymbol{\beta}) \mathbf{x}_i (y_i - v(\mathbf{x}_i' \boldsymbol{\beta}))$$

where $v(r) = g^{-1}(r)$, and

$$h(r) = \frac{1}{g'(v(r))V(v(r))}$$

Let \mathbf{J} be the Fisher information matrix

$$\mathbf{J}(\boldsymbol{\beta}) = -\frac{\partial U(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}'}$$

Define

$$\hat{W}_j(x) = \frac{1}{\sqrt{n}} \sum_{i=1}^n [I(x_{ij} \leq x) + \boldsymbol{\eta}'(x; \hat{\boldsymbol{\beta}}) \mathbf{J}^{-1}(\hat{\boldsymbol{\beta}}) \mathbf{x}_i h(\mathbf{x}_i' \hat{\boldsymbol{\beta}})] e_i Z_i$$

where

$$\boldsymbol{\eta}(x; \boldsymbol{\beta}) = -\sum_{i=1}^n I(x_{ij} \leq x) \frac{\partial v(\mathbf{x}_i' \boldsymbol{\beta})}{\partial \boldsymbol{\beta}}$$

and Z_i are independent $N(0, 1)$ random variables. Then the conditional distribution of $\hat{W}_j(x)$, given $(y_i, \mathbf{x}_i), i = 1, \dots, n$, under the null hypothesis H_0 that the model for the mean is correct, is the same asymptotically as $n \rightarrow \infty$ as the unconditional distribution of $W_j(x)$ (Lin, Wei, and Ying 2002).

You can approximate realizations from the null hypothesis distribution of $W_j(x)$ by repeatedly generating normal samples $Z_i, i = 1, \dots, n$, while holding $(y_i, \mathbf{x}_i), i = 1, \dots, n$, at their observed values and computing $\hat{W}_j(x)$ for each sample.

You can assess the functional form of covariate j by plotting a few realizations of $\hat{W}_j(x)$ on the same plot as the observed $W_j(x)$ and visually comparing to see how typical the observed $W_j(x)$ is of the null distribution samples.

You can supplement the graphical inspection method with a Kolmogorov-type supremum test. Let s_j be the observed value of $S_j = \sup_x |W_j(x)|$. The p -value $\Pr[S_j \geq s_j]$ is approximated by $\Pr[\hat{S}_j \geq s_j]$, where $\hat{S}_j = \sup_x |\hat{W}_j(x)|$. $\Pr[\hat{S}_j \geq s_j]$ is estimated by generating realizations of $\hat{W}_j(\cdot)$ (1,000 is the default number of realizations).

You can check the link function instead of the j th covariate by using values of the linear predictor $\mathbf{x}_i' \hat{\boldsymbol{\beta}}$ in place of values of the j th covariate x_{ij} . The graphical and numerical methods described previously are then sensitive to inadequacies in the link function.

An alternative aggregate of residuals is the moving sum statistic

$$W_j(x, b) = \frac{1}{\sqrt{n}} \sum_{i=1}^n I(x - b \leq x_{ij} \leq x) e_i$$

If you specify the keyword WINDOW(b), then the moving sum statistic with window size b is used instead of the cumulative sum of residuals, with $I(x - b \leq x_{ij} \leq x)$ replacing $I(x_{ij} \leq x)$ in the earlier equation.

If you specify the keyword LOESS(f), loess smoothed residuals are used in the preceding formulas, where f is the fraction of the data to be used at a given point. If f is not specified, $f = \frac{1}{3}$ is used. For data $(Y_i, X_i), i = 1, \dots, n$, define r as the nearest integer to nf and h as the r th smallest among $|X_i - x|, i = 1, \dots, n$. Let

$$K_i(x) = K\left(\frac{X_i - x}{h}\right)$$

where

$$K(t) = \frac{70}{81} (1 - |t|^3)^3 I(-1 \leq t \leq 1)$$

Define

$$w_i(x) = K_i(x)[S_2(x) - (X_i - x)S_1(x)]$$

where

$$S_1(x) = \sum_{i=1}^n K_i(x)(X_i - x)$$

$$S_2(x) = \sum_{i=1}^n K_i(x)(X_i - x)^2$$

Then the loess estimate of Y at x is defined by

$$\hat{Y}(x) = \sum_{i=1}^n \frac{w_i(x)}{\sum_{i=1}^n w_i(x)} Y_i$$

Loess smoothed residuals for checking the functional form of the j th covariate are defined by replacing Y_i with e_i and X_i with x_{ij} . To implement the graphical and numerical assessment methods, $I(x_{ij} \leq x)$ is replaced with $\frac{w_i(x)}{\sum_{i=1}^n w_i(x)}$ in the formulas for $W_j(x)$ and $\hat{W}_j(x)$.

You can perform the model checking described earlier for marginal models for dependent responses fit by generalized estimating equations (GEEs). Let y_{ik} denote the k th measurement on the i th cluster, $i = 1, \dots, K$, $k = 1, \dots, n_i$, and let \mathbf{x}_{ik} denote the corresponding vector of covariates. The marginal mean of the response $\mu_{ik} = E(y_{ik})$ is assumed to depend on the covariate vector by

$$g(\mu_{ik}) = \mathbf{x}_{ik}' \boldsymbol{\beta}$$

where g is the link function.

Define the vector of residuals for the i th cluster as

$$\mathbf{e}_i = (e_{i1}, \dots, e_{in_i})' = (y_{i1} - \hat{\mu}_{i1}, \dots, y_{in_i} - \hat{\mu}_{in_i})'$$

You use the following extension of $W_j(x)$ defined earlier to check the functional form of the j th covariate:

$$W_j(x) = \frac{1}{\sqrt{K}} \sum_{i=1}^K \sum_{k=1}^{n_i} I(x_{ikj} \leq x) e_{ik}$$

where x_{ikj} is the j th component of \mathbf{x}_{ik} .

The null distribution of $W_j(x)$ can be approximated by the conditional distribution of

$$\hat{W}_j(x) = \frac{1}{\sqrt{K}} \sum_{i=1}^K \left\{ \sum_{k=1}^{n_i} I(x_{ikj} \leq x) e_{ik} + \boldsymbol{\eta}'(x, \hat{\boldsymbol{\beta}}) \mathbf{I}_0^{-1} \hat{\mathbf{D}}_i' \hat{\mathbf{V}}_i^{-1} \mathbf{e}_i \right\} Z_i$$

where $\hat{\mathbf{D}}_i$ and $\hat{\mathbf{V}}_i$ are defined as in the section “[Generalized Estimating Equations](#)” on page 2819 with the unknown parameters replaced by their estimated values,

$$\boldsymbol{\eta}(x, \boldsymbol{\beta}) = - \sum_{i=1}^K \sum_{k=1}^{n_i} I(x_{ikj} \leq x) \frac{\partial \mu_{ik}}{\partial \boldsymbol{\beta}}$$

$$\mathbf{I}_0 = \sum_{i=1}^K \hat{\mathbf{D}}_i' \hat{\mathbf{V}}_i^{-1} \hat{\mathbf{D}}_i$$

and $Z_i, i = 1, \dots, K$, are independent $N(0, 1)$ random variables. You replace x_{ikj} with the linear predictor $\mathbf{x}_{ik}' \hat{\boldsymbol{\beta}}$ in the preceding formulas to check the link function.

Case Deletion Diagnostic Statistics

For ordinary generalized linear models, regression diagnostic statistics developed by Williams (1987) can be requested in an output data set or in the OBSTATS table by specifying the DIAGNOSTICS | INFLUENCE option in the MODEL statement. These diagnostics measure the influence of an individual observation on model fit, and generalize the one-step diagnostics developed by Pregibon (1981) for the logistic regression model for binary data.

Preisser and Qaqish (1996) further generalized regression diagnostics to apply to models for correlated data fit by generalized estimating equations (GEEs), where the influence of entire clusters of correlated observations, or the influence of individual observations within a cluster, is measured. These diagnostic statistics can be requested in an output data set or in the OBSTATS table if a model for correlated data is specified with a REPEATED statement.

The next two sections use the following notation:

- $\hat{\beta}$ is the maximum likelihood estimate of the regression parameters β , or, in the case of correlated data, the solution of the GEEs.
- $\hat{\beta}_{[i]}$ is the corresponding estimate evaluated with the i th observation deleted, or, in the case of correlated data, with the i th cluster deleted.
- p is the dimension of the regression parameter vector β .
- r_{pi} is the standardized Pearson residual $\frac{y_i - \mu_i}{\sqrt{v_i(1-h_i)}}$, where v_i is the variance of the i th response and h_i is the leverage defined in the section “[H | LEVERAGE](#)” on page 2832.
- v_i is the variance of response i , $\text{Var}(Y_i) = \phi V(\mu_i)$, where $V(\mu)$ is the variance function and ϕ is the dispersion parameter.
- w_i is the prior weight of the i th observation specified with the WEIGHT statement. If there is no WEIGHT statement, $w_i = 1$ for all i .

All unknown quantities are replaced by their estimated values in the following two sections.

Diagnostics for Ordinary Generalized Linear Models

The following statistics are available for generalized linear models.

DFBETA

The DFBETA statistic for measuring the influence of the i th observation is defined as the one-step approximation to the difference in the MLE of the regression parameter vector and the MLE of the regression parameter vector without the i th observation. This one-step approximation assumes a Fisher scoring step, and is given by

$$\hat{\beta} - \hat{\beta}_{[i]} \approx \text{DFBETA}_i = (\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}'_i\mathbf{W}_i^{\frac{1}{2}}(1-h_i)^{-\frac{1}{2}}r_{pi}$$

where h_i is the leverage defined in the section “[H | LEVERAGE](#)” on page 2832.

DFBETAS

The standardized DFBETA statistic for assessing the influence of the i th observation on the j th regression parameter is defined as the DFBETA statistic for the j th parameter divided by its estimated standard deviation, where the standard deviation is estimated from all the data.

$$\text{DFBETAS}_{ij} = \text{DFBETA}_{ij} / \hat{\sigma}(\beta_j)$$

DOBS / COOKD / COOKSD

In normal linear regression, the influence of observation i can be measured by Cook's distance (Cook and Weisberg 1982). A measure of influence of observation i for generalized linear models that is equivalent to Cook's distance for normal linear regression is given by

$$\text{DOBS}_i = p^{-1} h_i (1 - h_i)^{-1} r_{pi}^2$$

where h_i is the leverage defined in the section “**H / LEVERAGE**” on page 2832. This measure is the one-step approximation to $2p^{-1}[L(\hat{\beta}) - L(\hat{\beta}_{[i]})]$, where $L(\beta)$ is the log likelihood evaluated at β .

H / LEVERAGE

The Fisher scores, or expected, weight for observation i is $w_{ei} = \frac{w_i}{\phi V(\mu_i)(g'(\mu_i))^2}$. Let \mathbf{W} be the diagonal matrix with w_{ei} as the i th diagonal. The leverage h_i of the i th observation is defined as the i th diagonal element of the hat matrix

$$\mathbf{H} = \mathbf{W}^{\frac{1}{2}} \mathbf{X}(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1} \mathbf{X}'\mathbf{W}^{\frac{1}{2}}$$

Diagnostics for Models Fit by Generalized Estimating Equations (GEEs)

The diagnostic statistics in this section were developed by Preisser and Qaqish (1996). See the section “**Generalized Estimating Equations**” on page 2819 for further information and notation for generalized estimating equations (GEEs). The following additional notation is used in this section.

Partition the design matrix \mathbf{X} and response vector \mathbf{Y} by cluster; that is, let $\mathbf{X} = (\mathbf{X}'_1, \dots, \mathbf{X}'_K)'$, and $\mathbf{Y} = (\mathbf{Y}'_1, \dots, \mathbf{Y}'_K)'$ corresponding to the K clusters.

Let n_i be the number of responses for cluster i , and denote by $N = \sum_{i=1}^K n_i$ the total number of observations. Denote by \mathbf{A}_i the $n_i \times n_i$ diagonal matrix with $V(\mu_{ij})$ as the j th diagonal element. If there is a WEIGHT statement, the diagonal element of \mathbf{A}_i is $V(\mu_{ij})/w_{ij}$, where w_{ij} is the specified weight of the j th observation in the i th cluster. Let \mathbf{B} the $N \times N$ diagonal matrix with $g'(\mu_{ij})$ as diagonal elements, $i = 1, \dots, K$, $j = 1, \dots, n_i$. Let \mathbf{B}_i the $n_i \times n_i$ diagonal matrix corresponding to cluster i with $g'(\mu_{ij})$ as the j th diagonal element.

Let \mathbf{W} be the $N \times N$ block diagonal weight matrix whose i th block, corresponding to the i th cluster, is the $n_i \times n_i$ matrix

$$\mathbf{W}_{ei} = \mathbf{B}_i^{-1} \mathbf{A}_i^{-\frac{1}{2}} \mathbf{R}_i^{-1}(\hat{\alpha}) \mathbf{A}_i^{-\frac{1}{2}} \mathbf{B}_i^{-1}$$

where \mathbf{R}_i is the working correlation matrix for cluster i .

Let

$$Q_i = \mathbf{X}_i(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}_i'$$

where \mathbf{X}_i is the $n_i \times p$ design matrix corresponding to cluster i .

Define the adjusted residual vector as

$$\mathbf{E} = \mathbf{B}(\mathbf{Y} - \hat{\boldsymbol{\mu}})$$

and $\mathbf{E}_i = \mathbf{B}_i(\mathbf{Y}_i - \hat{\boldsymbol{\mu}}_i)$, the estimated residual for the i th cluster.

Let the subscript $[i]$ denote estimates evaluated without the i th cluster, $[it]$ estimates evaluated using all the data except the t th observation of the i th cluster, and let $i[t]$ denote matrices corresponding to the i th cluster without the t th observation.

The following statistics are available for generalized estimating equation models.

CH / CLUSTERH / CLEVERAGE

The leverage of cluster i is contained in the matrix $\mathbf{H}_i = \mathbf{Q}_i \mathbf{W}_{ei}$, and is summarized by the trace of \mathbf{H}_i ,

$$ch_i = \text{tr}(\mathbf{H}_i)$$

The leverage h_i of the t th observation in the i th cluster is the t th diagonal element of \mathbf{H}_i .

DFBETAC

The effect of deleting cluster i on the estimated parameter vector is given by the following one-step approximation for $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{[i]}$:

$$\text{DBETAC}_i = (\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}_i'(\mathbf{W}_{ei}^{-1} - \mathbf{Q}_i)^{-1}\mathbf{E}_i$$

DFBETACS

The cluster deletion statistic DFBETAC can be standardized using the variances of $\hat{\boldsymbol{\beta}}$ based on the complete data. The standardized one-step approximation for the change in $\hat{\boldsymbol{\beta}}_j$ due to deletion of cluster i is

$$\text{DBETACS}_{ij} = \frac{\text{DBETAC}_{ij}}{\hat{\phi}[(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}]_{jj}^{\frac{1}{2}}}$$

DFBETAO

Partition the matrices \mathbf{W}_{ei} and \mathbf{V}_i as

$$\mathbf{W}_{ei} = \begin{pmatrix} W_{eit} & \mathbf{W}_{eit[t]} \\ \mathbf{W}_{ei[t]t} & \mathbf{W}_{ei[t]} \end{pmatrix}$$

$$\mathbf{V}_i = \mathbf{W}_{ei}^{-1} = \begin{pmatrix} \mathbf{V}_{it} & \mathbf{V}_{it[t]} \\ \mathbf{V}_{i[t]t} & \mathbf{V}_{i[t]} \end{pmatrix}$$

and let $\mathbf{E}_{it} = \mathbf{B}_{it}(\mathbf{Y}_{it} - \hat{\boldsymbol{\mu}}_{it})$ and $\mathbf{E}_{i[t]} = \mathbf{B}_{i[t]}(\mathbf{Y}_{i[t]} - \hat{\boldsymbol{\mu}}_{i[t]})$.

The effect of deleting the t th observation from the i th cluster is given by the following one-step approximation to $\hat{\beta} - \hat{\beta}_{[it]}$:

$$\text{DBETAO}_{it} = (\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\tilde{\mathbf{X}}'_{it} \frac{\tilde{E}_{it}}{W_{eit}^{-1} - \tilde{Q}_{it}}$$

where $\tilde{\mathbf{X}}_{it} = \mathbf{X}_{it} - \mathbf{V}_{it[t]}\mathbf{V}_{i[t]}^{-1}\mathbf{X}_{i[t]}$, $\tilde{Q}_{it} = \tilde{\mathbf{X}}_{it}(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\tilde{\mathbf{X}}'_{it}$, and $\tilde{E}_{it} = \mathbf{E}_{it} - \mathbf{V}_{it[t]}\mathbf{V}_{i[t]}^{-1}\mathbf{E}_{i[t]}$. Note that W_{eit} , \tilde{Q}_{it} , and \tilde{E}_{it} are scalars.

DFBETAOS

The observation deletion statistic DFBETAO can be standardized using the variances of $\hat{\beta}$ based on the complete data. The standardized one-step approximation for the change in $\hat{\beta}_j$ due to deletion of observation t in cluster i is

$$\text{DBETAOS}_{itj} = \frac{\text{DBETAO}_{itj}}{\hat{\phi}[(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}]_{jj}^{1/2}}$$

DCLS | CLUSTERCOOKD | CLUSTERCOOKSD

A measure of the standardized influence of the subset m of observations on the overall fit is $(\hat{\beta} - \hat{\beta}_{[m]})'(\mathbf{X}'\mathbf{W}\mathbf{X})(\hat{\beta} - \hat{\beta}_{[m]})/p\hat{\phi}$. For deletion of cluster i , this is approximated by

$$\text{DCLS}_i = \mathbf{E}'_i(\mathbf{W}_{ei}^{-1} - \mathbf{Q}_i)^{-1}\mathbf{Q}_i(\mathbf{W}_{ei}^{-1} - \mathbf{Q}_i)^{-1}\mathbf{E}_i/p\hat{\phi}$$

DOBS | COOKD | COOKSD

The measure of overall fit in the section “DCLS | CLUSTERCOOKD | CLUSTERCOOKSD” on page 2834 for the deletion of the t th observation in the i th cluster is approximated by

$$\text{DOBS}_{it} = \frac{\tilde{E}_{it}^2 \tilde{Q}_{it}}{p\hat{\phi}(W_{eit}^{-1} - \tilde{Q}_{it})^2}$$

where \tilde{E}_{it} , \tilde{Q}_{it} , and W_{eit} are defined in the section “DFBETAO” on page 2833. In the case of the independence working correlation, this is equal to the measure for ordinary generalized linear models defined in the section “DOBS | COOKD | COOKSD” on page 2832.

MCLS | CLUSTERDFIT

A studentized distance measure of the type defined in the section “DCLS | CLUSTERCOOKD | CLUSTERCOOKSD” on page 2834 of the influence of the i th cluster is given by

$$\text{MCLS}_i = \mathbf{E}'_i(\mathbf{W}_{ei}^{-1} - \mathbf{Q}_i)^{-1}\mathbf{H}_i\mathbf{E}_i/p\hat{\phi}$$

Bayesian Analysis

In generalized linear models, the response has a probability distribution from a family of distributions of the exponential form. That is, the probability density of the response Y for continuous response variables, or the probability function for discrete responses, can be expressed as

$$f(y) = \exp \left\{ \frac{y\theta - b(\theta)}{a(\phi)} + c(y, \phi) \right\}$$

for some functions a , b , and c that determine the specific distribution. The canonical parameters θ depend only on the means of the response μ_i , which are related to the regression parameters β through the link function $g(\mu_i) = x'_i\beta$. The additional parameter ϕ is the dispersion parameter. The GENMOD procedure estimates the regression parameters and the scale parameter $\sigma = \phi^{\frac{1}{2}}$ by maximum likelihood. However, the GENMOD procedure can also provide Bayesian estimates of the regression parameters and either the scale σ , the dispersion ϕ , or the precision $\tau = \phi^{-1}$ by sampling from the posterior distribution. Except where noted, the following discussion applies to either σ , ϕ , or τ , although ϕ is used to illustrate the formulas. Note that the Poisson and binomial distributions do not have a dispersion parameter, and the dispersion is considered to be fixed at $\phi = 1$. The ASSESS, CONTRAST, ESTIMATE, OUTPUT, and REPEATED statements, if specified, are ignored. Also ignored are the PLOTS= option in the PROC GENMOD statement and the following options in the MODEL statement: ALPHA=, CORRB, COVB, TYPE1, TYPE3, SCALE=DEVIANC (DSCALE), SCALE=PEARSON (PSCALE), OBSTATS, RESIDUALS, XVARs, PREDICTED, DIAGNOSTICS, and SCALE= for Poisson and binomial distributions. The multinomial and zero-inflated Poisson distributions are not available for Bayesian analysis.

See the section “[Assessing Markov Chain Convergence](#)” on page 139 for information about assessing the convergence of the chain of posterior samples.

Several algorithms, specified with the [SAMPLING=](#) option in the BAYES statement, are available in GENMOD for drawing samples from the posterior distribution.

ARMS Algorithm for Gibbs Sampling

This section provides details for Bayesian analysis by Gibbs sampling in generalized linear models. See the section “[Gibbs Sampler](#)” on page 135 for a general discussion of Gibbs sampling. See Gilks, Richardson, and Spiegelhalter (1996) for a discussion of applications of Gibbs sampling to a number of different models, including generalized linear models.

Let $\theta = (\theta_1, \dots, \theta_k)'$ be the parameter vector. For generalized linear models, the θ_i s are the regression coefficients β_i s and the dispersion parameter ϕ . Let $L(D|\theta)$ be the likelihood function, where D is the observed data. Let $\pi(\theta)$ be the prior distribution. The full conditional distribution of $[\theta_i|\theta_j, i \neq j]$ is proportional to the joint distribution; that is,

$$\pi(\theta_i|\theta_j, i \neq j, D) \propto L(D|\theta)p(\theta)$$

For instance, the one-dimensional conditional distribution of θ_1 given $\theta_j = \theta_j^*, 2 \leq j \leq k$, is computed as

$$\pi(\theta_1|\theta_j = \theta_j^*, 2 \leq j \leq k, D) = L(D|(\theta = (\theta_1, \theta_2^*, \dots, \theta_k^*)')p(\theta = (\theta_1, \theta_2^*, \dots, \theta_k^*)')$$

Suppose you have a set of arbitrary starting values $\{\theta_1^{(0)}, \dots, \theta_k^{(0)}\}$. Using the ARMS (adaptive rejection Metropolis sampling) algorithm (Gilks and Wild 1992; Gilks, Best, and Tan 1995), you can do the following:

```
draw  $\theta_1^{(1)}$  from  $[\theta_1|\theta_2^{(0)}, \dots, \theta_k^{(0)}]$ 
draw  $\theta_2^{(1)}$  from  $[\theta_2|\theta_1^{(1)}, \theta_3^{(0)}, \dots, \theta_k^{(0)}]$ 
...
draw  $\theta_k^{(1)}$  from  $[\theta_k|\theta_1^{(1)}, \dots, \theta_{k-1}^{(1)}]$ 
```

This completes one iteration of the Gibbs sampler. After one iteration, you have $\{\theta_1^{(1)}, \dots, \theta_k^{(1)}\}$. After n iterations, you have $\{\theta_1^{(n)}, \dots, \theta_k^{(n)}\}$. PROC GENMOD implements the ARMS algorithm provided by Gilks (2003) to draw a sample from a full conditional distribution. See the section “[Adaptive Rejection Sampling Algorithm](#)” on page 136 for more information about the ARMS algorithm. The ARMS algorithm is the default method used to sample from the posterior distribution, except in the case of a normal distribution with a conjugate prior, in which case a closed form is available for the posterior distribution. See any of the introductory references in Chapter 7, “[Introduction to Bayesian Analysis Procedures](#),” for a discussion of conjugate prior distributions for a linear model with the normal distribution.

Gamerman Algorithm

The Gamerman algorithm, unlike a Gibbs sampling algorithm, samples parameters from their multivariate posterior conditional distribution. The algorithm uses the structure of generalized linear models to efficiently sample from the posterior distribution of the model parameters. For a detailed description and explanation of the algorithm, see Gamerman (1997) and the section “[Gamerman Algorithm](#)” on page 138.

Independence Metropolis Algorithm

The independence Metropolis algorithm is another sampling algorithm that draws multivariate samples from the posterior distribution. See the section “[Independence Sampler](#)” on page 137 for more details.

Posterior Samples Output Data Set

You can output posterior samples into a SAS data set through ODS. The following SAS statement outputs the posterior samples into the SAS data set Post:

ODS OUTPUT POSTERIORSAMPLE=Post

You can alternatively create the SAS data set Post with the **OUTPOST=Post** option in the **BAYES** statement.

The data set also includes the variables LogPost and LogLike, which represent the log of the posterior likelihood and the log of the likelihood, respectively.

Priors for Model Parameters

The model parameters are the regression coefficients and the dispersion parameter (or the precision or scale), if the model has one. The priors for the dispersion parameter and the priors for the regression coefficients are assumed to be independent, while you can have a joint multivariate normal prior for the regression coefficients.

Dispersion, Precision, or Scale Parameter

Gamma Prior The gamma distribution $G(a, b)$ has a probability density function

$$f(u) = \frac{b(bu)^{a-1}e^{-bu}}{\Gamma(a)}, \quad u > 0$$

where a is the shape parameter and b is the inverse-scale parameter. The mean is $\frac{a}{b}$ and the variance is $\frac{a}{b^2}$.

Improper Prior The joint prior density is given by

$$p(u) \propto u^{-1}, \quad u > 0$$

Inverse Gamma Prior The inverse gamma distribution $IG(a, b)$ has a probability density function

$$f(u) = \frac{b^a}{\Gamma(a)} u^{-(a+1)} e^{-b/u}, \quad u > 0$$

where a is the shape parameter and b is the scale parameter. The mean is $\frac{b}{a-1}$ if $a > 1$, and the variance is $\frac{b^2}{(a-1)^2(a-2)}$ if $a > 2$.

Regression Coefficients

Let β be the regression coefficients.

Jeffreys' Prior The joint prior density is given by

$$p(\beta) \propto |\mathbf{I}(\beta)|^{\frac{1}{2}}$$

where $\mathbf{I}(\beta)$ is the Fisher information matrix for the model. If the underlying model has a scale parameter (for example, a normal linear regression model), then the Fisher information matrix is computed with the scale parameter set to a fixed value of one.

If you specify the CONDITIONAL option, then Jeffreys' prior, conditional on the current Markov chain value of the generalized linear model precision parameter τ , is given by

$$|\tau \mathbf{I}(\beta)|^{\frac{1}{2}}$$

where τ is the model precision parameter.

See Ibrahim and Laud (1991) for a full discussion, with examples, of Jeffreys' prior for generalized linear models.

Normal Prior Assume β has a multivariate normal prior with mean vector β_0 and covariance matrix Σ_0 . The joint prior density is given by

$$p(\beta) \propto e^{-\frac{1}{2}(\beta - \beta_0)' \Sigma_0^{-1} (\beta - \beta_0)}$$

If you specify the CONDITIONAL option, then, conditional on the current Markov chain value of the generalized linear model precision parameter τ , the joint prior density is given by

$$p(\beta) \propto e^{-\frac{1}{2}(\beta - \beta_0)' \tau \Sigma_0^{-1} (\beta - \beta_0)}$$

Uniform Prior The joint prior density is given by

$$p(\beta) \propto 1$$

Deviance Information Criterion

Let θ_i be the model parameters at iteration i of the Gibbs sampler and let $LL(\theta_i)$ be the corresponding model log likelihood. PROC GENMOD computes the following fit statistics defined by Spiegelhalter et al. (2002):

- Effective number of parameters:

$$p_D = \overline{LL(\theta)} - LL(\bar{\theta})$$

- Deviance information criterion (DIC):

$$DIC = \overline{LL(\theta)} + p_D$$

where

$$\overline{LL(\theta)} = \frac{1}{n} \sum_{i=1}^n LL(\theta_i)$$

$$\bar{\theta} = \frac{1}{n} \sum_{i=1}^n \theta_i$$

PROC GENMOD uses the full log likelihoods defined in the section “[Log-Likelihood Functions](#)” on page 2802, with all terms included, for computing the DIC.

Posterior Distribution

Denote the observed data by D .

The posterior distribution is

$$\pi(\boldsymbol{\beta}|D) \propto L_P(D|\boldsymbol{\beta})p(\boldsymbol{\beta})$$

where $L_P(D|\boldsymbol{\beta})$ is the likelihood function with regression coefficients $\boldsymbol{\beta}$ as parameters.

Starting Values of the Markov Chains

When the BAYES statement is specified, PROC GENMOD generates one Markov chain containing the approximate posterior samples of the model parameters. Additional chains are produced when the Gelman-Rubin diagnostics are requested. Starting values (or initial values) can be specified in the INITIAL= data set in the BAYES statement. If INITIAL= option is not specified, PROC GENMOD picks its own initial values for the chains.

Denote $[x]$ as the integral value of x . Denote $\hat{s}(X)$ as the estimated standard error of the estimator X .

Regression Coefficients

For the first chain that the summary statistics and regression diagnostics are based on, the default initial values are estimates of the mode of the posterior distribution. If the INITIALMLE option is specified, the initial values are the maximum likelihood estimates; that is,

$$\beta_i^{(0)} = \hat{\beta}_i$$

Initial values for the r th chain ($r \geq 2$) are given by

$$\beta_i^{(0)} = \hat{\beta}_i \pm \left(2 + \left\lceil \frac{r}{2} \right\rceil\right) \hat{s}(\hat{\beta}_i)$$

with the plus sign for odd r and minus sign for even r .

Dispersion, Scale, or Precision Parameter λ

Let λ be the generalized linear model parameter you choose to sample, either the dispersion, scale, or precision parameter. Note that the Poisson and binomial distributions do not have this additional parameter.

For the first chain that the summary statistics and regression diagnostics are based on, the default initial values are estimates of the mode of the posterior distribution. If the INITIALMLE option is specified, the initial values are the maximum likelihood estimates; that is,

$$\lambda^{(0)} = \hat{\lambda}$$

The initial values of the r th chain ($r \geq 2$) are given by

$$\lambda^{(0)} = \hat{\lambda} e^{\pm \left(\left[\frac{r}{2} \right] + 2 \right) \hat{s}(\hat{\lambda})}$$

with the plus sign for odd r and minus sign for even r .

OUTPOST= Output Data Set

The OUTPOST= data set contains the generated posterior samples. There are $3+n$ variables, where n is the number of model parameters. The variable Iteration represents the iteration number, the variable LogLike contains the log of the likelihood, and the variable LogPost contains the log of the posterior. The other n variables represent the draws of the Markov chain for the model parameters.

Exact Logistic and Exact Poisson Regression

The theory of exact logistic regression, also called exact conditional logistic regression, is described in the section “Exact Conditional Logistic Regression” on page 4274 of Chapter 54, “The LOGISTIC Procedure.” The following discussion of exact Poisson regression, also called exact conditional Poisson regression, uses the notation given in that section.

Note that in exact logistic regression, the coefficients $C(\mathbf{t})$ are the number of possible response vectors \mathbf{y} that generate \mathbf{t} : $C(\mathbf{t}) = ||\{\mathbf{y} : \mathbf{y}'\mathbf{X} = \mathbf{t}'\}||$. However, when performing an exact Poisson regression, this value is replaced by

$$C(\mathbf{t}) = \sum_{\Omega} \prod_{i=1}^n \frac{N_i^{y_i}}{y_i!}$$

where $\Omega = \{\mathbf{y} : \mathbf{y}'\mathbf{X} = \mathbf{t}'\}$ and $N_i = \exp(o_i)$ is the exponential of the offset o_i for observation i . If an offset variable is not specified, then $N_i = 1$.

The probability density function (PDF) for \mathbf{T} is created by summing over all candidate sequences \mathbf{y} that generate an observable \mathbf{t}

$$\Pr(\mathbf{T} = \mathbf{t}) = \frac{C(\mathbf{t}) \exp(\mathbf{t}'\boldsymbol{\beta})}{\prod_{i=1}^n \exp(N_i e^{\mathbf{x}_i'\boldsymbol{\beta}})}$$

However, the conditional likelihood of \mathbf{T}_I given $\mathbf{T}_N = \mathbf{t}_N$ has the same form as that for exact logistic regression.

For details about hypothesis testing and estimation, see the sections “Hypothesis Tests” on page 4276 and “Inference for a Single Parameter” on page 4277 of Chapter 54, “The LOGISTIC Procedure.” See the section “Computational Resources for Exact Logistic Regression” on page 4284 of Chapter 54, “The LOGISTIC Procedure,” for some computational notes about exact analyses.

In exact logistic binary regression, each component $y_i, i = 1, \dots, n$, of \mathbf{y} can take a value of 0 or 1, so there are a finite number, 2^n , of candidate \mathbf{y} vectors to be considered. Since a Poisson-distributed response variable can take an infinite number of values, exact Poisson regression should evaluate an infinite number of \mathbf{y} vectors. However, by identifying the maximum value of y_i to check, S_i , for each observation i , the number of candidate \mathbf{y} vectors to check is reduced to $\prod_{i=1}^n S_i$. On a practical level, as S_i becomes large the probability of the Poisson random variable achieving this value drops to zero, so S_i can be thought of as the point at which the value does not matter. You can provide these maxima by specifying either an **OFFSET=** variable, o_i , or an **EXACTMAX=** variable, e_i , or you can let the algorithm choose a maximum for you. The way these two options interact to provide a maximum is described in the following list:

1. If an **EXACTMAX=** variable is specified, then $S_i = e_i$.
2. If the **EXACTMAX** option is specified without a variable, or if neither the **EXACTMAX=** nor **OFFSET=** options are specified, then you must also condition out the intercept or you must specify the **STRATA** statement. If you are conditioning out the intercept, then every S_i has an effective maximum of $\sum_{i=1}^n f_i y_{0i}$, where y_0 is the observed response and f_i is the frequency of the observation; this is the sufficient statistic for the intercept term. If you are performing a stratified analysis, these sums are computed within each stratum.
3. If an **offset** variable is specified and the **EXACTMAX** option is not specified (you are modeling proportions), then $N_i = \exp(o_i)$ must be a positive integer, and $S_i = N_i$ is the maximum possible value for each observation in the experiment; for example, if you are counting the number of rats in a cage that acquire a disease, then N_i is the number of rats in cage i .

OUTDIST= Output Data Set

The **OUTDIST=** data set contains every exact conditional distribution necessary to process the corresponding **EXACT** statement. For example, the following statements create one distribution for the **x1** parameter and another for the **x2** parameters, and produce the data set **dist** shown in Table 40.11:

```
data test;
  input y x1 x2 count;
  datalines;
0 0 0 1
1 0 0 1
0 1 1 2
1 1 1 1
1 0 2 3
1 1 2 1
1 2 0 3
1 2 1 2
1 2 2 1
;
```

```

proc genmod data=test exactonly;
  class x2 / param=ref;
  model y=x1 x2 / d=b;
  exact x1 x2/ outdist=dist;
run;
proc print data=dist;
run;

```

Table 40.11 OUTDIST= Data Set

Obs	x1	x20	x21	Count	Score	Prob
1	.	0	0	3	5.81151	0.03333
2	.	0	1	15	1.66031	0.16667
3	.	0	2	9	3.12728	0.10000
4	.	1	0	15	1.46523	0.16667
5	.	1	1	18	0.21675	0.20000
6	.	1	2	6	4.58644	0.06667
7	.	2	0	19	1.61869	0.21111
8	.	2	1	2	3.27293	0.02222
9	.	3	0	3	6.27189	0.03333
10	2	.	.	6	3.03030	0.12000
11	3	.	.	12	0.75758	0.24000
12	4	.	.	11	0.00000	0.22000
13	5	.	.	18	0.75758	0.36000
14	6	.	.	3	3.03030	0.06000

The first nine observations in the `dist` data set contain an exact distribution for the parameters of the `x2` effect (hence the values for the `x1` parameter are missing), and the remaining five observations are for the `x1` parameter. If a joint distribution was created, there would be observations with values for both the `x1` and `x2` parameters. For **CLASS** variables, the corresponding parameters in the `dist` data set are identified by concatenating the variable name with the appropriate classification level.

The data set contains the possible sufficient statistics of the parameters for the effects specified in the **EXACT** statement, and the `Count` variable contains the number of different responses that yield these statistics. In particular, there are six possible response vectors \mathbf{y} for which the dot product $\mathbf{y}'\mathbf{x}_1$ was equal to 2, and for which $\mathbf{y}'\mathbf{x}_{20}$, $\mathbf{y}'\mathbf{x}_{21}$, and $\mathbf{y}'\mathbf{1}$ were equal to their actual observed values (displayed in the “Sufficient Statistics” table).

NOTE: If you are performing an exact Poisson analysis, then the `Count` variable is replaced by a variable named `Weight`.

When hypothesis tests are performed on the parameters, the `Prob` variable contains the probability of obtaining that statistic (which is just the count divided by the total count), and the `Score` variable contains the score for that statistic.

The `OUTDIST=` data set can contain a different exact conditional distribution for each specified **EXACT** statement. For example, consider the following **EXACT** statements:

```

exact 'O1'    x1      /                outdist=o1;
exact 'OJ12'  x1 x2 / jointonly outdist=oj12;
exact 'OA12'  x1 x2 / joint      outdist=oa12;
exact 'OE12'  x1 x2 / estimate  outdist=oe12;

```

The O1 statement outputs a single exact conditional distribution. The OJ12 statement outputs only the joint distribution for x1 and x2. The OA12 statement outputs three conditional distributions: one for x1, one for x2, and one jointly for x1 and x2. The OE12 statement outputs two conditional distributions: one for x1 and the other for x2. Data set oe12 contains both the x1 and x2 variables; the distribution for x1 has missing values in the x2 column while the distribution for x2 has missing values in the x1 column.

Missing Values

For generalized linear models, PROC GENMOD ignores any observation with a missing value for any variable involved in the model. You can score an observation in an output data set by setting only the response value to missing. For models fit with generalized estimating equations (GEEs), observations with missing values within a cluster are not used, and all available pairs are used in estimating the working correlation matrix. Clusters with fewer observations than the full cluster size are treated as having missing observations occurring at the end of the cluster. You can specify the order of missing observations with the **WITHINSUBJECT=** option. See the section “[Missing Data](#)” on page 2821 for more information about missing values in GEEs.

Displayed Output for Classical Analysis

The following output is produced by the GENMOD procedure. Note that some of the tables are optional and appear only in conjunction with the REPEATED statement and its options or with options in the MODEL statement. For details, see the section “[ODS Table Names](#)” on page 2852.

Model Information

The “Model Information” table displays the two-level data set name, the response distribution, the link function, the response variable name, the offset variable name, the frequency variable name, the scale weight variable name, the number of observations used, the number of events if events/trials format is used for response, the number of trials if events/trials format is used for response, the sum of frequency weights, the number of missing values in data set, and the number of invalid observations (for example, negative or 0 response values with gamma distribution or number of observations with events greater than trials with binomial distribution).

Class Level Information

If you use classification variables in the model, PROC GENMOD displays the levels of classification variables specified in the CLASS statement and in the MODEL statement. The levels are displayed in the same sorted order used to generate columns in the design matrix.

Response Profile

If you specify an ordinal model for the multinomial distribution, a table titled “Response Profile” is displayed containing the ordered values of the response variable and the number of occurrences of the values used in the model.

Iteration History for Parameter Estimates

If you specify the ITPRINT model option, PROC GENMOD displays a table containing the following for each iteration in the Newton-Raphson procedure for model fitting: the iteration number, the ridge value, the log likelihood, and values of all parameters in the model.

Criteria for Assessing Goodness of Fit

In the “Criteria for Assessing Goodness of Fit” table, PROC GENMOD displays the degrees of freedom for deviance and Pearson’s chi-square, equal to the number of observations minus the number of regression parameters estimated, the deviance, the deviance divided by degrees of freedom, the scaled deviance, the scaled deviance divided by degrees of freedom, Pearson’s chi-square, Pearson’s chi-square divided by degrees of freedom, the scaled Pearson’s chi-square, the scaled Pearson’s chi-square divided by degrees of freedom, the log likelihood (excludes factorial terms) the full log likelihood, the Akaike information criterion, the corrected Akaike information criterion, and the Bayesian information criterion. The information in this table is valid only for maximum likelihood model fitting, and the table is not printed if the REPEATED statement is specified.

Last Evaluation of the Gradient

If you specify the model option ITPRINT, the GENMOD procedure displays the last evaluation of the gradient vector.

Last Evaluation of the Hessian

If you specify the model option ITPRINT, the GENMOD procedure displays the last evaluation of the Hessian matrix.

Analysis of (Initial) Parameter Estimates

The “Analysis of (Initial) Parameter Estimates” table contains the results from fitting a generalized linear model to the data. If you specify the REPEATED statement, these GLM parameter estimates are used as initial values for the GEE solution, and are displayed only if the PRINTMLE option in the REPEATED statement is specified. For each parameter in the model, PROC GENMOD displays the parameter name, as follows:

- the variable name for continuous regression variables
- the variable name and level for classification variables and interactions involving classification variables
- SCALE for the scale variable related to the dispersion parameter

In addition, PROC GENMOD displays the degrees of freedom for the parameter, the estimate value, the standard error, the Wald chi-square value, the p -value based on the chi-square distribution, and the confidence limits (Wald or profile likelihood) for parameters.

Lagrange Multiplier Statistics

If you specify that either the model intercept or the scale parameter is fixed, for those distributions that have a distribution scale parameter, the GENMOD procedure displays a table of Lagrange multiplier, or score, statistics for testing the validity of the constrained parameter that contains the test statistic, and the p -value.

Estimated Covariance Matrix

If you specify the model option COVB, the GENMOD procedure displays the estimated covariance matrix, defined as the inverse of the information matrix at the final iteration. This is based on the expected information matrix if the EXPECTED option is specified in the MODEL statement. Otherwise, it is based on the Hessian matrix used at the final iteration. This is, by default, the observed Hessian unless altered by the SCORING option in the MODEL statement.

Estimated Correlation Matrix

If you specify the CORRB model option, PROC GENMOD displays the estimated correlation matrix. This is based on the expected information matrix if the EXPECTED option is specified in the MODEL statement. Otherwise, it is based on the Hessian matrix used at the final iteration. This is, by default, the observed Hessian unless altered by the SCORING option in the MODEL statement.

Iteration History for LR Confidence Intervals

If you specify the ITPRINT and LRCI model options, PROC GENMOD displays an iteration history table for profile likelihood-based confidence intervals. For each parameter in the model, PROC GENMOD displays the parameter identification number, the iteration number, the log-likelihood value, parameter values.

Likelihood Ratio-Based Confidence Intervals for Parameters

If you specify the LRCI and the ITPRINT options in the MODEL statement, a table is displayed that summarizes profile likelihood-based confidence intervals for all parameters. For each parameter in the model, the table displays the confidence coefficient, the parameter identification number, lower and upper endpoints of confidence intervals for the parameter, and values of all other parameters at the solution.

LR Statistics for Type 1 Analysis

If you specify the TYPE1 model option, a table is displayed that contains the name of the effect, the deviance for the model including the effect and all previous effects, the degrees of freedom for the effect, the likelihood ratio statistic for testing the significance of the effect, and the p -value computed from the chi-square distribution with the effect's degrees of freedom.

If you specify either the SCALE=DEVIANCE or SCALE=PEARSON option in the MODEL statement, columns are displayed that contain the name of the effect, the deviance for the model including the effect and all previous effects, the numerator degrees of freedom, the denominator degrees of freedom, the chi-square statistic for testing the significance of the effect, the p -value computed from the chi-square distribution with

numerator degrees of freedom, the F statistic for testing the significance of the effect, and the p -value based on the F distribution.

Iteration History for Type 3 Contrasts

If you specify the model options ITPRINT and TYPE3, an iteration history table is displayed for fitting the model with Type 3 contrast constraints for each effect that contains the effect name, the iteration number, the ridge value, the log likelihood, and values of all parameters.

LR Statistics for Type 3 Analysis

If you specify the TYPE3 model option, a table is displayed that contains, for each effect in the model, the name of the effect, the likelihood ratio statistic for testing the significance of the effect, the degrees of freedom for the effect, and the p -value computed from the chi-square distribution.

If you specify either the SCALE=DEVIANCE or SCALE=PEARSON option in the MODEL statement, columns are displayed that contain the name of the effect, the likelihood ratio statistic for testing the significance of the effect, the F statistic for testing the significance of the effect, the numerator degrees of freedom, the denominator degrees of freedom, the p -value based on the F distribution, and the p -value computed from the chi-square distribution with the numerator's degrees of freedom.

Wald Statistics for Type 3 Analysis

If you specify the TYPE3 and WALD model options, a table is displayed that contains the name of the effect, the degrees of freedom of the effect, the Wald statistic for testing the significance of the effect, and the p -value computed from the chi-square distribution.

Parameter Information

If you specify the ITPRINT, COVB, CORRB, WALDCI, or LRCI option in the MODEL statement, or if you specify a CONTRAST statement, a table is displayed that identifies parameters with numbers, rather than names, for use in tables and matrices where a compact identifier for parameters is helpful. For each parameter, the table contains an index number that identifies the parameter, and the parameter name, including level information for effects containing classification variables.

Observation Statistics

If you specify the OBSTATS option in the MODEL statement, PROC GENMOD displays a table containing miscellaneous statistics. Residuals and case deletion diagnostic statistics are not available for the multinomial distribution. Case deletion diagnostics are not available for zero-inflated models.

For each observation in the input data set, the following are displayed:

- the value of the response variable
- the predicted value of the mean
- the value of the linear predictor The value of an OFFSET variable is added to the linear predictor.
- the estimated standard error of the linear predictor

- the value of the negative of the weight in the Hessian matrix at the final iteration. This is the expected weight if the EXPECTED option is specified in the MODEL statement. Otherwise, it is the weight used in the final iteration. That is, it is the observed weight unless the SCORING= option has been specified.
- approximate lower and upper endpoints for a confidence interval for the predicted value of the mean
- raw residual
- Pearson residual
- deviance residual
- standardized Pearson residual
- standardized deviance residual
- likelihood residual
- leverage
- Cook's distance statistic
- DFBETA statistic, for each parameter
- standardized DFBETA statistic, for each parameter
- zero-inflation probability for zero-inflated models
- response mean for zero-inflated models

ESTIMATE Statement Results

If you specify a REPEATED statement, the ESTIMATE statement results apply to the specified GEE model. Otherwise, they apply to the specified generalized linear model.

For each ESTIMATE statement, the table contains the contrast label, the estimated value of the contrast, the standard error of the estimate, the significance level α , $(1 - \alpha) \times 100\%$ confidence intervals for contrast, the Wald chi-square statistic for the contrast, and the p -value computed from the chi-square distribution. The mean of the contrast, defined as the inverse link function applied to the contrast, and $(1 - \alpha) \times 100\%$ confidence intervals for the mean are also displayed.

If you specify the EXP option, an additional row is displayed with statistics for the exponentiated value of the contrast.

CONTRAST Coefficients

If you specify the CONTRAST or ESTIMATE statement and you specify the E option, a table titled “Coefficients For Contrast *label*” is displayed, where *label* is the label specified in the CONTRAST statement. The table contains the contrast label, and the rows of the contrast matrix.

Iteration History for Contrasts

If you specify the ITPRINT option, an iteration history table is displayed for fitting the model with contrast constraints for each effect. The table contains the contrast label, the iteration number, the ridge value, the log likelihood, and values of all parameters.

CONTRAST Statement Results

If you specify a REPEATED statement, the CONTRAST statement results apply to the specified GEE model. Otherwise, they apply to the specified generalized linear model.

A table is displayed that contains the contrast label, the degrees of freedom for the contrast, and the likelihood ratio, score, or Wald statistic for testing the significance of the contrast. Score statistics are used in GEE models, likelihood ratio statistics are used in generalized linear models, and Wald statistics are used in both. Also displayed are the p -value computed from the chi-square distribution, and the type of statistic computed for this contrast: Wald, LR, or score.

If you specify either the SCALE=DEVIANCE or SCALE=PEARSON option for generalized linear models, columns are displayed that contain the contrast label, the likelihood ratio statistic for testing the significance of the contrast, the F statistic for testing the significance of the contrast, the numerator degrees of freedom, the denominator degrees of freedom, the p -value based on the F distribution, and the p -value computed from the chi-square distribution with numerator degrees of freedom.

LSMEANS Coefficients

If you specify the LSMEANS statement and you specify the E option, the “Coefficients for *effect* Least Squares Means” table is displayed, where *effect* is the effect specified in the LSMEANS statement. The table contains the effect names and the rows of least squares means coefficients.

Least Squares Means

If you specify the LSMEANS statement, the “Least Squares Means” table is displayed. The table contains for each effect the following: the effect name, and for each level of each effect the following:

- the least squares mean estimate
- standard error
- chi-square value
- p -value computed from the chi-square distribution

If you specify the DIFF option, a table titled “Differences of Least Squares Means” is displayed containing corresponding statistics for the differences between the least squares means for the levels of each effect.

GEE Model Information

If you specify the REPEATED statement, the “GEE Model Information” table displays the correlation structure of the working correlation matrix or the log odds ratio structure, the within-subject effect, the subject effect, the number of clusters, the correlation matrix dimension, and the minimum and maximum cluster size.

Log Odds Ratio Parameter Information

If you specify the REPEATED statement and specify a log odds ratio model for binary data with the LOGOR= option, then the “Log Odds Ratio Parameter Information” table is displayed showing the correspondence between data pairs and log odds ratio model parameters.

Iteration History for GEE Parameter Estimates

If you specify the REPEATED statement and the MODEL statement option ITPRINT, the “Iteration History For GEE Parameter Estimates” table is displayed. The table contains the parameter identification number, the iteration number, and values of all parameters.

Last Evaluation of the Generalized Gradient and Hessian

If you specify the REPEATED statement and select ITPRINT as a model option, PROC GENMOD displays the “Last Evaluation Of The Generalized Gradient And Hessian” table.

GEE Parameter Estimate Covariance Matrices

If you specify the REPEATED statement and the COVB option, PROC GENMOD displays the “Covariance Matrix (Model-Based)” and “Covariance Matrix (Empirical)” tables.

GEE Parameter Estimate Correlation Matrices

If you specify the REPEATED statement and the CORRB option, PROC GENMOD displays the “Correlation Matrix (Model-Based)” and “Correlation Matrix (Empirical)” tables.

GEE Working Correlation Matrix

If you specify the REPEATED statement and the CORRW option, PROC GENMOD displays the “Working Correlation Matrix” table.

GEE Fit Criteria

If you specify the REPEATED statement, PROC GENMOD displays the quasi-likelihood information criteria for model fit QIC and QIC_u in the “GEE Fit Criteria” table.

Analysis of GEE Parameter Estimates

If you specify the REPEATED statement, PROC GENMOD uses empirical standard error estimates to compute and display the “Analysis Of GEE Parameter Estimates Empirical Standard Error Estimates” table that contains the parameter names as follows:

- the variable name for continuous regression variables
- the variable name and level for classification variables and interactions involving classification variables
- “Scale” for the scale variable related to the dispersion parameter

In addition, the parameter estimate, the empirical standard error, a 95% confidence interval, and the Z score and p -value are displayed for each parameter.

If you specify the MODELSE option in the REPEATED statement, the “Analysis Of GEE Parameter Estimates Model-Based Standard Error Estimates” table based on model-based standard errors is also produced.

GEE Observation Statistics

If you specify the OBSTATS option in the REPEATED statement, PROC GENMOD displays a table containing miscellaneous statistics. For each observation in the input data set, the following are displayed:

- the value of the response variable and all other variables in the model, denoted by the variable names
- the predicted value of the mean
- the value of the linear predictor
- the standard error of the linear predictor
- confidence limits for the predicted values
- raw residual
- Pearson residual
- cluster number
- leverage
- cluster leverage
- cluster Cook’s distance statistic
- studentized cluster Cook’s distance statistic
- individual observation Cook’s distance statistic
- cluster DFBETA statistic for each parameter
- cluster standardized DFBETA statistic for each parameter
- individual observation DFBETA statistic for each parameter
- individual observation standardized DFBETA statistic for each parameter

Displayed Output for Bayesian Analysis

If a Bayesian analysis is requested with a BAYES statement, the displayed output includes the following.

Model Information

The “Model Information” table displays the two-level data set name, the number of burn-in iterations, the number of iterations after the burn-in, the number of thinning iterations, the response distribution, the link function, the response variable name, the offset variable name, the frequency variable name, the scale weight variable name, the number of observations used, the number of events if events/trials format is used for response, the number of trials if events/trials format is used for response, the sum of frequency weights, the number of missing values in data set, and the number of invalid observations (for example, negative or 0 response values with gamma distribution or number of observations with events greater than trials with binomial distribution).

Class Level Information

The “Class Level Information” table displays the levels of classification variables if you specify a CLASS statement.

Maximum Likelihood Estimates

The “Analysis of Maximum Likelihood Parameter Estimates” table displays the maximum likelihood estimate of each parameter, the estimated standard error of the parameter estimator, and confidence limits for each parameter.

Coefficient Prior

The “Coefficient Prior” table displays the prior distribution of the regression coefficients.

Independent Prior Distributions for Model Parameters

The “Independent Prior Distributions for Model Parameters” table displays the prior distributions of additional model parameters (scale, exponential scale, Weibull scale, Weibull shape, gamma shape).

Initial Values and Seeds

The “Initial Values and Seeds” table displays the initial values and random number generator seeds for the Gibbs chains.

Fit Statistics

The “Fit Statistics” table displays the deviance information criterion (DIC) and the effective number of parameters.

Descriptive Statistics of the Posterior Samples

The “Descriptive Statistics of the Posterior Sample” table contains the size of the sample, the mean, the standard deviation, and the quartiles for each model parameter.

Interval Estimates for Posterior Sample

The “Interval Estimates for Posterior Sample” table contains the HPD intervals and the credible intervals for each model parameter.

Correlation Matrix of the Posterior Samples

The “Correlation Matrix of the Posterior Samples” table is produced if you include the CORR suboption in the SUMMARY= option in the BAYES statement. This table displays the sample correlation of the posterior samples.

Covariance Matrix of the Posterior Samples

The “Covariance Matrix of the Posterior Samples” table is produced if you include the COV suboption in the SUMMARY= option in the BAYES statement. This table displays the sample covariance of the posterior samples.

Autocorrelations of the Posterior Samples

The “Autocorrelations of the Posterior Samples” table displays the lag1, lag5, lag10, and lag50 autocorrelations for each parameter.

Gelman and Rubin Diagnostics

The “Gelman and Rubin Diagnostics” table is produced if you include the GELMAN suboption in the DIAGNOSTIC= option in the BAYES statement. This table displays the estimate of the potential scale reduction factor and its 97.5% upper confidence limit for each parameter.

Geweke Diagnostics

The “Geweke Diagnostics” table displays the Geweke statistic and its p -value for each parameter.

Raftery and Lewis Diagnostics

The “Raftery Diagnostics” tables is produced if you include the RAFTERY suboption in the DIAGNOSTIC= option in the BAYES statement. This table displays the Raftery and Lewis diagnostics for each variable.

Heidelberger and Welch Diagnostics

The “Heidelberger and Welch Diagnostics” table is displayed if you include the HEIDELBERGER suboption in the DIAGNOSTIC= option in the BAYES statement. This table shows the results of a stationary test and a halfwidth test for each parameter.

Effective Sample Size

The “Effective Sample Size” table displays, for each parameter, the effective sample size, the correlation time, and the efficiency.

Monte Carlo Standard Errors

The “Monte Carlo Standard Errors” table displays, for each parameter, the Monte Carlo standard error, the posterior sample standard deviation, and the ratio of the two.

Displayed Output for Exact Analysis

If an exact analysis is requested with an **EXACT** statement, the displayed output includes the following tables. If the **METHOD=NETWORKMC** option is specified, the test and estimate tables are renamed “Monte Carlo” tables and a Monte Carlo standard error column ($\sqrt{p(1-p)/n}$) is displayed.

Sufficient Statistics

Displays if you request an **OUTDIST=** data set in an **EXACT** statement. The table lists the parameters and their observed sufficient statistics.

(Monte Carlo) Conditional Exact Tests

This table tests the hypotheses that the parameters of interest are insignificant. See the section “Exact Logistic and Exact Poisson Regression” on page 2839 for details.

(Monte Carlo) Exact Parameter Estimates

Displays if you specify the **ESTIMATE** option in the **EXACT** statement. This table gives individual parameter estimates for each variable (conditional on the values of all the other parameters in the model), confidence limits, and a two-sided p -value (twice the one-sided p -value) for testing that the parameter is zero. See the section “Exact Logistic and Exact Poisson Regression” on page 2839 for details.

(Monte Carlo) Exact Odds Ratios

Displays if you specify the **ESTIMATE=ODDS** or **ESTIMATE=BOTH** option in the **EXACT** statement. See the section “Exact Logistic and Exact Poisson Regression” on page 2839 for details.

Strata Summary

Displays if a **STRATA** statement is also specified. Shows the pattern of the number of events and the number of nonevents, or of the number of observations, in a stratum. See the section “STRATA Statement” on page 2796 for more information.

Strata Information

Displays if a **STRATA** statement is specified with the **INFO** option.

ODS Table Names

PROC GENMOD assigns a name to each table that it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed separately in Table 40.12 for a maximum likelihood analysis, in Table 40.13 for a Bayesian analysis, and in Table 40.14 for an Exact analysis. For more information about ODS, see Chapter 20, “Using the Output Delivery System.”

Table 40.12 ODS Tables Produced in PROC GENMOD for a Classical Analysis

ODS Table Name	Description	Statement	Option
AssessmentSummary	Model assessment summary	ASSESS	Default

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in Chapter 21, “[Statistical Graphics Using ODS](#).”

Before you create graphs, ODS Graphics must be enabled (for example, by specifying the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “[Enabling and Disabling ODS Graphics](#)” on page 600 in Chapter 21, “[Statistical Graphics Using ODS](#).”

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “[A Primer on ODS Statistical Graphics](#)” on page 599 in Chapter 21, “[Statistical Graphics Using ODS](#).”

Some graphs are produced by default; other graphs are produced by using statements and options. You can reference every graph produced through ODS Graphics with a name. The names of the graphs that PROC GENMOD generates are listed in [Table 40.15](#), along with the required statements and options.

ODS Graph Names

PROC GENMOD assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in [Table 40.15](#).

To request these graphs, ODS Graphics must be enabled and you must specify the statement and options indicated in [Table 40.15](#).

Examples: GENMOD Procedure

The following examples illustrate some of the capabilities of the GENMOD procedure. These are not intended to represent definitive analyses of the data sets presented here. You should refer to the texts cited in the references for guidance on complete analysis of data by using generalized linear models.

Example 40.1: Logistic Regression

In an experiment comparing the effects of five different drugs, each drug is tested on a number of different subjects. The outcome of each experiment is the presence or absence of a positive response in a subject. The following artificial data represent the number of responses r in the n subjects for the five different drugs, labeled A through E. The response is measured for different levels of a continuous covariate x for each drug. The drug type and the continuous covariate x are explanatory variables in this experiment. The number of responses r is modeled as a binomial random variable for each combination of the explanatory variable values, with the binomial number of trials parameter equal to the number of subjects n and the binomial probability equal to the probability of a response.

The following DATA step creates the data set:

```
data drug;
  input drug$ x r n @@;
  datalines;
A .1 1 10 A .23 2 12 A .67 1 9
B .2 3 13 B .3 4 15 B .45 5 16 B .78 5 13
C .04 0 10 C .15 0 11 C .56 1 12 C .7 2 12
D .34 5 10 D .6 5 9 D .7 8 10
E .2 12 20 E .34 15 20 E .56 13 15 E .8 17 20
;
```

A logistic regression for these data is a generalized linear model with response equal to the binomial proportion r/n . The probability distribution is binomial, and the link function is logit. For these data, drug and x are explanatory variables. The probit and the complementary log-log link functions are also appropriate for binomial data.

PROC GENMOD performs a logistic regression on the data in the following SAS statements:

```
proc genmod data=drug;
  class drug;
  model r/n = x drug / dist = bin
                        link = logit
                        lrci;
run;
```

Since these data are binomial, you use the events/trials syntax to specify the response in the MODEL statement. Profile likelihood confidence intervals for the regression parameters are computed using the LRCI option.

General model and data information is produced in [Output 40.1.1](#).

Output 40.1.1 Model Information

The GENMOD Procedure	
Model Information	
Data Set	WORK.DRUG
Distribution	Binomial
Link Function	Logit
Response Variable (Events)	r
Response Variable (Trials)	n

The five levels of the CLASS variable DRUG are displayed in [Output 40.1.2](#).

Output 40.1.2 CLASS Variable Levels

Class Level Information		
Class	Levels	Values
drug	5	A B C D E

In the “Criteria For Assessing Goodness Of Fit” table displayed in [Output 40.1.3](#), the value of the deviance divided by its degrees of freedom is less than 1. A p -value is not computed for the deviance; however, a deviance that is approximately equal to its degrees of freedom is a possible indication of a good model fit. Asymptotic distribution theory applies to binomial data as the number of binomial trials parameter n becomes large for each combination of explanatory variables. McCullagh and Nelder (1989) caution against the use of the deviance alone to assess model fit. The model fit for each observation should be assessed by examination of residuals. The OBSTATS option in the MODEL statement produces a table of residuals and other useful statistics for each observation.

Output 40.1.3 Goodness-of-Fit Criteria

Criteria For Assessing Goodness Of Fit			
Criterion	DF	Value	Value/DF
Deviance	12	5.2751	0.4396
Scaled Deviance	12	5.2751	0.4396
Pearson Chi-Square	12	4.5133	0.3761
Scaled Pearson X2	12	4.5133	0.3761
Log Likelihood		-114.7732	
Full Log Likelihood		-23.7343	
AIC (smaller is better)		59.4686	
AICC (smaller is better)		67.1050	
BIC (smaller is better)		64.8109	

In the “Analysis Of Parameter Estimates” table displayed in [Output 40.1.4](#), chi-square values for the explanatory variables indicate that the parameter values other than the intercept term are all significant. The scale parameter is set to 1 for the binomial distribution. When you perform an overdispersion analysis, the value of the overdispersion parameter is indicated here. See the section “[Overdispersion](#)” on page 2809 for a discussion of overdispersion.

Output 40.1.4 Parameter Estimates

Analysis Of Maximum Likelihood Parameter Estimates							
Parameter	DF	Estimate	Standard Error	Likelihood Ratio		Wald Chi-Square	Pr > ChiSq
				95% Confidence Limits			
Intercept	1	0.2792	0.4196	-0.5336	1.1190	0.44	0.5057
x	1	1.9794	0.7660	0.5038	3.5206	6.68	0.0098
drug A	1	-2.8955	0.6092	-4.2280	-1.7909	22.59	<.0001
drug B	1	-2.0162	0.4052	-2.8375	-1.2435	24.76	<.0001
drug C	1	-3.7952	0.6655	-5.3111	-2.6261	32.53	<.0001
drug D	1	-0.8548	0.4838	-1.8072	0.1028	3.12	0.0773
drug E	0	0.0000	0.0000	0.0000	0.0000	.	.
Scale	0	1.0000	0.0000	1.0000	1.0000		
NOTE: The scale parameter was held fixed.							

The preceding table contains the profile likelihood confidence intervals for the explanatory variable parameters requested with the LRCI option. Wald confidence intervals are displayed by default. Profile likelihood confidence intervals are considered to be more accurate than Wald intervals (see Aitkin et al. (1989)), especially with small sample sizes. You can specify the confidence coefficient with the ALPHA= option in the MODEL statement. The default value of 0.05, corresponding to 95% confidence limits, is used here. See the section “[Confidence Intervals for Parameters](#)” on page 2813 for a discussion of profile likelihood confidence intervals.

Example 40.2: Normal Regression, Log Link

Consider the following data, where x is an explanatory variable and y is the response variable. It appears that y varies nonlinearly with x and that the variance is approximately constant. A normal distribution with a log link function is chosen to model these data; that is, $\log(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}$ so that $\mu_i = \exp(\mathbf{x}_i' \boldsymbol{\beta})$.

```
data nor;
  input x y;
  datalines;
0 5
0 7
0 9
1 7
1 10
1 8
2 11
2 9
3 16
3 13
3 14
4 25
4 24
5 34
5 32
5 30
;
```

The following SAS statements produce the analysis with the normal distribution and log link:

```
proc genmod data=nor;
  model y = x / dist = normal
           link = log;
  output out      = Residuals
         pred     = Pred
         resraw   = Resraw
         reschi   = Reschi
         resdev   = Resdev
         stdreschi = Stdreschi
         stdresdev = Stdresdev
         reslik   = Reslik;
run;
```

The OUTPUT statement is specified to produce a data set that contains predicted values and residuals for each observation. This data set can be useful for further analysis, such as residual plotting.

The results from these statements are displayed in [Output 40.2.1](#).

Output 40.2.1 Log-Linked Normal Regression

The data set of predicted values and residuals ([Output 40.2.2](#)) is created by the OUTPUT statement. You can use the PLOTS= option in the PROC GENMOD statement to create plots of predicted values and residuals. Note that raw, Pearson, and deviance residuals are equal in this example. This is a characteristic of the normal distribution and is not true in general for other distributions.

Example 40.3: Gamma Distribution Applied to Life Data

Life data are sometimes modeled with the gamma distribution. Although PROC GENMOD does not analyze censored data or provide other useful lifetime distributions such as the Weibull or lognormal, it can be used for modeling complete (uncensored) data with the gamma distribution, and it can provide a statistical test for the exponential distribution against other gamma distribution alternatives. See Lawless (2003) or Nelson (1982) for applications of the gamma distribution to life data.

The following data represent failure times of machine parts, some of which are manufactured by manufacturer A and some by manufacturer B.

```

data lifdat;
    set A B;
run;

```

The following SAS statements use PROC GENMOD to compute Type 3 statistics to test for differences between the two manufacturers in machine part life. Type 3 statistics are identical to Type 1 statistics in this case, since there is only one effect in the model. The log link function is selected to ensure that the mean is positive.

```

proc genmod data = lifdat;
    class mfg;
    model lifetime = mfg / dist=gamma
                        link=log
                        type3;
run;

```

The output from these statements is displayed in [Output 40.3.1](#).

Output 40.3.1 Gamma Model of Life Data

NOTE: The scale parameter was estimated by maximum likelihood.							
LR Statistics For Type 3 Analysis							
Source	DF	Chi-Square		Pr > ChiSq			
mfg	1	0.02		0.8985			

The p -value of 0.8985 for the chi-square statistic in the Type 3 table indicates that there is no significant difference in the part life between the two manufacturers.

Using the following statements, you can refit the model without using the manufacturer as an effect. The LRCI option in the MODEL statement is specified to compute profile likelihood confidence intervals for the mean life and scale parameters.

```
proc genmod data = lifdat;
    model lifetime = / dist=gamma
                    link=log
                    lrci;
run;
```

Output 40.3.2 displays the results of fitting the model with the mfg effect omitted.

Output 40.3.2 Refitting of the Gamma Model: Omitting the mfg Effect

The GENMOD Procedure							
Analysis Of Maximum Likelihood Parameter Estimates							
Parameter	DF	Estimate	Standard Error	Likelihood Ratio 95% Confidence Limits		Wald Chi-Square	Pr > ChiSq
Intercept	1	6.1391	0.0775	5.9904	6.2956	6268.10	<.0001
Scale	1	0.8274	0.0714	0.6959	0.9762		
NOTE: The scale parameter was estimated by maximum likelihood.							

The intercept is the estimated log mean of the fitted gamma distribution, so that the mean life of the parts is

$$\mu = \exp(\text{INTERCEPT}) = \exp(6.1391) = 463.64$$

The SCALE parameter used in PROC GENMOD is the inverse of the gamma dispersion parameter, and it is sometimes called the gamma *index parameter*. See the section “[Response Probability Distributions](#)” on page 2799 for the definition of the gamma probability density function. A value of 1 for the index parameter corresponds to the exponential distribution. The estimated value of the scale parameter is 0.8274. The 95% profile likelihood confidence interval for the scale parameter is (0.6959, 0.9762), which does not contain 1. The hypothesis of an exponential distribution for the data is, therefore, rejected at the 0.05 level. A confidence interval for the mean life is

$$(\exp(5.99), \exp(6.30)) = (399.57, 542.18)$$

Example 40.4: Ordinal Model for Multinomial Data

This example illustrates how you can use the GENMOD procedure to fit a model to data measured on an ordinal scale. The following statements create a SAS data set called `lcecream`. The data set contains the results of a hypothetical taste test of three brands of ice cream. The three brands are rated for taste on a five-point scale from very good (vg) to very bad (vb). An analysis is performed to assess the differences in the ratings of the three brands. The variable `taste` contains the ratings, and the variable `brand` contains the brands tested. The variable `count` contains the number of testers rating each brand in each category.

The following statements create the `lcecream` data set:

```

data Icecream;
    input count brand$ taste$;
    datalines;
70  ice1  vg
71  ice1  g
151 ice1  m
30  ice1  b
46  ice1  vb
20  ice2  vg
36  ice2  g
130 ice2  m
74  ice2  b
70  ice2  vb
50  ice3  vg
55  ice3  g
140 ice3  m
52  ice3  b
50  ice3  vb
;

```

The following statements fit a cumulative logit model to the ordinal data with the variable taste as the response and the variable brand as a covariate. The variable count is used as a FREQ variable.

```

proc genmod data=Icecream rorder=data;
    freq count;
    class brand;
    model taste = brand / dist=multinomial
                        link=cumlogit
                        aggregate=brand
                        type1;
    estimate 'LogOR12' brand 1 -1 / exp;
    estimate 'LogOR13' brand 1  0 -1 / exp;
    estimate 'LogOR23' brand 0  1 -1 / exp;
run;

```

The AGGREGATE=BRAND option in the MODEL statement specifies the variable brand as defining multinomial populations for computing deviances and Pearson chi-squares. The RORDER=DATA option specifies that the taste variable levels be ordered by their order of appearance in the input data set—that is, from very good (vg) to very bad (vb). By default, the response is sorted in increasing ASCII order. Always check the “Response Profiles” table to verify that response levels are appropriately ordered. The TYPE1 option requests a Type 1 test for the significance of the covariate brand.

If $\gamma_j(\mathbf{x}) = \Pr(\text{taste} \leq j)$ is the cumulative probability of the j th or lower taste category, then the odds ratio comparing \mathbf{x}_1 to \mathbf{x}_2 is as follows:

$$\frac{\gamma_j(\mathbf{x}_1)/(1 - \gamma_j(\mathbf{x}_1))}{\gamma_j(\mathbf{x}_2)/(1 - \gamma_j(\mathbf{x}_2))} = \exp[(\mathbf{x}_1 - \mathbf{x}_2)' \boldsymbol{\beta}]$$

See McCullagh and Nelder (1989, Chapter 5) for details on the cumulative logit model. The ESTIMATE statements compute log odds ratios comparing each of brands. The EXP option in the ESTIMATE statements exponentiates the log odds ratios to form odds ratio estimates. Standard errors and confidence intervals are also computed.

Output 40.4.1 displays general information about the model and data, the levels of the CLASS variable brand, and the total number of occurrences of the ordered levels of the response variable taste.

Output 40.4.1 Ordinal Model Information

The GENMOD Procedure			
Model Information			
Data Set	WORK.ICECREAM		
Distribution	Multinomial		
Link Function	Cumulative Logit		
Dependent Variable	taste		
Frequency Weight Variable	count

2	g	162	
3	m	421	
4	b	156	
5	vb	166	

Output 40.4.2 displays estimates of the intercept terms and covariates and associated statistics. The intercept terms correspond to the four cumulative logits defined on the taste categories in the order shown in Output 40.4.1. That is, Intercept1 is the intercept for the first cumulative logit, $\log(\frac{p_1}{1-p_1})$, Intercept2 is the intercept for the second cumulative logit, $\log(\frac{p_1+p_2}{1-(p_1+p_2)})$, and so forth.

Output 40.4.2 Parameter Estimates

brand ice2		<.0001
brand ice3		.
Scale		

NOTE: The scale parameter was held fixed.

The Type 1 test displayed in [Output 40.4.3](#) indicates that Brand is highly significant; that is, there are significant differences among the brands. The log odds ratios and odds ratios in the “ESTIMATE Statement Results” table indicate the relative differences among the brands. For example, the odds ratio of 2.8 in the “Exp(LogOR12)” row indicates that the odds of brand 1 being in lower taste categories is 2.8 times the odds of brand 2 being in lower taste categories. Since, in this ordering, the lower categories represent the more favorable taste results, this indicates that brand 1 scored significantly better than brand 2. This is also apparent from the data in this example.

Example 40.5: GEE for Binary Data with Logit Link Function

Output 40.5.1 displays a partial listing of a SAS data set of clinical trial data comparing two treatments for a respiratory disorder. See “Gee Model for Binary Data” in the SAS/STAT Sample Program Library for the complete data set. These data are from Stokes, Davis, and Koch (2000).

Patients in each of two centers are randomly assigned to groups receiving the active treatment or a placebo. During treatment, respiratory status, represented by the variable outcome (coded here as 0=poor, 1=good), is determined for each of four visits. The variables center, treatment, sex, and baseline (baseline respiratory status) are classification variables with two levels. The variable age (age at time of entry into the study) is a continuous variable.

Explanatory variables in the model are Intercept (x_{ij1}), treatment (x_{ij2}), center (x_{ij3}), sex (x_{ij4}), age (x_{ij5}), and baseline (x_{ij6}), so that $x' = [x_{ij1}, x_{ij2}, \dots, x_{ij6}]$ is the vector of explanatory variables. Indicator variables for the classification explanatory variables can be automatically generated by listing them in the CLASS statement in PROC GENMOD. To be consistent with the analysis in Stokes, Davis, and Koch (2000), the four classification explanatory variables are coded as follows via options in the CLASS statement:

$$x_{ij2} = \begin{cases} 0 & \text{placebo} \\ 1 & \text{active} \end{cases} \quad x_{ij3} = \begin{cases} 0 & \text{center 1} \\ 1 & \text{center 2} \end{cases}$$

$$x_{ij4} = \begin{cases} 0 & \text{male} \\ 1 & \text{female} \end{cases} \quad x_{ij6} = \begin{cases} 0 & 0 \\ 1 & 1 \end{cases}$$

Suppose y_{ij} represents the respiratory status of patient i at the j th visit, $j = 1, \dots, 4$, and $\mu_{ij} = E(y_{ij})$ represents the mean of the respiratory status. Since the response data are binary, you can use the variance function for the binomial distribution $v(\mu_{ij}) = \mu_{ij}(1 - \mu_{ij})$ and the logit link function $g(\mu_{ij}) = \log(\mu_{ij}/(1 - \mu_{ij}))$. The model for the mean is $g(\mu_{ij}) = \mathbf{x}_{ij}'\boldsymbol{\beta}$, where $\boldsymbol{\beta}$ is a vector of regression parameters to be estimated.

20	1	5	P	F	13	1	1	1	1	1	4	1

The GEE solution is requested with the REPEATED statement in the GENMOD procedure. The option SUBJECT=ID(CENTER) specifies that the observations in a single cluster be uniquely identified by center and id within center. The option TYPE=UNSTR specifies the unstructured working correlation structure. The MODEL statement specifies the regression model for the mean with the binomial distribution variance function. The following SAS statements perform the GEE model fit:

```
proc genmod data=resp descend;
  class id treatment(ref="P") center(ref="1") sex(ref="M")
    baseline(ref="0") / param=ref;
  model outcome=treatment center sex age baseline / dist=bin;
  repeated subject=id(center) / corr=unstr corrw;
run;
```

These statements first fit the generalized linear (GLM) model specified in the MODEL statement. The parameter estimates from the generalized linear model fit are not shown in the output, but they are used

as initial values for the GEE solution. The DESCEND option in the PROC GENMOD statement specifies that the probability that outcome = 1 be modeled. If the DESCEND option had not been specified, the probability that outcome = 0 would be modeled by default.

Information about the GEE model is displayed in [Output 40.5.2](#). The results of GEE model fitting are displayed in [Output 40.5.3](#). Model goodness-of-fit criteria are displayed in [Output 40.5.4](#). If you specify no other options, the standard errors, confidence intervals, Z scores, and *p*-values are based on empirical standard error estimates. You can specify the MODELSE option in the REPEATED statement to create a table based on model-based standard error estimates.

QICu	499.6081

The nonsignificance of age and sex make them candidates for omission from the model.

Example 40.6: Log Odds Ratios and the ALR Algorithm

Since the respiratory data in [Example 40.5](#) are binary, you can use the ALR algorithm to model the log odds ratios instead of using working correlations to model associations. In this example, a “fully parameterized cluster” model for the log odds ratio is fit. That is, there is a log odds ratio parameter for each unique pair of responses within clusters, and all clusters are parameterized identically. The following statements fit the same regression model for the mean as in [Example 40.5](#) but use a regression model for the log odds ratios instead of a working correlation. The LOGOR=FULLCLUST option specifies a fully parameterized log odds ratio model.

```
proc genmod data=resp descend;
  class id treatment(ref="P") center(ref="1") sex(ref="M")
    baseline(ref="0") / param=ref;
  model outcome=treatment center sex age baseline / dist=bin;
  repeated subject=id(center) / logor=fullclust;
run;
```

The results of fitting the model are displayed in [Output 40.6.1](#) along with a table that shows the correspondence between the log odds ratio parameters and the within-cluster pairs. Model goodness-of-fit criteria are shown in [Output 40.6.2](#). The QIC for the ALR model shown in [Output 40.6.2](#) is 511.86, whereas the QIC for the unstructured working correlation model shown in [Output 40.5.4](#) is 512.34, indicating that the ALR model is a slightly better fit.

GEE Fit Criteria	
QIC	511.8589
QICu	499.6516

You can fit the same model by fully specifying the z matrix. The following statements create a data set containing the full z matrix:

```
data zin;
  keep id center z1-z6 y1 y2;
  array zin(6) z1-z6;
  set resp;
  by center id;
  if first.id
    then do;
      t = 0;
      do m = 1 to 4;
        do n = m+1 to 4;
          do j = 1 to 6;
            zin(j) = 0;
          end;
          y1 = m;
          y2 = n;
          t + 1;
          zin(t) = 1;
          output;
        end;
      end;
    end;
  end;
run;
```

```
proc print data=zin (obs=12);
run;
```

Output 40.6.3 displays the full **z** matrix for the first two clusters. The **z** matrix is identical for all clusters in this example.

Output 40.6.3 Full **z** Matrix Data Set

Obs	z1	z2	z3	z4	z5	z6	center	id	y1	y2
1	1	0	0	0	0	0	1	1	1	2

12	0	0	0	0	0	1	1	2	3	4

The following statements fit the model for fully parameterized clusters by fully specifying the **z** matrix. The results are identical to those shown previously.

```
proc genmod data=resp descend;
  class id treatment(ref="P") center(ref="1") sex(ref="M")
    baseline(ref="0") / param=ref;
  model outcome=treatment center sex age baseline / dist=bin;
  repeated subject=id(center) / logor=zfull
    zdata=zin
    zrow =(z1-z6)
    ypair=(y1 y2);
run;
```

Example 40.7: Log-Linear Model for Count Data

In this example the data, from Thall and Vail (1990), concern the treatment of people suffering from epileptic seizure episodes. These data are also analyzed in Diggle, Liang, and Zeger (1994). The data consist of the number of epileptic seizures in an eight-week baseline period, before any treatment, and in each of four two-week treatment periods, in which patients received either a placebo or the drug Progabide in addition to other therapy. A portion of the data is displayed in Table 40.16. See “Gee Model for Count Data, Exchangeable Correlation” in the SAS/STAT Sample Program Library for the complete data set.

Table 40.16 Epileptic Seizure Data

Patient ID	Treatment	Baseline	Visit1	Visit2	Visit3	Visit4
104	Placebo	11	5	3	3	3
106	Placebo	11	3	5	3	3
107	Placebo	6	2	4	0	5
.						
.						
.						
101	Progabide	76	11	14	9	8
102	Progabide	38	8	7	9	4
103	Progabide	19	0	4	3	0
.						
.						
.						

Model the data as a log-linear model with $V(\mu) = \mu$ (the Poisson variance function) and

$$\log(E(Y_{ij})) = \beta_0 + x_{i1}\beta_1 + x_{i2}\beta_2 + x_{i1}x_{i2}\beta_3 + \log(t_{ij})$$

where

Y_{ij} = number of epileptic seizures in interval j

t_{ij} = length of interval j

$$x_{i1} = \begin{cases} 1 & \text{weeks 8–16 (treatment)} \\ 0 & \text{weeks 0–8 (baseline)} \end{cases}$$

$$x_{i2} = \begin{cases} 1 & \text{progabide group} \\ 0 & \text{placebo group} \end{cases}$$

The correlations between the counts are modeled as $r_{ij} = \alpha$, $i \neq j$ (exchangeable correlations). For comparison, the correlations are also modeled as independent (identity correlation matrix). In this model, the regression parameters have the interpretation in terms of the log seizure rate displayed in Table 40.17.

Table 40.17 Interpretation of Regression Parameters

Treatment	Visit	$\log(E(Y_{ij})/t_{ij})$
Placebo	Baseline	β_0
	1–4	$\beta_0 + \beta_1$
Progabide	Baseline	$\beta_0 + \beta_2$
	1–4	$\beta_0 + \beta_1 + \beta_2 + \beta_3$

The difference between the log seizure rates in the pretreatment (baseline) period and the treatment periods is β_1 for the placebo group and $\beta_1 + \beta_3$ for the Progabide group. A value of $\beta_3 < 0$ indicates a reduction in the seizure rate.

Output 40.7.1 lists the first 14 observations of the data, which are arranged as one visit per observation:

Output 40.7.1 Partial Listing of the Seizure Data

Obs	id	y	visit	trt	bline	age
1	104	5	1	0	11	31
2	104	3	2	0	11	31
3	104	3	3	0	11	31
4	104	3	4	0	11	31
5	106	3	1	0	11	30
6	106	5	2	0	11	30
7	106	3	3	0	11	30
8	106	3	4	0	11	30
9	107	2	1	0	6	25
10	107	4	2	0	6	25
11	107	0	3	0	6	25
12	107	5	4	0	6	25
13	114	4	1	0	8	36
14	114	4	2	0	8	36

Some further data manipulations create an observation for the baseline measures, a log time interval variable for use as an offset, and an indicator variable for whether the observation is for a baseline measurement or a visit measurement. Patient 207 is deleted as an outlier, as in the Diggle, Liang, and Zeger (1994) analysis. The following statements prepare the data for analysis with PROC GENMOD:

```
data new;
  set thall;
  output;
  if visit=1 then do;
    y=bline;
    visit=0;
    output;
  end;
run;
```

```
data new;
  set new;
  if id ne 207;
  if visit=0 then do;
    x1=0;
    ltime=log(8);
  end;
  else do;
    x1=1;
    ltime=log(2);
  end;
run;
```

For comparison with the GEE results, an ordinary Poisson regression is first fit. The results are shown in Output 40.7.2.

Output 40.7.2 Maximum Likelihood Estimates

The GENMOD Procedure							
Analysis Of Maximum Likelihood Parameter Estimates							
Parameter	DF	Estimate	Standard Error	Wald 95% Confidence Limits		Wald Chi-Square	Pr > ChiSq
Intercept	1	1.3476	0.0341	1.2809	1.4144	1565.44	<.0001
x1	1	0.1108	0.0469	0.0189	0.2027	5.58	0.0181

x1*trt	1	-0.3016	0.0697	-0.4383	-0.1649	18.70	<.0001
Scale	0	1.0000	0.0000	1.0000	1.0000		

NOTE: The scale parameter was held fixed.

The GEE solution is requested with the REPEATED statement in the GENMOD procedure. The SUBJECT=ID option indicates that the variable id describes the observations for a single cluster, and the CORRW option displays the working correlation matrix. The TYPE= option specifies the correlation structure; the value EXCH indicates the exchangeable structure.

The following statements perform the analysis:

```
proc genmod data=new;
  class id;
  model y=x1 | trt / d=poisson offset=ltime;
  repeated subject=id / corrw covb type=exch;
run;
```

These statements first fit a generalized linear model (GLM) to these data by maximum likelihood. The estimates are not shown in the output, but are used as initial values for the GEE solution.

Information about the GEE model is displayed in [Output 40.7.3](#). The results of fitting the model are displayed in [Output 40.7.4](#). Compare these with the model of independence displayed in [Output 40.7.2](#). The parameter estimates are nearly identical, but the standard errors for the independence case are underestimated. The coefficient of the interaction term, β_3 , is highly significant under the independence model and marginally significant with the exchangeable correlations model.

Output 40.7.3 GEE Model Information

Row5	0.5941	0.5941	0.5941	0.5941	1.0000

If you specify the COVB option, you produce both the model-based (naive) and the empirical (robust) covariance matrices. Output 40.7.6 contains these estimates.

Output 40.7.6 Covariance Matrices

Covariance Matrix (Model-Based)				
	Prm1	Prm2	Prm3	Prm4
Prm1	0.01223	0.001520	-0.01223	-0.001520
Prm2	0.001520	0.01519	-0.001520	-0.01519
Prm3	-0.01223	-0.001520	0.02495	0.005427
Prm4	-0.001520	-0.01519	0.005427	0.03748

Covariance Matrix (Empirical)				
	Prm1	Prm2	Prm3	Prm4
Prm1	0.02476	-0.001152	-0.02476	0.001152
Prm2	-0.001152	0.01348	0.001152	-0.01348
Prm3	-0.02476	0.001152	0.03751	-0.002999
Prm4	0.001152	-0.01348	-0.002999	0.02931

The two covariance estimates are similar, indicating an adequate correlation model.

Example 40.8: Model Assessment of Multiple Regression Using Aggregates of Residuals

This example illustrates the use of cumulative residuals to assess the adequacy of a normal linear regression model. Neter et al. (1996, Section 8.2) describe a study of 54 patients undergoing a certain kind of liver operation in a surgical unit. The data consist of the survival time and certain covariates. After a model selection procedure, they arrived at the following model:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \epsilon$$

where Y is the logarithm (base 10) of the survival time; X_1 , X_2 , X_3 are *blood-clotting score*, *prognostic index*, and *enzyme function*, respectively; and ϵ is a normal error term. A listing of the SAS data set containing the data is shown in [Output 40.8.1](#). The variables Y , X_1 , X_2 , and X_3 correspond to Y , X_1 , X_2 , and X_3 , and $\text{Log}X_1$ is $\log(X_1)$. The PROC GENMOD fit of the model is shown in [Output 40.8.2](#). The analysis first focuses on the adequacy of the functional form of X_1 , *blood-clotting score*.

Output 40.8.1 Surgical Unit Example Data

54	2.4955	8.8	78	72	0.94448

In order to assess the adequacy of the fitted multiple regression model, the ASSESS statement in the following SAS statements is used to create the plots of cumulative residuals against X1 shown in [Output 40.8.3](#) and [Output 40.8.4](#) and the summary table in [Output 40.8.5](#):

```
ods graphics on;

proc genmod data=Surg;
  model Y = X1 X2 X3 / scale=Pearson;
  assess var=(X1) / resample=10000
                    seed=603708000
                    crpanel;
run;
```

Output 40.8.2 Regression Model for Linear X1

The GENMOD Procedure							
Analysis Of Maximum Likelihood Parameter Estimates							
Parameter	DF	Estimate	Standard Error	Wald 95% Confidence Limits	Wald Chi-Square	Pr >	ChiSq
Intercept	1	0.4836	0.0426	0.4001 0.5672	128.71	<.0001	
X1	1	0.0692	0.0041	0.0612 0.0772	288.17	<.0001	
X2	1	0.0093	0.0004	0.0085 0.0100	590.45	<.0001	
X3	1	0.0095	0.0003	0.0089 0.0101	966.07	<.0001	
Scale	0	0.0469	0.0000	0.0469 0.0469			
NOTE: The scale parameter was estimated by the square root of Pearson's Chi-Square/DOF.							

See Lin, Wei, and Ying (2002) for details about model assessment that uses cumulative residual plots. The RESAMPLE= keyword specifies that a p -value be computed based on a sample of 10,000 simulated residual paths. A random number seed is specified by the SEED= keyword for reproducibility. If you do not specify the seed, one is derived from the time of day. The keyword CRPANEL specifies that the panel of four cumulative residual plots shown in [Output 40.8.4](#) be created, each with two simulated paths. The single residual plot with 20 simulated paths in [Output 40.8.3](#) is created by default.

To request these graphs, ODS Graphics must be enabled and you must specify the ASSESS statement. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For specific information about the graphics available in the GENMOD procedure, see the section “[ODS Graphics](#)” on page 2856.

Output 40.8.3 Cumulative Residual Plot for Linear X1 Fit

Output 40.8.4 Cumulative Residual Panel Plot for Linear X1 Fit**Output 40.8.5** Summary of Model Assessment

Assessment Summary				
Assessment Variable	Maximum Absolute Value	Replications	Seed	Pr > MaxAbsVal
X1	0.0380	10000	603708000	0.1084

The p -value of 0.1084 reported on [Output 40.8.3](#) and [Output 40.8.5](#) suggests that a more adequate model might be possible. The observed cumulative residuals in [Output 40.8.3](#) and [Output 40.8.4](#), represented by the heavy lines, seem atypical of the simulated curves, represented by the light lines, reinforcing the conclusion that a more appropriate functional form for X1 is possible.

The cumulative residual plots in [Output 40.8.6](#) provide guidance in determining a more appropriate functional form. The four curves were created from simple forms of model misspecification by using simulated data. The mean models of the data and the fitted model are shown in [Table 40.19](#).

Output 40.8.6 Typical Cumulative Residual Patterns

Table 40.19 Model Misspecifications

Plot	Data $E(Y)$	Fitted Model $E(Y)$
(a)	$\log(X)$	X
(b)	$X + X^2$	X
(c)	$X + X^2 + X^3$	$X + X^2$
(d)	$I(X > 5)$	X

The observed cumulative residual pattern in [Output 40.8.3](#) and [Output 40.8.4](#) most resembles the behavior of the curve in plot (a) of [Output 40.8.6](#), indicating that $\log(X_1)$ might be a more appropriate term in the model than X_1 .

The following SAS statements fit a model with LogX1 in place of X1 and request a model assessment:

```
proc genmod data=Surg;  
  model Y = LogX1 X2 X3 / scale=Pearson;  
  assess var=(LogX1) / resample=10000  
                    seed=603708000;  
run;
```

Output 40.8.8 Cumulative Residual Plot with Log(X1)**Example 40.9: Assessment of a Marginal Model for Dependent Data**

This example illustrates the use of cumulative residuals to assess the adequacy of a marginal model for dependent data fit by generalized estimating equations (GEEs). The assessment methods are applied to CD4 count data from an AIDS clinical trial reported by Fischl, Richman, and Hansen (1990) and reanalyzed by Lin, Wei, and Ying (2002). The study randomly assigned 360 HIV patients to the drug AZT and 351 patients to placebo. CD4 counts were measured repeatedly over the course of the study. The data used here are the 4328 measurements taken in the first 40 weeks of the study.

The analysis focuses on the time trend of the response. The first model considered is

$$E(y_{ik}) = \beta_0 + \beta_1 T_{ik} + \beta_2 T_{ik}^2 + \beta_3 R_i T_{ik} + \beta_4 R_i T_{ik}^2$$

where T_{ik} is the time (in weeks) of the k th measurement on the i th patient, y_{ik} is the CD4 count at T_{ik} for the i th patient, and R_i is the indicator of AZT for the i th patient. Normal errors and an independent working correlation are assumed.

The following statements create the SAS data set `cd4`:

```

data cd4;
  input Id Y Time Time2 TrtTime TrtTime2;
  Time3 = Time2 * Time;
  TrtTime3 = TrtTime2 * Time;
  datalines;
1      264.00024      -0.28571      0.08163      -0.28571      0.08163

711      240.00026      18.14286      329.16327      18.14286      329.16327
;

```

The following SAS statements fit the preceding model, create the cumulative residual plot in [Output 40.9.1](#), and compute a p -value for the model.

To request these graphs, ODS Graphics must be enabled and you must specify the ASSESS statement. For general information about ODS Graphics, see Chapter 21, “[Statistical Graphics Using ODS](#).” For specific information about the graphics available in the GENMOD procedure, see the section “[ODS Graphics](#)” on page 2856.

Here, the SAS data set variables Time, Time2, TrtTime, and TrtTime2 correspond to T_{ik} , T_{ik}^2 , $R_i T_{ik}$, and $R_i T_{ik}^2$, respectively. The variable Id identifies individual patients.

```

ods graphics on;

proc genmod data=cd4;
  class Id;
  model Y = Time Time2 TrtTime TrtTime2;
  repeated sub=Id;
  assess var=(Time) / resample
                        seed=603708000;
run;

```

Output 40.9.1 Cumulative Residual Plot for Quadratic Time Fit

The cumulative residual plot in [Output 40.9.1](#) displays cumulative residuals versus time for the model and 20 simulated realizations. The associated p -value, also shown in [Output 40.9.1](#), is 0.18. These results indicate that a more satisfactory model might be possible. The observed cumulative residual pattern most resembles plot (c) in [Output 40.8.6](#), suggesting cubic time trends.

The following SAS statements fit the model, create the plot in [Output 40.9.2](#), and compute a p -value for a model with the additional terms T_{ik}^3 and $R_i T_{ik}^3$:

```
proc genmod data=cd4;
  class Id;
  model Y = Time Time2 Time3 TrtTime TrtTime2 TrtTime3;
  repeated sub=Id;
  assess var=(Time) / resample
                seed=603708000;
run;
```

Output 40.9.2 Cumulative Residual Plot for Cubic Time Fit

The observed cumulative residual pattern appears more typical of the simulated realizations, and the p -value is 0.45, indicating that the model with cubic time trends is more appropriate.

Example 40.10: Bayesian Analysis of a Poisson Regression Model

This example illustrates a Bayesian analysis of a log-linear Poisson regression model. Consider the following data on patients from clinical trials. The data set is a subset of the data described in Ibrahim, Chen, and Lipsitz (1999).

```
data Liver;
  input X1-X6 Y;
  datalines;
19.1358    50.0110    51.000    0    0    1    3
23.5970    18.4959    3.429    0    0    1    9

```

The primary interest is in prediction of the number of cancerous liver nodes when a patient enters the trials, by using six other baseline characteristics. The number of nodes is modeled by a Poisson regression model with the six baseline characteristics as covariates. The response and regression variables are as follows:

Y	Number of Cancerous Liver Nodes
X1	Body Mass Index
X2	Age, in Years
X3	Time Since Diagnosis of Disease, in Weeks
X4	Two Biochemical Markers (each classified as normal=1 or abnormal=0)
X5	Anti Hepatitis B Antigen
X6	Associated Jaundice (yes=1, no=0)

Two analyses are performed using PROC GENMOD. The first analysis uses noninformative normal prior distributions, and the second analysis uses an informative normal prior for one of the regression parameters.

In the following BAYES statement, COEFFPRIOR=NORMAL specifies a noninformative independent normal prior distribution with zero mean and variance 10^6 for each parameter.

The initial analysis is performed using PROC GENMOD to obtain Bayesian estimates of the regression coefficients by using the following SAS statements:

```

proc genmod data=Liver;
  model Y = X1-X6 / dist=Poisson link=log;
  bayes seed=1 coeffprior=normal;
run;

```

Maximum likelihood estimates of the model parameters are computed by default. These are shown in the “Analysis of Maximum Likelihood Parameter Estimates” table in [Output 40.10.1](#).

Output 40.10.1 Maximum Likelihood Parameter Estimates

The GENMOD Procedure					
Bayesian Analysis					
Analysis Of Maximum Likelihood Parameter Estimates					
Parameter	DF	Estimate	Standard Error	Wald 95% Confidence Limits

Output 40.10.13 Diagnostic Plots for X2

Output 40.10.14 Diagnostic Plots for X3

Output 40.10.15 Diagnostic Plots for X4

Output 40.10.16 Diagnostic Plots for X5

Output 40.10.17 Diagnostic Plots for X6

In order to illustrate the use of an informative prior distribution, suppose that researchers expect that a unit increase in body mass index (X1) will be associated with an increase in the mean number of nodes of between 10% and 20%, and they want to incorporate this prior knowledge in the Bayesian analysis. For log-linear models, the mean and linear predictor are related by $\log(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}$. If $X1_1$ and $X1_2$ are two values of body mass index, μ_1 and μ_2 are the two mean values, and all other covariates remain equal for the two values of X1, then

$$\frac{\mu_1}{\mu_2} = \exp(\beta(X1_1 - X1_2))$$

so that for a unit change in X1,

$$\frac{\mu_1}{\mu_2} = \exp(\beta)$$

If $1.1 \leq \frac{\mu_1}{\mu_2} \leq 1.2$, then $1.1 \leq \exp(\beta) \leq 1.2$, or $0.095 \leq \beta \leq 0.182$. This gives you guidance in specifying a prior distribution for the β for body mass index. Taking the mean of the prior normal distribution to be

the midrange of the values of β , and taking $\mu \pm 2\sigma$ to be the extremes of the range, an $N(0.1385, 0.0005)$ is the resulting prior distribution. The second analysis uses this informative normal prior distribution for the coefficient of X1 and uses independent noninformative normal priors with zero means and variances equal to 10^6 for the remaining model regression parameters.

In the following BAYES statement, COEFFPRIOR=NORMAL(INPUT=NormalPrior) specifies the normal prior distribution for the regression coefficients with means and variances contained in the data set NormalPrior.

An analysis is performed using PROC GENMOD to obtain Bayesian estimates of the regression coefficients by using the following SAS statements:

```
data NormalPrior;
  input _type_ $ Intercept X1-X6;
  datalines;
Var 1e6 0.0005      1e6      1e6      1e6      1e6      1e6
Mean 0.0 0.1385      0.0      0.0      0.0      0.0      0.0
;

proc genmod data=Liver;
  model Y = X1-X6 / dist=Poisson link=log;
  bayes seed=1 plots=none coeffprior=normal(input=NormalPrior);
run;
```

The prior distributions for the regression parameters are shown in [Output 40.10.18](#).

Output 40.10.18 Regression Coefficient Priors

The GENMOD Procedure		
Bayesian Analysis		
Independent Normal Prior for Regression Coefficients		
Parameter	Mean	Precision
Intercept	0	1E-6
X1	0.1385	2000
X2	0	1E-6
X3	0	1E-6
X4	0	1E-6
X5	0	1E-6
X6	0	1E-6

Initial values for the MCMC are shown in [Output 40.10.19](#). The initial values of the covariates are joint estimates of their posterior modes. The prior distribution for X1 is informative, so the initial value of X1 is further from the MLE than the rest of the covariates. Initial values for the rest of the covariates are close to their MLEs, since noninformative prior distributions were specified for them.

Output 40.10.19 MCMC Initial Values and Seeds

Initial Values of the Chain						
Chain	Seed	Intercept	X1	X2	X3	X4
1	1	2.14282	0.010595	-0.01434	-0.00301	-0.28062
Initial Values of the Chain						
		X5	X6			
		0.334983	0.231213			

Goodness-of-fit, summary, and interval statistics are shown in [Output 40.10.20](#). Except for X1, the statistics shown in [Output 40.10.20](#) are very similar to the previous statistics for noninformative priors shown in [Output 40.10.4](#) through [Output 40.10.7](#). The point estimate for X1 is now positive. This is expected because the prior distribution on β_1 is quite informative. The distribution reflects the belief that the coefficient is positive. The $N(0.1385, 0.0005)$ distribution places the majority of its probability density on positive values. As a result, the posterior density of β_1 places more likelihood on positive values than in the noninformative case.

Output 40.10.20 Fit Statistics

Fit Statistics						
DIC (smaller is better)				833.074		
pD (effective number of parameters)				6.869

Example 40.11: Exact Poisson Regression

The following data, taken from Cox and Snell (1989, pp. 10–11), consists of the number, Notready, of ingots that are not ready for rolling, out of Total tested, for several combinations of heating time and soaking time:

```
data ingots;
  input Heat Soak Notready Total @@;
  lnTotal= log(Total);
  datalines;
7 1.0 0 10 14 1.0 0 31 27 1.0 1 56 51 1.0 3 13
7 1.7 0 17 14 1.7 0 43 27 1.7 4 44 51 1.7 0 1
7 2.2 0 7 14 2.2 2 33 27 2.2 0 21 51 2.2 0 1
7 2.8 0 12 14 2.8 0 31 27 2.8 1 22 51 4.0 0 1
7 4.0 0 9 14 4.0 0 19 27 4.0 1 16
;
```

The following invocation of PROC GENMOD fits an asymptotic (unconditional) Poisson regression model to the data. The variable Notready is specified as the response variable, and the continuous predictors Heat and Soak are defined in the CLASS statement as categorical predictors that use reference coding. Specifying the offset variable as lnTotal enables you to model the ratio Notready/Total.

```
proc genmod data=ingots;
  class Heat Soak / param=ref;
  model Notready=Heat Soak / offset=lnTotal dist=poisson link=log;
  exact Heat Soak / joint estimate;
  exactoptions statustime=10;
run;
```

The EXACT statement is specified to additionally fit an exact conditional Poisson regression model. Specifying the lnTotal offset variable models the ratio Notready/Total; in this case, the Total variable contains the largest possible response value for each observation. The JOINT option produces a joint test for the significance of the covariates, along with the usual marginal tests. The ESTIMATE option produces exact parameter estimates for the covariates. The STATUSTIME=10 option is specified in the EXACTOPTIONS statement for monitoring the progress of the results; this example can take several minutes to complete due to the JOINT option. If you run out of memory, see the SAS Companion for your system for information about how to increase the available memory.

The “Criteria For Assessing Goodness Of Fit” table is displayed in [Output 40.11.1](#). Comparing the deviance of 10.9363 to an asymptotic chi-square distribution with 11 degrees of freedom, you find that the p -value is 0.449. This indicates that the specified model fits the data reasonably well.

Output 40.11.1 Unconditional Goodness of Fit Criteria

The GENMOD Procedure			
Criteria For Assessing Goodness Of Fit			
Criterion	DF	Value	Value/DF
Deviance	11	10.9363	0.9942
Scaled Deviance	11	10.9363	0.9942
Pearson Chi-Square	11	9.3722	0.8520
Scaled Pearson X2	11	9.3722	0.8520
Log Likelihood		-7.2408	
Full Log Likelihood		-12.9038	
AIC (smaller is better)		41.8076	
AICC (smaller is better)		56.2076	
BIC (smaller is better)		49.3631	

From the “Analysis Of Parameter Estimates” table in [Output 40.11.2](#), you can see that only two of the Heat parameters are deemed significant. Looking at the standard errors, you can see that the unconditional analysis had convergence difficulties with the Heat=7 parameter (Standard Error=264324.6), which means you cannot fit this unconditional Poisson regression model to this data.

Output 40.11.2 Unconditional Maximum Likelihood Parameter Estimates

Analysis Of Maximum Likelihood Parameter Estimates						
Parameter	DF	Estimate	Standard Error	Wald	95% Confidence Limits	Wald Chi-Square
Intercept	1	-1.5700	1.1657	-3.8548	0.7147	1.81
Heat	7	-27.6129	264324.6	-518094	518039.0	0.00
